From a neurochemical standpoint ACh, glutamate, serotonin and noradrenaline are the major transmitter systems affected by AD, with relative sparing of dopamine, gamma amino butyric acid (GABA) and most peptides (Francis *et al.*, 1993; Francis, 2003). This chapter examines both cognitive and non-cognitive (behavioural) aspects of neurotransmission, the latter also being considered to relate to structural and functional alterations in the central nervous system (CNS). Such changes are important, in part because carers find behavioural disturbances difficult to cope with, and the presence of such behaviours in AD patients often leads to the need for institutionalization. The chapter will focus on cholinergic and glutamatergic systems.

29.1 ACETYLCHOLINE

Neuropathologically, loss of neurones from the nucleus of Meynert (CH4, cholinergic nucleus) is well documented in AD, although the extent of the loss reported varies from moderate to severe, and it has been suggested that in AD cholinergic dysfunction exceeds degeneration (Perry *et al.*, 1982). This is consistent with studies of cholinergic markers in biopsy samples from patients who had AD for approximately 3 years, where reduction in functional cholinergic measures, acetylcholine synthesis and choline uptake exceeded the reduction in ChAT activity (Francis *et al.*, 1985).

On the basis of the above evidence, neocortical cholinergic innervation appears to be lost at an early stage of the disease. Beach and colleagues (2000) recently reported neurofibrillary

tangles in the entorhinal cortex and a 20–30 per cent loss of ChAT activity in brains from patients at the earliest stages of AD, namely Braak stages I and II. However, another study using the Clinical Dementia Rating scale (CDR) suggests that the greatest reduction in markers of the cholinergic system occurs between moderate (CDR 2) and end-stage (CDR 5) disease with little change between non-demented and the moderate stage (CDR 0–2) (Davis *et al.*, 1999). In contrast a recent study of MCI, the suggested AD prodrome, reported an increase in ChAT activity in some cortical regions (DeKosky *et al.*, 2002). The acknowledged problems of these latter studies is that ChAT activity is not the rate-limiting step of ACh synthesis and hence there could be cholinergic dysfunction before structural loss, possibly linked to aberrant sprouting. Changes in cholinergic neurones appear to relate to aspects of cognitive function (Francis *et al.*, 1985) as well non-cognitive behaviour (Minger *et al.*, 2000). It has also been suggested that ACh is centrally involved in the process of conscious awareness (Perry *et al.*, 1999), and that the variety of clinical symptoms associated with cholinergic dysfunction in AD and related disorders reflects disturbances in the conscious processing of information. There is evidence that implicit memory for example (which does not involve conscious awareness) is relatively intact in AD (Postle *et al.*, 1996).

Nicotinic and muscarinic (M2) ACh receptors, most of which are considered to be located on cholinergic terminals, are reduced in AD (Court *et al.*, 2001; Lai *et al.*, 2001). Reductions in nicotinic receptors are confined to the $\alpha 4\beta 2$ subtype. The postsynaptic cholinergic system (usually present upon glutamatergic neurones) appears to be less affected, which encourages hope for therapeutic intervention. Postsynaptic muscarinic M1 receptors (Perry *et al.*, 1990) are relatively preserved, although there may be a degree of functional uncoupling. The enzyme responsible for the breakdown of ACh, acetylcholinesterase, is reduced, perhaps in part due to a loss of cholinergic terminals, while butyrylcholinesterase activity (the function of which is not yet fully understood and which is present in extrasynaptic areas and plaques) increases.

29.1.1 Acetylcholine and cognition

A prediction of the cholinergic hypothesis is that drugs likely to potentiate this function should improve cognition in AD patients. There are a number of treatment approaches to the amelioration of the cholinergic deficit; however, the use of acetylcholinesterase inhibitors (AChEIs) is the most well-developed approach (Francis *et al.*, 1999).

During the late 1980s and early 1990s, the first cholinomimetic compound, tacrine, underwent large-scale clinical studies and established the benefits of ChEI treatment in patients with a diagnosis of probable AD. A so-called second generation of ChEIs has been developed including donepezil, rivastigmine, metrifonate and galantamine (Francis *et al.*, 1999). Such compounds demonstrate a clinical effect and

magnitude of benefit of at least that reported for tacrine, but with a more favourable clinical profile. Evidence has emerged from clinical trials of cholinomimetics that such drugs may improve the abnormal non-cognitive, behavioural symptoms of AD. Physostigmine, tacrine, rivastigmine and metrifonate have variously been reported in placebo-controlled trials to decrease psychotic symptoms (hallucinations and delusions), agitation, apathy, anxiety, disinhibition, pacing, aberrant motor behaviour and lack of cooperation (Cummings and Kaufer, 1996). In a recent study, muscarinic M2 receptor density was increased in the frontal cortex of AD patients with delusions and in the temporal cortex of those with hallucinations, compared with patients without psychotic symptoms. This suggests a role for M2 receptors in the psychosis of AD and may provide a rationale for treatment of behaviourally disturbed AD patients with M2 antagonists (Lai *et al.*, 2001).

Possibly related to these findings in AD, a dementia with Lewy bodies (DLB) open label trial of rivastigmine showed almost all patients responded positively on one or more of these measures (McKeith *et al.*, 2000). Visual hallucinations are more common in DLB, which, in turn, is associated with greater reductions in ChAT activity than observed in AD (Perry *et al.*, 1994).

29.1.2 The cholinergic system and AD pathology

Many preclinical studies indicate that activation of cholinergic receptors influence the metabolism of one of the two key proteins involved in AD, amyloid precursor protein (APP), diverting metabolism away from the formation of amyloid (A β) (Nitsch, 1996; Francis *et al.*, 1999). In support of this hypothesis two recent clinical studies showed that muscarinic M1 agonists were able to reduce cerebrospinal fluid (CSF) concentrations of A β (Hock *et al.*, 2000; Nitsch *et al.*, 2000). Furthermore, nicotinic receptor stimulation is associated with reduced plaque densities in the human brain (Court *et al.*, 1998). These results suggest that compounds being developed for symptomatic treatment may have a serendipitous effect on the continuing emergence of pathology by reducing the production of A β . There is also evidence for a possible beneficial role of cholinergic neurotransmission by modulation in the generation of neurofibrillary tangles via reduced phosphorylation of tau protein. One of the primary intracellular enzymes responsible, glycogen synthase kinase-3 (GSK3) can be regulated by muscarinic activation (Sadot *et al.*, 1996). Cholinergic neurotransmission may also be a specific target for A β , since it has been shown to reduce both choline uptake and ACh release *in vitro* (Auld *et al.*, 1998). Furthermore, A β is reported to bind with high affinity to the $\alpha 7$ subtype of the nicotinic receptor, suggesting that cholinergic function through this receptor may be compromised because of high levels of (soluble) peptide in AD brains (Wang *et al.*, 2000).

29.2 GLUTAMATE

Glutamate is the principal excitatory neurotransmitter of the brain, being used at approximately two-thirds of synapses. The majority of neurones and glia have receptors for glutamate. An integral part of protein, energy and ammonia metabolism of all cells with a high intracellular concentration, it has been difficult to distinguish the presynaptic transmitter pool of glutamate from the metabolic pool (Francis *et al.*, 1993). Considered to be the main neurotransmitter of neocortical and hippocampal pyramidal neurones, glutamate is thus involved in higher mental functions such as cognition and memory (Francis *et al.*, 1993). An important mechanism by which glutamate may contribute to learning and memory functions is via long-term potentiation (LTP) at pyramidal neurone synapses. LTP is a form of synaptic strengthening following brief, high frequency, stimulation.

Histological studies in AD indicate loss of pyramidal neurones and their synapses together with surrounding neuropil (Esiri, 1991). Corticocortical and corticofugal-projecting pyramidal neurones are lost, together with those of the entorhinal and hippocampal CA1 region. Remaining neurones are subject to neurofibrillary tangle formation. Uptake of D-aspartate, a putative marker of glutamatergic nerve endings, is reduced in many cortical areas in the AD brain (Procter *et al.*, 1988).

Biochemical evidence suggests a presynaptic 'double blow' as the activity of glutamatergic neurones is heavily influenced by the cholinergic system, also dysfunctional in AD. The clinical relevance of these changes is emphasized because both glutamatergic and cholinergic dysfunction are strong correlates of cognitive decline in AD. Glutamatergic (and cholinergic) cells die over a period of years and in a very specific regional and neurochemically selective pattern (Francis *et al.*, 1993). The selectivity is intriguing, because cholinergic neurones of the basal forebrain die while those of the pons are spared; glutamatergic neurones of the frontal, temporal and parietal cortex are lost while apparently similar neurones in the motor and sensory cortex are unaffected. Factors that may lead to necrosis or apoptosis in selected groups of neurones in AD may include tangles, A β toxicity, microglia, free radical generation, excitotoxicity (too much or too little glutamatergic neurotransmission) and withdrawal of trophic factors. The strongest evidence suggests that most of glutamatergic pyramidal neurones die as a consequence of the presence of neurofibrillary tangles within the cytoplasm (Kowall and Beal, 1991). However, this may only account for up to 50 per cent of such cells.

Glutamate is synthesized in nerve terminals by one of several possible enzymes. First, glutamine can be converted to glutamate by the action of the mitochondrial enzyme glutaminase (Procter *et al.*, 1988); alternatively glutamate can be produced by transamination from aspartate in the cytosol. Direct measurement of glutaminase activity is unaffected in AD (Procter *et al.*, 1988). By contrast glutaminase-positive neurones are reduced in number and subject to tangle formation

(Kowall and Beal, 1991). Several groups have shown reductions in the concentration of glutamate in AD tissue and lumbar CSF (Lowe *et al.*, 1990). Although glutamate neurotransmission failure was not extensive in these studies, glutamate concentration was reduced by 14 per cent in temporal lobe biopsy samples and by 86 per cent in the terminal zone of the perforant pathway at autopsy of AD patients (Hyman *et al.*, 1987).

We have recently begun to investigate the status of the newly discovered vesicular glutamate transporters (VGLUT), VGLUT1 and VGLUT2 (Bellocchio *et al.*, 2000). These proteins are only present in the glutamatergic neurone terminals and therefore represent a useful marker of their number. Preliminary western blotting studies indicate that there is a reduction in VGLUT1 (but not VGLUT2) in the parietal cortex in AD but not in the temporal cortex (Kirvell *et al.*, 2002). However, in a different study vesicular glutamate uptake rate was lower in the temporal cortex from AD patients (Westphalen *et al.*, 2003). This lack of change in protein, but with a reduction in the protein's related activity, suggests a functional downregulation of the protein in both cases. The exact consequences of such changes remain to be determined.

Upon release into the synapse, approximately 95 per cent of glutamate is removed by glutamate transporter proteins named GLT, GLAST and EAAC. These are mainly present upon glial cells. Studies of D-aspartate binding to transporter sites in both fresh and frozen postmortem tissue reveal significant reductions in many cortical areas. However, the relevance of this measure to glutamate uptake is doubtful. Antibodies directed against the individual glutamate transporters produce conflicting data. Reduced levels of GLT protein (but not its mRNA), with normal levels of both GLAST and EAAC have been reported, not confirmed by our own studies (unpublished). Even assuming there was no reduction of transporter protein, there is considerable evidence for oxidative damage of proteins such as these glutamate transporters. This might explain the functional deficit in glutamate uptake hypothesized above (Danbolt, 2001).

Postsynaptic glutamate receptors fall into two main classes, ionotropic and metabotropic. The ionotropic subtypes, N-methyl-D-aspartate (NMDA) and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate subtypes have varying permeability to Na⁺ and Ca²⁺ ions. The metabotropic subtypes couple to adenylyl cyclase, phospholipase C or ion channels. The ionotropic subtypes are of particular interest given the proposed mechanism of action of the novel compound memantine on the NMDA receptor (see below). Studies have demonstrated reductions in the NMDA receptor complex in the hippocampus and neocortex.

29.2.1 Glutamate and cognition

A role for glutamate and glutamate receptors in learning and memory is widely recognized. For example NMDA antagonists impair learning and memory, while NMDA agonists and

facilitators improve memory (Francis *et al.*, 1993). Likewise AMPAkinases (positive modulators of AMPA receptor function) facilitate learning and memory (Lynch, 1998). Circumstantial evidence of the involvement of glutamatergic pathways includes the well-established role of structures such as the hippocampus in learning and memory. More specifically, lesions of certain glutamatergic pathways impair learning and memory. In addition, glutamate and glutamate receptors are involved in mechanisms of synaptic plasticity (LTP and long-term depression [LTD] of the synapse) which are considered to underlie learning and memory. Loss of synapses and pyramidal cell perikarya from the neocortex of AD patients correlate with measures of cognitive decline. The latter is considered to be the best evidence for a functional role of glutamatergic involvement in cognitive dysfunction in AD (Francis *et al.*, 1993).

29.2.2 The glutamatergic system and AD pathology

Excitotoxic cell death involves excess activation of receptors, leading to raised intracellular Ca^{2+} and consequent activation of a cascade of enzymes, resulting in cell death by necrosis or apoptosis (Lipton, 1999). During the 1980s it was also suggested that endogenous glutamate could accumulate and become excitotoxic, perhaps as a result of impaired clearance (as a consequence of disrupted transporter function or indirectly in conditions of reduced energy availability). There is some evidence that energy levels may be reduced in AD due to perturbed mitochondrial function (Francis *et al.*, 1993) and considerable evidence for oxidative damage of proteins including the glutamate transporter (Keller *et al.*, 1997). Others have cautioned that there is no simple relationship between raised extracellular glutamate concentrations and cell death *in vivo*. It remains possible that changes in numbers of glutamate receptors or changes in ion selectivity may lead over time to cell death. For instance the large numbers of calcium-permeable AMPA receptors present on basal forebrain cholinergic neurones may be linked to their loss in AD (Ikonovic and Armstrong, 1996).

A further possible contribution to cell death is linked to reduced glutamatergic neurotransmission. Activation of receptors linked to phospholipase C (such as some metabotropic glutamate receptors) has been shown to increase the secretion of neuroprotective forms of APP and decrease $\text{A}\beta$ while at the same time reducing the phosphorylation state of tau. If glutamate neurotransmission is reduced as a consequence of tangle formation, one may hypothesise that $\text{A}\beta$ production may increase and tau become more hyperphosphorylated in neurones innervated by the affected neurone (Francis *et al.*, 1999).

29.3 INTERACTIONS BETWEEN CHOLINERGIC AND GLUTAMATERGIC SYSTEMS

It is important to remember that glutamatergic neurones of the neocortex and hippocampus are influenced by ACh through

nicotinic and muscarinic receptors (Chessell and Humphrey, 1995; Dijk *et al.*, 1995). Terminals of cholinergic neurones are found in all layers of the neocortex, synapsing with pyramidal neurones in layers II/III and V (Turrini *et al.*, 2001). Both muscarinic and nicotinic receptors activate pyramidal neurones and hence facilitate glutamate release in a rat model (Chessell and Humphrey, 1995; Dijk *et al.*, 1995). It therefore follows that treatment of patients with cholinomimetics is likely to increase glutamatergic function.

29.4 TREATMENT STRATEGIES BASED ON GLUTAMATERGIC NEUROTRANSMISSION

Cholinergic stimulation is one pathway to enhancement of glutamatergic function. Other treatment strategies that more directly increase the activity of remaining glutamatergic neurones, without causing excitotoxicity, represent an important target for the symptomatic treatment of AD, and may have a disease-modifying effect. Several approaches have been tried including positive modulation of both AMPA and NMDA receptors. AMPAkinases, which are considered to work by increasing the sensitivity of these receptors, are currently in clinical trial for MCI (Johnson and Simmon, 2002). Modulation of the NMDA receptor has been attempted via the glycine co-agonist site with clear indication in preclinical studies that the partial agonist d-cycloserine improved learning and memory (Myhrer and Paulsen, 1997). Clinical studies have suggested some benefit but full-scale trials have not been initiated (Schwartz *et al.*, 1996). There is currently no evidence that these drugs enhance excitotoxicity.

Perhaps the most surprising development is the success of the uncompetitive NMDA antagonist, memantine, in clinical trials in moderate and severe AD (Reisberg *et al.*, 2003). At first sight one would consider that such an approach – blockade of a receptor that would normally be activated in learning and memory – to be counterintuitive. However, there is evidence that this molecule acts like magnesium ions, able to prevent background activation of the NMDA receptor ('noise'), whilst allowing activation of this receptor for LTP formation (Francis, 2003). There is also a report of a clinical trial by Forest Laboratories Inc. (Tariot *et al.*, 2004) that shows a benefit of the addition of memantine to established treatment with a ChEI in AD patients. Since ChEIs are likely to act in part by increasing glutamate release ('signal') (Dijk *et al.*, 1995; Francis *et al.*, 1999), the benefit may be hypothesised to come from the combination of a reduction in glutamate 'noise' (by memantine) and an increase in discrete glutamate signals (donepezil) (Francis, 2003).

29.5 CONCLUSION

The changes in cholinergic neurotransmission seen in the brains of patients dying with AD provided the rationale for the development of compounds aimed at symptom relief.

Treatment of AD patients with ChEIs has confirmed the relevance of this finding. However, it has long been recognized that the major changes in AD are likely to involve the more abundant cortical glutamatergic pyramidal neurones. Hence the need for this to be addressed. Since increasing cholinergic function will also increase glutamatergic activity, there may be synergistic benefit from co-administration of drugs that target both the cholinergic system (ChEIs) and glutamatergic systems (e.g. memantine). As disease-modifying treatments become available it is likely that symptomatic therapy will continue to be required, and indeed there is evidence that such treatments may also slow disease progression.

Although Alzheimer (1907) highlighted the two key histological lesions, neurofibrillary tangles (NFT) and amyloid plaques 100 years ago, recent developments in molecular biology, molecular genetics, immunohistochemistry, image analysis and protein chemistry have transformed our understanding of the pathogenesis of Alzheimer's disease (AD). For practising neuropathologists, immunohistochemistry in particular has become an essential part of the diagnostic armoury to complement the neurohistology of the common neurodegenerative conditions.

30.1 PATHOLOGY OUTSIDE THE CENTRAL NERVOUS SYSTEM

General post-mortem examination does not reveal any abnormalities outside the nervous system. Patients with AD die from terminal respiratory illness, and bronchopneumonia is most often the cause of death. Ongoing investigations have, however, revealed that subtle biochemical abnormalities may not be restricted to the brain. AD may, like a systemic illness, cause secondary changes in the cerebrospinal fluid (CSF) and peripheral blood, which reflect neuronal metabolism of the A β amyloid and tau proteins. As the disease progresses, the metabolic pools of A β and tau increase within the CSF and blood. Towards the end stages of illness, the A β levels may decrease as the brain acts as a metabolic 'sink' (Ritchie *et al.*, 2003).

That sensory outposts associated with the brain undergo degeneration has been known for some time. The optic nerve

(Hinton *et al.*, 1986) and retinal ganglion cells (Blanks *et al.*, 1989) show degenerative changes and the anterior olfactory nucleus develops NFTs (Esiri and Wilcock, 1984). In addition, abnormalities in the processes of olfactory neurones in the nasal mucosa have been reported (Talamo *et al.*, 1989) and tau-reactive filaments, absent from controls, have been described in the olfactory mucosa in biopsy specimens of patients with probable AD (Tabaton *et al.*, 1991a). Deposition of A β in the periphery of the lens may also be linked to AD, although more studies are required to confirm this association (Goldstein *et al.*, 2003).

30.2 MACROSCOPIC PATHOLOGY

The naked eye appearances of the brain range from unremarkable to grossly abnormal. The leptomeninges may be thickened, particularly over the convexity, and may show orange-brown areas of various sizes, indicating old, circumscribed subarachnoid haemorrhage, which most often results from amyloid (congoophilic) angiopathy. The cranial nerves are normal and the large cerebral vessels in uncomplicated cases of AD have not been damaged more by atherosclerosis than expected from the patient's age. Brain weight is quite often reduced, sometimes below 1000 g. Since brain weight normally depends on the patient's age, sex and constitution, the degree of atrophy should be considered in the light of these factors. More appropriately, the severity of cerebral atrophy can be assessed by comparing the volume of the brain with the capacity of the intracranial space (Davis and Wright,

1977). A discrepancy between the findings of neuroimaging and neuropathology is not unusual: cerebral atrophy reported on computed tomography (CT) or magnetic resonance imaging (MRI) scans may not always be confirmed at post-mortem examination. Agonal changes of haemodynamics, post-mortem delay, and the effects of fixation on the brain may be responsible for this discrepancy. The normal ratio of 8:1 of total brain weight to that of the brain stem and cerebellum may decrease, indicating loss of tissue from the cerebral hemispheres. The atrophy is usually diffuse and symmetrical, although the frontoparietal region and the temporal lobes may be more severely affected than the rest of the brain (Figure 30.1). Moderate-to-severe atrophy is easy to discern: the sulci are widened and the gyri narrowed both on the outside and on coronal slices. The latter also reveal enlarged lateral ventricles with rounded angles and additional space between the hippocampi and the wall of the temporal horns. Decrease in the thickness of neocortical ribbon, apart from extreme cases of atrophy, is difficult, and may prove deceptive, to assess on naked-eye appearances. A quantitative study, however, revealed a decrease of neocortical areas of all lobes in AD, whereas in patients over the age of 80 only the temporal cortex was atrophied (Hubbard and Anderson, 1981, 1985). Reduction in cortical area may result from a decrease in the length rather than in the width of cortex, indicating loss of columns of cells and fibres perpendicular to the pial surface. A correlation appears to exist between the length, but not the thickness, of the cortical ribbon and dementia score (Duyckaerts *et al.*, 1985). Apart from occasional small, orange-coloured old haemorrhages in the cortex, suggestive of amyloid angiopathy, uncomplicated AD usually is not associated with any other focal lesions.

Figure 30.1 On the left, a coronal slice of the brain of a patient with severe Alzheimer's disease showing atrophy: the lateral ventricle is enlarged with rounding of its angle and there is additional space between the hippocampus and the inferior horn of the lateral ventricle. Several gyri are narrowed and the lateral fissure is widened. On the right, a slice of the right hemi-brain of a normal subject.

30.3 HISTOLOGY, ULTRASTRUCTURE, IMMUNOCYTOCHEMISTRY AND MORPHOMETRY

The neurohistological features of AD are complex and variable. The two hallmark lesions, amyloid plaques and NFTs (Figure 30.2), are complemented by granulovacuolar degeneration, Hirano bodies, neuronal loss, abnormalities of neuronal processes and synapses, astrocytic and microglial response, and vascular changes. The white matter also may be affected (Esiri *et al.*, 1997).

30.3.1 Amyloid plaques

The amyloid or neuritic plaque (also referred to as a 'senile' plaque) is one of the major lesions found in the AD brain, and these plaques were first described by Blocq and Marinesco in 1892. These structures, ranging in size from 50 to 200 μm (Terry, 1985), can be readily demonstrated in frozen and paraffin-embedded sections by silver impregnation methods (Figure 30.3). The lesion consists of an $\text{A}\beta$ amyloid core with a corona of argyrophilic axonal and dendritic processes, $\text{A}\beta$ amyloid fibrils, glial cell processes and microglial cells. Neuritic processes in the periphery of the plaque are frequently dystrophic and contain paired helical filaments, which are composed largely of ubiquitinated and phosphorylated tau protein (Gonatas *et al.*, 1967; Hanger *et al.*, 1991). In 1927, Divry demonstrated that the core of the AD plaque contained a congophilic amyloid substance, which gave an apple green colour under polarized light. The plaque amyloid is composed of 5–10 nm filaments made up of a 40–43 amino acid (4 kDa) protein (Masters *et al.*, 1985), and now referred to as $\text{A}\beta$ protein.

Three types of plaque have been identified in conventional silver staining preparations: 'primitive' or 'early', 'classical' or 'mature', and 'burnt-out' or 'compact'. On the basis of light and electron microscopic studies, a three-stage evolution of the plaque has been proposed. The first stage is the

Figure 30.2 Neurofibrillary tangles and neuritic plaques in the neocortex. Modified Bielschowsky silver impregnation.

'primitive' plaque, composed of a small number of distorted neurites, largely presynaptic in origin with few amyloid fibres, astrocytic processes and the occasional microglial cell. The second stage is the 'classical' or 'mature' plaque with a dense amyloid core with a halo of dystrophic neurites, astrocytic processes and cell bodies and the occasional microglial cell. The final stage in this sequence is the 'burnt-out' plaque consisting of a dense core of amyloid (Terry *et al.*, 1981; Esiri and Morris, 1997). The relationship between dystrophic neurites, neurofibrillary degeneration and A β amyloid deposition is not fully understood, but the neurites and tangles appear to be downstream of A β accumulation. These three stages of plaque development have not been confirmed in experimental transgenic mice and therefore the temporal relationships suggested above remain speculative: it may yet transpire that the three types of plaques are independent of each other.

Studies using antibodies raised against A β protein have revealed the presence of a much more widespread deposition of amyloid than is visualized by traditional staining methods (Majocha *et al.*, 1988; Gentleman *et al.*, 1989; Armstrong *et al.*, 1996; Figures 30.4–30.8). A β immunoreactivity has been detected throughout the central nervous system including

the neocortex, hippocampus, thalamus, amygdala, caudate nucleus, putamen, nucleus basalis of Meynert, mid-brain, pons, medulla oblongata, the cerebellar cortex and spinal cord (Joachim *et al.*, 1989; Ogomori *et al.*, 1989). These deposits take a variety of forms and include subpial, vascular, dysphoric, punctate or granular, diffuse, stellar, ring-with-core, and compact deposits (Ogomori *et al.*, 1989). A laminar pattern of A β deposits in the neocortex has been

described with concentrations in layers II, III and V (Majocha *et al.*, 1988).

A β protein is a 38–43 residue polypeptide cleavage product of a larger precursor protein, the amyloid precursor protein (APP) (Kang *et al.*, 1987). Although most cells have the potential for producing APP, neurones and platelets express APP to high levels. Moreover, neurones process the APP with β -secretase (BACE) to a greater extent than most other cell types, and this in turn leads to the formation of full A β sequences. The hypothesis that A β deposition is an early event in the pathogenesis of AD has been given support by the presence of extracellular A β in diffuse plaques not associated with any neuritic change, or astrocytic involvement

(Yamaguchi *et al.*, 1991). More condensed A β is, however, associated with a neuritic change, reactive astrocytosis and microglial infiltration and phagocytosis. Most species of A β have been detected by immunohistochemistry using antibodies that recognize epitopes within the full length A β_{1-42} or a truncated A β_{1-40} . The predominant species in sporadic AD is A $\beta_{42(43)}$ and this is found in plaques of all morphological types. Diffuse plaques contain mainly A $\beta_{42(43)}$ (Mann *et al.*, 1996a, b).

A number of other proteins co-localize with A β including apolipoprotein E (ApoE), a widely distributed protein involved in the transport of cholesterol. There are three common isoforms of ApoE which are encoded by three alleles, $\epsilon 2$, $\epsilon 3$

(a)

(b)

Figure 30.7 Congophilic angiopathy. Blood vessels stained with Congo red showing birefringence under polarized light (a) and A β -amyloid immunohistochemistry (b).

and $\epsilon 4$, and there is a strong association between the presence of the $\epsilon 4$ allele and the age of onset of AD. ApoE has been shown to bind to A β and a high proportion of A β and ApoE deposits tend to be co-localized. Thus, both diffuse and compact A β plaques may be immunolabelled by anti-A β and anti-ApoE antibodies (Cairns *et al.*, 1997b; Armstrong *et al.*, 1998). The presence of one or more $\epsilon 4$ alleles leads to both an earlier onset and a more severe A β amyloidosis (Roses, 1994). The relationship between A β and ApoE is still imperfectly understood, as ApoE knock-out mice have an increased amount of A β deposition on a transgenic APP background.

The plaques are also immunohistochemically positive for a number of neuroactive substances. Acetylcholinesterase, a marker of the cholinergic system, can be demonstrated within and around the neuritic elements of the corona. Many of these elements derive from cholinergic neurones in the basal forebrain, particularly the nucleus basalis of Meynert (nbM), the diagonal band of Broca and the medial septal nuclei. Several other neurotransmitters have been demonstrated in the plaque. These include substance P, neuropeptide Y, neurotensin, cholecystokinin, 5-hydroxytryptamine (5HT) and catecholamine (Walker *et al.*, 1988; Hauw *et al.*, 1991). Ubiquitin, a protein acting as a signal for degradation of abnormal proteins, is also present in intracellular neurites and NFTs (Perry *et al.*, 1987). The protease inhibitor $\alpha 1$ -antichymotrypsin has been localized to the plaque using immunohistochemical methods (Walker *et al.*, 1988). Serum amyloid P (SAP) component is a glycoprotein complex produced in the liver, distributed in serum, and has been detected

in diffuse and consolidated A β deposits, NFTs and neuritic degeneration (Akiyama *et al.*, 1991).

The distribution of plaques varies widely not only within architectonic units but also from one individual to another. The plaques are more numerous in associative regions of neocortex than in sensory areas and are also largest in those laminae characterized by large pyramidal neurones (Rogers and Morrison, 1985). Accumulations of A β protein are found in the neocortex of non-demented elderly individuals without any neurofibrillary change, suggesting that A β deposition precedes neurofibrillary changes. However, NFT formation has been reported in areas devoid of A β (Braak *et al.*, 1986; Duyckaerts *et al.*, 1988; Delaère *et al.*, 1990; Armstrong *et al.*, 1993), indicating that factors in addition to A β may be required to cause aggregation of tau. Tangle-bearing neurones generally project into areas with A β deposition, suggesting some form of retrograde transport of the toxic elements which are associated with A β .

30.3.2 Neurofibrillary tangles

The second histological hallmark of AD is the NFT. These are not specific to AD, since they occur in other neurodegenerative disorders, including Down's syndrome, postencephalitic parkinsonism, dementia pugilistica, amyotrophic lateral sclerosis–parkinsonism–dementia complex of Guam, subacute sclerosing panencephalitis, dementia with tangles with and without calcification, and in myotonic dystrophy (Kiuchi *et al.*,

Figure 30.8 A high-power electron micrograph showing A β -amyloid fibrils (A) surrounding a blood vessel: dyschoric angiopathy. (Courtesy Dr I Janota, Institute of Psychiatry, London.)

1991). Globose NFTs also develop in progressive supranuclear palsy and sporadic motor neurone disease, but their morphology and ultrastructure differ from those seen in AD.

In AD, NFTs are common in the medial temporal structures, in the hippocampus, amygdala and parahippocampal gyrus, and they also occur throughout the neocortex and the deep grey matter including the lentiform nucleus, the nbM, the thalamus, the mamillary bodies, substantia nigra, locus caeruleus, periaqueductal grey matter, the raphé nuclei of the brain stem and the pedunculopontine nucleus.

NFTs are intracellular inclusions composed of ubiquitinated and phosphorylated tau. Their configuration is determined in part by the shape of neurones in which they develop. NFTs are

Figure 30.9 A neuritic plaque (P) and neurofibrillary tangles (T) demonstrated by anti-tau immunohistochemistry.

flame-shaped in pyramidal neurones, whilst in the neurones of the brain stem they assume more complex, globose forms. They can be easily discerned in histological sections stained with haematoxylin and eosin, but are best demonstrated by one of the silver impregnation techniques or with Congo red, which renders them birefringent under polarized light. They can be demonstrated by immunocytochemistry using antibodies against tau and ubiquitin (Figure 30.9).

Electron microscopy reveals the fine structural details (Figure 30.10). NFTs are mainly composed of paired helical filaments (Kidd, 1963), which in turn are formed by two filaments wound around each other. Each filament has a diameter of 10 nm with cross-over points every 80 nm, resulting in the typical periodicity of a double helix. A negative staining technique has demonstrated that each filament is composed of four protofilaments with a diameter of 3–5 nm (Wisniewski *et al.*, 1984). However, computer-assisted electron microscopy has modelled different substructures, indicating that paired helical filaments are not composed of fibrous protofilaments, as are normal neurofilaments, but are constructed from compact globular subunits, which are stacked to form the two filamentous structures of paired helical filaments (Crowther and Wischik, 1985). NFTs also contain straight filaments with an average diameter of 15 nm. These straight and the paired helical filaments may form hybrid filaments, displaying both morphologies, share surface epitopes and have identically shaped structural units. These common features indicate that paired helical and straight filaments are related and they represent only

Figure 30.10 A high-power electron micrograph revealing paired helical filaments of a neurofibrillary tangle. (Courtesy the late Professor LW Duchon, Institute of Psychiatry, London.)

somewhat different assemblies of the same basic molecular unit (Crowther, 1991).

A major component of the NFT is a microtubule-associated protein called tau, which is involved in microtubule assembly and stabilization. In the adult human brain there are six isoforms of tau and all of these are hyperphosphorylated in AD (Hanger *et al.*, 1991; Goedert *et al.*, 1992). Antibodies that recognize specific phosphorylation-dependent epitopes may be used to identify the three sites of tau aggregation: the NFT, dystrophic neurites of plaques and neurofibril threads. Phosphorylation-dependent antibodies may also be used to distinguish the tauopathy in AD from other neurological disorders (Cairns *et al.*, 1997a).

Biochemically, NFTs are also seen to be composed of phosphorylated isoforms of tau, a microtubule-associated glycoprotein (Goedert *et al.*, 1988), and monoclonal antibodies can be used to quantify NFTs (Harrington *et al.*, 1991). They also contain ubiquitin, and anti-ubiquitin antibodies give strongly positive reaction with NFTs (Mori *et al.*, 1987; Perry *et al.*, 1987).

Whilst NFTs are intracytoplasmic neuronal inclusions, they may become extracellular after the neurone that contained them has vanished. These extraneuronal NFTs are most often seen in the hippocampus and entorhinal cortex in advanced disease, and both their antigenic properties and ultrastructural features differ from their intraneuronal counterparts (Tabaton *et al.*, 1991b). They are chiefly composed of straight, not paired, helical filaments and react differently with antibodies to tau and ubiquitin. A small subset of extraneuronal tangles gives positive reactions with antibodies to both tau and A β protein. The degradation of the NFT (the transition from intracellular to extracellular form) is a series of distinct stages involving complex molecular events that alter both the antigenicity and configuration of the tangle (Bondareff *et al.*, 1990). It is the insolubility of NFTs that is most likely to be responsible for the occurrence of extraneuronal forms (Terry, 1990). The extraneuronal NFTs may be enveloped by glial processes and eventually be internalized as part of their degradative cycle.

30.3.3 Granulovacuolar degeneration

Granulovacuolar degeneration was first described by Simchowicz (1911) in the hippocampal neurones of patients with senile dementia (Figure 30.11). Granulovacuoles are abnormal cytoplasmic structures: one or more vacuoles of 3.5 μ m in diameter each contain a single granule. The electron microscope shows a dense granular core, embedded in a translucent matrix. This granular component gives a positive reaction with antibodies to tubulin (Price *et al.*, 1985), to phosphorylated epitopes of the heavy neurofilament peptide (Kahn *et al.*, 1985), to tau (Dickson *et al.*, 1987) and, in some neurones, to ubiquitin (Leigh *et al.*, 1989). A detailed immunocytochemical study has demonstrated that most epitopes of the tau molecule are sequestered in granulovacuoles

and this tau protein is antigenically similar to that found in paired helical filaments. This finding indicates that granulovacuolar degeneration in hippocampal pyramidal neurones vulnerable to neurofibrillary degeneration may offer an alternative metabolic pathway for an abnormal molecule, which contributes to the formation of both granulovacuoles and tangles (Bondareff *et al.*, 1991). Granulovacuoles are now considered to be special autophagosomes that are formed by the sequestration of electron-dense material by a two-layered membrane. Granulovacuoles are virtually restricted to the pyramidal neurones of the hippocampus and in severe AD cases the neuronal cytoplasm is replete with these abnormal structures. They also occur, much less often, in a variety of diseases, including progressive supranuclear palsy, amyotrophic lateral sclerosis–parkinsonism–dementia complex of Guam and tuberous sclerosis.

30.3.4 Hirano bodies

These abnormal structures were first described by Hirano (1965). They are most commonly seen in and amongst the pyramidal cells of the hippocampus. Hirano bodies occur in normal subjects and their frequency increases with advancing age. However, patients with AD have significantly more Hirano bodies than age-matched controls. They also occur in various neurological diseases, including Pick's disease, motor neurone disease and kuru, as well as in animals infected with kuru and scrapie (Gibson and Tomlinson, 1977). Hirano bodies stand out in sections stained with haematoxylin and eosin as bright pink, homogeneous structures that are circular in cross-section with a diameter up to 25 μ m, and rectangular or spindle-shaped up to 30 μ m in length in longitudinal sections. Ultrastructurally, they are composed of a complex, crystalline array of interlacing filaments forming a lattice-like or 'herring-bone' configuration (Tomonaga, 1974). They stain positively with antibodies to actin (Goldman, 1983) and immunostaining for tau has also been reported (Galloway *et al.*, 1987).

Figure 30.11 Granulovacuolar degeneration (arrows) and Hirano bodies (arrowheads) in the pyramidal cell layer of the hippocampus. Haematoxylin and eosin.

30.3.5 Neuronal loss

Neuronal loss is far more difficult to assess than the histological abnormalities previously described, although the decrease of particular neuronal populations is more readily accepted than in normal ageing (Terry, 1990). Whilst well-defined, neuronal groups, like the locus caeruleus, are easier to count, the cerebral cortex presents considerable technical problems. Nevertheless, it has been established that there is a significant decrease of 36–46 per cent in the concentration of large neurones, particularly from layers 3 and 5 of the neocortex (Terry *et al.*, 1981). The loss of the large cortical neurones is age-dependent: the column of these cells is reduced in patients under 80 years of age, but appears to be normal for age in older subjects (Hubbard and Anderson, 1985). This neuronal loss, however, does not affect the neocortex evenly; it appears to be restricted to the frontal and temporal lobes, whereas the parietal and occipital regions are less involved (Mountjoy *et al.*, 1983). The hippocampus is even more severely affected: neuronal fall-out reaches an average of 47 per cent (Ball, 1977) and the number of pyramidal neurones is reduced by 40 per cent in area H1 (Mann *et al.*, 1985). This loss appears to correlate with the number of tangle-bearing cells, whilst the end plate and area H2 are less affected. There is also a substantial decrease of neurones in the cholinergic NbM (Whitehouse *et al.*, 1981), in the cholinergic pedunclopontine nucleus (Jellinger, 1988), in the noradrenergic locus caeruleus (Tomlinson *et al.*, 1981; Marcyniuk *et al.*, 1986) and in the serotonergic raphé nuclei in the brain stem (Yamamoto and Hirano, 1985).

30.3.6 Abnormalities of neuronal processes and synapses

Neuropil threads or 'curly' fibres and dystrophic neurites have been well documented in silver-impregnated preparations developed by Gallyas (1971), but they attracted attention when it was realized that their occurrence was associated with the severity of dementia (Braak *et al.*, 1986). Neuropil threads or curly fibres are slender, short structures found in the neuropil of the cortex. Dystrophic neurites, some of which contribute to the formation of plaques, also appear as somewhat contorted, thread-like structures in these preparations. These abnormal neurites are likely to be a heterogeneous population of dendrites and axons (Tourtellotte and Van Hoesen, 1991). Their ultrastructural and immunocytochemical features are strikingly similar to those of NFTs, indicating that they also originate from the altered neuronal cytoskeleton. Neuropil threads immunostain with antibodies to tau (Kowall and Kosik, 1987; Probst *et al.*, 1989) and to ubiquitin (Joachim *et al.*, 1987). Electron microscopy has revealed that they are often in dendrites and contain straight filaments of 14–16 nm in diameter in addition to paired helical filaments (Tabaton *et al.*, 1989; Yamaguchi *et al.*, 1990b). Moreover, they are often in the dendrites of those nerve cells

that contain NFTs in their cell body (Braak and Braak, 1988). There is increasing evidence that their distribution is more closely associated with NFTs than with plaques. In addition to abnormal neurites, there are quantitative changes: the terminal segments of dendrites of pyramidal cells in layer 2 of the parahippocampal gyrus are fewer and shorter than in normal adult brains (Buell and Coleman, 1979). Considerable decrease of synapses also occurs and this loss is likely to contribute to the development of the disease (Davis *et al.*, 1987). Moreover, immunocytochemical quantification of synaptophysin, a protein localized in presynaptic terminals, revealed an average decrease of 50 per cent in the density of the granular neuropil immunoreaction in the parietal, temporal and mid-frontal cortex (Masliah *et al.*, 1989). In the electron microscope, some presynaptic terminals were distended and contained altered synaptic organelles, including swollen vesicles and dense bodies, similar to those seen in dystrophic neurites. These latter structures gave positive staining with antibodies to synaptophysin and immunoreactivity was mainly localized to the outer membranes of synaptic vesicles and dense bodies. This finding lends further support to the view that progressive synaptic derangements occurs in the neocortex of AD (Masliah *et al.*, 1991).

30.3.7 Glial changes

Astrocytes can be readily observed immunohistochemically by using an antibody to glial fibrillary acidic protein (GFAP; see Figure 30.12). Both NFTs and plaques have been found to be more prevalent in the pyramidal cell-rich layers II, III and V than in other laminae (Mann *et al.*, 1985; Majocha *et al.*, 1988; Braak *et al.*, 1989) and both have been associated with patterns of gliosis in AD (Beach *et al.*, 1989; Itagakai *et al.*, 1989; Cairns *et al.*, 1992) where perivascular gliosis is prominent throughout the cerebrum. In AD extensive gliosis has a laminar pattern in the neocortex, but there does not appear to be an AD-specific pattern of subcortical gliosis (Beach and McGeer, 1988; Beach *et al.*, 1989). In addition to NFTs, plaques and dystrophic neurites, reactive astrocytosis is associated with degenerating neurones in AD. In the pathogenesis of the plaque it appears as though A β deposition is an early event preceding gliosis (Yamaguchi *et al.*, 1990a).

It has been proposed by Probst *et al.* (1987) that microglial cells, normally associated with phagocytosis, are a possible source of A β in AD. The presence of major histocompatibility complex (MHC) class II antigens on reactive microglia in association with plaques in AD is indicative of an immune response, although the significance of such expression on the cell surfaces of reactive microglial cells is uncertain. Reactive microglial cells have been found in association with diffuse A β deposits and, more frequently, with compact cores of plaques (Itagakai *et al.*, 1989). Leukocyte common antigen and complement receptors, including the cell adhesion molecules, the β -2 integrins, have been localized on microglial

Figure 30.12 Astrocyte cell bodies and processes encircling a plaque. Glial fibrillary acidic protein immunohistochemistry.

cells around plaques (Akiyama and McGeer, 1990). These data are consistent with a phagocytic role for microglia and provide evidence for an inflammatory response of brain tissue in AD (see Chapter 33).

30.3.8 Vascular abnormalities

When stained with the dye Congo red, cerebral blood vessels containing amyloid appear apple green under polarized light. Pantelakis (1954) called this deposition congophilic angiopathy (see Figure 30.7, p. 396). These congophilic changes affect leptomeningeal and cortical arterioles, and occasionally intracortical capillaries and venules. The parieto-occipital cortex is usually more affected than that in the frontal and temporal lobes and the change is most easily identified in the striate cortex in the occipital lobe. The brain stem and cerebellar cortex are less frequently affected.

Vascular amyloid is now known to be the same protein as the A β amyloid found in plaques. Although vascular amyloid is frequently present in AD, it may be absent even when there are abundant plaques and parenchymal deposits. Occasionally, A β appears to extend from the vessel wall into the surrounding cerebral tissue; this is referred to as dysphoric angiopathy (or the drusige Entartung of Scholz). This is commonly seen

in lamina III of the striate cortex and adjacent occipital cortex, occasionally in Ammon's horn and in the cerebellum (Hauw *et al.*, 1991).

Two forms of familial cerebral amyloid angiopathy or hereditary cerebral haemorrhage with amyloidosis have been identified. In both the Dutch (Levy *et al.*, 1990) and Icelandic forms there is an autosomal dominant form of inheritance. Patients suffer from recurrent cerebral haemorrhages that lead to an early death (before 40 years of age in Icelandic patients, and between 50 and 60 years in Dutch patients). The amyloid fibrils in patients with hereditary cerebral haemorrhage with amyloidosis – Icelandic type (HCHWA-I) are made up of cystatin C, a degradation product of a larger protease inhibitor. In the Dutch patients (HCHWA-D) the amyloid fibrils are composed of a 39 amino acid peptide homologous to A β protein found in amyloid angiopathy in AD, Down's syndrome, sporadic cerebral amyloid angiopathy (CAA) and normal ageing. Mutations in the A β coding sequence in these families proved to be seminal for understanding the role of A β in AD pathogenesis.

30.3.9 White matter changes

Although the degenerative process in AD primarily affects the grey matter, the white matter may not be spared. CT scans may show areas of hypodensity. The precise pathological substrate remains controversial. Since amyloid angiopathy is often part of AD, it is possible that the white matter changes result mainly from vascular causes. Symmetrical, incomplete infarctions of the white matter histologically correspond to partial loss of myelin sheaths, axons and oligodendrocytes. These changes are accompanied by mild astrocytosis and macrophage response, whilst there is hyaline fibrosis of small vessels. Cavitating infarctions do not develop and this white matter damage, which occurs in the absence of hypertensive vascular degeneration, is thought to be caused by hypoperfusion (Brun and England, 1986). However, severe loss of cortical neurones may also contribute to fibre loss and consequent pallor of white matter.

30.4 FAMILIAL ALZHEIMER'S DISEASE

AD is a disease primarily of old age and it is difficult to determine the proportion of genetic cases as many family members will die before expressing the disease. Familial forms of AD with multiple affected individuals are rare and account for probably fewer than 5 per cent of AD cases. Mutations in the APP gene and two related genes, presenilin-1 (PS1) and presenilin-2 (PS2), account for the majority of early-onset autosomal dominant cases of familial AD (Goate *et al.*, 1991; Lamb, 1997). Although clinical features may differ between families, the neuropathological features are not markedly different between familial Alzheimer's disease (FAD) and early-onset sporadic cases (Davies, 1986). However, prominent

Figure 30.13 Lewy bodies (L) and dystrophic neurites (N) in the midbrain of a patient who died with familial Alzheimer's disease with the APP717 valine-isoleucine mutation. (α -Synuclein immunohistochemistry.)

cerebellar plaques and A β deposition have been reported in familial cases (Iseki *et al.*, 1990; Struble *et al.*, 1991; Fukutani *et al.*, 1996, 1997). Computerized methods of image analysis have been used to more accurately define the pathological phenotype of AD. Using these techniques, differences in A β load have been reported. Mann *et al.* (1996a, b) have shown that both APP and PS mutations lead to measurable increases in A β load.

In those cases with an early onset, below 65 years of age, the duration of illness tends to be shorter, and the density of NFTs and plaques is often greater, than in sporadic, late-onset patients. Cortical and brain stem Lewy bodies may coexist with AD in APP (Lantos *et al.*, 1992) and PS mutation patients (Figure 30.13). It is now known that the Lewy body and dystrophic neurites of Parkinson's disease and dementia with Lewy bodies contain the protein α -synuclein (Spillantini *et al.*, 1997). Familial and sporadic forms of AD may also be found in combination with cerebrovascular disease. Rare sporadic cases of AD have been found in combination with other neurodegenerative disorders including Pick's disease, Creutzfeldt–Jakob disease, motor neurone disease and progressive supranuclear palsy.

30.5 PATHOGENESIS

The aetiology and pathogenesis of AD are not fully understood. Although many risk factors have been proposed, the evidence for most of these is weak except for age, family history and ApoE genotype. A genetic contribution to the aetiology of AD has received strong support in the last few years and it is likely that more genes (such as LRP, α_2 M and IDE) will be associated with the disease. In the more common non-familial, sporadic cases, and in discordant monozygotic twins, environmental factors may be important in the aetiology.

The discovery of mutations in the APP and PS genes, all of which lead to over-production of A β or preferential production of a long 42-amino acid form of A β , has confirmed the

central role of APP and A β deposition in the pathogenesis of AD (Goate *et al.*, 1991; Lamb, 1997). Deposition of A β appears to be an early event in both AD and Down's syndrome and precedes the development of plaques, NFTs, microgliosis and astrocytosis (Rozeumuller *et al.*, 1989). The amyloid deposits characteristic of AD, 42–43 amino acid A β fragments, are the abnormal proteolytic cleavage products of APP. It is known that A β has both toxic (Yanker *et al.*, 1989) and trophic (Whitson *et al.*, 1989) effects on neurones in culture, which may relate to plaque and NFT formation.

Metal ions such as aluminium have been implicated as an environmental toxic agent in the pathogenesis of AD, since it has toxic effects on neurones in culture and its accumulation in renal patients is known to be encephalopathic. Accumulations of aluminosilicates in the central region of the core of plaques and within neurones containing NFTs have been reported (Candy *et al.*, 1986). Another environmental factor implicated in A β deposition is head trauma. Roberts *et al.* (1991) showed that in a series of patients suffering sustained head injury, there were extensive deposits of A β in the neocortex, suggesting that severe head injury can trigger A β deposition in a few days. Whether these patients would have gone on to develop AD is unknown.

Although varying amounts of A β with a range of morphologies may be found in cognitively normal elderly individuals, it is quantitatively much more severe and cyto-architectonically defined in AD (Majocha *et al.*, 1988; Cairns *et al.*, 1991). The importance of overexpression of APP and its abnormal cleavage product, A β , in the pathogenesis of AD has been demonstrated by recent transgenic mouse models (Borchelt *et al.*, 1998). Transgenic mice expressing the full length human APP develop A β deposits similar in morphology to those found in AD, but as noted above, differing somewhat in their human 'subtype' counterparts. These animal models will be useful for testing anti-amyloid drugs.

30.6 NEUROPATHOLOGY AND CLINICAL FINDINGS

Alzheimer first suggested a correlation between the presence of NFTs, plaques and dementia in 1906. Roth *et al.* (1966) and Wilcock and Esiri (1982) demonstrated that elderly patients' mental test scores correlated with the neuropathological lesions characteristic of AD. Many other neuropathological and neurochemical changes (Zubenko *et al.*, 1991) have been associated with AD and the accuracy of clinical diagnosis ranges from 43 to 87 per cent (Boller *et al.*, 1989; Jellinger *et al.*, 1990) and, in one sample of 26 cases, 100 per cent (Morris *et al.*, 1988). Conversely, inaccuracy in the ante-mortem diagnosis of AD is common, and for this reason, post-mortem examination remains an essential component of AD research. An accurate differential diagnosis is made difficult by the problems of distinguishing between mild dementia and the cognitive changes of normal ageing ('mild

cognitive impairment') – the earliest clinically recognizable form of AD.

Although not all studies have produced positive findings, there is general agreement that cases with earlier onset, shorter duration of illness and greater cognitive impairment have more cortical plaques, whereas late-onset cases, which take a milder course, tend to show less cortical change (Bowen *et al.*, 1979; Hansen *et al.*, 1988). High correlations were observed between cognitive performance and plaque counts in brain biopsies from dementing patients examined earlier in the course of illness (Mann *et al.*, 1986, 1988; Neary *et al.*, 1986). Plaques and NFTs were detected in 38 (75 per cent) of 51 unselected non-demented patients who died between the ages of 55 and 64 years (Ulrich, 1985). These lesions were consistently found in the entorhinal cortex, the hippocampus, or both, suggesting that this region is a site of origin of the lesions. A morphometric analysis of cerebral slices by de la Monte (1989) showed that patients with 'preclinical' AD had shrinkage of white matter comparable to that found in AD, yet the cortical areas were normal, suggesting that white matter degeneration is an intrinsic component of AD. In clinical AD there was global cerebral atrophy of both cortex and white matter. Neuronal death in patients with AD is closely associated with extensive synapse loss in the neocortex, and this has been correlated with cognitive impairment (Terry *et al.*, 1991). Measures of the morphological substrates of brain function frequently show an overlap between AD and control groups (Coleman and Flood, 1987). There does not appear to be a consistent relationship between the pattern of vascular amyloid and the distribution of plaques. Neither is there a correlation between vascular amyloid and dementia (Mountjoy *et al.*, 1982). More recent studies have confirmed that the A β amyloid *per se* is probably not the best indicator of severity of disease – rather, the soluble A β , which are a prelude to plaque formation, show a closer correlation with the degree of neurodegeneration (McLean *et al.*, 1999).

30.7 DIAGNOSTIC PROBLEMS AND CRITERIA

Despite the fact that the neurohistological abnormalities of AD have been established, the neuropathological diagnosis is not always straightforward (Cruz-Sanchez *et al.*, 1995). There are several reasons to explain this problem.

First, the histopathology of AD is complex and the various abnormalities, previously described, when severe and extensive enable a diagnosis to be made. However, there are considerable differences from case to case, and this histological heterogeneity of disease presents the most formidable difficulties for the neuropathologist. The severity and distribution of any of the histological lesions may vary considerably and are influenced by the age and genetic background of the patient, amongst other factors. Quantitative morphometry and neurochemistry have supported the view that AD is not a uniformly diffuse disorder: morphological abnormalities and neurochemical deficits tend to be more severe and more

extensive in younger patients. There may be subtle differences in the pathology of familial and sporadic cases, and atypical cases exist both in the familial and sporadic forms.

Second, although there are several histological abnormalities in AD, only A β deposition approaches a level of specificity, since many of these lesions occur in normal ageing and in other diseases of the nervous system.

Third, AD may be associated with other diseases, most commonly with vascular disease and rarely with other neurodegenerative disorders.

For these reasons, it is important to establish a set of neuropathological or neurochemical criteria. Although several attempts have been made, no universally accepted criteria exist for the neuropathological diagnosis of AD. A Working Party, convened by the Medical Research Council in the United Kingdom, offered only minimal criteria for sampling and examination of AD tissues (Wilcock *et al.*, 1989). An attempt has been made to define AD in terms of hippocampal pathology. Based on quantitative morphometry, it was suggested that more than 20 tangle-bearing neurones per mm³ and fewer than 5600 neurones per mm³ should be diagnostic (Ball *et al.*, 1985). This threshold, however, has proven too low and would include 30 per cent of mentally normal elderly people (Anderson and Hubbard, 1985). A North American panel of neuropathologists has recommended age-adjusted plaque and tangle counts. In patients under 50, plaques and tangles in excess of 2–5 per mm² in the neocortex should secure the diagnosis of AD. Between 60 and 65 years, there should be more than 8 plaques per mm², between 66 and 75 years more than 10 and over the age of 75, more than 15. In the first two age groups, some neurofibrillary tangles may be found, but in the last group these may not be necessary for diagnosis (Khachaturian, 1985). The value of these criteria has, however, been diminished by the statement that these figures can be revised downwards by as much as 50 per cent in the presence of positive clinical history of AD.

A survey of the practical application of these criteria has revealed considerable variations in the use of criteria and the methods of examination (Wisniewski *et al.*, 1989). A European Multicentre Study found that subjective assessment currently was more reliable to compare cases from different laboratories, since quantitative values are greatly influenced by the neurohistological technique employed (Duyckaerts *et al.*, 1990).

The most widely used protocol for neuropathological assessment is that developed by the Task Force of the Consortium to Establish a Registry for AD (CERAD). This takes clinical findings into consideration, and neuropathological criteria for 'definite', 'probable' and 'possible' AD are proposed (Mirra *et al.*, 1991). This system is based on a semi-quantitative assessment of plaque scores. The presence or absence of tangles does not enter into the formal assessment. The more recent National Institute on Aging and Reagan Institute (NIA-RI) criteria require both semi-quantitative measures of plaque and tangle distribution and additional sampling (Geddes *et al.*, 1997; Hyman and Trojanowski,

1997). A change from previous criteria is the opinion that any Alzheimer lesions should be considered as pathological even when they appear to be incidental. By acknowledging that a spectrum of changes exists within AD, these criteria may prove more successful than previous ones (Geddes *et al.*, 1997; Hyman and Trojanowski, 1997).

In the final analysis, it is likely that a combination of morphologic and biochemical assays will yield a set of criteria through which a secure diagnosis of AD will be made. Current indications are that blood, CSF and brain tissue levels of A β (soluble, insoluble), tau and β -secretase (BACE) may provide a more practical method for the diagnosis and therapeutic monitoring of AD (McLean *et al.*, 1999; Holsinger *et al.*, 2002, 2004).

This chapter was originally written by Peter Lantos and Nigel Cairns and appeared as chapter 37 in the second edition of Dementia. It was updated by Colin Masters for this third edition.

		References	422

Neurodegenerative dementias are characterized by an insidious onset of memory and personality changes that follow a progressive course over at least a 6-month period in the absence of acute medical, psychiatric and/or neurological diseases. Numerous factors may increase the risk for their development: advanced age, genetic predisposition, gender, low educational level, various environmental factors (e.g. head injury, exposure to aluminium, pesticides, electromagnetic field) and altered autoimmune mechanism. A consistent feature of the neurodegenerative process, highly correlated with the extent of cognitive impairment, is the presence of neurofibrillary pathology (neurofibrillary tangles (NFTs), dystrophic neurites and neuritic plaques; see Plate 8).

Immunohistochemical studies have identified a number of proteins that are present within neurofibrillary pathology. Neurofilament proteins, actin, ubiquitin, vimentin, amyloid protein (A β), microtubule associated protein 2 and tau protein have been found within NFTs (Plate 8). The term 'tauopathies' has now been introduced to refer to a rather heterogeneous group of neurodegenerative disorders attributable to characteristic filamentous tau deposits and/or altered tau processing (Box 31.1).

The discovery of numerous tau protein mutations in frontotemporal lobe dementia and parkinsonism linked to chromosome 17 (FTDP-17) provides further proof of the central role of tau abnormalities in the aetiology of neurodegenerative disorders and its importance for the dementia syndrome. This chapter will address the normal function of tau protein, mechanisms of its aggregation into intracellular filamentous structures found in tauopathies, biochemical and

genetic characteristics of tauopathies, tau protein diagnostic advances and therapeutic developments for prevention of tau aggregation.

31.1 TAU PROTEIN: STRUCTURE AND BIOLOGICAL ROLE

Tau protein is a family of hydrophilic, heat-stable and soluble microtubule-associated proteins (MAPs). Its major functions include stabilization of microtubules (MTs), stimulation of MT polymerization, and suppression of MT dynamics and, together with MAP1B, tau may regulate axonal elongation and neuronal migration. Tau protein is predominantly expressed within neurones and axons of the central and peripheral nervous system, and, albeit at low level, is also found in astrocytes, oligodendrocytes and neuronal nuclei. Its mRNA is also present in non-neuronal tissue, including heart, kidney, liver, muscles, pancreas, testis and fibroblasts. In progressive supranuclear palsy (PSP), frontotemporal dementia (FTD), severe Alzheimer's disease (AD), animal models of tauopathies and ganglion cell tumours, tau protein is also overtly expressed in glial cells, in particular oligodendrocytes.

The human gene encoding tau protein (MAPT) is located on chromosome 17 (17q21) and consists of 16 exons. Alternative RNA splicing of exons 2, 3 and 10 in the adult human brain results in six different tau isoforms (see Plate 9). These contain:

- an acidic *N*-terminal domain (containing zero, 0N; one, 1N; or two, 2N; 29 amino acid *N*-terminal inserts, due

*Pick's complex denoting overlap between 3R and 4R, and tau-less tauopathies. (Modified according to Kertesz, 2003.)

to alternative splicing of exons 2 and 3) that interacts with plasma membrane and associates with phospholipase C- γ ;

- a proline-rich middle domain; and
- a C-terminal domain (encoded by exons 9–12) containing three or four tandem repeats (3R and 4R, respectively, formed by alternative splicing of exon 10: referred to as the 'microtubule-binding domain').

These isoforms consist of 352–441 amino acids, with an apparent molecular weight ranging from 45 to 65 kDa.

Exons 4A, 6 and 8 are not characteristic for the human brain mRNA: human mRNA containing either exon 6 or 8 has not been described, whereas mRNA containing exon 4A is found only in the larger human, rodent and bovine peripheral isoform of tau protein. This higher molecular weight tau protein ('big tau') is expressed as a result of alternative splicing and inclusion of the large exon 4A in the N-terminal portion of the tau protein molecule, with an extra 254 amino acid insert (Goedert *et al.* 1992). In the adult rat brain, almost all neurones extending processes into the peripheral neuronal system express 'big tau', except for the bipolar neurones of the olfactory, vestibular and spiral ganglia. Retinal ganglion cells are the only central nervous system (CNS) neurones whose processes remain entirely within the CNS, which express high levels of 'big tau'.

The expression of the different tau isoforms is developmentally regulated. In the embryonic brain, only the shortest of the six isoforms (0N3R) is expressed. In the adult human brain, all six isoforms are present and the 4R isoforms are predominant in the adult human and rodent brain. However, even in adulthood, not all six tau isoforms are present in all neuronal cell lines. Thus, tau mRNAs containing exon 10 are not found in the granular cells of the dentate gyrus (Goedert *et al.*, 1989).

31.1.1 Role of tau protein in MT assembly and tubulin polymerization

Tau, MAP1 and MAP2 proteins regulate the assembly of microtubules. Tau protein binds to spectrin and actin filaments, and can serve as a linker of MTs to other cytoskeletal components such as neurofilaments. It can also interact with various cytoplasmic organelles, including plasma membrane and mitochondria.

Tau protein binds to the α - and β -tubulin subunits via 3- or 4- repeat domains, promoting the formation of microtubules (see Plate 10). The 4R tau binds to the MT \approx 3-fold more strongly than 3R tau, and confers the ability to assemble MT more effectively than 3R tau. Two isoforms of five tandem repeat tau protein have been described in chicken brain, and they have the greatest ability to promote MT assembly (Yoshida and Goedert, 2002).

The most potent MT-binding site to induce MT polymerization is the region between MT tandem repeats 1 and 2 corresponding to 274–281 amino acids. This region is unique to the 4R tau, and contributes to the 40-fold tubulin binding difference between 3R and 4R tau alone. The MT-binding region of tau protein also binds to both RNA and residues 250–298 of presenilin 1 (PS1). This region of PS1 is also involved in the binding of GSK3 β . Since the MT-binding region can also inhibit protein phosphatase 2A (PP2A) activity by competing for binding tau protein at the MT-binding domains, this region may be involved in regulating the extent of post-translational modification of the tau protein (e.g. phosphorylation).

31.2 TAU AGGREGATION AND FORMATION OF FILAMENTOUS STRUCTURES IN TAUPATHIES

Intracellular filamentous structures present in various tauopathies are polymers of the repeat region of tau protein:

- paired helical filaments (PHFs), ultrastructural components of NFTs, dystrophic neurites and neuritic plaques consist of double helical stack filaments, with a longitudinal spacing between crossovers of 65 and 80 nm and a width between 10–15 nm and 27–34 nm;
- straight filaments (SFs), measuring 10–15 nm in width; and
- twisted-ribbon-like filaments with an irregular periodicity of 90–130 nm (found in some familial dementias, e.g. familial progressive subcortical gliosis, cortical basal degeneration [CBD], familial multiple system tauopathy).

Although full-length recombinant tau protein does not aggregate in physiological conditions, at high concentrations and/or low pH, it can aggregate with the MT-binding fragment. Similarly, tau protein can form oligomers upon binding to MTs *in vitro*. The hexapeptide interaction motif at the C-terminal end of the tau protein molecule (³⁰⁶VQIVYK³¹¹) within the R3 MT domain (encoded by exon 11) and its related hexapeptide (²⁷⁵VQIINK²⁸⁰) within the R2 (encoded by exon 10) are able to assemble into thin filaments without a helical appearance, and these filaments can nucleate PHFs from full-length tau. Furthermore, point mutations within this hexapeptide prevent tau aggregation (von Bergen *et al.*, 2001). The repeat region of the tau protein alone can assemble into filaments by forming a β sheet structure. This finding has been confirmed for both native filaments and filaments assembled *in vitro* from expressed wild and mutant tau proteins. Similarly, fibrillization of recombinant tau can be induced by treatment with various agents, including phosphotransferases, polyanionic compounds and fatty acids. However, under similar conditions other proteins also tend to show PHF-like assemblies *in vitro*, e.g. the C-terminal end of amyloid protein precursor (APP) and α 1-antichymotrypsin.

The N-terminal tau domain is not able to form filaments, and it appears to have an inhibitory effect on the formation of tau aggregates. This is further confirmed by the fact that 'big' tau, the isoform found in the peripheral nervous system containing the longest N-terminal domain, does not form filamentous aggregates.

Several putative mechanisms for the formation of intracellular filaments, including PHFs and SFs, have been suggested:

- proteolytic processing of tau protein;
- mechanisms that detach or decrease the association of tau protein from the MT-binding site;
- mutations in the MAPT gene; and
- enhancement of tau aggregation by the presence of other proteins.

31.2.1 Proteolytic processing of tau protein

Peptides containing little more than the MT-binding region of the tau protein molecule are capable of polyamine-induced self-assembly *in vitro*. Furthermore, NFTs in neurodegenerative disorders contain N- and/or C-terminally truncated tau protein. Although the C-terminal end of the tau protein molecule inhibits polymerization *in vitro*, this inhibitory effect is eliminated following activation of various caspases, and only then can the self-assembly of tau protein occur.

Aggregation of tau protein requiring only the C-terminal truncation downstream of the MT-binding region of the protein molecule has been pursued in this model, based upon the molecular findings that tau protein extracted from PHFs is truncated at the C-terminal end (Glu391; Wischik *et al.* 1988) (Plate 10). Monoclonal antibodies raised against this site immunolabel PHFs that are stripped of their 'fuzzy coat' (the N- and the C-terminal portion of the tau protein molecule). The remaining MT-binding region in this model is considered sufficient to promote self-assembly with other tau MT domains, based on its self-propagating properties. Namely, the truncated tau aggregate generated after the first binding (or 'digestion' cycle) is able to bind full-length tau protein, even with increased affinity. This self-propagation cycle has been demonstrated *in vitro* using tau bound to a solid phase (Wischik and Harrington, 2000). Anionic surfaces presented as micelles or vesicles may well serve to nucleate this type of tau fibrillization. In this model, phosphorylation of tau protein does not enhance tau-tau binding but rather inhibits binding by 24–50-fold.

C-terminal caspase cleavage of the tau protein at Asp421 has 67 per cent more and 10-fold faster polymerization than the full-length tau protein. Furthermore, caspase cleavage and truncation at Asp421 is also observed in A β -treated neurones. This may provide a link between amyloid deposition and the neurofibrillary changes in AD.

31.2.2 Post-translational modification of tau protein: role of phosphorylation

Post-translational modifications are important for the physiological activity of tau protein, and contribute to pathological assembly of the protein into intraneuronal or glial tau pathology. Such modifications include phosphorylation, glycosylation, acetylation and nitration. Nitrated tau aggregates are present in various tauopathies, including AD, Down's syndrome (DS), CBD, PSP, Pick's disease and FTDP-17. The extent of O-glycosylation is equal to the extent of serine/threonine (Ser/Thr) phosphorylation of the tau protein molecule, suggesting a role both in modulating tau protein function and the formation of PHFs.

Of 79 putative tau phosphorylation sites, at least 30 have been identified. These residues are predominantly outside the MT-binding region with the exception of six phosphorylation sites located in R1-R4: Ser262(R1), Ser285(R1-R2 interrepeat),

Table 31.1 Phosphorylated and proteolytic sites of the tau protein in fetal and adult human brain and various proposed stages of tangle development. (According to Wischik et al., 1988; Jicha et al., 1997; Brion et al., 1999; Buée, 2000; Augustinack et al., 2002; Lauckner et al., 2003)

Tangle stages	Phosphorylation and truncation sites of tau protein
Fetal and adult human brain	pSer199, pSer202, pThr205, pThr231, pSer262, pSer396, pSer404
Pre-tangles	pThr153, pSer199/pS202/pThr205, pThr231, pSer262, pSer396, pSer404, pSer409, pSer422
Intracellular NFTs	pSer46, pThr175/pThr181, pSer199, pSer202, pSer214, pSer262/pSer356, pS396/pSer404, pSer422
Extracellular NFTs	pSer199/pSer202/pThr205, pThr212/pSer214, pSer396/pSer404, Glu391 truncation
Glial/astrocytic tau filaments and NFTs	pSer199/pSer202/pThr205, pSer262/pSer356, pSer396/pSer404

Glu, glutamine; NFTs, neurofibrillary tangles; Ser, serine; Thr, threonine

Ser305(R2-R3 interrepeat), Ser324(R3) and Ser352 and Ser356(R4). The extent of phosphorylation of tau protein is inversely associated with attachment to the MT network, especially when phosphorylated at sites Ser214 and Ser262. Phosphorylation outside the MT-binding region also influences MT assembly, reducing the tau-tubulin binding affinity (Plate 10).

Although tau protein hyperphosphorylation is considered to facilitate and induce self-assembly of each of the six tau isoforms into PHFs and SFs (see Plate 11), the same sites of tau phosphorylation are also present in fetal and native adult human tau protein (Table 31.1). Thus, phosphorylated Ser199 (pSer199) is expressed in the hippocampus in childhood, in neurones vulnerable to neurodegeneration in young adults, in early and late stages of AD, and in other neurodegenerative disorders with neurofibrillary pathology. Similarly, other tau phosphorylated sites (pSer202, pThr205, pSer262: pSer396, and pSer404) are found in fetal, adult human and AD brain tissue. In addition to pSer199 and pSer202, diffuse intraneuronal accumulation of pSer409 and pSer422 is present in the so-called 'pretangle' stage of tau aggregates (Table 31.1; Plate 11). pSer262 is the only site in the first repeat of tau that is phosphorylated. pSer262 neither alters the binding affinity of tau to MT nor abolishes the MT-binding, regardless of the phosphorylation state of flanking domains.

31.2.2.1 PROTEIN KINASES AND PHOSPHATASE INHIBITORS

Up-regulation of protein kinases and down-regulation of phosphatase inhibitor activities are both implicated in the abnormal phosphorylation of the tau protein molecule in neurodegenerative disorders (Box 31.2).

Box 31.2 Protein kinases, phosphatases and modulators of tau phosphorylation involved in regulating (de)phosphorylation of the tau protein molecule in normal ageing and dementia

Proline-directed kinases (Ser-Pro and Thr-Pro sites)

- Glycogen synthase kinase-3 (GSK-3)
- Cyclin-dependent kinase-5 (cdk5)
- Protein kinase A (PKA)
- Mitogen-activated kinases
- Microtubule-affinity-regulating kinases (MARK)

Tyrosine-directed kinases

- Tyrosine kinase fyn
- MAP kinases (stress-activated kinases)
- Phospho-JNK (c-jun NH₂-terminal kinase)
- p38
- Extracellular signal-regulated kinase 1 (ERK-1)
- ERK-2

Protein phosphatases (Ser/Thr sites)

- Protein phosphatase 1 (PP1)
- PP2A
- PP2B
- PP2C

Modulators of tau phosphorylation

- Pin1 (prolyl isomerase binding to Thr231 and isomerizing Pro232)
- Cholesterol

Numerous protein kinases are involved in both the physiological and pathological phosphorylation of tau protein. Thus, GSK3 β is involved in developmental Wnt signalling (important for proper axis formation during embryonic development), and it also phosphorylates tau at the same sites that are phosphorylated in AD. Similarly, exposure of cortical and primary neuronal cultures to amyloid protein induces GSK3 β activity (Takashima *et al.*, 1998). This activity is also regulated by other protein kinases, e.g. protein kinase B (PKB) that inactivates GSK3 β . The increase in PKB levels corresponds with an increase in total tau protein levels.

Different protein kinases phosphorylate tau protein at different sites (Table 31.2), and can influence tau-MT-binding. MAPK and GSK proline-directed kinases phosphorylate most Ser-Pro and Thr-Pro motifs in the regions flanking the MT repeat domain of tau protein, and these phosphorylated sites have little effect on tau-MT interactions. In contrast, MARK and PKA phosphorylate several sites within the MT-binding repeats including Ser262, Ser324 and Ser356. These sites, along with pSer214 (phosphorylated by PKA only), strongly decrease affinity of tau for MTs and inhibit filament formation. Similarly, Rho kinase tau phosphorylation leads to decreased activity of tau in promoting MT assembly. Intraneuronal cdc2 accumulation appears to progress the deposition of pSer202/pThr205 tau sites and suggests that cdc2

Table 31.2 Implication of protein kinases and phosphatase inhibitors in phosphorylation of the tau protein molecule. MAPK family includes SAPK/JNK-P, p38-P, MAPK/ERK-P. MAPK family and GSK3 β are present in neuronal populations and also in some astrocytes and oligodendrocytes. In addition to these kinases, Rho kinase phosphorylates tau at Thr245, Thr377, Ser409 and also phosphorylates Ser262 to some extent, and leads to decreased activity of tau to promote MT assembly (Amano et al., 2003). PKA and GSK3 β also phosphorylate additional sites (Adapted from Tseng et al., 1999; Benneceib et al., 2000; Tomizawa et al., 2001; Ferrer et al., 2002, 2003; Rank et al., 2002).

TTK, tau-tubulin kinase; TPK, tau-protein kinase

is involved in the abnormal phosphorylation of tau and consequent aggregation into PHFs at an early stage (Pei *et al.*, 2002).

Various protein kinases are differentially expressed in tau deposits in neurones and glial cells in the tauopathies (Ferrer *et al.*, 2001). Thus, MAPK/ERK-P has been detected in a subset of neurones and glial cells bearing phosphorylated tau deposits, but rarely in NFTs; p38-P immunoreactivity in a majority of tangle-bearing neurones (in AD, PSP and CBD), pretangle neurones, astrocytes and coiled bodies (in PSP and CBD), neuritic plaque corona in AD, Pick's bodies in Pick's disease; SAPK/JNK-P immunoreactivity in neurones and in glial cells that accumulate tau aggregates in AD, Pick's disease, PSP and CBD; CaM kinase II is selective for neurones but not glial cells.

Protein phosphatases rapidly dephosphorylate tau protein (Box 31.2). Their activity is developmentally regulated and counterbalances the action of protein kinases. Reduction of protein phosphatase activities is linked to the formation of PHF-tau. Phosphatases are associated directly (PP2A) or indirectly (e.g. PP1 via tau protein) with microtubules. In neurodegenerative disorders, particularly AD, the levels of expression of protein phosphatase mRNA and activity of the enzymes are substantially depleted in brain areas harbouring the highest density of tau pathology.

31.2.3 Mutations in the MAPT gene

Alterations in tau genotype have been extensively investigated with respect to their contribution to the development of neurodegenerative dementias. The extended tau haplotypes H1 and H2 (referring to contiguous polymorphisms in exons 1, 7 and 13 and in intron 9), covering the entire human tau gene, are associated with various neurodegenerative disorders. Thus H1 haplotype is overrepresented in PSP, FTDP-17 and, more inconsistently, in CBD, Parkinson's disease and AD, but not in amyotrophic lateral sclerosis. In contrast,

the H2 haplotype is associated with FTD with fluent, anomic aphasia. The tau gene haplotypes have a synergistic effect on apolipoprotein E (ApoE) ϵ 2 and ϵ 4 alleles, and can significantly increase the risk for AD and FTD (Short *et al.*, 2002). Although the over-representation of H1 haplotype seems to be characteristic for the 4R tauopathies, this is not the case for argyrophilic grain disease (AGD).

The discovery of mutations in the MAPT gene in fronto-temporal lobe dementia linked to chromosome 17 consolidated the evidence about the importance of tau protein pathology alone in generating a dementia syndrome. To date, various missense, deletion, silent and intronic mutations in the MAPT gene have been identified in both familial and sporadic forms of dementia. The mutations are localized in exons 1, 9–13 and in introns 9–11 (Table 31.3). Overall, the frequency of tau mutations in non-AD tauopathies is relatively low (on average 6 per cent), and is increased in familial forms of tauopathies (11–33 per cent; Poorkaj *et al.*, 2001).

31.2.3.1 EFFECT OF TAU MUTATIONS ON TAU-MICROTUBULE BINDING

It has been suggested that altered tau properties owing to mutations can lead to an increase in unbound MT mutant tau isoforms in the neuronal cytoplasm, and increase the ability of tau to self-aggregate into filament structures. Indeed, the majority of missense mutations impair the ability of tau protein to bind and polymerize microtubules, irrespective of post-translational modifications. However, a non-significant impact of tau missense mutations upon tau-microtubule interactions has also been reported. These inconsistent findings may reflect differences in various tau mutations with respect to their ability to bind to microtubules, promote MT assembly and bundle MTs. Thus, some mutations (e.g. G272V or P301L) have more subtle effects on MTs in comparison to V337M or R406W, especially since the former two mutations are present in 3R but

Table 31.3 *Tau protein mutations, clinical phenotypes and their effect upon tau protein properties*

Mutations	Clinical phenotypes	Tau properties
Exon 1: R5H; R5L	PSP FTDP-17	Decreased tau binding to MT Increased tau fibrillation Neuronal and glial inclusions
Intron4: E4+39	PSP	Not described
Exon9: K257T; I260V; L266V; G272V	Pick's disease Pick-like disease FTDP-17	Decrease in MT assembly Tau positive Pick's body-like inclusions. Filaments contain 3R and 4R tau (predominantly 3R)
Intron 9: E9+33	Familial FTD	Not described Altered alternative splicing of tau protein
Exon 10: N279K; ΔK280; L284L; N296H; N296N; ΔN296; P301L; P301S; S305N; S305S	PPND PSP FTDP-17 AD CBD PSP/CBD	Decreased tau ability to bind to MT Inclusions consisting of twisted ribbons of 4R tau isoforms in neurons and glia
Intron 10: E10+3; E10+11; E10+12; E10+13; E10+14; E10+16; E10+19; E10+29; E10+33	FTDP-17 PSP CBD Familial MSA Familial PSG	Increase in exon 10 inclusions, except for E10+19 and E10+29, where there is decrease
Exon 11: L315R; S320Y; S320F	Pick's disease	Decrease in MT assembly Pick's body inclusions Filaments contain 3R and 4R (absence of ON3R isoform)
Intron 11: E11+34	AD	Not described
Exon12: V337M; E342V; S352L*; K369I	FTDP-17 Pick's disease	Decrease in MT assembly Neuronal pathology identical to AD or similar to PD Decreased phosphorylation of tau protein Accelerated filament formation 4R tau isoforms (with exception of V337M and K369I mutations that have 3R filaments)
Exon13: G389R; R406W	Pick's disease PSP	Decrease in MT assembly Pick-body like inclusions Straight and twisted filaments R406W alters tau susceptibility for phosphorylation 3R and 4R tau

*Recessive taupathy with acute respiratory failure

PPND, palidopontonigral degeneration; PSG, progressive subcortical gliosis

not in 4R tau, suggesting that the effect of tau mutations on microtubules is site- and isoform-dependent. In addition, mutations affecting the alternative splicing of exon 10 (N279K, delK280, L284L, N296N, S305S, S305N and intronic mutations proximal to the 5'-splice site of exon 10) alter the ratio of tau mRNA with or without exon 10 (E10+/E10-). All but one of these splicing mutations (delK280) and two tau mutations in the intronic sequence following the stem loop structure in exon 10 (E10+19 and E10+29) cause an increase in the proportion of 4R tau, and reduce the level of 3R isoforms. These three mutations result in an increase in 3R tau, decrease in 4R and decrease in MT assembly.

The diverse effects of tau mutations may account for the different clinical and pathological phenotypes in the various taupathies, especially the heterogeneous FTDP-17 disorders. In support of this is the example of clinical and biochemical

diversity of three tau mutations in the same codon (N296) in exon 10 of the MAPT gene. Two mutations, N296N and N296H are associated with similar autosomal dominant FTDP-17-like phenotypes with age of onset in the mid-50s. In contrast, the third mutation (delN296) gives rise to atypical PSP in individuals homozygous for the mutation, whereas in heterozygotic individuals the phenotype is similar to idiopathic Parkinson's disease. The N296N mutation increases the inclusion of exon 10 in tau mRNA and therefore increases the ratio of 4R/3R tau protein. The N296H mutation, however, causes increased splicing out of exon 10: reduces the ability of tau to promote tubulin polymerization and increases tau aggregation (Grover *et al.*, 2002).

delN296 has no or very little effect on splicing, but since asparagine at position 296 is key to disruption of the MT-binding region, delN296 causes a large reduction in the

ability of tau to promote MT assembly (delN296>N296H). Its effect on tau filament formation appears to be inconsistent, with both increased (delN296>N296H) and no effect reported on the self-aggregation of tau into filaments.

Some of the mutations in exons 9 and 12 (e.g. K257T, G272V, V337M and K369I) also stimulate the heparin-induced assembly of filaments *in vitro*. Two mutations within exon 10, P301L and P301S cause the same effect. These two mutations lead to neuronal and glial pathology with narrow, twisted and ribbon-like filaments composed of 4R tau, similar to those found in PSP (Spillantini *et al.*, 1998). Transgenic mice expressing tau containing the G272V mutation develop oligodendroglial fibrillary lesions consisting of both straight and twisted filaments, associated with phosphorylation of tau protein at Ser202/Thr205 sites (Götz *et al.*, 2001a). Ultrastructural differences in the spacing of microtubules have been reported for the mutation V337M in exon 12 using transfected cells and transgenic mice. In the latter, tau aggregates form in the hippocampus, and MT are lost in degenerating neurones.

Correlations between genotype and phenotype have now been described for FDTP-17. Mutations within exon 10 and the intron following exon 10 result in filamentous neuronal and glial tau pathology. In exon 10 mutations, the tau filaments are narrow twisted ribbons consisting predominantly of 4R tau isoforms, whereas in the case of intronic mutations, the filaments are wide twisted ribbons, formed exclusively from 4R tau isoforms. Missense mutations outside exon 10 lead to predominantly neuronal pathology with PHFs and SFs consisting of all six tau isoforms (Spillantini *et al.*, 1997).

31.2.3.2 TAU MUTATIONS AND TAU PROTEIN PHOSPHORYLATION

Mutations in tau protein also affect its phosphorylation. Thus, decreased phosphorylation is found at Ser202/Thr205 and Ser396/Ser404 sites in neuroblastoma cell lines transfected with 0N4R tau isoforms carrying the missense mutations P301L, V337M and R406W. The integrity of microtubules is not affected, but intracellular tau protein levels are increased with all mutations. Additional studies on *in vitro* phosphorylation of wild type 2N4R tau and mutant forms (P301L, V337M and R406W) by GSK3 β found alteration in the extent of phosphorylation in P301L or V337M tau in comparison to R406W tau. The latter mutation decreases phosphorylation at various tau sites. These phosphorylation sites are similar to those in V337M mutation, except for the Ser396/Ser404 site which is increased in the latter mutation.

These *in vitro* results differ from the tau phosphorylation status in brain tissue from some FTDP-17 individuals. Thus, the Sarcosyl-insoluble fraction of R406W tau extracted from brain tissue of a FTDP-17 case is highly phosphorylated in contrast to the soluble R406W tau that is less phosphorylated than wild-type tau. On the other hand, P301L and P301S transgenic mice brains exhibit a higher degree of tau phosphorylation at numerous sites in Sarcosyl and acid-extractable fractions and filaments (Götz *et al.*, 2001b).

31.2.4 Facilitation of tau aggregation in the presence of other proteins

Tau aggregation can be facilitated by co-incubation of the tau protein with other proteins. Thus, co-incubation with sulphated glycosaminoglycans in close to physiological conditions will result in tau assembly only when tau protein is present at 40–100 times higher than physiological concentrations. Similarly, thrombin induces rapid tau protein hyperphosphorylation, and this is related to p44/42 mitogen activated protein kinase activation.

31.2.4.1 HEPARIN AND TAU AGGREGATION

A short segment of tau located in the third MT-binding domain (residues 317–335) is probably the minimal segment of that region able to grow into filaments *in vitro* in the presence of heparin. The 1/2R peptides corresponding to either N- or C-terminal halves of this segment are unable to form filaments. The C-terminal domain contains a sequence spanning from residues 391–407 that grows into filaments *in vitro*, irrespective of whether it is incubated with heparin (Pérez *et al.*, 2001).

31.2.4.2 A β AND TAU AGGREGATION

Positive correlation between amyloid deposits and tangles has been demonstrated in various neuropathological studies for both AD and DS, although the sites of initiation of these two distinct neuropathological features are different (Braak and Braak, 1991). However, some of the taupathies (including CBD, PSP, senile dementia with tangles, FTDP-17) do not exhibit amyloid pathology.

Transgenic animals with amyloid protein precursor (APP) and presenilin proteins 1 and 2 (PS1 and PS2) carrying pathogenic mutations have been used to address the relationship between altered amyloid protein processing and tau aggregates. Thus, Tg2576 mice (with APP695 K595N/M596L mutation), as well as having a substantial degree of brain amyloid deposition, have phosphorylated tau protein within some dystrophic neurites of senile plaques. The major kinase for tau phosphorylation is GSK3 β , although a smaller contribution from GSK3 α , cdk5 and MAPK has also been noted. This suggests that brain amyloidosis has a potential role in inducing taupathy. However, such findings are not consistent. Although elderly transgenic mice with the London mutation (APP V717F) exhibit amyloid plaques and develop hyperphosphorylated tau restricted to dystrophic neurites only, they do not develop filamentous PHF structures. Similar findings have been reported for other APP transgenic models, including the Swedish mutation alone (codon 670/671), APP V717I mutation or the two combined. This indicates that transgenic APP models alone, despite the over expression of APP by 7-fold, are only able to recapitulate the early cytoskeletal changes present in preclinical AD. Furthermore, not all APP mutations have an effect on the phosphorylation state of tau. Thus, the AD-causative V642I

mutation of APP results in the secretion of A β ₄₂, in the presence of unaltered levels of phosphorylated tau protein.

The characteristic AD phenotype (plaques and tangles) develops only in transgenic animals that express both APP and tau proteins mutations. Thus, in Lewis *et al.* (2001) animal model, crossbreeding Tg2576 transgenic mice (which usually develop amyloid deposits by 9–12 months of age) with hemizygous JNPL3 mice (over expressing P301L tau mutation and developing tangle formation by 6 months of age) results in the development of amyloid and tau protein deposits. Likewise, when A β ₄₂ fibrils are injected in the somatosensory cortex and hippocampus in mice expressing tau carrying the P301L mutation, there is a 5-fold increase in neurofibrillary changes in neurones which project into injection sites, and an increase in the level of phosphorylated tau (Götz *et al.*, 2001c). Increased phosphorylation of tau protein also occurs in rat brain after injection with A β _{25–35}.

Tissue culture studies provide further evidence of a link between the processing of APP and tau protein. Thus cultured hippocampal neurones from wild-type and human tau transgenic mice treated with fibrillar A β degenerate, in contrast to tau knockout neurones. The A β _{1–42} promotes aggregation of tau protein *in vitro* in a dose-dependent manner. This A β mediated aggregated tau serves as a substrate for tau kinase II (TPKII), leading to an 8-fold increase in TPK-II dependent tau phosphorylation containing pThr231 (Rank *et al.*, 2002). The carboxyl-terminal end of APP has also been shown to be involved in induction of tau phosphorylation by increasing GSK3 β activity.

31.2.4.3 PRESENILINS AND TAU AGGREGATION

Presenilin 1 (PS1, residues 250–298) binds to both tau and GSK3 β . PS1 point mutations that cause AD (C263R and P264L) result in an increased ability of PS1 to bind to GSK3 β and increase its tau-directed kinase activity, resulting in hyperphosphorylation of tau protein (Takashima *et al.*, 1998). In AD, PS1 mutations may promote neuritic dystrophy and tangle formation by interfering with Notch1 signalling and enhancing pathological changes in tau.

The strongest evidence that PS1 contributes to tau phosphorylation comes from studies exploring PS1 mutations in association with A β , in both *in vitro* studies and transgenic animal models. Thus, in cultures treated with A β , PS1 mutations M146V and I143T significantly increase neuritic dystrophy and AD-like changes in tau such as hyperphosphorylation, release from MTs, and increased tau protein levels. In transgenic mice with Swedish APP (K670N, M671L) and PS1 M146L gene mutations, hyperphosphorylation of the tau protein lags behind the accumulation of A β deposits and is manifested by punctate intraneuronal deposits and dystrophic neurites in the cortex and hippocampus (Kurt *et al.*, 2003). Transgenic mice carrying both the Swedish APP mutation and PS1 P264L mutation develop neurites containing phosphorylated tau, and this correlates with activation of MAP kinase pathways (Savage *et al.*, 2002). Mice transgenic for

both human tau and PS1 M146L mutation also produce an increase in tau phosphorylation similar to that which occurs in transgenic mice carrying human tau, suggesting that the presenilin mutations alone may not be sufficient to induce neurofibrillary pathology. Similarly, I143T and G384A PS1 mutations *in vitro* do not increase tau phosphorylation.

31.2.4.4 α -SYNUCLEIN AND TAU AGGREGATION

The C-terminal end of α -synuclein can bind to the MT-binding region of the tau protein, and can stimulate the protein kinase A-catalysed phosphorylation of tau protein at Ser262 and Ser356 residues. Furthermore, high concentrations of tubulin inhibit the tau- α -synuclein binding. These findings suggest that α -synuclein modulates tau phosphorylation and indirectly affects the stability of axonal MTs.

31.2.4.5 APOLIPOPROTEIN E AND TAU AGGREGATION

ApoE plays a role in lipid metabolism and in humans is represented by three isoforms (ApoE2, ApoE3 and ApoE4, corresponding to three alleles, ϵ 2, ϵ 3 and ϵ 4, respectively). Although ApoE is a glial protein, it is also found in a small number of cortical neurones, restricted to cell body and proximal dendrites. In AD, a small number of neurones devoid of NFTs contain ApoE diffuse cytoplasmic accumulation. ApoE is also found in some tangle-bearing neurones, predominantly in extracellular NFTs.

The ϵ 4 allele of ApoE gene is a strong susceptibility factor for some of the tauopathies, including AD, DLB, Pick's disease and CBD. However, in other tauopathies, including the tangle-only form of AD ('senile dementia with tangles') and AGD, there is a low prevalence of the ApoE ϵ 4 allele or an increase in the ϵ 2 allele when compared with age-matched or AD subjects. This inconsistent association of ApoE ϵ 4 allele with tauopathies mirrors the findings regarding ApoE ϵ 4 allele influence on neurofibrillary pathology. Thus no differences, and an increase in neurofibrillary pathology burden (tangles and neuritic plaques) and phosphorylated tau have been described in ApoE ϵ 4 allele carriers (Mukaetova-Ladinska *et al.*, 1997).

Previous studies have failed to demonstrate ApoE influence upon tau phosphorylation, leading to the conclusion that ApoE intraneuronal accumulation may be secondary in tangle-bearing neurones in response to repair processes induced by tangle-associated neuronal damage. However, isoform-specific interactions of ApoE with tau may regulate intraneuronal tau metabolism and alter the rate of filamentous formation and/or the extent of phosphorylation. Flaherty *et al.* (1999) tested the effects of ApoE isoforms (E2, E3 and E4) on tau phosphorylation in brain microtubule fractions and found that ApoE attenuates tau hyperphosphorylation in the fractions, but the pattern was indistinguishable for the different isoforms. Binding studies with fragments of ApoE demonstrate that the tau-binding region of ApoE3 corresponds to its receptor-binding domain and is distinct from the region that binds lipoprotein particles or A β peptide. ApoE fragments,

especially the truncated ApoE4 (Delta 272–299), can induce tangle-like intraneuronal inclusions containing phosphorylated tau and high molecular weight neurofilaments.

The influence of ApoE and its isoforms upon tau aggregation has been explored further in animal studies. Transgenic mice expressing human ApoE4 isoform have impaired axonal transport, axonal degeneration and hyperphosphorylated tau protein in their brains. Kobayashi *et al.* (2003) examined the effect of specific isoforms using transgenic ‘knock-in’ (KI) mice. There were no significant differences in levels of tau phosphorylation between ApoE3-KI and ApoE4-KI mouse hippocampi. Selective up-regulation of pSer235 and pSer413 and decrease at pSer202/pThr205 and pThr205, with an increase in protein level of tau protein kinase I/glycogen synthase kinase 3 β (TPKI/GSK3 β) and extracellular signal-regulated kinase 2 (ERK2) were demonstrated for ApoE4-KI mice, when compared with ApoE3-KI mice. However, ApoE-deficient mice which show learning and memory impairments also exhibit hyperphosphorylation localized *N*-terminally to the MT-binding domain of tau (Genis *et al.*, 2000).

31.3 TAU PROTEIN: PATHOLOGICAL AND BIOCHEMICAL CHANGES IN NEURODEGENERATION

31.3.1 Tau pathology in ageing

Intraneuronal tau aggregates are characteristic for the ageing human and primate brain. However, these changes are not unique to the brain tissue and NFTs and ‘curly fibres’ can also be found in other organs, including liver, pancreas, ovary, testis and thyroid in elderly individuals with AD. The frequency of neurofibrillary pathology, especially NFTs, increases with age. Thus, it is estimated that nearly half of people over the age of 50 years and all the elderly over 75 years will exhibit NFTs restricted predominantly to the medial temporal lobe. A community-based neuropathological study conducted in elderly people in the UK (70–103 years at death) found NFTs in 61 per cent of the elderly with dementia and 34 per cent of non-demented individuals (Neuropathology Group of the Medical Research Council Cognitive Function and Ageing Study [MRC CFAS], 2001).

31.3.2 Comparative pathology in taupathies

The clinical manifestations of the taupathies differ due to involvement of specific neuroanatomical domains and distinct neuropathological and molecular substrates. More extensive and widespread tau pathology, including numerous NFTs, neuritic plaques and dystrophic neurites in various allo- and neocortical areas, is commonly found in AD, elderly DS individuals and in some individuals with DLB. In general the development of NFTs is initiated in the medial temporal lobe areas, particularly the α -layer of the entorhinal cortex, and then progresses via the hippocampal area back to the pre- α layer of the entorhinal cortex (corresponding to

Braak stages [BST] 1 and 2). More pronounced tangle pathology in entorhinal and transentorhinal cortex (BST 3 and 4) follows before its appearance in neocortical areas, including primary sensory and striate areas (BST 5 and 6) (Braak and Braak, 1991). The most affected neocortical areas in AD are the temporal and parietal neocortex, followed by the frontal and occipital lobes (Mukaetova-Ladinska *et al.*, 1993). Widespread neurofibrillary pathology in AD correlates with the severity of cognitive impairment and non-cognitive changes (Mukaetova-Ladinska *et al.*, 2000).

In PSP, CBD and multiple system atrophy (MSA), the development of neurofibrillary pathology within neurones, and oligodendroglia in the case of MSA, is initiated within the subcortical ganglia and centres including basal ganglia, subthalamus, brain stem (PSP), cerebellar nuclei and substantia nigra (CBD, MSA), and white matter (MSA). Neocortical areas are relatively spared or even intact. Similar findings have been described for frontal lobe dementia, especially FTDP-17. The subcortical location of tau pathology in these disorders contributes to slow cognitive decline and impaired attentional control and frontal ‘executive’ function.

Tau aggregates in the form of tangles are also found in glial cells in some of the taupathies (e.g. FTDP-17, PSP, severe stages AD) and they contain phosphorylated tau, both as diffuse aggregates and within tangle formation. Tau protein also accumulates in astrocytes in PSP (referred to as ‘tufted’ astrocytes). In AGD, the argyrophilic grains are tau-immunoreactive comma-shaped structures.

Cerebellar neurones in general have substantially less tau protein than neurones in other cortical and medial temporal lobe areas (Mukaetova-Ladinska *et al.*, 1993). However, in some forms of neurodegenerative dementia, e.g. PSP and CBD, ‘doughnut’-shaped structures, positive to tau protein, are found in the molecular layers of the cerebellum (in up to 46 per cent of PSP and 29 per cent of CBD patients).

31.3.3 Tau protein incorporation in neurofibrillary pathology

The pattern of incorporation of tau protein into neurofibrillary pathology, especially tangles, undergoes three putative stages:

1. pre-tangles, characterized by non-fibrillar punctate cytoplasmic and dendritic accumulations;
2. intraneuronal tangles, containing fibrillar tau positive structures; and
3. extracellular NFTs (‘ghost tangles’) when the PHFs remain present in the neuropil once the neuronal cell membrane has been disrupted (see Plate 12).

The sequence of these events includes phosphorylation of various sites of the tau protein molecule, followed by proteolytic cleavage at both the *N*- and the *C*-terminal end, resulting in a ‘protease-resistant PHF core’ (Table 31.1 p. 411). In advanced stages of AD in particular, astrocytes also contain NFTs. Aggregates of phosphorylated tau are found in the astrocytes in various taupathies, including Pick’s disease, but

Plate 20 (a, c) Alzheimer's disease patient. (b, d) Dementia with Lewy bodies 'common form' patient. The two cases show similar intensity and distribution of β A 4 staining (a, b) throughout the temporal lobes, including the hippocampal formation (arrows). The lamina of plaques in the dentate molecular layer is clearly visible, especially in the DLB tissue. The Alzheimer's disease patient shows intense staining for PHF-tau (c) in the whole of the temporal neocortex and hippocampus. BY contrast, PHF-tau staining in DLB (d) is confined to the CA1 sector of the hippocampus and part of the entorhinal cortex.

(a)

(b)

Plate 21 Microvacuolation in the temporal cortex. This patient shows an extreme degree of vacuolar degeneration of the neuropil sufficient to raise a suspicion of a prion disorder. Creutzfeldt-Jakob disease was excluded by prion immunocytochemistry. At low power (a) the changes are most marked in cortical layer 3 (above the arrowheads). At higher power (b) amyloid plaques (arrow) typical of Alzheimer's disease are present. This case showed widespread cortical Lewy body formation.

(e)

(f)

Plate 26 (a–f) *Tau immunopathology in FTLD. In FTDP-17 associated with + 16 splice site mutation (a, b) – there are numerous tau-immunoreactive neurones (a) and glial cells (b) in which the aggregated tau is present as amorphous deposits or tangle-like structures. Numerous tau-immunoreactive swollen cells are present (c). In FTDP-17 associated with Q336R mutation the aggregated tau is present as rounded inclusions (Pick bodies) within neurones of the cerebral cortex (d) and hippocampus dentate gyrus (e) that are similar in appearance to those seen in sporadic FTLD with Pick-type histology (f). Swollen cells similar to those in + 16 mutation (c) are also present (not shown).*

not frontotemporal lobar degeneration. In FTDP-17, straight filaments appear to be phosphorylated at Ser202/Thr205 and Ser212/Thr214 sites (G372V mutation; Götz *et al.*, 2001a). Certain tau phosphorylation sites (e.g. Ser202/Thr205 and phosphorylation at ¹⁵⁹PPGQK¹⁶³ site), together with truncation at Glu391 within the NFTs, have now been associated with neuronal apoptosis.

31.3.4 3R/4R tau isoforms in tauopathies

The comparative biochemistry of tauopathies points to differences in post-translational modifications and isoform content of tau protein (see Plate 13a). Additional changes also appear as the disease progresses. In general, in sporadic tauopathy, 3R and 4R tau isoforms accumulate in AD, 3R in Pick's disease, and 4R in PSP, CBD, AGD and FTDP-17. In familial tauopathies, mutations that affect the splicing of exon 10 accumulate 4R tau and phenotypically mimic CBD/PSP, while the majority of others simulate an NFT-predominant form of dementia.

Immunoprobes have been raised against cognate regions for the 3R and 4R tau isoforms, corresponding to the amino acid sequences deriving from the junction of exons 9 and 11 and exon 10, respectively (de Silva *et al.*, 2003). This has led to determination of specific distribution of 3R and 4R tau proteins in the human brain, both in normal ageing and neurodegenerative disorders. Although initial studies found an absence of 4R tau mRNA in dentate fascia neurones in the adult human brain in AD and PSP, tangle-bearing neurones in this region contain 4R tau isoforms (de Silva *et al.*, 2003). 4R tau isoforms are also present in the astrocytic tau inclusions in Pick's disease, pre-tangles, NFTs, astrocytic plaques, tufted astrocytes, coiled bodies and argyrophilic threads in PSP and CBD, and argyrophilic grains.

In AD, all six tau isoforms are subjected to phosphorylation and are incorporated into PHFs, resulting in a tau triplet at 60, 64 and 68 kDa and a minor band at 72 kDa detected by immunoblotting (see Plate 13b). In Pick's disease, only phosphorylated 3R isoforms assemble into filaments and there is a tau doublet at 60 and 64 kDa with a minor band at 68 kDa, whereas in PSP and CBD, phosphorylated 4R tau isoform aggregates provide the 64 and 68 kDa bands. Arai *et al.* (2004) reported additional, shorter amino-terminally cleaved tau of 33 kDa in PSP and a doublet of 37 kDa in CBD (Plate 13b). In the familial multiple system tauopathy 64, 68 and a minor 72 kDa band are present, and contain predominantly 4R tau isoforms (Spillantini *et al.*, 1997). AGD is characterized by 4R tau isoform aggregates: in BST 1 it contains 64 and 68 kDa and a minor 72 kDa band, whereas by BST 2 and 3 there is an additional minor 60 kDa band (Tolnay *et al.*, 2002).

31.3.5 Comparative biochemistry of tauopathies

In ageing, there is a gradual loss of the soluble, axonally bound tau protein that occurs in the absence of significant neurofibrillary or amyloid pathology. In contrast, in AD and

DS the loss of soluble tau protein is more pronounced than in elderly controls. This tau loss is accompanied by significant increase in insoluble, PHF-derived tau protein (Mukaetova-Ladinska *et al.*, 1993) (Figure 31.1a). This is not the case for DLB or Parkinson's disease: in these two disorders there is a slight decrease in soluble tau protein, but the levels of insoluble tau (truncated at Glu391 or phosphorylated at Ser202/Thr205) are similar to those found in age-matched controls (Harrington *et al.* 1994). Only when DLB and AD are matched for extent of neurofibrillary pathology by Braak stages does the level of phosphorylated and PHF-tau become identical in these two disorders (Figure 31.1b).

Phosphorylation of tau protein appears to occur quite late in the disease progression as judged by phosphorylated Ser202/Thr205 site in soluble tau fraction (corresponding to BST 6), whereas in the Sarcosyl-insoluble fraction various phosphorylated tau sites are detected relatively early on, together with C-terminal truncation of the tau protein (Mukaetova-Ladinska *et al.*, 2000) (Figure 31.1c). The use of quantitative biochemistry has been useful in detecting very subtle tau changes at molecular level in the absence of obvious pathology, e.g. tau-less tauopathy characterized by loss of soluble tau protein only (Zhukareva *et al.*, 2002).

31.4 TAU PROTEIN AS A CEREBROSPINAL FLUID MARKER FOR DEMENTIA

Cerebrospinal fluid (CSF) has been extensively investigated as a target for developing clinically sensitive and specific diagnostic tools to differentiate between and aid the clinical diagnosis of neurodegenerative disorders. Various proteins and enzymes involved in neurodegenerative disorders have been investigated as CSF markers. The most consistent findings are those of increased CSF tau and a decrease in A β ₁₋₄₂ protein levels in early and incipient AD which differentiate this disease from age-associated memory impairment, depression, and other types of dementia. However, there are also reports that tau (total and/or phosphorylated) and A β ₁₋₄₂ measures may not differentiate between various dementia syndromes in the clinical setting. Furthermore, a subgroup of cognitively impaired individuals with a post mortem confirmed AD exhibited a CSF tau protein content similar to that of cognitively intact subjects (Clark *et al.*, 2003). Inconsistency between the findings may be attributable to ApoE genotype, since it has been demonstrated that ApoE ϵ 4 allele carriers have a higher level of CSF-tau concentrations (Tapiola *et al.*, 2000). However, not all studies have confirmed this.

31.4.1 CSF total tau protein

CSF total tau protein (t-tau) is now considered to be a marker for axonal damage and neuronal degeneration, whereas the presence of phosphorylated tau protein (p-tau) reflects

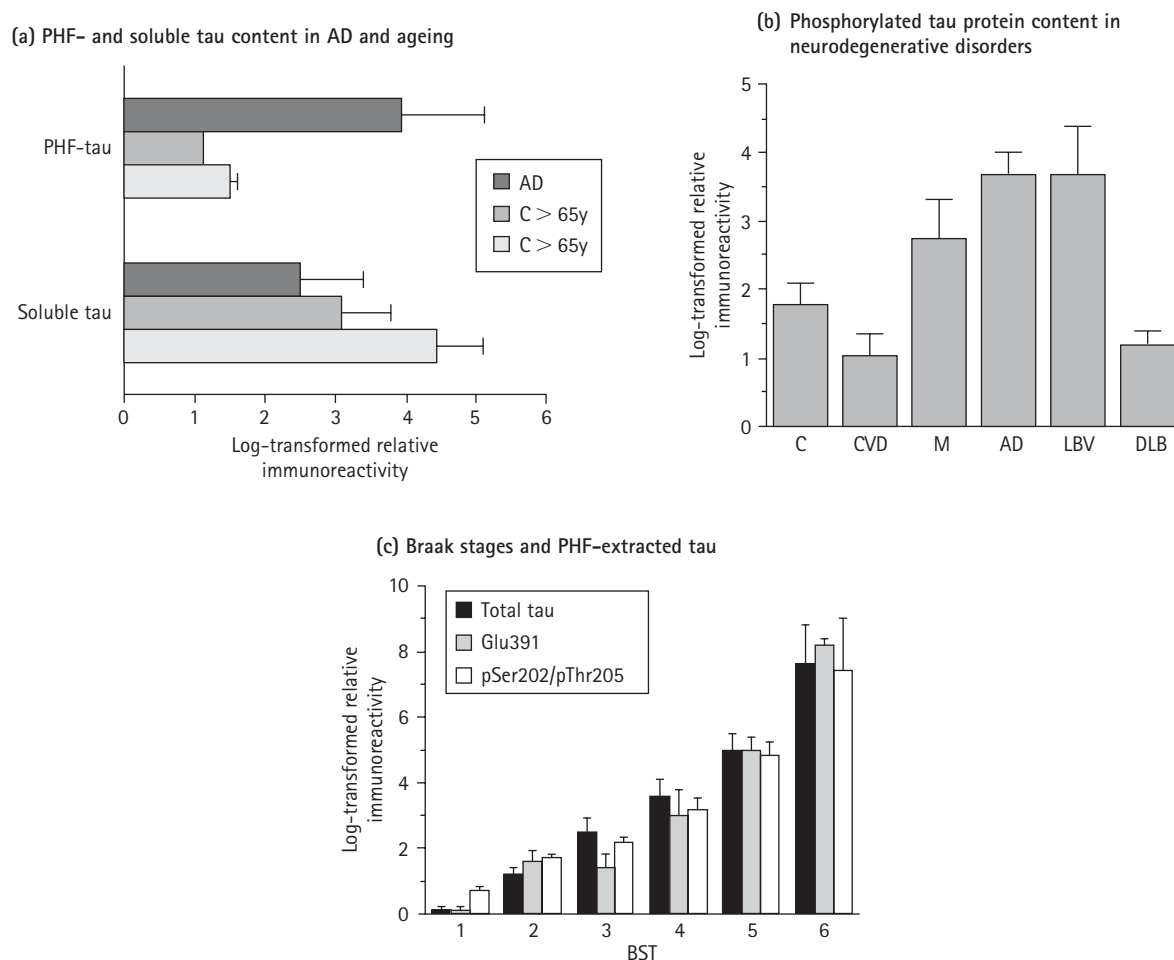

Figure 31.1 Comparative tau biochemistry. (a) Loss of soluble tau and increase in PHF-tau in AD. In AD, there is significant loss of soluble tau ($P = 0.001$) and an increase in PHF-tau ($P = 0.0001$) compared with both young and elderly controls. (b) Increase in phosphorylated Sarcosyl insoluble tau is present in AD, LBV and mixed type of dementia, but not DLB or CVD (ANOVA: $F = 2.72$, $P = 0.035$). (c) With increase in Braak stage, there is a progressive increase in PHF-extracted tau, including total PHF-extracted tau, truncated PHF-tau at Glu391 and Sarcosyl insoluble phosphorylated tau (pSer202/pThr205 sites). Tau measures: soluble tau, Ab 7.51; PHF-tau, mAb 423 (a); Sarcosyl insoluble, phosphorylated tau, mAb AT8 (b); Glu391 truncated tau, mAb 423; phosphorylated tau, mAb AT8; total tau, mAb 7.51 (c). AD, Alzheimer's disease; BST, Braak stages; C, control; CVD, cerebrovascular dementia; DLB, dementia with Lewy bodies; LBV, Lewy body variation of AD; M, mixed type dementia.

* $P \leq 0.05$. (Figures adapted after Mukaetova-Ladinska et al., 1993, 1996 (a); Mukaetova-Ladinska et al., 2000 (b), and Harrington et al., 1994 and Mukaetova-Ladinska et al., 2000 (c).)

neurofibrillary pathology. Overall, CSF t-tau protein increases as a function of age and in AD, there is up to 3-fold increase in CSF t-tau protein level in comparison to elderly controls (Frank *et al.*, 2003) (Table 31.4). Familial forms of AD (e.g. PS1 A431V mutation) also have an increase in t-tau, and a modest increase in t-tau protein has been found in FTDP-17 with P301L and G272V tau mutations. Age-dependent reference values for t-tau protein measurements have now been established: for subjects 21–50 years old at <300 pg/mL; for age 51–70 years at <450 pg/mL; and 70–93 years at <500 pg/mL (Buerger *et al.*, 1999). In AD, the cut-off value of CSF tau at 375 pg/mL has 59.1 per cent sensitivity and 89.5 per cent specificity for the diagnosis of AD (Shoji *et al.*, 2002).

Increased CSF t-tau is also found in vascular dementia, DLB, Creutzfeldt–Jakob disease, normal pressure hydrocephalus, vitamin B₁₂ deficiency encephalopathy, stroke (transient increase in t-tau level) and traumatic brain injury with diffuse axonal damage. In contrast subcortical forms of dementia, including Parkinson's disease, PSP, CBD and alcoholic dementia are not usually associated with an increase in t-tau level (Table 31.4).

In mild dementia, CSF t-tau levels are significantly higher in the majority of AD subjects when compared with normal ageing. Progression of cognitive decline has been shown to be closely linked to elevation of t-tau in some cross-sectional clinical studies (Hampel *et al.*, 2003). However, longitudinal

TBI, traumatic brain injury

studies have failed to confirm these findings (Tapiola *et al.*, 2000). In subarachnoid haemorrhage, an increased level of t-tau has been correlated with both injury severity and unfavourable clinical outcome (Kay *et al.*, 2003).

31.4.2 CSF phosphorylated tau protein

Several quantitative assays using immunoprobes against phosphorylated sites of tau protein have now been developed to assess the extent of phosphorylation of tau protein in CSF: pThr181, pSer199, pThr231, and assays based on two phosphorylation tau sites: pThr231/pSer235 and pSer396/pSer404.

pSer199 is positively correlated with t-tau, appears to be elevated in CSF in both sporadic and familial forms of AD and can be used to discriminate between AD and other forms of dementia. pThr181 level is also increased in AD in comparison to FTD, vascular dementia, Parkinson's disease, acute stroke and control subjects, and may be a useful discriminator between AD and DLB (Table 31.5).

pThr231 appears to be an early marker of pathology in AD, preceding the formation of PHFs, and the CSF measurements confirm it as a highly sensitive marker for AD (90.2 per cent sensitivity level in comparison to t-tau; both markers have specificity of 92.3 per cent) (Buerger *et al.*, 2002). pThr231 distinguishes AD from FTD and major depression

Table 31.5 Use of total and phosphorylated tau protein markers in CSF to discriminate between neurodegenerative disorders. (Modified from Riemenschneider *et al.*, 2002; Schönknecht *et al.*, 2003 and Hampel *et al.*, 2003, 2004)

Total tau and phosphorylation tau sites	Improved diagnosis/ Differential diagnosis
t-tau	Progressive MCI versus stable MCI AD versus vascular dementia and major depression
pThr181	AD versus DLB
pSer199	AD versus other dementias
pThr231	Progression of MCI to AD AD versus FTD and major depression
pSer396/pSer404	AD versus vascular dementia

(Table 31.5). Furthermore, CSF pThr231, but not t-tau, is increased in minimal cognitive impairment (MCI) and correlates with cognitive decline and conversion from MCI to AD, but not with severity of dementia (Buerger *et al.*, 2002). Assays based on pThr231/Ser235 identify a higher level of phosphorylated tau in MCI subjects, and seem able to differentiate MCI subjects who later develop AD from memory ‘complainers’ (Arai *et al.*, 2000). In the course of AD progression, the pThr231 level tends to decline in contrast to an unaltered t-tau level (Hampel *et al.*, 2001). Hampel *et al.* (2003) suggested that the decline in CSF pThr231 might be explained by the incorporation of pThr231 into PHFs.

Overall, a review of current literature supports the role of CSF p-tau in improving early diagnosis of dementia and in aiding differential diagnoses (Hampel *et al.*, 2003, 2004). Although reduction in CSF A β_{42} and increase in t-tau have high sensitivity and specificity in discriminating AD from controls, the specificity compared with other dementias is moderate. The combination of CSF p-tau with other CSF markers may improve the accuracy of diagnosis. Thus, in DLB, a decrease of A β_{42} with unchanged levels of tau protein in CSF was found, and an increase in p-tau combined with a decrease in A β makes an AD diagnosis more accurate. (Papassotiropoulos *et al.*, 2003). The cut-off points of 444 pg/mL for CSF A β_{42} and 195 pg/mL for CSF p-tau gave a sensitivity and specificity of 92 per cent and 89 per cent respectively, to distinguish AD patients from controls.

31.4.3 MMSE correlation with CSF tau measurements

Although most studies have found an increase in both total and phosphorylated tau in AD, the association of these changes with disease duration remains controversial. An absence of

correlation with cognitive decline (Gomez-Tortosa *et al.*, 2003) and an increase with dementia severity (Arai *et al.*, 1997) have been reported. Non-significant elevation of CSF-tau has also been detected in non-symptomatic carriers of APP (KN670/671ML, E693G) and PS1 (M146V, H163Y) mutations. These findings suggest that CSF-tau protein levels are altered before the onset of symptoms, and may help identify MCI patients who will progress to AD. This has been confirmed in two recent studies, in which the MCI group which progressed to AD had particularly high levels of t-tau and p-tau compared with the MCI patients who progressed to non-AD dementias, and to the MCI group which did not show progression.

Correlative biochemico-neuroradiological studies have reported that both CSF t-tau and p-tau levels correlate with ventricular widening on MRI brain scans over a 16-month period, suggesting that CSF-tau levels reflect the intensity of the disease process: the higher the tau level, the more rapid is progression of the disease (Wahlund and Blennow, 2003). Interestingly, ventriculoperitoneal shunt treatment in subjects with probable AD results in stable or improved cognitive functioning and a decrease in levels of CSF-tau.

31.4.4 CSF tau measurements and treatment

The use of cholinesterase inhibitors (ChEIs) and other novel therapeutic interventions currently being developed may potentially use monitoring CSF biomarkers for diagnostic and outcome purposes. To date a limited number of studies have addressed the CSF-tau changes in relation to available antidementia therapeutic compounds. Treatment with a vitamin B $_{12}$ -B $_6$ -folate combination does not result in significant changes in the levels of CSF-tau in MCI individuals. Cholesterol-lowering treatment with simvastatin (20 mg/day for 12 weeks) reduces α -secretase cleaved APP (sAPP) and β -sAPP, with unaltered levels of t-tau, p-tau and A β_{42} (Sjögren *et al.*, 2003), suggesting that simvastatin acts directly on the processing of APP, but not tau protein, by inhibiting both the α - and the β -secretase pathways.

A limited number of studies have described monitoring CSF-tau in dementia subjects treated with ChEIs. The results suggest that use of ChEIs does not change the level of CSF-tau protein over 1–2 years’ treatment. Thus, 1 year’s treatment with rivastigmine does not alter CSF-tau levels, in contrast to a significant increase seen in tacrine-treated and untreated AD patients. These changes were mainly present in ApoE ϵ 4 carriers (Stefanova *et al.*, 2003). Similar results of unchanged t-tau and p-tau following treatment with donepezil, rivastigmine, galantamine and metrifonate have been reported. This would suggest that the ChEIs may be modifying the course of the AD process by stalling the progression of neurofibrillary pathology and neuronal loss. This remains to be confirmed neuropathologically.

31.5 THERAPY FOR TAUPATHIES

Since tau protein incorporation within various filamentous structures results in highly protease-resistant insoluble products, and leads eventually to neuronal cell death, the goals of any tau-directed therapy will need to be prevention of their formation and/or dissolving these structures once they are formed. In light of the complexity of altered tau protein metabolism and the non-uniform neuropathological phenotype in neurodegenerative dementias, it seems appropriate to search for a key step that is shared by the different mechanisms which lead to tau pathology-driven dementia.

31.5.1 Decreasing tau protein phosphorylation

Two of the most promising pharmacological therapeutic approaches for treatment of neurodegeneration at present are the development of drugs that can:

- inhibit sequestration of both normal and hyperphosphorylated tau protein into insoluble aggregates, and
- reverse or modify the hyperphosphorylation of tau and correct the existing protein phosphorylation/dephosphorylation imbalance.

The problem with this approach is finding sufficient specificity for treatment without affecting other essential cellular functions reliant on cellular signalling mechanisms.

The use of mood stabilizers for symptomatic treatment of agitation seems to have some neuroprotective effect in terms of inhibiting apoptosis and slowing of neurofibrillary formation. It seems to do this by inhibiting tau protein hyperphosphorylation. Lithium ions interact with the Mg^{2+} binding site of GSK3 β and inhibit activity of the enzyme. This decreases the extent of tau phosphorylation without affecting neuronal morphology. Lithium can also protect, both *in vitro* and *in vivo*, against A β toxicity and can inhibit neuronal tau hyperphosphorylation induced by A β .

GSK3 β selective inhibitors that compete with the ATP-binding site of the enzyme (e.g. SB216763 and SB415286) have been explored for their therapeutic potential. Another GSK3-specific inhibitor (AR-A014418) *in vitro*, does not suppress the activity of another 26 kinases, including cdk2 and cdk5. It inhibits tau phosphorylation in tissue culture models over-expressing 4R tau, protects against cell death via blocking P13/PKB signalling pathway and also inhibits A β -mediated neurodegeneration.

p38 mitogen-activated protein kinase and cdk5 are also explored as therapeutic targets for therapeutic interventions in AD. Another group of kinases, the CLK family, has been demonstrated as involved in regulating the use of exon 10: even when regulatory elements of this exon contain mutations. These kinases cause exon 10 to be skipped by influencing specific changes in pre-mRNA processing pathways. Changes in the phosphorylation of splicing factors might serve as a

therapeutic target in familial forms of tauopathy over-expressing 4R tau, as is the case in FTDP-17 or AGD.

31.5.2 Inhibition of tau polymerization

The process of tau aggregation represents a potential target for developing therapeutic agents that inhibit the high affinity tau-tau binding interaction. Furthermore, targeting the MT-binding region of the tau molecule may also reverse the proteolytic stability of insoluble tau filaments. Wischik and Harrington (2000) reported a concentration-dependent untwisting of PHFs by methylene blue that led to their disappearance. They also identified diaminophenothiazines that were able to inhibit tau-tau aggregation *in vitro*.

31.5.3 Stabilizing microtubules

Another possibility for tau-targeted interventions may involve developing agents that will stabilize the MTs, alter signalling events in neurones and/or modulate MT properties (e.g. via cytosolic complexes, involving Arl2, cofactor D and protein phosphatase 2A). One of the candidates could be Pin1 (peptidyl prolyl cis/trans isomerase), which binds to phosphorylated tau proteins (pThr231 site). Pin1 may also be able to restore the ability of hyperphosphorylated tau proteins to polymerize MTs. Stabilization of MTs may be one of the earliest stages in prevention of overt neurodegenerative changes, since both the ageing and neurodegenerative processes cause a reduction in the number of MTs and in their assembly. Pin1 is also involved in neurones re-embarking on the cell cycle, which may be another therapeutic target.

31.5.4 Amyloid route

The relationship between A β deposition and tau protein aggregation remains unclear. Although previous hypotheses suggested that these two processes are independent, recent data suggest that there may be an interaction between the two pathological processes. A β ₂₅₋₃₅ neurotoxicity leads to hyperphosphorylation of the tau protein molecule, and similarly inhibition of phosphatases resulting in hyperphosphorylated tau contributes to development of amyloid deposits. The formation of PHF-like filaments in tissue culture can be induced by aggregated A β ₄₂ synthetic peptide, with pSer422 preventing this PHF-like aggregation. Oral and subcutaneous administration of small molecular weight glycosaminoglycans, e.g. heparin C3, have been shown to decrease the extent of tau hyperphosphorylation in animals, without affecting the cholinergic brain system.

31.5.5 Neurotrophin route

The 'antinerve growth factor transgenic mice' (Capsoni *et al.*, 2000) outlines the influence of neurotrophins in development

of AD-type pathology. This mouse model develops neuronal cell loss, phosphorylated and insoluble tau and NFTs, suggesting that neurotrophins mediate the neurodegenerative process. Regulation of neurotrophin activity may not only have impact on the onset and progression of the disease process, but be used for the development of treatments for prevention of tau-aggregation and hyperphosphorylation. Calorie restriction and diet may also have an impact on the latter via increasing the levels of neurotrophins, specifically brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3). FGF (fibroblast growth factor-2) in a dose-dependent manner increases the expression of tau and its level of phosphorylation and increases GSK3 levels, but reduces MAP2 expression (Tatebayashi *et al.*, 2003).

31.5.6 The future

Small interfering RNA (siRNA) has some therapeutic promise in relation to silencing dominantly acting disease genes, especially if mutant alleles can be targeted selectively, e.g. single-nucleotide polymorphism or disease mutation. Using two *Drosophila* models (one with mutant R406W and V337M tau [Wittmann *et al.*, 2001], and the other a wild-type tau protein [Jackson *et al.*, 2002]), it was demonstrated that the formation of tau pathology is a late event, a byproduct rather than an early cause of neuronal cell loss. Tau expressed in these two models may interact with an important neurodevelopmental pathway, the Wnt pathway, which may be of potential importance for therapeutic interventions directed at non-overt preclinical stages of dementia.

31.6 CONCLUSIONS

Although the relationship between tau and other neuropathological markers associated with the neuropathology of dementia still remains somewhat controversial, there is no doubt that tau pathology alone can contribute to the development of dementia syndromes. The discovery of the tau protein mutations that cause dementia supports the latter. Furthermore, these mutations shed light on a more complex picture of tau function, post-translational modifications and interactions with MTs and aggregation. Molecular epidemiology demonstrates alterations in tau protein metabolism in a dynamic context: age-associated decline of tau protein is followed by incorporation of the tau protein into PHFs and filamentous structures, leading to further depletion of axonally bound tau protein. These biochemical changes, in turn, are closely linked to the appearance of clinical symptoms of dementia.

One of the major problems in testing any therapeutic approach targeted towards altered tau processing is the lack of adequate animal or cell models that truly reflect neurodegenerative disease. The novel transgenic tau animal models alone, or those coupled with the APP and PS1 mutations,

represent the best attempts at recapitulating the abnormal pathology of neurodegenerative dementias. These animal models and organotypic slice cultures seem promising as disease model systems to test novel therapeutic agents aimed at arresting the formation of insoluble tau aggregates.

The details of the molecular neuropathology of Alzheimer's disease (AD), from the amyloid precursor protein (APP) through to the production of amyloid A β , plaque formation, neurodegeneration and to final neuronal death is discussed in this chapter. This process, like Alexander's Gordian knot, has been scrutinized over the last two decades with the hope now that a decisive therapeutic incision is not too distant. Points in the biochemical pathway that may be amenable to therapeutic intervention are highlighted.

The theory that A β amyloid underlies the neurodegenerative changes in AD is currently pre-eminent (Figure 32.1). Integral to this thesis is the presumed neurotoxicity of A β . This peptide is the main constituent of the amyloid plaque, one of the characteristic pathological features of AD. It is also found in vessel walls as a congophilic amyloid angiopathy (Glennier and Wong, 1984; Masters *et al.*, 1985). Neurofibrillary changes are also major features in the brains of patients with AD. Tau protein, a microtubule-associated protein, is ubiquitinated, phosphorylated and accumulates as neurofibrillary tangles (NFTs) and dystrophic neurites (Kosik *et al.*, 1986; Wood *et al.*, 1986). The link between A β accumulation and tau-associated NFTs remains unknown, although NFTs appear to be downstream of the events that surround A β accumulation in the AD brain.

The biogenesis of A β from APP and putative mechanisms for its neurotoxicity, together with factors such as apolipoprotein E (ApoE) and α 2-macroglobulin (α 2M), which may

interact with A β and affect its clearance from the brain, is the focus of this chapter. Recent and more detailed reviews on these subjects can be found elsewhere (Blacker and Tanzi, 1998; Hardy *et al.*, 1998; Multhaup *et al.*, 1998; Price *et al.*, 1998; Lansbury, 1999; Scheper *et al.*, 1999; Butterfield, 2002, 2003; Citron, 2002; Lahiri *et al.*, 2002; Suh and Checler, 2002; Walsh *et al.*, 2002; Atwood *et al.*, 2003; Bertram and Tanzi, 2004).

32.1 A β AMYLOID ACCUMULATION AND PLAQUE DEVELOPMENT

One of the two characteristic microscopic features of AD is the accumulation of A β amyloid in plaques of varying morphology. These are extracellular or perivascular congophilic deposits of aggregated A β with a high content of β -pleated sheet secondary structure. The amyloid plaque itself is the end result of a process of A β oligomerization, fibril formation, aggregation, and precipitation occurring in several stages, with each stage potentially having a different impact on surrounding neurones. Initially it is postulated that a soluble species of A β forms oligomers that may represent the toxic species (McLean *et al.*, 1999). The oligomers may then aggregate into protofibrillar structures, which may first be seen as precipitates in diffuse amyloid plaques; this progresses

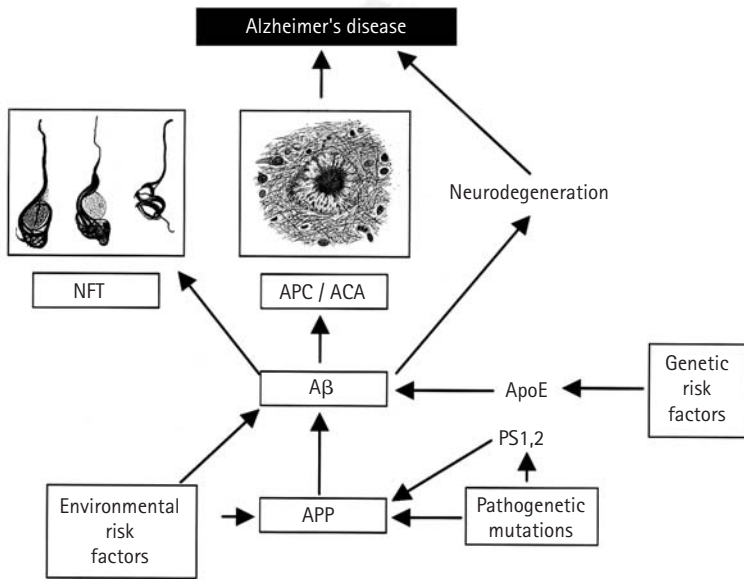

Figure 32.1 The amyloidocentric pathway that leads to Alzheimer's disease proceeds from the proteolytic processing of the amyloid β precursor protein (APP) into the A β amyloid. The amyloid forms visible plaques (amyloid plaque cores, APC; amyloid congophilic angiopathy, ACA). The relationship between A β and neurofibrillary tangle (NFT) formation remains unclear. The mechanisms that underlie the basic neurodegenerative changes in Alzheimer's disease are also uncertain. This pathway is subject to modulation by environmental and genetic factors at various points.

with dystrophic neurite formation both within the neuropil and around dense crystalloid precipitates of amyloid cores. Following this, an intermediate stage is reached where the plaque increases in complexity before a final stage of a non-neuritic 'burned out' or 'end-stage plaque' is reached.

In AD, processing of APP creates a high ratio of A β_{42} ('long' A β of 42 amino acids) to A β_{40} ('short' A β of 40 amino acids). These processes are discussed later in this chapter. The more insoluble long A β is the primary constituent of the amyloid plaque. However, immunocytochemical techniques have demonstrated that diffuse plaques contain not only A β_{42} but also A β_{40} and, in a small proportion of plaques (most of which have a dense amyloid core), A $\beta_{(16-40/42)}$ (the p3 fragment) (Dickson, 1997). Perivascular amyloid identified in the congophilic angiopathies predominantly consists of A β_{40} (Suzuki *et al.*, 1994; Barelli *et al.*, 1997).

Plaque morphology also varies as a function of topographic location. Smaller granular deposits are seen in the deep grey matter nuclei, and linear streaks occur in the molecular layer of the cerebellum. The morphology of the amyloid plaque therefore varies depending upon both location and stage of development.

The number of amyloid plaques at post mortem does not correlate well with the severity of clinical disease (McKee *et al.*, 1991; Morris *et al.*, 1991; Terry *et al.*, 1991; Berg *et al.*, 1998). However, plaque formation may correlate with the degree of neuronal injury as identified by the cellular pro-apoptotic response as measured by the TUNEL technique (Sheng *et al.*, 1998). The poor correlation may also be explained in part by a process of growth and resolution of plaques with the establishment of a plateau phase for plaque production (Hyman and Tanzi, 1992). There is also an emerging view that the soluble A β_{42} load may be more closely related to clinical severity (McLean *et al.*, 1999), whether or not the A β_{42} exists as an oligomer or complexed to other proteins (Lorenzo and Yanker,

1994; Howlett *et al.*, 1995). A major argument raised by opponents of the amyloid theory is that individuals can have numerous plaques but no clinical cognitive impairment. This may be countered by the observation, as will be elaborated below, that A β , whilst being the crucial factor in inducing neurodegeneration in AD, will only act upon compromised cells, such compromise appearing, for example, in the form of age-related oxidative stress (Lockhart *et al.*, 1994). Furthermore, A β and the plaque are components within a very complex biological system that relies on numerous other pathological processes before AD develops clinically. These processes are mediated by both genetic and environmental risk factors.

The damage caused by the soluble, aggregated or fibrillar A β may induce a reactive astrocytic and microglial 'inflammatory' response. A β may interact with metal ions, including iron, zinc and copper. These interactions in turn may lead to the production of neurotoxic free radicals, contributing to the load of reactive oxygen species generated by microglia. Overall, the AD brain is under considerable oxidative stress; these aspects of neurotoxicity of A β are discussed in more detail below.

32.2 GENETIC EVIDENCE FOR THE ROLE OF A β IN ALZHEIMER'S DISEASE

The most convincing support for the central role of A β and APP in the pathogenesis of AD is that all of the known fully penetrant autosomal dominant gene mutations that cause early-onset AD lead to an increase of A β_{42} production (Table 32.1). Mutations in the APP gene itself lead to the development of aberrant APP that is preferentially processed to produce an increase in the A $\beta_{42:40}$ ratio. All causative APP mutations identified to date occur in proximity to the A β domain of the protein. Similarly, multiple mutations in the two presenilin genes have a dramatic effect on the A $\beta_{42:40}$ ratio.

Table 32.1 Pathogenic mutations that cause Alzheimer's disease

Mutations	Mechanism of action	Effect
APP gene dosage or aberrant regulation Down's syndrome (trisomy 21)	Upregulation of APP gene promoter up to 5–6-fold	Increased total A β
Pathogenic APP gene mutations <i>APP codons:</i>		
670/671 ('Swedish')	Increase β -secretase cleavage	Excess total A β production
692 and 693 ('Dutch and Flemish')	Decrease α -secretase activity?	Resultant increase in β - and γ -activity with consequent increased total A β
715 ('French')	Affects γ -secretase activity	Increased amounts of A β p3 fragment
717 ('London')	Altered γ -secretase activity	Increased ratio of A β _{42:40}

32.3 AMYLOID PRECURSOR PROTEIN

The APP is a transmembrane protein that is found in most cell types including neuronal and glial cells (Figure 32.2). It is especially enriched in the alpha-granule of platelets. The APP gene is located on chromosome 21 (Kang *et al.*, 1987). The pathogenic APP mutations account for less than 5 per cent of all cases of AD inherited in an autosomal dominant manner.

The precise physiological function of APP is unknown, though no doubt is complex and possibly related to synaptic plasticity, repair and regeneration. The structural domains suggest that it may have a role in cell–cell (synapse) or cell–matrix interactions (neurite stabilization). In the platelet, APP has been shown to be involved in inhibition of platelet aggregation via an effect on arachidonic acid metabolism (Henry *et al.*, 1998). There is also evidence to suggest that APP is affected by metal ion binding, calcium levels and heparin binding. APP has also been associated with cell proliferation and neurite outgrowth in response to nerve growth factor (Milward *et al.*, 1992; Small *et al.*, 1994; Yankner, 1996). Other *in vitro* experiments have suggested that a deficiency of APP renders cells more susceptible to a variety of neurotoxic insults.

32.4 APP PROCESSING BY α -, β - AND γ -SECRETASES

APP exists in three major isoforms of 695, 751 and 770 amino acids. The 695-amino-acid isoform (APP695) is predominantly expressed in neurones (Kang *et al.*, 1987; Tanzi *et al.*, 1987). The APP751 and APP770 isoforms are predominantly expressed in peripheral tissues and astrocytes (Golde *et al.*, 1990; Kang and Müller-Hill, 1990). APP is synthesized in the endoplasmic reticulum and is then transported through the Golgi apparatus to the cell surface. In its transmembrane orientation (as shown in Figure 32.2) it undergoes proteolytic cleavage to

produce A β . The half-life of APP is short and is processed by at least two pathways (α - and β -/ γ -secretase activities). In peripheral cells, α -secretase activity predominates, cleaving the A β domain of APP at position 16/17. This leads to the production of soluble ectodomain protein sAPP α (Evin *et al.*, 1994). The soluble ectodomains of APP (both sAPP α and sAPP β) do not aggregate and do not participate in plaque formation. α -Secretase activity leaves in the membrane a small carboxyl-terminal fragment which undergoes further processing. The α -secretase activity may be sequence non-specific and act on several other transmembrane proteins. Furthermore, recent work has identified a disintegrin and metalloprotease (ADAM), as being a potent effector of α -secretase activity (Lammich *et al.*, 1999). Increase of ADAM-10 expression and activity may theoretically be effective as a treatment for AD.

A β therefore exists in several forms depending on the site of cleavage by as yet largely undefined α -, β - or γ -secretases. The length of the A β fragment varies depending on the site of cleavage leading to a product between 39 and 43 amino acids in length. The N-terminal 28 residues are from the extracellular portion of APP, and the 11–15 C-terminal residues are derived from the transmembrane domain. It is the A β ₄₂ which is considered to be the more insoluble and toxic moiety and is a product of γ -secretase cleavage of the APP molecule. β - and γ -secretase activity involves cleavage of APP at sites corresponding to positions 1 (β -secretase) and 40 or 42 (γ -secretase) of the A β fragment, releasing the insoluble amyloidogenic peptide A β _(1–40/42) commonly referred to as A β ₄₂. Determination of the identity of γ -secretase could have important therapeutic implications. Recent evidence suggests an intimate relationship between PS1 and γ -secretase, and there is increasing evidence that the active site of γ -secretase lies within the transmembrane domains of the PS molecule (De Strooper *et al.*, 1999; Struhl and Greenwald, 1999; Wolfe *et al.*, 1999; Ye *et al.*, 1999). The macromolecular complex which constitutes γ -secretase activity is presently discerned as >400 kDa in

Figure 32.2 (a) The structural domains of APP are schematically shown. Within the large extracellular ectodomain there are heparin-binding sites (HBD-1,2), metal-binding sites (ZnBD), growth-promoting domains (GPD), carbohydrate-attachment sites (CHO; CS-GAG), and alternatively spliced exons (KPI, OX2, exon 15). The shorter cytoplasmic domain has interacting motifs for G₀ protein, clathrin (NPXY) and the Fe65 family of proteins. (b) The A β (juxtatransmembrane and transmembrane) domains are shown in more detail. The β -, α - and γ -secretase sites are shown, with the major cleavage sites indicated by unbroken arrows. The critical pathogenic mutations are shown to be clustered near the secretase sites (see also Table 32.1).

mass, and contains at least three other molecules: Aph1, Pen2 and nicastrin (Iwatsubo, 2004). Active development of inhibitors of γ -secretase has progressed at a radical pace, and the results of clinical trials are expected soon.

32.5 APP MUTATIONS AND A β PRODUCTION

The various APP mutations inevitably produce increased ratios of A β ₄₂ through a variety of mechanisms (Table 32.1). The mutations at codons 670/671 (the 'Swedish' mutation), increase β -secretase cleavage and lead to an overall excess amyloid production (Cai *et al.*, 1993). Mutations at codon 717 (the 'London' mutation), 715 (the 'French' mutation), 716 (the 'Florida' mutation) and 723 (the 'Australian' mutation) act at the γ -secretase site, increasing the ratio of A β _{42:40} (Suzuki *et al.*, 1994; Brooks *et al.*, 1995; Eckman *et al.*, 1997; Ancolio *et al.*, 1999; Kwok *et al.*, 2000). Mutations at 692 and 693 (the 'Dutch' and 'Flemish' mutations) are either associated with α -secretase activity, presumably leading to a decrease in this pathway with a resultant increase in β - and γ -activity (Haass *et al.*, 1994) or yield a mutant A β peptide

with enhanced toxicity or propensity to aggregation. In Down's syndrome (trisomy 21), where there is an extra copy of the APP gene, there is a similar increase in the overall levels of A β ₄₂ (Teller *et al.*, 1996).

It is necessary to elucidate the mechanisms that regulate the activity of the secretase enzymes involved in APP metabolism, as a greater understanding of these processes will aid the development of therapeutic interventions. One factor that may predict which form of cleavage is utilized is cell type, with glial cells and neurones (both differentiated and undifferentiated) producing different isoforms of APP (Haass *et al.*, 1991; Baskin *et al.*, 1992; Hung *et al.*, 1992). Another factor that influences the cleavage pathway may be the release of APP by protein kinase C (PKC), which leads to a predominance of the α -secretase pathway (Caporaso *et al.*, 1992; Gillespie *et al.*, 1992; Sinha and Lieberburg, 1992). Of interest, PKC mediated α -secretase activity may be induced by neurotransmitters and other first-messenger ligands (Buxbaum *et al.*, 1992; Lahiri *et al.*, 1992; Nitsch *et al.*, 1992). If these first and second messenger pathways prove to directly influence the production of A β ₄₂, then these systems could provide another target for pharmacological intervention.

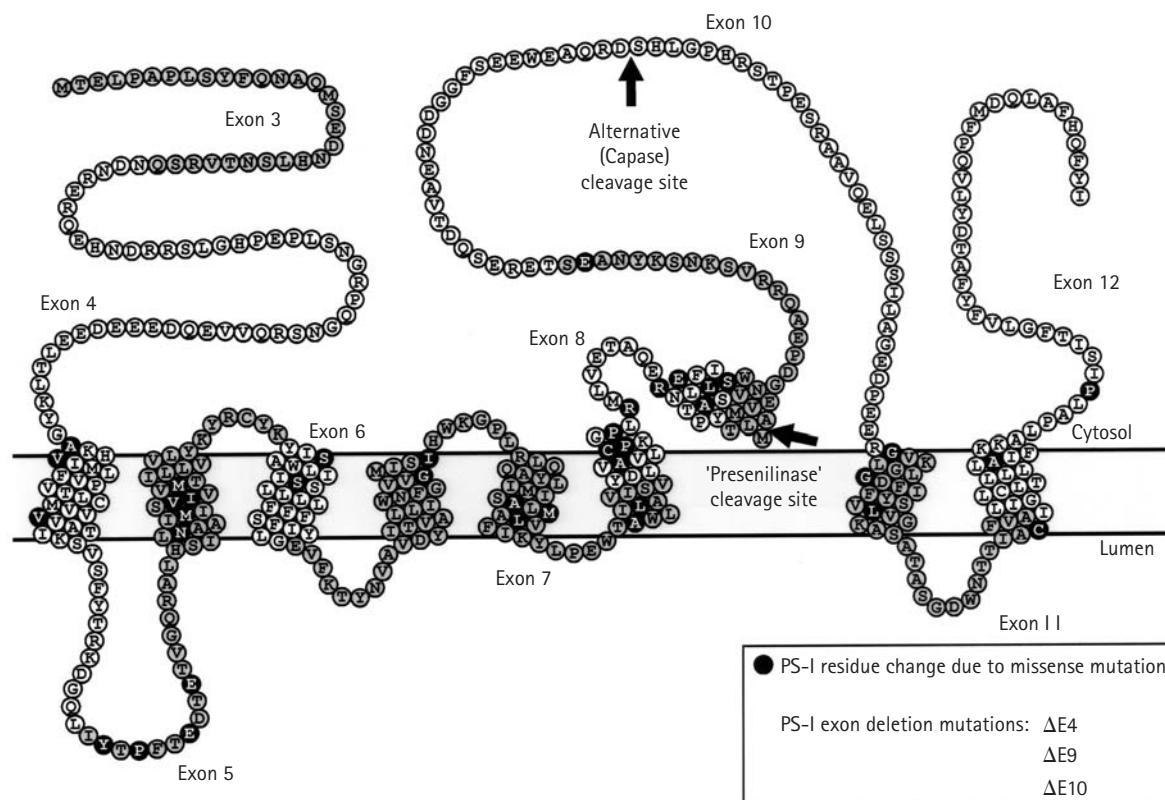

Figure 32.3 A model of the presenilin 1 molecule. The multiple mutations that cause early-onset Alzheimer's disease are seen to cluster in the transmembrane domains and in proximity to the normal 'presenilinase' cleavage site. The cytosolic loop between transmembrane domains 6 and 7 may play a critical role in γ -secretase activity.

32.6 PRESENILINS 1 AND 2

The PS1 gene is located on chromosome 14 and PS2 on chromosome 1. In the brain, PS1 is found in both neurones and glia. It has a multipass transmembrane orientation (Figure 32.3). PS2 expression in the pancreas and muscle exceeds other sites including the brain (Rogaev, 1998). The presenilin molecules undergo cleavage by unidentified mechanisms to yield N- and C-terminal fragments. The functions of PS1 and PS2 are unknown, though it has been proposed that they may have a role in signalling pathways from plasma membranes to the cell nucleus during cell differentiation, or they may play a role in receptor trafficking and protein recycling.

A link between PS mutations and A β production has been confirmed as an increased ratio of A $\beta_{42:40}$ is noted in transfected cell lines and transgenic mice expressing mutant forms of PS1 (Borchelt *et al.*, 1996; Citron *et al.*, 1996; Duff *et al.*, 1996; Lemere *et al.*, 1996). Knock-out PS1 cells lose γ -secretase activity, consistent with the concept of PS harbouring the active γ -secretase site (De Strooper *et al.*, 1998). Furthermore, patients and at-risk individuals with PS mutations have increased ratios of A $\beta_{42:40}$ (Scheuner *et al.*, 1996). PS1 may have an anti-apoptotic activity (Roperch *et al.*, 1998) and mutations in PS1 may sensitize neuronal cells to apoptosis

by disruption of intracellular calcium levels (Keller *et al.*, 1998).

In summary, all the identified genotypes in autosomal dominant AD have, as their common denominator, an increase in the production of A β_{42} . This observation suggests a direct causal relationship between A β_{42} and the development of AD.

32.7 A β AND NEUROTOXICITY

Despite the above evidence that an increase in the proportion of A β_{42} is a common end point for all the autosomal dominant mutations that lead to AD, the exact mechanism of underlying A β_{42} and neuronal degeneration remains unclear (Box 32.1).

A β has been shown to be directly neurotoxic to hippocampal neurones that are particularly sensitive to oxidative stress and are affected first in the spread of AD throughout the cerebral cortex. While some authors have been unable to demonstrate neurotoxicity of A β when it exists in an immature, non-fibrillar, amorphous aggregate (Lorenzo and Yanker, 1994), there is now an emerging consensus that the smaller oligomeric aggregates of A β , in association with factors such as

Box 32.1 *A β toxicity-proposed mechanisms*

- Generation of reactive oxygen species, metal mediated
- Physical disruption of cellular membrane
- Receptor-mediated uptake and apoptotic signalling
- Disturbance of intracellular calcium homeostasis

metal ions, constitute the principal forms of the toxic A β species. A β can potentiate the neuronal insult of excitatory amino acids (Koh *et al.*, 1990), oxidative stress (Lockhart *et al.*, 1994) and glucose deprivation (Copani *et al.*, 1991). This may explain why the cumulative exposure of the ageing brain to other risk factors renders it more vulnerable to the toxic effects of A β . A β has also been shown *in vitro* to cause plasma membrane lipid peroxidation, impairment of ion motive ATPases, glutamate uptake and uncoupling of γ -protein linked receptors (Behl *et al.*, 1994; Butterfield *et al.*, 1994; Hensley *et al.*, 1994; Mark *et al.*, 1996). These pathological processes may contribute to a loss of intracellular calcium homeostasis that has been reported in cultured neurones (Mattson *et al.*, 1993). A β , when introduced into neuronal cultures, leads to a gradual increase in intracellular calcium, though this activity is not affected by the addition of either calcium channel blockers or chelating agents (Lorenzo and Yanker, 1994; Whitson and Appel, 1995). A β may also impair redox activity in mitochondria, leading to the production of free radicals (Shearman *et al.*, 1994). Cellular damage mediated by A β is inhibited by vitamin E (Behl *et al.*, 1992). This supports the above observation that a free-radical-based process, mediated by A β , leads to neuronal damage and that this process, *in vitro*, can be inhibited by antioxidants. The use of antioxidants in the treatment of AD has been investigated clinically in recent years and some clinical efficacy has been shown with vitamin E (Sano *et al.*, 1997). Preliminary trials with compounds which target the redox-active metal binding sites on A β have yielded encouraging results (Ritchie *et al.*, 2003).

32.8 APOLIPOPROTEIN E, α 2-MACROGLOBULIN AND OTHER GENETIC MODIFIERS OF ENVIRONMENTAL RISK IN ALZHEIMER'S DISEASE

32.8.1 Apolipoprotein E

ApoE isoforms represent a major genetic susceptibility factor for sporadic AD, affecting all people over the age of 60 years. It is the first of what may prove to be a multiple set of genetic risk factors that have the potential to modify any putative environmental risk factor.

The ApoE gene, located on chromosome 19, was the first polymorphic gene to be associated with a complex disease using positional cloning strategies. The ApoE gene products vary depending upon the inherited pair of polymorphic alleles. There are three allelic varieties ϵ 2, ϵ 3 and ϵ 4. ApoE is a

glycoprotein of 299 amino acids that is a normal constituent of plasma and cerebrospinal fluid (CSF) lipoprotein particles. The physiological function of the protein is to mediate cholesterol uptake, storage, transport and metabolism. There is a binding site for A β present near the C-terminus of the ApoE molecule (Wisniewski *et al.*, 1993). ApoE is a component of the VLDL and HDL complexes involved in cellular uptake and metabolism of cholesterol (Mahley, 1988). ApoE is normally upregulated and released from astrocytes following neuronal injury and not only affects lipid metabolism following this trauma, but may also complex with VLDL to increase neurite outgrowth and synaptogenesis. However, the different ApoE genotypes differentially affect this process. Individuals carrying the ϵ 4 allele have a decreased capacity for compensatory neurite outgrowth and synaptogenesis following neuronal injury (Poirier, 1994).

It has also been demonstrated that individuals with at least one ϵ 4 allele develop greater numbers of neuritic plaques (Olichney *et al.*, 1996) irrespective of whether or not they have clinical AD (Rebeck *et al.*, 1993; Schmechel *et al.*, 1993; Polvikoski *et al.*, 1995). ApoE ϵ 4 also complexes with A β , whereas ApoE ϵ 3 does not have the same affinity, thus promoting protofibril formation, which, as has been alluded to already, may be the immediate neurotoxic product in AD. A model therefore exists that outlines the interaction between A β and ApoE which explains why the latter exists as one of many contributing genetic risk factors to the development of AD. At the very least, it links the metabolism of cholesterol into the A β -mediated pathway of AD causation.

Not only is the genotype that an individual carries relevant as a risk factor for AD, but variations in ApoE levels may also be an important factor in predicting disease onset. The promoter of ApoE that regulates the synthesis of the lipoprotein is polymorphic. The allelic variants at -491 (Bullido *et al.*, 1998), -427 (Artiga *et al.*, 1998) and -219 (Lambert *et al.*, 1998) of the ApoE promoter region, when homozygous, may be associated with increased risk of AD, and a combination of the adverse alleles of the promoter and coding regions confer even greater risk of developing AD (Artiga *et al.*, 1998).

Clinically, possession of the ϵ 4 allele increases the risk of developing AD at any particular age. In individuals who are ϵ 4 heterozygotes, there is an approximate doubling of risk and for those that are homozygous for ϵ 4 the risk is increased by a factor of between 6 and 8 (National Institute on Aging/Alzheimer's Association Working Group, 1996). Possession of an ϵ 4 allele may lead to an earlier age of onset (Blacker *et al.*, 1997; Burlinson *et al.*, 1998) and there may be an even greater risk of developing AD in females who carry the ϵ 4 allele (Poirier *et al.*, 1993; Payami *et al.*, 1994; Duara *et al.*, 1996). There are, however, conflicting reports regarding the rate of decline associated with different genotypes. The ApoE ϵ 2 allele may confer protection against the development of AD (Corder *et al.*, 1994; Myers *et al.*, 1996).

The ϵ 4 allele also confers additional risk of developing AD in those patients who have suffered strokes (Slooter *et al.*, 1997), though other authors, in smaller studies, have failed to replicate

this finding (Burlinson *et al.*, 1998). Other cerebral insults such as head injuries have been associated with increased A β deposition in patients who carry an $\epsilon 4$ allele (Nicoll *et al.*, 1995). Determining the ApoE status of a patient may be of value in aiding the diagnosis of AD where there is already a high clinical suspicion of the condition. However, there may only be a marginal increase in diagnostic accuracy (American College of Medical Genetics/American Society of Human Genetics Working Group on Apolipoprotein E and Alzheimer's Disease, 1995; National Institute on Aging/ Alzheimer's Association Working Group, 1996). In isolation, knowledge of the ApoE genotype of any given individual lacks the sensitivity, specificity or positive predictive value to be useful as a screening tool.

32.8.2 $\alpha 2$ -Macroglobulin, low density lipoprotein receptor-related protein and insulin degrading enzyme

Whilst the ApoE gene was the first polymorphic marker to be identified as a genetic modifier of risk for AD, other candidate genetic loci are being investigated, including $\alpha 2$ -macroglobulin ($\alpha 2M$), a protease inhibitor found in association with amyloid plaques in AD. The gene for $\alpha 2M$ is located on chromosome 12: binds A β with high affinity, and may influence fibril formation and the toxicity of A β *in vitro* (Hughes *et al.*, 1998). The activity of $\alpha 2M$ has also been associated with low density lipoprotein receptor-related protein (LRP1). Both $\alpha 2M$ and LRP1 are upregulated following neuronal injury (Lopes *et al.*, 1994). Furthermore, $\alpha 2M$ is thought to mediate A β degradation via endocytosis through LRP1 (Narita *et al.*, 1997). As ApoE and APP are also ligands of LRP1, it is postulated that different isoforms of ApoE and $\alpha 2M$ may interact differentially and competitively for this system, affecting the clearance of A β .

Several investigators have now shown that, like ApoE, different LRP1 genotypes are associated with the development of AD (Kang *et al.*, 1997; Hollenbach *et al.*, 1998), mediated possibly through an increase in A β burden. $\alpha 2M$ genotypes, unlike ApoE genotypes, have seemingly no effect on the age of onset in AD (Liao *et al.*, 1998). The odds ratio for AD associated with the γ/γ $\alpha 2M$ genotype was shown to be 1.77 (1.16–2.70, $P < 0.01$) and in combination with ApoE $\gamma 4$ was 9.68 (3.91–24.0, $P < 0.001$). In the same study, there was no increased risk of AD demonstrated in heterozygotic individuals with γ/γ genotype, and stratification of the sample based on the presence or absence of the ApoE $\gamma 4$ allele demonstrated a similar overrepresentation of the γ/γ genotype in both strata (Liao *et al.*, 1998). This finding was demonstrated in a population-based study. This initial work suggests that the $\alpha 2M$ γ/γ genotype may increase the risk of developing AD, that this risk is independent of the effects of ApoE $\gamma 4$, and that the risks are additive and substantial. The studies to date require further replication and the effect requires demonstration in different populations in a similar manner to studies defining the risks associated with ApoE $\gamma 4$. If future studies do conclude that $\alpha 2M$ is an independent risk factor

for AD, then predictive testing considering both genes (and also including genotyping of the ApoE promoter regions) could be developed with much higher positive predictive values than those demonstrated with ApoE testing alone.

Whole genome search strategies (Blacker *et al.*, 2003; Ertekin-Taner *et al.*, 2004) have yielded other 'hot spots' of interest, the most intriguing of which is that on chromosome 10, close to the insulin degrading enzyme (IDE) locus. Attempts to identify IDE as a risk factor have so far failed, but it remains an attractive candidate for its demonstrated role in promoting the clearance of A β from the brain (Farris *et al.*, 2004).

32.9 INTERVENTIONS

Being able to determine the risk that a given individual has of developing AD late in life has few clinical implications at present. As proven disease-modifying treatments for AD do not exist, the main benefit of defining a population at high risk of developing AD is to identify a cohort for clinical trials of drugs with a postulated preventative or significant disease-modifying action.

Current therapeutic interventions for AD operate far downstream from the postulated initial toxicity of A β_{42} . Their efficacy is dependent upon augmenting the activity of surviving cholinergic neurones; the cholinesterase inhibitors (donepezil, galantamine) have shown only modest effect on clinical progression of AD and have no demonstrable disease-modifying effect. To prevent neuronal damage and clinical impairment, effective therapies must either affect the initial production of A β_{42} from APP or mediate its toxicity or clearance. Specific interventions may therefore target inhibition of γ -secretase, upregulate the α -secretase pathway, influence the phosphorylation state of the APP molecule, chelate metal ions, scavenge free radicals, affect the postulated overactivation of microglial cells in response to amyloid deposition or a combination of these. These actions may, if the amyloid theory is correct, decrease A β_{42} production and amyloid plaque formation, protect neurones from the postulated neurotoxic effects of this system or aid clearance of A β_{42} from the brain.

32.10 CONCLUSIONS

This chapter has highlighted the complexity and intricacies of the various systems that tie A β to the neuronal degeneration of AD. Intensive investigation of these biochemical systems has elucidated several potential targets for rational therapeutic intervention. The test of the amyloid theory will be in the examination of interventions that modulate the production and accumulation of A β_{42} , initially in mice before human trials take place. In preparation for these trials, defining a high-risk population based on genetic risk factors will continue with the hope that more effective disease-modifying drugs will be available for trial in the not too distant future.

Vascular factors in Alzheimer's disease

ROBERT STEWART

33.1 Challenges for research	436	33.5 Causal links between vascular disease and Alzheimer's disease	439
33.2 Vascular factors and clinical Alzheimer's disease	437	33.6 Implications	441
33.3 Vascular factors and Alzheimer's disease pathology	438	References	441
33.4 White matter lesions and Alzheimer's disease	438		

The growing recognition of vascular factors in Alzheimer's disease (AD) has challenged preconceived ideas about the nature of dementia. Assumptions about AD and vascular dementia as distinguishable clinical disorders have been steadily eroded as the large overlap between assumed underlying pathology and observed clinical syndromes has become increasingly evident. In neuropathological research, the focus on neuritic plaques and neurofibrillary tangles as the hallmarks of 'Alzheimer pathology' is challenged by an increasing body of research highlighting associated abnormalities in the vasculature. Developments in neuroimaging have been a mixed blessing. The ability to detect more minor levels of vascular disturbance is undoubtedly useful in investigating causal pathways and a long way on from relying on clinical evidence of cerebral infarction. However, detectable 'abnormalities' now include a larger proportion that are coincidental rather than causal, particularly in older age groups.

33.1 CHALLENGES FOR RESEARCH

A major obstacle for research in this area has been the assumption that AD and vascular dementia are discrete disorders at a pathological and clinical level. This assumption arose, one suspects, because of a need for clinicians to assign diagnoses rather than because of any supportive evidence. The authors of the seminal post-mortem studies in the 1960s and 1970s recognized that people with dementia could have Alzheimer pathology, could have cerebral infarction or could have both. Mixed dementia was retained in all subsequent diagnostic systems but received little or no research attention. Research instead focused on AD, using clinical and pathological

diagnostic criteria, which excluded potentially mixed disease because of the higher interrater agreement attained by using a narrow syndrome definition. Vascular factors in AD became a difficult area to research because AD could only be diagnosed in the absence of vascular factors.

A more fundamental challenge to understanding the role of vascular factors in AD is the limited interface between epidemiological and biological research. Epidemiological research investigates associations between potential risk factors and a specified disorder, accepting that causal processes in between may not be measurable in the population. These causal processes can be represented as a 'black box' between exposure and outcome. Biological research on the other hand focuses on potential causal processes within the 'box'. However, in the absence of tissue biopsies (which are impractical in dementia research), findings at a molecular or cellular level cannot be linked directly to clinical symptoms/syndromes observed in life. Because of this lack of connection, AD has become in effect two disorders – one a process of nerve cell death with particular features at a cellular level that can only be observed at autopsy, the second a clinical disorder characterized by its symptoms and clinical course. AD the pathological disorder is likely to be have been present for a decade or two before AD the clinical disorder becomes apparent. However, large numbers of people with significant levels of AD pathology show no clinical evidence of dementia (Neuropathology Group of the Medical Research Council Cognitive Function and Ageing Study, 2001). Diagnostic criteria for AD as a clinical disorder attempt to predict the presence of AD pathology by the time of death (McKhann *et al.*, 1984). However, these criteria poorly reflect mixed disease (Holmes *et al.*, 1999), which will become increasingly common with population ageing.

The role of vascular factors in AD may therefore be considered from two perspectives. One concerns the association between vascular disease, vascular risk factors and risk of AD as a clinically defined syndrome. The second concerns vascular abnormalities associated with Alzheimer pathology. These will be considered separately before research findings are described which may link the strands together.

33.2 VASCULAR FACTORS AND CLINICAL ALZHEIMER'S DISEASE

The most commonly used criteria for 'probable' AD require that other potential causes of dementia are not present. There is obviously a strong subjective element involved in deciding what represents a sufficient potential 'cause', an issue which has become steadily more problematic with increasingly sophisticated techniques for identifying mild degrees of comorbidity (and with ageing populations where significant comorbidity is to be expected). An inevitable byproduct of this classification system is that AD samples tend to be relatively healthy, and it is not surprising that several early case-control studies found similar or lower levels of vascular risk factors.

33.2.1 Associations between vascular risk factors and AD

Progress only began to be made when studies began to use screened community samples and applied more broad definitions of AD, allowing people with comorbid cerebrovascular disease to be included if this was not clearly causal. There is now a substantial body of prospective epidemiological research supporting a role for vascular risk factors in the aetiology of AD. Identified risk factors include large vessel atherosclerosis as estimated by carotid ultrasound or the ankle:brachial blood pressure index (Hofman *et al.*, 1997), conventional risk factors for cerebrovascular disease such as hypertension (Skoog *et al.*, 1996b; Kivipelto *et al.*, 2001), type 2 diabetes (Brayne *et al.*, 1998; Ott *et al.*, 1999) and atrial fibrillation (Ott *et al.*, 1997), as well as conventional cardiovascular risk factors such as raised cholesterol levels (Notkola *et al.*, 1998; Kivipelto *et al.*, 2001) and smoking (Ott *et al.*, 1998). They also include risk factors such as raised homocysteine levels (Clarke *et al.*, 1998; Seshadri *et al.*, 2002) and insulin resistance (Kuusisto *et al.*, 1997) and protective factors such as moderate alcohol intake (Ruitenberg *et al.*, 2002) and increased physical activity (Yoshitake *et al.*, 1995; Laurin *et al.*, 2001) where other causal pathways may be involved, but whose associations with AD may have a vascular component.

33.2.2 Effects of dementia on vascular risk factors

Despite strong associations with cerebrovascular disease, associations between hypertension and dementia (including

AD) proved remarkably difficult to demonstrate for some time. Raised blood pressure in mid-life is associated with later cognitive impairment and dementia (Elias *et al.*, 1993; Launer *et al.*, 1995). However, this has tended only to be apparent in studies with follow-up periods of 10 years or more. Studies with shorter follow up often find no association (Posner *et al.*, 2002), and cross-sectional studies frequently show associations between dementia and low rather than high blood pressure (Guo *et al.*, 1996). Skoog's analysis of a cohort with 15-year follow-up data found that participants with AD had raised systolic blood pressure at the start of the study but lower blood pressure by the time dementia had developed (Skoog *et al.*, 1996b). This does not appear to be accounted for by antihypertensive treatment since randomized trials of these agents show no deleterious effects on cognition (Prince *et al.*, 1996; Forette *et al.*, 1998). It is therefore likely that there are metabolic changes associated with early dementia, which account for this reversal of association. These illustrate a further difficulty with investigating vascular risk factors since AD cannot be assumed to be a 'passive' outcome but instead may influence the exposures in question. Weight loss occurs in early dementia (Barrett-Connor *et al.*, 1996; Nourhashemi *et al.*, 2003) as well as declining blood pressure. The extent to which these processes influence other vascular risk factors, such as cholesterol levels, insulin resistance and glucose tolerance, has not been adequately investigated. However, there are obvious implications for prevention and treatment.

33.2.3 Interactions with ApoE genotype

Several studies have investigated the role of apolipoprotein E (ApoE) genotype in the relationship between vascular risk factors and AD. The ApoE $\epsilon 4$ allele was first recognized for its associations with cholesterol metabolism, and has been found at least in some studies to be associated with stroke (Margaglione *et al.*, 1998; McCarron *et al.*, 1999). However, there is no evidence to date that cholesterol levels or other vascular factors substantially explain the well established association between $\epsilon 4$ and AD (Slooter *et al.*, 1999; Prince *et al.*, 2000). The focus instead has shifted to investigating interactions between vascular factors and $\epsilon 4$ as risk factors, although findings remain conflicting and difficult to synthesise. A preliminary finding from one community study was that vascular disease was more strongly associated with AD in the presence of ApoE $\epsilon 4$ (Hofman *et al.*, 1997). Subsequent findings from later examinations in the same study did not support this interaction (Slooter *et al.*, 1999), although other studies have reported similar interactions (Johnston *et al.*, 2000). For some vascular risk factors, $\epsilon 4$ interactions have been found in the opposite direction. Insulin resistance and smoking, for example, have been found to be more strongly associated with AD in people without $\epsilon 4$ (Kuusisto *et al.*, 1997; Ott *et al.*, 1998). Because interactions tend not to be reported as absent, it is difficult at present to exclude publication bias as an explanation for these results.

33.2.4 The role of clinical stroke

An important question arising is the extent to which associations between vascular risk factors and AD are explained by cerebral infarction. Most of the studies cited above have, in secondary analyses, divided AD cases into those with and without clinical evidence of cerebrovascular disease and most have found that associations remain in the less mixed group. An exception may be atrial fibrillation, which appears to be particularly associated with AD co-occurring with stroke (Ott *et al.*, 1997). The association between stroke itself and AD is almost impossible to investigate because of the way in which AD is defined. However, there have been important findings which question the extent to which the two are separable:

- The majority of people developing dementia after stroke do so in the absence of further clinical infarction (Tatemichi *et al.*, 1994).
- Post-stroke dementia frequently follows an AD-like clinical course (Kokmen *et al.*, 1996).
- Post-stroke dementia is frequently associated with evidence of prestroke cognitive decline (Hénon *et al.*, 2001).
- Cognitive impairment is a risk factor for later first onset of stroke (Ferucci *et al.*, 1996).
- Post-stroke dementia is associated with an increased risk of stroke recurrence (Moroney *et al.*, 1997).

For dementia associated with stroke, these findings suggest that the stroke episode itself, although undoubtedly having an impact on cognitive function, may frequently occur in the context of more insidious and gradual decline. This may reflect comorbid AD in a substantial number of cases.

33.3 VASCULAR FACTORS AND ALZHEIMER'S DISEASE PATHOLOGY

Epidemiological research therefore supports a role for conventional vascular risk factors in the aetiology of clinical AD. Parallel neurobiological research has suggested that vascular processes may be an important feature of AD at a pathological level.

33.3.1 Cerebral amyloid angiopathy

Traditionally research into the role of amyloid in AD has focused on its deposition in parenchymal neuritic plaques. However, other pathology associated with the disorder has long been recognized. Cerebral amyloid angiopathy (CAA) describes the deposition of β -amyloid, amongst other proteins, in the walls of cortical vessels. CAA increases with age and is particularly common in AD (Yamada, 2000). It is also recognized to be a risk factor for cerebrovascular disorders such as small and large vessel haemorrhage, leukoencephalopathy and infarction, and is a feature of some familial early-onset dementia syndromes. CAA is therefore a feature of AD

but also a potential cause of cognitive decline in its own right. This was demonstrated in a recent autopsy follow up of a large and well-characterized community population, which found a strong and synergistic relationship between 'conventional' AD pathology and CAA on cognitive function in life (Pfeiffer *et al.*, 2002). The effect of CAA on cognitive function was apparent in those with clinical AD and so was not fully explained by overt cerebrovascular disease, suggesting that it may underlie some of the gradual decline traditionally attributed to parenchymal pathology. The mechanism has yet to be elucidated through which small vessel abnormalities may result in neurodegeneration. However, further support is provided by a study that found blood vessels isolated from the brains of people with AD were neurotoxic *in vitro* (Grammas *et al.*, 1999).

33.3.2 Microangiopathy

A growing body of evidence suggests that vascular abnormalities in AD are not restricted to arterial and arteriolar amyloid deposition, but are also seen in cerebral microvessels and capillaries. Microangiopathic changes include basement membrane thickening and collagen accumulation (Farkas *et al.*, 2000), as well as smooth muscle cell irregularities, endothelial degeneration and other abnormalities (Kalaria and Skoog, 2002). The underlying causal pathways have yet to be established but might include oxidative stress or blood–brain barrier dysfunction secondary to AD pathology itself or secondary to a common underlying risk factor (Kalaria and Skoog, 2002). Microangiopathy may itself exacerbate AD through effects on the microcirculation, compromising the normal removal of neurotoxic β -amyloid (de la Torre and Mussivand, 1993; Preston *et al.*, 2003), and could also exacerbate the cell damage associated with comorbid cerebral vascular disease (Stewart, 1998).

33.4 WHITE MATTER LESIONS AND ALZHEIMER'S DISEASE

Neuroimaging findings lie somewhere between epidemiology and pathology in AD research since associations are investigated with the clinical disease but inferences are made regarding underlying pathological processes. White matter hyperintensities (WMH) on magnetic resonance imaging (MRI) are frequently found in association with AD, although they are by no means a characteristic feature. The pathological processes underlying WMH have not been definitely established, at least in part because of methodological difficulties involved in linking neuroimaging appearances observed in life with post-mortem findings some time later. Arteriosclerotic changes are often seen in association with white matter alterations, and ischaemia due to small vessel occlusion or hypoperfusion may underlie the dysmyelination and neuronal loss also observed. However, blood–brain barrier disturbance and transient episodes of cerebral oedema may also underlie

WMH (Pantoni and Lammie, 2002). Vascular amyloid deposition has been considered as a possible factor accounting for white matter changes in AD, and both CAA and WMH are found in combination in a rare genetic syndrome (Haan *et al.*, 1990). However, white matter changes have generally not been found to be associated with vascular amyloid in groups with dementia (Erkinjuntti *et al.*, 1996).

Whatever the precise pathology, there is reasonable epidemiological evidence to suggest that WMH represent sub-clinical cerebrovascular disease in many cases. WMH have been consistently found to be associated with conventional risk factors for cerebrovascular disease such as hypertension (Breteler *et al.*, 1994b; Liao *et al.*, 1997; Dufouil *et al.*, 2001), smoking (Liao *et al.*, 1997), hypercholesterolaemia (Breteler *et al.*, 1994b) and atherosclerosis (Bots *et al.*, 1993). There is also a reasonable body of evidence to suggest that, at a population level, they are associated with worse cognitive function (Breteler *et al.*, 1994a; Kuller *et al.*, 1998), in people both with and without dementia (Skoog *et al.*, 1996a). However, a focus on population-level associations in large studies runs the risk of glossing over considerable individual heterogeneity. WMH are common findings in older populations and may be present at an apparently severe degree without detectable evidence of cognitive impairment (Fein *et al.*, 1990). WMH appear to be associated with dementia, although findings have been less consistent than for studies of cognitive function (Smith *et al.*, 2000; Piguet *et al.*, 2003). More specific associations with AD are less easy to establish because of variation in the way in which diagnostic criteria are applied and in the extent to which WMH are considered as excluding AD. What can at least be claimed with reasonable confidence is that WMH are frequently present in people with clinical AD (if only because both are common and age-associated) and that they represent comorbid cerebrovascular disease in many cases.

33.5 CAUSAL LINKS BETWEEN VASCULAR DISEASE AND ALZHEIMER'S DISEASE

The neuropathological findings summarized above suggest that vascular abnormalities are a feature of AD pathology and may be important in its clinical expression. White matter hyperintensities in AD may or may not be a marker of these particular pathological features but do suggest the involvement of vascular processes because of well-recognized associations with risk factors for cerebrovascular disease. The next question to consider concerns pathways that might explain the association observed in life between vascular risk factors and AD.

33.5.1 Links at a pathological level

Various pathways have been proposed, which may explain an association between AD and vascular risk factors and which relate to links at the level of pathological processes. These will be summarized.

- *Ischaemic injury and amyloid deposition:* β -amyloid production appears to be a non-specific response to cerebral trauma but has been described in particular in the hippocampi of rodents after severe but transient ischaemia (Kogure and Kato, 1993), providing a potential link between ischaemia/infarction and AD pathology.
- *Inflammation:* There is growing recognition that inflammatory processes are important in mediating cerebral damage following stroke (Emsley and Tyrrell, 2002). Inflammation is also an important feature of AD pathology (Halliday *et al.*, 2000), and might conceivably underlie links between the two processes.
- *The blood-brain barrier:* Increased permeability of the blood-brain barrier has been found in association with transient ischaemia (Pluta *et al.*, 1996), and this has been suggested to underlie both perivascular amyloid deposition and white matter changes (Tomimoto *et al.*, 1996).
- *Abnormal protein glycation:* Advance glycation end products, metabolic oxidation products associated with diabetes and hyperglycaemia (Vlassara *et al.*, 1992) have also been found in association with neurofibrillary tangles and neuritic plaques in AD (Dickson, 1997). These may underlie, at least in part, the association between diabetes and AD that does not appear to be entirely mediated through cerebrovascular disease (Stewart and Liolitsa, 1999).

33.5.2 Links at a cognitive level

The mechanisms above suggest that vascular factors may directly influence the pathological processes that are believed to underlie AD. However, clinical AD might still be 'caused' without any direct interaction at a pathological level but instead by interaction in clinical manifestations. Alzheimer pathology develops slowly, possibly over as long a period as 20 years. The chance of someone developing dementia depends a great deal on the extent to which a given level of pathology affects cognition and on the extent to which a person can compensate for this. Alzheimer pathology begins in the hippocampus and manifests in its early stages as declining memory function. Mild levels of cerebrovascular disease on the other hand would be expected to exert most damage on deep white matter and on fronto-subcortical connections. The consequent disruption of executive functions such as selective attention and mental flexibility may be enough to 'unmask' early AD that might not otherwise have become apparent for several years. Vascular factors may therefore accelerate the age of onset of clinical AD.

33.5.3 Links at a functional level

The 'onset' of dementia is defined, at least in research settings, as the point where declining cognitive function starts to interfere with daily functioning. This is not an entirely

satisfactory definition of 'incidence' since it involves a considerable degree of subjective judgement on the part of the participant, their family and the research worker. It also assumes a process that can be isolated from all the other factors influencing daily functioning in older people. A given level of cognitive impairment may be more likely to be classified as problematic if daily function is already impaired – for example because of motor system impairment owing to cerebrovascular disease. Or, from the opposite perspective, a person in good physical health may be able to sustain a greater degree of cognitive decline before this can be said to be problematic.

33.5.4 Evidence for these causal links

The hypothetical causal pathways summarized above suggest that vascular factors might act directly to increase the progression of AD pathology, or alternatively they might lower the threshold (cognitive or functional) at which clinical dementia manifests for a given degree of neurodegeneration. These two processes can be tested empirically since they predict different associations between vascular factors and neuropathological findings. Clinicopathological studies that have investigated cerebrovascular pathology as an exposure have tended to support the second mechanism. Cerebrovascular disease and AD overlap substantially in community-derived samples and are clearly not in themselves sufficient to cause dementia since either pathology can be severe with no evidence of dementia in life (Neuropathology Group of the Medical Research Council Cognitive Function and Ageing Study, 2001). However, AD pathology has not in general been found to be more severe in the presence of cerebrovascular disease. Instead, women with mild Alzheimer pathology in the Nun Study were found to be more likely to have had dementia in life if cerebral infarction was also present (Snowdon *et al.*, 1997). The OPTIMA study in Oxford similarly found that cognitive function had been most impaired in people with early Alzheimer pathology if cerebrovascular disease was also present (Esiri *et al.*, 1999), suggesting an effect on cognitive rather than functional reserve.

Findings to date for detectable levels of cerebrovascular disease therefore suggest that this acts to 'cause' AD through reducing the pathological threshold for clinical dementia. However, findings for certain vascular risk factors suggest that there may also be effects on AD pathology itself. A post-mortem study of people without dementia found higher senile plaque counts in those with coronary artery disease (Sparks *et al.*, 1990) and higher neurofibrillary tangle counts in those with previous hypertension (Sparks *et al.*, 1995). Neuropathological follow-up studies in a cohort of Japanese-American men have found higher levels of AD pathology associated with increased mid-life blood pressure (Petrovitch *et al.*, 2000) and diabetes (Peila *et al.*, 2002). These findings differ from those for cerebrovascular disease and suggest either that vascular risk factors influence AD pathology through different mechanisms. Alternatively it is possible that cerebrovascular disease and AD pathology are associated with

higher levels of mortality in combination, diluting their association in older cohorts.

33.5.5 Common underlying factors

Associations between vascular factors and AD need not imply direct causal links between the two but might, at least in part, arise from common underlying processes. ApoE genotype has been considered in this respect although, as discussed earlier, has not been found to explain substantially the co-occurrence of cerebrovascular disease and AD. Both AD and cerebrovascular disease are 'disorders of ageing', i.e. they become more common with increased age. However, 'ageing' as a process is not synonymous with increased chronological age and there is substantial individual variation in the physiological changes that occur in the transition from mid- to late life. 'Ageing' is likely to be influenced by a variety of factors, both genetic and acquired. Many of these are unknown, e.g. genetic factors common to diseases of ageing. Others may be unquantifiable, e.g. lifetime exposure to oxidative stress. Dementia is conventionally stressed as a disorder distinct from 'normal ageing'. However, it is likely that there are processes that mediate general vulnerability to ageing processes whether these are experienced in the brain parenchyma or in the vasculature.

A more specific factor that might link both vascular factors and AD is insulin resistance. This is recognized to be important in underlying the clustering of vascular risk factors such as hypertension, type 2 diabetes mellitus and hypercholesterolaemia (Reaven, 1988), all of which have been found to be associated with AD as summarized above. However, insulin levels themselves in theory could have direct effects on cognitive function. Insulin receptors are dense in the hippocampus (Marks *et al.*, 1991). Their role in hippocampal function is not understood, but increased levels of insulin have been found to inhibit hippocampal synaptic activity *in vitro* (Palovcik *et al.*, 1984). Insulin has also been found to reduce choline acetyltransferase activity (Brass *et al.*, 1992), a key factor in the cognitive impairment associated with AD, and there are links which can be made between insulin growth factor-1 and the enzyme pathways which regulate tau protein phosphorylation – and hence neurofibrillary tangle formation (Stewart and Liolitsa, 1999). Insulin resistance has been found to be associated independently with AD in a population study (Kuusisto *et al.*, 1997) but mediating pathways for this have yet to be established.

33.5.6 Direction of cause and effect

Since vascular risk factors emerge in mid-life and a considerable period before AD incidence begins to increase, it is generally assumed that any causal processes are directed from the vascular risk factor to AD. However, this does not exclude adverse effects of AD on the vasculature at a later stage. Links at a pathological level between vascular factors and AD may be complex and bi-directional. For example, hypertension might cause small vessel disease and, consequently, cerebral ischaemia

or infarction. This might in turn precipitate deposition of both parenchymal and vascular amyloid causing neuronal loss. However, the presence of vascular abnormalities independently associated with co-occurring AD might also increase the extent of ischaemia and neurodegeneration associated with arteriosclerotic disease. Vascular factors might therefore be both a cause and a consequence of AD. At a clinical level, it is likely that worsening cognitive function owing to early AD may have adverse effects on risk for vascular disease, particularly through difficulties with adherence to treatment regimes from declining memory function (Rost *et al.*, 1990). Surprisingly this has received scant attention despite the frequent co-occurrence of AD and common vascular risk factors such as hypertension and type 2 diabetes.

33.6 IMPLICATIONS

This chapter has focused on evidence for the involvement of vascular factors in AD, and on processes that might underlie these associations. Clearly there are potentially important implications for prevention and treatment of dementia. A reduction in vascular risk across a population would in theory reduce the risk of later dementia, whether vascular risk factors were acting on AD pathology or reducing cognitive/functional reserve. However, 'treatment' of AD (i.e. reducing cognitive/functional decline) through modifying vascular risk would only be effective if there are direct effects on neurodegenerative processes. Observational evidence to date has not demonstrated clear associations between co-occurring cerebrovascular disease and progression of dementia, although there has been little research in this area (Lee *et al.*, 2000; Mungas *et al.*, 2001). A commonly neglected implication concerns the care of people with dementia. In terms of clinical care, people with AD will commonly have disorders such as hypertension or diabetes, which require pharmacotherapy and medical review. Neurodegenerative processes themselves may have effects on factors such as blood pressure and body composition, altering susceptibility to drug effects and side effects, and requiring close attention. In terms of formal and informal social care, people with AD will often also have clinically apparent cerebrovascular disease, which may already be affecting non-cognitive areas of functioning, increasing the level of support required. Vascular factors may have an important impact on quality of life for people with AD and their caregivers regardless of whether relationships with AD reflect cause, effect or coincidence. However, this aspect of the interface has received scant attention to date.

Genetics of Alzheimer's disease

MARGIE SMITH

34.1 Molecular genetics of early-onset Alzheimer's disease	444	34.4 Conclusion	448
34.2 Risk factors and candidate genes	446	References	448
34.3 Diagnostic genetic testing for Alzheimer's disease	448		

Major advances in our understanding of the pathogenesis of Alzheimer's disease (AD) have come from molecular studies of patients with autosomal dominant early-onset AD (EOAD). Mutations in the amyloid protein precursor (APP) and presenilin genes (PS1 and PS2) located on chromosomes 21:14 and 1 respectively exert their effect in a fully penetrant manner. More recently, studies of late-onset AD (LOAD) have led to the determination of a number of possible risk loci. On the basis of these studies it has been postulated that the pathogenesis of LOAD is probably multifactorial. Continued research in this complex area of the genes and proteins involved in AD will help establish a logical basis for therapeutics and management.

34.1 MOLECULAR GENETICS OF EARLY-ONSET ALZHEIMER'S DISEASE

34.1.1 Mutations in the APP gene

The APP gene was implicated as a potential locus for AD mutations on the basis of four main intersecting lines of evidence. First, it is well known that individuals with Down's syndrome (trisomy 21) develop the pathological lesions of AD by the fourth decade. This evidence implied a relationship between chromosome 21 and AD pathology (Mann *et al.*, 1984, 1989). Second, a 40–42 amino acid proteolytic peptide (A β) of the full length APP is a major constituent of senile plaques (Masters *et al.*, 1985; Goldgaber *et al.*, 1987; Kang *et al.*, 1987). Genetic linkage studies have shown an additional line of evidence for linkage to a locus associated with EOAD in the region of chromosome 21 containing the APP gene (St George-Hyslop *et al.*, 1987; Goate *et al.*, 1989). Finally, a mis-sense mutation (APP E693Q) was identified in the A β region

of the APP gene characterized by hereditary cerebral haemorrhage with amyloidosis of the Dutch type (HCHWA-D) (Levy *et al.*, 1990; Kamino *et al.*, 1992). This is a rare disorder caused by severe β A4 amyloid deposition in meningeal and cerebral microvessels (Levy *et al.*, 1990; Van Broeckhoven *et al.*, 1990). It has recently been shown that E693G mutation causes AD by increasing amyloid β -protofibril formation and decreasing amyloid β levels in plasma and conditioned media (Nilsberth *et al.*, 2000). Three different mutations have now been reported at codon 693: the 'Dutch' mutation (Glu22Gln), the Arctic Glu22Gly mutation and 'Italian' mutation (Glu22Lys). Peptides of the wild-type 'Dutch' and 'Italian' variants were made and their cytotoxic effects were evaluated in human cerebral endothelial cells in culture. The effect of each mutation was different under these conditions, the E22Q peptide exhibiting the highest content of beta-sheet formation and aggregation properties. In contrast the 'Dutch' variant peptide induced apoptosis of cerebral endothelial cells. These results indicate that a change in amino acid at position 22 confers distinct structural properties on the peptides that affect the onset of the inexorable disease process (Miravalle *et al.*, 2000). After the initial finding of the E693Q mutation, a sequence variation affecting the valine at codon 717 (position 46 relative to the β A4 sequence) was found to be associated with the EOAD phenotype. At least 13 families worldwide have been identified with a V717I mutation, conferring an age of onset for AD in the mid-fifties (Goate *et al.*, 1991; Hardy *et al.*, 1991; Naruse *et al.*, 1991; Fidani *et al.*, 1992; Sorbi *et al.*, 1993, 1995; Brooks *et al.*, 1995; Campion *et al.*, 1996, 1999; Matsumura *et al.*, 1996; Finckh *et al.*, 2000). A 'mixed' phenotype of AD and/or severe cerebral amyloid angiopathy is caused by a mutation (A692G) at the β A4 residue 21 adjacent to the E693Q HCHWA-D (Hendriks *et al.*, 1992). This finding provided supporting evidence for the hypothesis that HCHWA-D and AD are

pathological variants of the same disease, being associated with a phenotype of AD or other β A4 amyloidosis related disorders. A double mutation (K670N and M671L) in a large Swedish EOAD kindred with a mean age of onset of 55 years was identified (Mullan *et al.*, 1992). More recently four other APP mutations have been identified the Austrian (Thr714Ile) (De Jonghe *et al.*, 2000), Florida (Ile716Val) (Eckman *et al.*, 1997), French (Val715Met) (Ancolio *et al.*, 1999) and Australian (Leu723Pro) (Kwok *et al.*, 2000a).

The Swedish mutation was the first APP mutation for which a direct effect on β A4 processing could be demonstrated (Mullan *et al.*, 1992). This double point mutation (the 'Swedish' mutation) Lys670Met and Asp671Leu is upstream of the β -secretase cleavage site and results in a 5–8-fold increase in the formation of both $A\beta_{40}$ and $A\beta_{42}$ (Citron *et al.*, 1992). Two single point mutations at amino acid 717: (the 'London' mutation Val717Ile; and the 'Indiana' mutation Val717Phe) are adjacent to the γ -secretase site and specifically increase the production of $A\beta_{42}$ (Suzuki *et al.*, 1994), which is known to form insoluble amyloid fibrils (Selkoe, 1994). Synthetic peptides containing the HCHWA mutation show accelerated fibril formation (Wisniewski *et al.*, 1991). The majority of APP mutations molecular effect is to increase $A\beta_{42}$ production (Hardy, 1997); however, overexpression of the Val715Met mutation in human HEK293 cells and murine neurones reduces the total $A\beta$ production and increases the recovery of the physiologically secreted product, APP α . It was thought that some cases of familial AD may be associated with a reduction of in the overall production of $A\beta$ but could be caused by increased production of truncated forms of $A\beta$ ending at the 42 position (Ancolio *et al.*, 1999).

Whilst APP mutations identified to date do not contribute to LOAD, it is possible that genetic variability within the promoter contributes to the risk of developing AD (Wavrant-De Vrieze *et al.*, 1999).

34.1.2 Mutations in the PS1 gene

After the initial finding of an EOAD locus on chromosome 21 it became apparent that the majority of EOAD kindreds did not show linkage to chromosome 21 (Schellenberg *et al.*, 1988; Tanzi *et al.*, 1987; Van Broeckhoven *et al.*, 1987; St George-Hyslop *et al.*, 1990). The PS1 gene was identified in 1995 through positional cloning strategies. Five mutations were identified in eight of 14 pedigrees analysed (Sherrington *et al.*, 1995). All the mutations occurred within highly conserved domains of the PS1 protein as shown by comparison to the murine homologue that provides supporting evidence that these mutations are indeed pathogenic. Not all mutations occur at residues that are conserved between PS1 and PS2. The PS1 gene was previously denoted as the S182 or AD3 locus; 133 mutations have been detected in the PS1 gene (they can be viewed at the following website: <http://molgen-www.uia.ac.be/>)

The age of onset of AD due to PS1 mutations is accelerated; however, variability in age onset is observed. The M139V and

M146V mutations have an age onset around 40 years (Clark *et al.*, 1995; Van Broeckhoven, 1995), whereas for kindreds identified with the E280 and C410Y mutations the age of onset is between 45 and 50 (Clark *et al.*, 1995; Sherrington *et al.*, 1995); the Ala409Thr mutation has an onset of 85 years (Aldudo *et al.*, 1999). EOAD linked to chromosome 14 is estimated to account for 70 per cent of all EOAD pedigrees (St George-Hyslop *et al.*, 1992; Van Broeckhoven *et al.*, 1992).

The phenotype of PS1 mutations is heterogeneous. It was initially thought that the only difference between AD and EOAD was the earlier age of onset (Sherrington *et al.*, 1995); however, there are five reports of AD associated with spastic paraparesis (SP) of the lower limbs. The brain pathology in one kindred was described as unique with large plaques lacking the classical core of amyloid fibrils. The term 'cotton wool' was coined by virtue of their size and appearance (Crook *et al.*, 1998). PS1 mutations associated with SP include a small deletion in exon 4 (DeltaI83/M84) (Steiner *et al.*, 2001), an insertion of six nucleotides in the coding region of exon 5 (from TAC to TTTATATAC) between amino acids K155 and Y156, point mutations in the coding region of exon 8 (Val261Phe) (Farlow *et al.*, 2000) and (Arg278Thr) (Kwok *et al.*, 1997), a point mutation in the splice acceptor consensus of intron 8 resulting in in-frame skipping of exon 9 and an amino acid change at the splice junction of exon 8 and exon 10 (g.58304G > A, c.869–955del) (Sato *et al.*, 1998; Kwok *et al.*, 2000b), (g.58304G > T, c.869–955del) (Perez-Tur *et al.*, 1995; Hutton *et al.*, 1996; Kwok *et al.*, 1997; Kwok *et al.*, 2000b) and large genomic deletions (g.56305–62162del) (Kwok *et al.*, 1997; Smith *et al.*, 2001) identified in an Australian kindred and (g.56681–61235) the Delta9Finn kindred (Crook *et al.*, 1998). Interestingly a point mutation in the splice donor consensus site of intron 4 resulting in three different transcripts with a single-codon insertion, partial and complete deletion of exon 4 respectively, the latter two resulting in a frame-shift and premature stop codon (g.23024delG, c.338–339insTAC, c.170–338del, c.88–338del) (Tysoe *et al.*, 1998) is not associated with spastic paraparesis. It was hypothesized that this mutation leads to AD through haplo insufficiency of full length PS1. This is in direct contrast to other PS1 mutations, which are thought to confer a 'toxic' gain of function in which $A\beta_{42}$ secretion is selectively increased (Tysoe *et al.*, 1998). Other phenotypes associated with EOAD are frontotemporal features (Raux *et al.*, 2000), myoclonic seizures (Ezquerria *et al.*, 1999), and a psychiatric disorder (Tedde *et al.*, 2000).

Mutations are located throughout the PS1 protein; however, their distribution may not be random. Mutations tend to occur at residues conserved between PS1 and PS2 and as such the majority are in transmembrane domains. Specifically the cluster of mutations in transmembrane 1: 2, 3, 4, and 6 line up on one side of the α -helix. This helical face may be important for the interaction with other transmembrane proteins (Clark *et al.*, 1995). It has been suggested that disruption of the helical faces impairs presenilin function so that more $A\beta_{42}$ is produced (Hardy and Crook, 2001). The majority of PS1 mutations cluster in exon 8, which is close to

the cleavage site. If this is a functional domain then disruption of its function may be critical to pathogenicity. The clustering of APP mutations around the α -secretase, β -secretase, and γ -secretase sites lead to different molecular mechanisms; however, the final outcome is the same.

The normal biological and pathological functions of PS1 are poorly understood; however, there is ample evidence for a role of PS1 in the proteolytic processing of APP and in Notch processing (Wolfe *et al.*, 1999). PS1 is endoproteolytically cleaved between amino acids 291 and 299 resulting in a N-terminal fragment of 30 kDa and a C-terminal fragment of 18 kDa (Thinakaran *et al.*, 1996). The proteolytic cleavage site is located in that part of PS1 encoded by exon 9; therefore the delta 9 mutant does not undergo cleavage and accumulates as full length PS1 (Thinakaran *et al.*, 1996). Conversely, the efficiency of processing is not affected by missense mutations in AD brains (Hendriks *et al.*, 1997), in brains of transgenic mice (Duff *et al.*, 1996), and in transfected cells (Borchelt *et al.*, 1996). Cells transfected with PS1 mutants (M146V, A246G, A260V, G384A, C410T) have impaired proteolysis (Mercken *et al.*, 1996) and in lymphocytes of mutation carriers (Takahashi *et al.*, 1999). There is no correlation between different PS1 mutations, age onset and $A\beta_{42(43)}$ production in transfected embryonic kidney cells (Mehta *et al.*, 1998).

34.1.3 Mutations in the PS2 gene

Directly after the identification of the PS1 cDNA sequence, 'expressed sequence tags' (ESTs) were described with considerable homology to two different segments within the PS1 open reading frame (T03796). Cloning of the full-length cDNA of this corresponding gene, mapped to chromosome 1 enabled the identification of missense mutations in cDNAs in affected Volga-German subjects (Levy-Lahad *et al.*, 1995). Evidence of the physical genome mapping of PS2 on chromosome 1q42.1 was performed using fluorescence *in-situ* hybridization (Tokano *et al.*, 1997). The majority of kindreds analysed exhibited the N141I missense mutation thereby identifying a founder effect. EOAD onset in these kindreds generally occurs later than in EOAD kindreds linked to chromosome 14 but with a broader range of age at onset from 54.8 ± 8.4 . The mean duration of disease is 11.3 ± 4.6 years and mean age at death approximately 66 years. Clinically kindreds with PS1 mutations have a more aggressive disease than those with PS2 mutations (Lampe *et al.*, 1994). The wide variation in age of onset indicates that other genetic and or environmental factors influence the age of onset. Non-penetrance over the age of 80 years has also been observed (Sherrington *et al.*, 1996). The penetrance is over 95 per cent for PS2 kindred; however, presymptomatic individuals harbouring the mutation over the age of 80 may escape disease. A total of 15 kindreds have been identified with a PS2 mutation. The majority of these mutations are localized to exons 5, 7 and 12 of the PS2 gene.

The exon 5 T122P mutation is highly penetrant unlike the previously reported PS2 mutations N141I and M239V

(Levy-Lahad *et al.*, 1995). Consistent with the variable penetrance of the N141I and M239V mutations, the M239I mutation has associated phenotypic variability with some affected having an earlier onset and more severe course than the index case (Finckh *et al.*, 2000).

34.2 RISK FACTORS AND CANDIDATE GENES

The study of LOAD is in its infancy, with risk loci on chromosomes 6, 9, 10 and 12 having been identified. With the recent completion of the human genome project putative genes that map to a region of linkage can be identified. This strategy should identify new genetic risk factors. However, none of the numerous studies involving more than 100 candidate genes have revealed convincing evidence for any predisposing risk alleles (Finckh, 2003) other than apolipoprotein E (ApoE).

34.2.1 ApoE as a risk factor

Analysis has shown that that the ApoE locus cannot account for all the genetic risk associated with sporadic early and late-onset forms of AD (Templeton, 1995). The association of ApoE with LOAD has been studied extensively (Saunders, 2000). Polymorphisms within the ApoE promoter region correlate with increased transcriptional activity of the ApoE gene *in vitro*. Association studies of ApoE polymorphisms suggest that the -491 A/T genotype, the -491AA genotype, the -219 T/G, the -427 C/T genotype and the Th1/E47cs genotype increase the risk of developing AD. Not surprisingly results from other groups show positive, and partial association of ApoE polymorphisms and increased risk of developing AD (Bullido *et al.*, 1998). Recently sequence haplotype variation in 5.5 Kb of genomic DNA encompassing the whole of the ApoE locus and adjoining flanking regions in 96 individuals from four populations: 22 single nucleotide polymorphisms and 31 distinct haplotypes were identified (Fullerton *et al.*, 2000). Significantly seven of these polymorphisms were located upstream of exon 1 with the potential to alter transcription.

34.2.2 Candidate genes on chromosome 12

In 1997 a complete genomic screen identified linkage to a locus on chromosome 12 in a 36 cM region between markers D12S373 and D12S390. Other chromosomes of interest were 4, 6 and 20 (Pericak-Vance *et al.*, 1997). Two other linkage studies using independent LOAD cases provided supporting evidence for a locus on chromosome 12 (Rogaeva *et al.*, 1998; Wu *et al.*, 1998). However, Wu *et al.* (1998) were unable to confirm the precise location. A follow-up study of the families reported by Pericak-Vance *et al.* (1997) which controlled for family size, the presence of an ApoE $\epsilon 4$ allele, and presence of dementia with Lewy bodies found that linkage to chromosome 12 was stronger in families with the affected individuals lacking an ApoE $\epsilon 4$ allele and having a diagnosis of dementia

with Lewy bodies (Scott *et al.*, 2000). The highest LOD score was observed in affected individuals whose ApoE genotype did not contain an $\epsilon 4$ allele. This region may therefore harbour a new late-onset gene with reduced dependence on the $\epsilon 4$ allele. This finding suggests that LOAD is genetically complex involving many genes in addition to ApoE.

34.2.2.1 LOW-DENSITY LIPOPROTEIN RECEPTOR

Two candidate genes within the region of linkage to chromosome 12 have been identified, the α_2 -macroglobulin gene (A2M) and the low density lipoprotein receptor-related protein (LRP). LRP has been shown to be a multiligand endocytic receptor that mediates the internalization and degradation of ligands. LRP and its ligands, A2M, ApoE, and Kunitz protease containing isoforms of β -APP (Kang *et al.*, 1997) are all genetically associated with AD. A2M is a multifunctional binding protein that is thought to be involved in the degradation and clearance of $A\beta$ (Borth, 1992). Kang *et al.* (1997) investigated the role of ApoE as a ligand for three receptors, the low density lipoprotein receptor (LDL-R), very low density lipoprotein receptor (VLDL-R) and LRP. This study aimed to determine if there was an association between these receptors and Alzheimer's disease (AD). An association between a silent polymorphism in exon 3 (C766T) within the LRP gene and AD was significant after corrections were made for multiple testing. The association was not found to be significant when the effects of known risk factors for AD were applied. When the ApoE $\epsilon 4$ was applied the effect of LRP no longer reached statistical levels of significance. It was concluded that LRP although being a candidate gene may be a minor risk factor and that independent verification on a large number of samples was required. One other LRP polymorphism, a tetranucleotide repeat has been thought to be associated with AD.

Associations between AD and these two polymorphisms are controversial with some groups reporting an association whilst others have found no significant association (Lendon *et al.*, 1997; Lambert *et al.*, 1999; Bertram *et al.*, 2000a; Kang *et al.*, 1997; 2000). Recently Kang *et al.* (2000) provided the first *in vivo* evidence that the LRP pathway may modulate $A\beta$ deposition by regulating the removal of soluble $A\beta$.

34.2.2.2 α_2 -MACROGLOBULIN

A2M is a ligand for LRP, an abundant pan-protease inhibitor that is found immunohistochemically in neuritic plaques and has been implicated in the binding, degradation, and clearance of $A\beta$ (Borth, 1992). Association studies have been performed using two polymorphisms in the A2M gene, a 5 bp intronic insertion/deletion at the splice acceptor site of exon 18 (Matthijis and Marynen, 1991) and a missense mutation (Val1000Ile). Association studies have yielded conflicting results with reports of positive (Dodel *et al.*, 2000; Verpillat *et al.*, 2000) and negative associations (Gibson *et al.*, 2000; Koster *et al.*, 2000). It is possible that A2M deletion

polymorphism's genetic contribution accounts for a small fraction of AD cases.

34.2.3 Chromosome 9

The initial genomic screens reported linkage to regions of chromosomes 4, 6, 12, and 20 (Pericak-Vance *et al.*, 1997); however, in a second genomic screen using over 466 families, the highest LOD score was to a region on chromosome 9 (Pericak-Vance *et al.*, 2000). Independent genomes scan for LOAD also reported linkage to the same region (Kehoe *et al.*, 1999).

34.2.4 Chromosome 6

Linkage analysis by two independent groups (Pericak-Vance *et al.*, 1997; Kehoe *et al.*, 1999) showed evidence of linkage to chromosome 6. Three markers of interest on chromosome 6 were observed: D6S1004, D6S1019 and D6S391 (Pericak-Vance *et al.*, 1997). Kehoe *et al.* (1999) reported a multipoint peak located part way between that reported by Pericak-Vance *et al.* (1997) at D61018. In a later screen using 2-point linkage analysis on chromosome 6, linkage was found but not in this region (Pericak-Vance *et al.*, 2000). Linkages to several markers flanking the tumour necrosis factor locus have recently been reported. However, linkage was only observed in ApoE ϵ kindred (Collins *et al.*, 2000). This latter finding indicates the complexity of LOAD genotyping with some susceptibility genes being modulated by the ApoE status of the individual.

34.2.5 Chromosome 10

There is increasing evidence that for one or more susceptibility loci on chromosome 10 (Bertram *et al.*, 2000b; Ertekin-Taner *et al.*, 2000; Majores *et al.*, 2000; Myers *et al.*, 2000; Pericak-Vance *et al.*, 2000). The largest genomic scan to date was performed in a quest to find the remaining AD genes using 446 families (730 affected sib-pairs). The data were further stratified into an autopsy-confirmed subset of 199 families. Significantly the autopsy confirmed subset had an MLS of 4.31 on chromosome 9. Parametric and non-parametric linkage analysis was used (Pericak-Vance *et al.*, 2000). Recent studies have suggested that insulin-degrading enzyme (IDE) in neurones and microglia degrades $A\beta$. Parametric and non-parametric linkage analysis of 435 AD families found that seven genetic markers on chromosome 10 map near the IDE gene. Significant linkage for adjacent markers (D10S1671, D10S583, D10S170 and D10S566) was most pronounced in late-onset kindred (Bertram *et al.*, 2000b). A two-stage genome-wide screen was performed using sibling pairs with LOAD and an age of onset greater than 65 years. Non-parametric analysis stratified by the presence or absence of ApoE $\epsilon 4$ alleles provided evidence of a LOAD susceptibility locus on chromosome 10, close to marker D10S1211. This locus was found to modify the risk for AD independently of the ApoE genotype.

34.3 DIAGNOSTIC GENETIC TESTING FOR ALZHEIMER'S DISEASE

The identification of three genes causative for EOAD, APP and recently PS1 and PS2 raises the question of the role for genetic testing in AD. A consensus statement discussing the ethical aspects of the clinical introduction of genetic testing for AD concluded, 'except for autosomal dominant early-onset families, genetic testing in asymptomatic individuals is unwarranted'. Predictive testing for EOAD was offered in research settings following the identification of APP mutations on chromosome 21 using established Huntington's disease guidelines (Lennox *et al.*, 1994). The experience of three individuals belonging to a Swedish kindred with early-onset autosomal dominant AD was documented. Only three members of this large kindred proceeded with predictive testing, indicating a low demand for testing. One individual who was found to harbour the mutation reacted with depressive and suicidal feelings whilst the other two subjects expressed relief (Lannfelt *et al.*, 1995).

The ApoE gene, which confers some susceptibility to late-onset AD, has high commercial potential but the sensitivity and specificity of the test is low. An asymptomatic individual with an $\epsilon 4$ allele will not necessarily develop AD. However, testing for ApoE $\epsilon 4$ maybe useful as an aid for the diagnosis of individuals presenting with AD. Use of ApoE genetic testing as a diagnostic adjunct in patients already presenting with dementia may prove useful, but it remains under investigation. The premature introduction of genetic testing and possible adverse consequences 'are to be avoided' (Post *et al.*, 1997). Athena Neurosciences in 1996 introduced the Admark ApoE Genetic Test 'for greater certainty in differential diagnosis of AD'. The requesting physician must sign a consent stating that the individual has dementia prior to ApoE genotyping being performed.

Predictive testing is performed when a known family mutation has been identified in at least one other affected family member. Pretest assessment and counselling involves obtaining an accurate pedigree, neurological examination (not compulsory) and psychological appraisal. This is critical to understanding the individual's ability to cope with the results of the test. EOAD contributes less than 5 per cent of all AD cases; therefore there is no logical reason to perform genetic testing beyond this small cohort.

34.4 CONCLUSION

Genetic studies of EOAD have had a significant impact on our understanding of the pathogenesis of AD that in turn has led to research into diagnostic and therapeutic strategies and the availability of predictive testing of EOAD families. However, as people with EOAD represent only 5 per cent of all those with AD, some of the focus of genetic research has now shifted towards LOAD. Currently in LOAD, there appears to be a

complex interplay of many risk factors, much as is seen in other pathogenic processes such as atherosclerosis. The current complexity of this area undermines the role for risk factor testing in LOAD. Understanding this genetic interplay is pivotal and likely to be the focus of genetic research in the next decade.

Transgenic mouse models of Alzheimer's disease

SIMON P BROOKS AND STEPHEN B DUNNETT

35.1 Disease aetiology	452	35.7 Transgenic mouse models with presenilin mutations	459
35.2 Cellular pathology of Alzheimer's disease	452	35.8 Double transgenic (DTg) mouse models	459
35.3 The influence of background strain and mouse sex	453	35.9 Triple transgenic (TTg) mouse models	460
35.4 Transgenic mouse models with APP mutations	453	35.10 Conclusions	461
35.5 Transgenic β -CTF mouse models	458	References	461
35.6 Transgenic mouse models of tau mutations	458		

The purpose of this chapter is to review the recent developments in the field of transgenic (Tg) mouse models of Alzheimer's disease (AD). The Tg models were a great leap forward for scientists and the technology is still in its infancy, but already double and even triple Tg models of disorders have been developed that seek to recapitulate the primary core symptoms of diseases in a single model. This chapter will review the progress that has been made with Tg models of AD, initially looking at advances gained from using the single Tg models, and later at the very recent developments of double and triple Tg models.

35.1 DISEASE AETIOLOGY

The aetiology of the early-onset familial AD (EOFAD) can be simply defined as being genetic, the causes being mutations in either the amyloid precursor protein (APP) gene or in the presenilin 1 (PS1) or 2 (PS2) genes which reside on chromosomes 21, 14 and 1 respectively (Blanquet *et al.*, 1987; Goldgaber *et al.*, 1987; Levy-Lahad *et al.*, 1995; Sherrington *et al.*, 1995). Age of onset in EOFAD can begin as early as 35 years of age and disease progression is extremely rapid, resulting in death at around 7 years after the initial diagnosis. In contrast late-onset AD is essentially of unknown origin although over 40 per cent of patients possess the apolipoprotein E (ApoE) ϵ 4 allele, compared with 15 per cent in the general population. However, there is no evidence to suggest that ApoE ϵ 4 is a causative factor in late-onset AD, despite the finding that it decreases the age of onset from on average 84 years of age to 68 (Corder *et al.*, 1993) and has been found

to accelerate plaque formation (Baum *et al.*, 2000). Tg models that over express the ApoE ϵ 4 gene do not develop neurofibrillary tangles or plaques and generally lack AD pathology, the only factor that links them to AD is the finding that there appears to be hyperphosphorylation of tau (see below) in these animals (Tesseur *et al.*, 2000). In light of these findings, we will not focus on the ApoE ϵ 4 models of late-onset AD but on EOFAD and associated animal models of the core pathological biomarkers of AD, the neuritic plaques and neurofibrillary tangles. The genetic nature of EOFAD makes it accessible to recapitulation through the creation of transgenic animals that carry one of the human mutations.

35.2 CELLULAR PATHOLOGY OF ALZHEIMER'S DISEASE

35.2.1 The amyloid precursor protein, presenilins and plaque formation

One of the core pathologies that defines AD is the presence of insoluble deposits of peptide that over time form into abnormal plaques. These plaques are comprised of deposits of amyloid peptide, which have been created through the cleaving of the 110–130 kDa APP by a specific class of protease, the secretases (Kang *et al.*, 1987). The amyloid peptide found in the plaques of AD brains consists mainly of the 40–42-residue β -amyloid peptides (Glennner and Wong 1984; Masters *et al.*, 1985), which accumulate to form neurotoxic aggregations (Selkoe, 2001) that are hypothesized to be responsible for neuronal degeneration and dementia (Dahlgren *et al.*, 2002).

It is believed that the presenilin mutations (PS1 and PS2), that are known to be involved in EOFAD, cause dysregulation of APP. It has been reported that patients with PS1 mutations have greater number of A β ₄₂ plaques compared with patients with the other forms of the disease (Mann *et al.*, 1996) suggesting that PS1 mutations preferentially increase A β ₄₂ peptide production. PS1 has been shown to reduce amyloid peptides 5-fold, whereas the mutated PS1 increases the production of amyloid peptides in a way that induces an increase in ratio between A β ₄₂ and A β ₄₀ by selectively increasing A β ₄₂ production. It is believed that the presenilins regulate amyloid production through an interaction with secretase proteomes, but no evidence is available as to how this interaction occurs. However, it seems that β secretase cleaves APP to create β -CTFs (c-terminal fragments) which then get truncated by γ -secretase creating A β and it may be that the presenilins interfere with this process (see Sato *et al.*, 1997).

Both the plaques and neurofibrillary tangles (see below) identified in the brains of demented people have a well characterized distribution within the hippocampus and neocortex (Tomlinson *et al.*, 1970; Corsellis, 1976) although tangles have been identified in subcortical regions (Ishii, 1966; Tomlinson *et al.*, 1981; Whitehouse *et al.*, 1982).

35.2.2 Neurofibrillary tangles (NFTs)

NFTs are neuronal inclusions of paired helical filaments (PHFs) comprising hyperphosphorylated and ubiquitinated tau protein (Goedert *et al.*, 1995; Buee *et al.*, 2000). The exact role of tau protein in the brain is not fully understood but it appears to be a structural component of the neuronal cytoskeleton. Mutations in the gene on chromosome 17 that encode tau induces the formation of NFTs in another dementia, namely frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17). This disease is characterized by dementia in the absence of amyloid plaques and tau mutations have been found to cause NFTs and cell death (Clark *et al.*, 1998; Goedert *et al.*, 1998; D'Souza, 1999).

35.2.3 Cholinergic deficit

Whilst changes in several neurotransmitter systems have been identified in AD (see Dunnett, 1994) the most consistent and profound neurotransmitter disturbance in AD is a cholinergic deficit (Coyle *et al.*, 1982; Geula and Mesulam, 1994; Procter *et al.*, 1996) which correlates with the degree of dementia (Perry *et al.*, 1978; Bierer *et al.*, 1995) and with the density of amyloid plaques (Perry *et al.*, 1978; Geula and Mesulam, 1994). A more recent study has found that cholinergic loss better reflects tangle density (Geula *et al.*, 1998) than plaque density. The importance of the cholinergic system in AD is highlighted through the use of cholinomimetic compounds to treat the symptoms of AD (Parnetti *et al.*, 1997), although pharmacokinetic factors have largely limited their widespread usefulness.

35.3 THE INFLUENCE OF BACKGROUND STRAIN AND MOUSE SEX

Factors other than the transgene can influence the characteristics of any given mouse model of AD. Three factors of particular note are:

- the background strain on which the transgenic line is developed and subsequently backcrossed or maintained;
- the sex of the animal; and
- the specific promoter that has been used to drive the neuronal expression of the transgene.

With regards to background strains, an excellent review by Hsiao (1998) draws attention to differences in mortality rates between inbred C57BL/6j mice that had had the TG2576 transgene array transferred to them and the greatly reduced mortality rate when the host mice contained alleles from the SJL strain. Strain variation also produced changes in the behavioural manifestation of the disease progression between the latter cross-strain (C57BL/6j \times SJL) and FVB/N mice, with the FVB/N mice exhibiting neophobia and thigmotactic behaviour and the C57BL/6j \times SJL mice showing no behavioural abnormalities prior to death (see Hsiao, 1998).

Sex differences have been identified in APP transgenic mice resulting in an increased plaque load in female Tg2576 mice compared with age-matched males carrying the same transgene (Callahan *et al.*, 2001). A study by Park and colleagues (2003) did not find an initial sex difference in the Tg2576 mice, but the administration of lovastatin (which lowers plasma cholesterol) did produce sex specific effects on levels of A β , which were found to be significantly elevated in only the female mice. However, human sex differences have been found in studies in human AD with women being reported to be more susceptible than males to the disease (Molsa *et al.*, 1982), so it is not surprising that these apparent differences can be reflected in the mouse models.

35.4 TRANSGENIC MOUSE MODELS WITH APP MUTATIONS

35.4.1 APP transgenics

The first Tg mouse model to show deposits and plaques with a regional distribution similar to that for AD was created by Kawabata *et al.* (1991). This particular mouse expressed human mutant APP C-terminal fragments. Since this time several different lines of enquiry have produced a number of mutant mouse lines that over-express different mutant genes. The most prominent and most researched of these mouse models are the APP models of AD that are usually designed to express human mutant APP and reliably produce animals with neuritic plaques in the cerebral cortex and hippocampus. Specific APP mutations are named after the place of origin of the kindred families predisposed to AD in humans. Some transgenic

models are based on over-expression of the normal human APP, but the more effective Tg models involve the transfer of a mutant allele into the Tg mouse, for example, the Swedish mutation in the Tg2576 transgenic line. The most widely used APP mutations are the Swedish, Indiana, London, Dutch and Flemish mutations. In this review, the different mutations will be addressed as APP/Swe, APP/Ind, APP/Lon, APP/Dut and APP/Flu respectively. See the summary table (Table 35.1, pp. 456–457) for a general overview of some of the specific differences between the more commonly used APP mice.

In 1991 it was discovered that injections of A β into the rat neocortex or hippocampus resulted in the formation of plaque-like structures complete with neuritic degeneration (Kowall *et al.*, 1991) and that a memory deficit was produced in mice by injecting the same protein intraventricularly (Flood *et al.*, 1991). These findings coupled with publication of the mouse genome, led directly to the development of Tg APP mice that were designed to express high levels of human mutant APP, with the hope of producing β -amyloid plaques in the mouse brain with both the temporal and spatial patterning of AD.

35.4.2 APP expression and histology of APP mice

The APP/Ind mouse with the V717 human mutation (Games *et al.*, 1995) expressed a 10-fold higher expression of mutant human A β in the Tg mouse brains than found in previous models. The expression of human mutant A β was under the control of the PDGF (platelet derived growth factor) promoter and hence was preferentially regionalized by neurones of the cortex, hippocampus, hypothalamus and cerebellum in the Tg animals. Interestingly, levels of APP in the thalamus of homozygotic mice were higher than levels of APP in the hippocampus of the heterozygotic animals, yet the heterozygotic animals showed marked hippocampal pathology whereas the homozygotes showed relatively little thalamic pathology (Johnson-Wood *et al.*, 1997). Compared with 4-month old animals, 8-month animals showed an 8-fold increase in A β levels, and a 400-fold increase by 18 months of age in the cortex. In the hippocampus at 8 months old the increase was 17-fold, and at 18 months 500-fold (Johnson-Wood *et al.*, 1997) illustrating the progressive nature of the disease-like pathology in these animals.

Plaques were found to be present at 4 month of age. Aggregate size was roughly 20 μ m in diameter, which increased up to around 150 μ m at 8 months of age (Johnson-Wood *et al.*, 1997), confirming previous findings by Games *et al.* (1995). By 10 months of age many large A β deposits were found throughout the frontal and cingulate cortex and the molecular layers of the hippocampus, especially the dentate gyrus. Chen *et al.* (2000) characterized plaque formation in limbic regions of the APP/Ind mutations and found very few plaques were present in the hippocampal formation at 9 months of age, but by 16 months plaque density was higher

especially in layers II and III of the entorhinal cortex, in the molecular layer of the dentate gyrus, and in striatum molecular lacunosum of area CA1. By 21 months plaques were present throughout the hippocampus, in the cingulate cortex, the insular dorsal cortex to the rhinal fissure and entorhinal cortex. No plaques were present in control mice. Synaptic and dendritic density were reduced in the molecular layer of the hippocampal dentate gyrus, as found with the synaptophysin and the dendritic marker MAP-2 (Games *et al.*, 1995).

The Tg2576 mice (Hsiao *et al.*, 1996) carrying the Swedish mutation are very widely used and have also been well characterized. The Swedish mutation mice show a similar pathology to the Indiana mutation mice with general increase in amyloid in hippocampus and cortex (Callahan *et al.*, 2001). They show A β deposits in the brain at 9–11 months (Hsiao *et al.*, 1996). A problem with these models is that they do not reflect the temporal or spatial pattern produced by endogenous APP. However, a genomic model has been developed recently (R1.40) that uses a copy of the Swedish mutant APP that is expressed with the endogenous human promoter. This model has A β deposits by 14 months (Lamb *et al.*, 1997; Lamb *et al.*, 1999; Kulnane and Lamb, 2001). R1.40 mice express high levels of CTF α and β and APP in brain tissue in contrast to Wild-type (Wt) brains that express high levels of APP, low levels of CTF α and no CTF β (Lehman *et al.*, 2003). Therefore the Swedish mutation increases CTF β production through the secretase- β pathway (Lehman *et al.*, 2003).

In the APP/Swe, mice the hippocampus showed the highest brain proportion of CTF β of all brain areas studied with the cortex showing an intermediate level (Lehman *et al.*, 2003). A β ₄₀ was also exhibited at significantly higher levels in the hippocampus than any other brain region. At 13.5 months these mice exhibited abundant A β deposits in the striatum, dentate gyrus and hippocampus (Hsiao *et al.*, 1996; Callahan *et al.*, 2001; Sigurdsson *et al.*, 2001). These deposits were primarily made up of A β ₄₂ (63 per cent in younger animals and 70 per cent in older animals) (Kulnane and Lamb, 2001). R1.40 mice showed almost nothing in the hippocampus until 22 months when deposits were present in the same regions as for Tg2576 (Lehman *et al.*, 2003). As in humans, most A β deposits stain for A β ₄₂ with a subset staining for A β ₄₀.

In the olfactory bulb both models showed low to moderate levels of A β by 22 months, and in the cerebellum APP was significantly higher in the APP/Swe animals but A β ₄₂ levels were not different (Lehman *et al.*, 2003). No tau deposits or NFTs were found but there was evidence of tau phosphorylation (Kulnane and Lamb, 2001).

A fourth APP mouse is called the London mouse (APP/Lon). At 17–22 months of age these mice exhibited amyloid plaques that were concentrated in the frontal cortex layers IV–VI, in the hippocampus, the amygdala and entorhinal cortex (Bronfman *et al.*, 2000). In the hippocampus plaques were found in the subiculum primarily but also the striatum radiatum, and the CA1 and CA3 regions. Thioflavin-S staining confirmed the amyloid nature of the plaques (Bronfman *et al.*, 2000).

A comparative study of the APP/Swe and APP/Lon mutated mice by Moechars *et al.* (1999) found considerable strain variations. In all of the old APP/Lon mice and 50 per cent of the old APP/Swe mice amyloid deposits and neuritic plaques were detected, being most abundant in the hippocampus and the cortex. In APP/Swe mice the deposits were fewer but larger (130 μm) and located in the primary olfactory cortex and amygdala. There was preferential staining for A β_{40} in the APP/Swe mice and A β_{42} in the APP/Lon mice (Moechars *et al.*, 1999). Deposits were absent in Wt mice. Plaques appeared to be similar to those found in AD brains, but no NFTs were found although an epitope typical for hyperphosphorylated tau was detected in dystrophic neurites associated with amyloid plaques. All Tg APP mice had a higher mortality rate during the first year (21–72 per cent) compared with Wt (4.3 per cent) mice (Moechars *et al.*, 1999).

In the Flemish and Dutch mutations (APP/Fle and APP/Dut) only relatively minor histological changes were apparent, such as spongiosis of the neuropil in the frontal cortical regions and the parahippocampal and cerebellar areas (Kumar-Singh *et al.*, 2000). The use of a GFAP antibody detected glial activation in the cerebral cortex, cerebellar and limbic areas including the hippocampus. Neuronal expression of mutant APP was greatest in cortical layers II, IV and V, which were also areas where neurones were found to contain condensed nuclei. High APP levels were also found in the pyramidal layer of the hippocampus, olfactory bulbs, basal pontine nucleus and the cranial nerve nuclei (Kumar-Singh *et al.*, 2000). A similar profile was found for the APP/RK mouse (Moechars *et al.*, 1999) that failed to develop plaques despite large increases in APP expression in the cortex, amygdala, striatum and the hippocampal pyramidal layer and the granular cells of the dentate gyrus.

Although the above mice were designed to carry a mutant APP allele the temporal and spatial profile of amyloid deposition and plaque development can vary markedly between transgenic lines and mouse strains.

Creating a Tg mouse that contains two familial AD mutations (Swe/Ind) had the effect of inducing an early onset of amyloid deposition and plaque development in mice at around 16 weeks of age (Mucke *et al.*, 2000; Christi *et al.*, 2001) with plaques developing in the molecular layer of the dentate gyrus and the deeper layers of the neocortex (Mucke *et al.*, 2000). These mice have been reported to show spatial learning deficits at 3 months of age (Janus *et al.*, 2000) and an enhanced startle response and a reduction in PPI before the plaques were identified (McCool *et al.*, 2003).

35.4.3 Cholinergic transmission in the APP mice

There is evidence to suggest that there are ongoing changes in the cholinergic neurones in AD mice. A decreased density of SYN-IR sensitive presynaptic terminals has been found in the hippocampus that precedes plaque formation in APP mice (Games *et al.*, 1995; Hsia *et al.*, 1999). Twelve-month old

APP/Ind mice show AChE-immunoreactive dystrophic fibres in the vicinity of amyloid plaques (Sturchler-Pierrat *et al.*, 1997). In contrast, Gau *et al.* (2002) found no differences in four cholinergic markers (VAcHT, SDHACU, ChAT, AChE) between Tg and Wt APP/Ind mice across three age groups (14, 18 and 23 months) despite ongoing amyloidogenesis. In 17–22-month-old London mutation mice AChE fibres are reorganized in the hippocampus and amyloid plaques are surrounded by dystrophic AChE-positive fibres. Also an increased density of AChE fibres in the CA1 region of the hippocampus and dentate gyrus of 17–22-month-old APP/Lon mice was found, suggesting compensatory sprouting (see Bronfman *et al.*, 2000). Extensive cholinergic differentiation was found in the subiculum of aged APP/Lon mice (about 60 per cent reduction in AChE staining) and in some amyloid plaques AChE staining appeared in the core whilst around most plaques AChE fibres appeared distorted (Bronfman *et al.*, 2000). However, no changes in the total AChE activity were found in the hippocampus, frontal or parietal cortex areas (Bronfman *et al.*, 2000). It has been suggested that, because behavioural deficits precede amyloid deposition, it may be that soluble A β peptides have a detrimental effects on cellular function even prior to plaque formation (Hsia *et al.*, 1999).

35.4.4 Electrophysiology in the APP mice

In electrophysiological studies, APP mice have been shown to exhibit interesting responses to glutamate challenges and widespread but subtle changes in glutamatergic function. In APP/Lon mice Masliah *et al.* (2000) found decreased binding and affinity for aspartate uptake and a decrease in expression of EAAT1 and 2 (glutamate transporters). The authors suggest that an increased APP expression disturbs astroglial transport of excitatory amino acids leading to increased susceptibility to glutamate toxicity. APP has been reported to perform a role in neurotrophic and neuroprotective activity in cell culture (Masliah *et al.*, 1996) and *in vivo* (Masliah *et al.*, 1998; Mucke *et al.*, 1994). APP has also been shown to be protective against glutamate toxicity in the Tg mouse (Masliah *et al.*, 1997). In AD similar findings have been found, that glial glutamate transport is decreased (Cowburn *et al.*, 1988; Masliah *et al.*, 1996; Li *et al.*, 1997). Hence in APP mice an increased APP expression disrupts normal functioning of the glutamate transporter system, possibly through amyloid β peptide-mediated inhibition (Harris *et al.*, 1996), resulting in an increased risk of excitotoxicity (Masliah *et al.*, 2000).

APP mice showed disparity between reaction to kainate and NMDA challenges. Kainate had an LD50 of 28 mg/kg and 32 mg/kg for the APP/Fle and /Dut mice respectively whereas Wt mice were not affected at 32 mg/kg. In contrast NMDA had an LD50 of 70 mg/kg in the Wt mice and the LD50 ranged between 160 and 200 mg/kg in the Tg mice suggesting an decreased sensitivity to NMDA excitation (Kumar-Singh *et al.*, 2000). These findings together with

Table 35.1 Key features of the most commonly used Tg APP mouse lines

Familial transgene	Line	Mouse strain	cDNA	APP mutation	Promoter	Reference	Major pathology	Functional deficits
	1	B6/D2	C-TF	None	human Thy-1	Kawabata <i>et al.</i> , 1991	8 months – plaques, tangles, dystrophic neurites in cortex, hippocampus and amygdala	NR
Wild type	NSE: β -APP751	JU	751	None	NSE: β -APP751	Quon <i>et al.</i> , 1991	Cortical and hippocampal β -amyloid deposits	NR
	MTA4	B6 x LT/Sv	695	None	hMTII	Beer <i>et al.</i> , 1991	\uparrow APP expression in pyramidal and Purkinje cells	Hypoactivity and motor deficits
Dutch	APP/Du/	FVB/N	695	E693Q	Mouse Thy-1	Kumar-Singh <i>et al.</i> , 2000	No amyloid deposits. Glial reaction, apoptosis with extensive spongiosis	8 weeks \uparrow agitation + bouts of wild running. 6 months \uparrow aggression + some seizures. Premature death
Flemish	APP/FI/	FVB/N	695	A692G	Mouse Thy-1	Kumar-Singh <i>et al.</i> , 2000	No amyloid deposits. Glial reaction, apoptosis with extensive spongiosis	8 weeks \uparrow agitation + bouts of wild running. 6 months \uparrow aggression + some seizures. Premature death
Indiana	Line 109	SWx (B6/D2)	695, 751, 770 M671L +	V717F	PDGF	Games <i>et al.</i> , 1995	6 months – A β deposits. Plaques became present in hippocampus, corpus callosum and cortex associated with distorted neurites	3 months – reference, working and operant memory deficits \uparrow freezing + stereotypy. From 6 months – object recognition deficits
London	APP/Ld/2	FVB/Nx(B6)	695	V642I	Mouse Thy-1	Moechars <i>et al.</i> , 1999	13 months – amyloid plaques in hippocampus and cortex. Reactive astrocytes and microglia, plus dystrophic neurites	8 weeks \uparrow agitation. 3 months \downarrow ambulation, \uparrow anxiety, spatial navigation deficits. 6 months some seizures

Swedish	Tg 2576	B6/SJL x (B6)	695	K670N-M671L	Hamster prion	Hsiao <i>et al.</i> , 1996	9–11 months – amyloid deposits in hippocampus and cortex later developing in the striatum	9–10 months spatial memory and spontaneous alternation deficits

Key to mouse strain abbreviations: B6, C57BL/6j; D2, DBA/2; B6D2F1 x (B6), for example, denotes a C57BL/6j first generation cross with DBA/2 strain which is then backcrossed (denoted with parenthesis) onto a C57BL/6j background; C-TF, C-Terminal Fragment

reports that suggest no evidence for apoptosis in the APP mice are suggestive of a down-regulation in the number of NMDA receptors, which may contribute to the cognitive decline in some of these mouse strains. Moechars *et al.* (1999) found that LTP was significantly decreased after tetanic stimulation in APP/Lon mice of 5–7 months old in CA1 region of the hippocampus and that these mice were also less sensitive to an NMDA challenge than non-transgenic mice at 3–4 months of age but more sensitive to kainite (Moechars *et al.*, 1999).

35.4.5 Behavioural changes in the APP mice

As a general rule of thumb the APP Tg mice have been shown to develop both reactive and cognitive deficits that appear to worsen over time. Of interest though is the finding that behavioural deficits can precede plaque formation, or, in the case of the APP/Dut and APP/Fle mice, behavioural deficits are present in the absence of plaque formation.

APP/Ind mice have been found to show cognitive deficits in the form of reference memory errors on a radial arm maze task from 3 months of age and the object recognition task from 5 months in the homozygote animals and 9–10 months in the heterozygote animals (Dodart *et al.*, 1999). Complementary results were also obtained in a water maze task in mice of 13 months old (Chen *et al.*, 2000), although no deficits were found in the object recognition task. In addition, Dodart *et al.* (1999) also ran operant tasks consisting of 15-minute daily session for 5 days in which the mice had to press a lever and then travel around a 5-cm long partition to acquire the reward; 21 days later the mice were retested on a single session for retention. The results confirmed that at 3 months of age Wt mice performed better (produced more reinforced bar presses) than Tg mice.

APP/Lon mice have been reported to exhibit an increased fear response as measured by freezing behaviour, which increased from 0 per cent at 7–9 weeks to 35 per cent at 17–30 weeks of age (Moechars *et al.*, 1998). At 3–6 months of age these mice were impaired at the acquisition of a hidden platform water maze task but not the cued (visual) platform task when compared with non-Tg littermates. Likewise the Tg animals performed poorly in the probe task 24 hours later, spending significantly less time in the target quadrant, and producing significantly less platform crossings than non-Tg animals. These deficits preceded plaque formation (Moechars *et al.*, 1998).

Interestingly both the APP/Dut and the APP/Fle mutation have been shown to develop behavioural deficits that are characteristic of AD, but in the absence of APP deposits (Kumar-Singh *et al.*, 2000). These mice also have an increased mortality rate as over the first 180 days of life only 3 per cent of Wt mice died compared with 8 and 16 per cent of the APP/Fle and APP/Dut Tg mice respectively with no obvious signs of illness. In roughly 15 per cent of the mice that survived for longer than 18 months, seizures developed that were unrelated to the APP transgene expression. Mice

were normal up to 8 weeks of age, then started to show increased reactivity to an open environment, aggression towards other mice, and signs of emotionality, such as hyperactivity and increased aggression, which are correlated with expression level of the transgene. Thus, for example, around 33 per cent of Flemish and 44 per cent of Dutch Tg mice residents attacked in the first minute of contact compared with none of the Wt mice, and overall 78 and 83 per cent of mice attacked within the 3 minutes allotted compared with 11 per cent of the Wt mice (Kumar-Singh *et al.*, 2000). APP/RK Tg mice have also been shown to exhibit increased aggression relative to the WT mice (see also Moechars *et al.*, 1996).

35.5 TRANSGENIC β -CTF MOUSE MODELS

35.5.1 β -CTF mice

Different mouse models have also been developed to express the amyloidogenic human APP carboxy terminal fragment (Nalbantaglu *et al.*, 1997; Berger-Sweeney *et al.*, 1999; Rutten *et al.*, 2003). Taken generally, these mice express high levels of β -CTFs (Rutten *et al.*, 2003), hippocampal cell loss (Nalbantaglu *et al.*, 1997) and degeneration (Berger-Sweeney *et al.*, 1999) in the cortex and hippocampus, but fail to develop neuritic plaques. These mice show increased immunoreactivity for A β that became stronger and more prevalent with age.

35.5.2 Behaviour in the β -CTF mouse models

Behaviourally, the Tg animals over-expressing the CTFs of APP exhibited cognitive deficits when placed in the water maze, but were not impaired at a visually cued platform tasks (Nalbantaglu *et al.*, 1997; Berger-Sweeney *et al.*, 1999). The cognitive deficit in these mice may be related to an abnormality in LTP generation that has been found in these animals (Nalbantaglu *et al.*, 1997).

35.6 TRANSGENIC MOUSE MODELS OF TAU MUTATIONS

35.6.1 Tau mice

Mice expressing the tau mutation were developed to look at a group of disorders where these mutations caused cell death in man. The principal disease that underlies the tau pathologies is FTDP-17, for which patients carry at least one mutation of the tau gene. Probably the most well characterized mutations of the tau gene are the P301L and P301S variants but animal models for other mutations of the tau gene have been developed including V337M, and R406W.

Studies using mice with mutations at position 301 on the tau gene have found tau expressed in the cerebellum, hippocampus, thalamus, hypothalamus, spinal cord, brain stem fimbria fornix, amygdala, striatum, olfactory bulb and

cortex. (Lewis *et al.*, 2000; Götz *et al.*, 2001; Allen *et al.*, 2002). In the hippocampus CA1 cells were found to be affected but not CA3 cells (Götz *et al.*, 2001) and in the CA1 pyramidal neurones human tau was present in axons but also in cell bodies and apical dendrites. Phosphorylated tau was found in the hippocampus and cortex (Götz *et al.*, 2001). Allen *et al.* (2002) reported that temporal cortex layers II, IV and V showed most cortical reactivity to tau-reactive antibodies. Somatodendritic tau immunoreactivity thought to represent pre-tangles had a wider distribution in the brain, including cortex (especially piriform and entorhinal) hippocampus and basal ganglia. The tangles at the ultrastructural level was comprised of filaments which were straight (10–30 nm diameter) but others had a twisted ribbon appearance (Lewis *et al.*, 2000). Ribbon-like filaments were also found by Allen *et al.* (2002) but were of a smaller size of between 5 and 15 nm, and a small number of AD-like paired helical filaments with a cross-over spacing of about 70–80 nm were also identified. In 11-month-old tau-expressing mice with the V337M human mutation the expressed mutant protein was found in the hippocampal regions CA1, 2 and 3 in cell bodies and dendrites. The tau was of paired-helical type, and made from phosphorylated tau. In the hippocampus, mutant tau was expressed at 70 per cent of the expression of endogenous tau as compared with 10 per cent of whole brain tau (Tanemura *et al.*, 2002). In these mice atrophied and misshaped cells were found, similar to those seen in human AD brains (Ginsberg *et al.*, 1997).

In contrast, both the P301L and the P301S mice show motor deficits associated with a 48–49 per cent reduction in motor neurones in the brain stem and gliosis in the anterior horns (Lewis *et al.*, 2000 and Allen *et al.*, 2002 respectively). Gliosis and co-localized NFTs were found in neurones in the brain stem, diencephalons, basal telencephalon and spinal cord in the P301L mice (Lewis *et al.*, 2000).

Transgenic mice expressing the shortest tau isoform (T44) have also been generated (Ishihara *et al.*, 2001). In 18-month-old animals, staining of filamentous lesions in cortical neurones was similar to that seen in AD and stained for Congo red and Gallyas silver suggesting that the older animals have A β in their lesions (Ishihara *et al.*, 2001) as in AD. These filamentous lesions were found primarily in the hippocampus, entorhinal cortex and amygdala, less in the neocortex, and not at all in the spinal cord (Ishihara *et al.*, 2001). As in AD, intraneuronal inclusions in the old Tg mice were ubiquitinated. The inclusions in the older mice (24 months) contained exclusively straight tau filaments. The Tau aggregates in the Tg animals were insoluble whereas in the Wt mice 90 per cent of endogenous tau was soluble (Ishihara *et al.*, 2001).

Mice that express human R406W tau have also been developed (Tatebayashi *et al.*, 2002) and at 5 months old exhibit mutant tau prominently in the hippocampus (17.8 per cent of endogenous tau) followed by the neocortex (17 per cent), olfactory bulb (14.3 per cent), the striatum (14.1 per cent) and the thalamus (7.59 per cent). Mutant tau was recorded only at trace level in the cerebellum, mid-brain and the spinal cord (Tatebayashi *et al.*, 2002).

35.6.2 Behaviour in transgenic tau mice

Behavioural disturbances in the P301L and P301S tau mice are largely motor in nature, developing in heterozygotes at 6.5 months and homozygotes at 4.5 months of age (Lewis *et al.*, 2000). Phenotypical changes include lack of body extension during tail elevation and spontaneous back paw clenching whilst standing, delayed righting reflex and rope grasping, weak limbs and dystonic posture, reduction in body weight, and an increase in docility. These animals also developed a neurological phenotype characterized by muscle weakness and tremor (Allen *et al.*, 2002). These motor disturbances are uncharacteristic of AD and are reflective of the spinal cord cell loss (Lewis *et al.*, 2000; Allen *et al.*, 2002).

In contrast the R406W mice at 16–23 months of age exhibited largely cognitive abnormalities. In tests for cued and contextual fear responses Tg mice showed less freezing after foot shock during the conditioning phase and after a 48-hour delay with a cue in a different context. Mortality was higher in the Tg animals (Tatebayashi *et al.*, 2002). A deficit in prepulse inhibition response was found (Tatebayashi *et al.*, 2002) but the motor deficits were not as pronounced as in the P301 mice.

35.7 TRANSGENIC MOUSE MODELS WITH PRESENILIN MUTATIONS

A second route for inducing an increase in A β ₄₂ has been through the development of PS1 mutant mice (Borchelt *et al.*, 1996; Duff *et al.*, 1996). Patients with PS1 mutations associated with AD have greater number of A β ₄₂ plaques compared with patients with the sporadic disease (Mann *et al.*, 1996). Signs of apoptosis and neurodegeneration have been reported in PS1 mice (Chui *et al.*, 1999) and, as would be expected, there is an increased expression of diffuse A β ₄₂ in the brain (Duff *et al.*, 1996; Schuener *et al.*, 1996). However, PS1 mutant mice do not form A β deposits (Borchelt *et al.*, 1996; Duff *et al.*, 1996; Holcomb *et al.*, 1999; Barrow *et al.*, 2000) suggesting that A β levels do not reach the necessary threshold to start forming aggregates (McGowen *et al.*, 1999). Consequently these single mutation PS1 mouse were soon surpassed by the use of these mice in double Tg mouse models as it was found that the PS1 transgene potentiates the deposition of A β in APP mice (Borchelt *et al.*, 1997; Holcomb *et al.*, 1998).

35.8 DOUBLE TRANSGENIC (DTg) MOUSE MODELS

35.8.1 APP/PS1 double transgenic mice

Double Tg mice carrying an APP mutation and a PS1 mutation have by now been well characterized and show that the addition of the PS1 mutation increases amyloid deposition

and plaque formation at an earlier time point in the animals life than the single APP mutation alone.

When PS1 \times APP/Swe mouse lines were created the PS1 control mice failed to develop an AD pathology but the DTg mice developed large numbers of fibrillar A β deposits in the cerebral cortex and hippocampus earlier in life than the pure APP/Swe littermates (Holcomb *et al.*, 1998; Gordon *et al.*, 2002). Plaque number (per mm²) was found to be highest in the visual cortex at 54 weeks of age (132 ± 11.3) and lowest in the entorhinal cortex at (101.1 ± 13.1), although the cingulate cortex and the entorhinal cortex had the highest mean plaque area at 54 weeks of age ($\approx 300 \mu\text{m}^2$) (Wengenack *et al.*, 2000). Plaques appear near to the mid-line and spread laterally and ventrally through the cortex over time (Wengenack *et al.*, 2000). Roughly a 41 per cent increase in A $\beta_{42(43)}$ was found at 6 weeks in double versus single APP Tg mice. Congo red and thioflavin-S showed A β deposits in cortex and hippocampus in all DTg mice at 13–16 weeks of age, but this was absent in APP/Swe mice, and these deposits increased with age from 5 per section to 77 per section in 24–32 week old mice (Holcomb *et al.*, 1998). Importantly, amyloid deposition occurs primarily in the cortex and hippocampus whilst the subcortical regions were almost amyloid free, and generally plaque number and amyloid burden increased with age and appeared to be relatively stable between individuals (Wengenack *et al.*, 2000). In addition 8-month-old APPSwe/PS1 double Tg mice showed a decrease in the number of vesicular acetylcholine transporter (VACH-T)-immunoreactive synapses in the frontal cortex, which were reduced in size in the hippocampus (Wong *et al.*, 1999).

These APP/PS1 mice have been reported to have behavioural deficits on both cognitive (Holcomb *et al.*, 1998; Holcomb *et al.*, 1999) and motor tests (Holcomb *et al.*, 1999) by 9 months of age. A study by Puoliväli and colleagues (2002) showed that the age-dependent impairment in water maze performance in these DTg mice correlates with the total amount of A β in the hippocampus at a stage when the amyloid deposits cover less than 1 per cent of the hippocampal volume.

In a study by Wirths and colleagues (2001), mice with the human PS1 mutation (M146L) were crossed with a mouse line carrying three APP mutations (Swe, Dut, and Lon) to create a single mouse line. Onset of plaque deposition was 8 months, whilst the onset of neuropil deposits in single Tg mice was at 19 months (Wirths *et al.*, 2001). These double Tg mice expressed an almost 2-fold increase in A β relative to the other control mouse lines (Blanchard *et al.*, 2003). A β accumulation was detected at 2–4 months of age with the order of deposition as follows: subiculum and dorsal CA1, entorhinal cortex, the rest of hippocampus, and then cortex (Blanchard *et al.*, 2003). Human AD brain sections that were used for comparable analysis showed strong APP expression in pyramidal neurones in the hippocampus, neocortex, and in neuritic plaques. A β staining showed extracellular staining in aged AD brains but there was no evidence of neuronal staining. In DTg mice APP was found throughout the cortex and hippocampus at all ages and in the neuritic component of plaques.

A β staining was only found in some young animals (8 months old) extracellularly, but was present in all mice intraneuronally at this time point in hippocampal pyramidal cells and granular cells of the dentate gyrus and cortical pyramidal cells (Wirths *et al.*, 2001). In aged DTg mice this intraneuronal staining was virtually absent, but extracellular A β deposits were found that were indistinguishable from plaques in PM human brain (Wirths *et al.*, 2001).

A recent paper using APP/Ind \times PS1 mutant mice examined these mice for signs of tau immunoreactivity and found that these DTg mice at 8–12 weeks of age showed A β deposits with no tau immunoreactivity, but at 24 weeks old the DTg mice exhibited plaques throughout the cortex and hippocampus, and tau labelling confined to areas exhibiting heavy A β load, primarily the parietal, cingulate and temporal cortex, but occasionally hippocampus (Kurt *et al.*, 2003). Immunogold labelling revealed hyperphosphorylated tau epitomes in some dystrophic neurites in 24-month-old DTg mice. There was also evidence of straight filaments (10–12 nm wide) in some 8-month-old mice, with one mouse showing single and paired helical filaments (Kurt *et al.*, 2003). The importance of this paper is that it clearly demonstrates that these DTg APP/PS1 mice develop tau pathology in addition to plaques and it shows that tau pathology comes later than plaques but that it is associated with them.

There is relatively little information regarding functional deficits in the APP/PS1 double mutation mice, although a cross-strain Tg2576 \times PS1 line have been found to exhibit increased locomotor activity and decreased spontaneous alternation in a Y-maze by 6 months of age when compared with non-Tg and PS1 mice, but did not differ on the spontaneous alternation task from APP (Tg2576) mice until 9 months of age (Holcomb *et al.*, 1999). None of the mice strains in the latter study exhibited spatial learning deficits in a water maze test.

35.8.2 Other double mutation mouse models

Increased plaque burden can also be induced in APP mice by creating DTg mice that express an APP mutation and human AChE. The mean estimated plaque burden for these mice was 40 per cent higher in 12-month-old doubly transgenic mice than in the APP/Swe mice controls (Rees *et al.*, 2003). In a recent study of a PS1/Tau double mutation mouse (Boutajangout *et al.*, 2002) expression of PS1 with tau was not sufficient to produce neurofibrillary tangles even in neurones co-expressing an accumulation of the human mutant tau isoform.

35.9 TRIPLE TRANSGENIC (TTg) MOUSE MODELS

TTg mouse models are still relatively scarce. Of greatest interest to AD research are models that attempt to draw

together both the plaque and the NFT pathologies into a single model, as in the human condition, but TTg mice have been developed to examine the role of genes in a single feature of AD pathology.

A TTg model has been developed that was designed to over-express cdk5 and p35 in tau mice (Van den Haute *et al.*, 2001) in an effort to increase tau phosphorylation. However, no increased phosphorylation was found, in contrast to the double Tg P301L X p25 mice that did produce increased phosphorylation (Noble *et al.*, 2003).

At least two mouse lines have been successfully created that develop plaques and NFTs. The presenilin PS1 (M146V) mutation and the APP/Swe mutation have been inserted in to Tg mice expressing mutant P301L tau (Oddo *et al.*, 2003). These mice progressively developed tangles and plaques as did a similar mouse line developed by Oddo *et al.* (2003). These latter mice were Dtg APP/Swe X tau P301L crossed with PS1 M146V knock-in mice. A β deposition was found to precede tau pathology. Pathological sequence was interneuronal A β immunoreactivity in cortical areas, followed by extracellular A β deposits, especially in the frontal cortex (layers IV and V). By 15 months of age posterior cortical areas were affected as were some limbic regions. MC1 staining (which detects conformational changes in tau) and AT8 became apparent at 12 months of age. Tau deposits became increasingly evident in the CA1 cells of the hippocampus followed by cortex (Oddo *et al.*, 2003).

35.10 CONCLUSIONS

The ultimate goal of Tg models of disease is to provide a therapeutic platform on which to test new compounds and novel therapeutic approaches for curing disease.

Traditionally drug therapies in humans with AD have focused on augmenting the existing (but diminishing) cholinergic neurotransmission through the use of cholinomimetic and acetylcholinesterase-inhibiting compounds (Christie *et al.*, 1981; Davis and Mohs, 1982). While this approach is still widely used, it has a limited success rate (\approx 40 per cent) and is only useful in mild and moderate AD patients (Levy, 1994) and is a disease management strategy rather than a preventative cure. One of the major advantages to come from the development of transgenic animal models of AD is their use in drug trials for novel therapeutic compounds and strategies. In recent years A β immunization has been reported to reduce plaque number and improve memory deficits in Tg animals (Janus *et al.*, 2000; Morgan *et al.*, 2000; and see Hirschfield and Hawkins, 2003, for a review) and has inadvertently stimulated a re-examination of the role of amyloid in AD (see Bishop and Robinson, 2002, for a review). Other compounds such as the antioxidant *Ginkgo biloba* have also been found to reverse spatial learning deficits in Tg2576 mice without changing plaque burden or soluble A β levels (Stackman *et al.*, 2003). Alternative approaches to drug

therapies such as the use of viral vectors to stimulate an immune response have now been used. An adeno-associated virus vaccine expressing the cholera toxin B subunit and an A β fusion protein has recently been reported to reverse memory deficits and reduce A β deposition in APP London mice (Zhang *et al.*, 2003). Transgenic mice may also prove to be useful to trial novel neural transplant approaches for AD.

So whilst Tg technology is still relatively young, the development of mouse models that incorporate more than a single gene are bringing scientists ever closer to complete models of diseases and as such they represent a significant breakthrough in our search for a cure for diseases such as AD.

How effective are cholinergic therapies in improving cognition in Alzheimer's disease?

DAVID G WILKINSON

36.1 Cholinergic treatments and their assessment	465	36.3 Conclusion	471
36.2 Treatment strategies	466	References	471

Nearly 10 years after the dramatic success of L-dopa therapy for Parkinson's disease, it seemed that a similar treatment approach for Alzheimer's disease (AD) may be on the horizon when substantial presynaptic cholinergic abnormalities were found in the post-mortem brains of affected individuals (see Chapter 29). The results so far have been relatively modest which may not be surprising if we reconsider that these were rather overoptimistic and unrealistic expectations. First, even quite marked cholinergic loss is not necessarily associated with cognitive impairment. For instance, studies of Parkinson's disease show that choline acetyltransferase (ChAT) loss is more severe in patients with dementia than in those without, despite the fact that plaque densities are similar (Perry *et al.*, 1985). While this supports the cholinergic hypothesis, the fact that ChAT levels are also reduced in non-demented patients appears to challenge this. Olivopontocerebellar atrophy (OPCA) also presents an interesting conundrum. For example, in one pedigree the patients show a 40–50 per cent reduction in ChAT levels in temporal and frontal cortex, 20–40 per cent decrements in hippocampus and degeneration of the nucleus basalis of Meynert (nbM), but no evidence of dementia (Kish *et al.*, 1990). One possible interpretation of these data would be to suggest that the importance of forebrain acetylcholine (ACh) in cognition and memory may have been overestimated. By extrapolation then, the cognitive deficits occurring as a direct result of loss of ACh may be quite subtle, so it is perhaps not surprising that cognitive benefits resulting from increasing ACh levels are small. What is becoming clear is that the cholinergic deficit seen in any chronic brain disease may be the result of a variety of insults, rather than the cause of a specific condition like AD.

There are, of course as well as cholinergic deficits, numerous other neurotransmitter deficits in AD, notably in noradrenaline (NA), 5-hydroxytryptamine (5HT), gamma-aminobutyric acid (GABA), glutamate, somatostatin, neuropeptide Y and corticotrophin releasing factor (CRF) (see Rosser, 1988 for review), all or any of which may possibly limit the potential therapeutic effect of increasing ACh levels. We also now have data on drugs affecting other neurotransmitters, which have shown improvements in cognition in AD, one of which, memantine, has been licensed for use in moderate and severe AD (Reisberg *et al.*, 2003).

36.1 CHOLINERGIC TREATMENTS AND THEIR ASSESSMENT

The fact that cholinomimetics have some effects on cognition is, of course, some validation of the presence of a cholinergic deficit. However, of the many treatment approaches only cholinesterase inhibitors (ChEIs) have been consistently able to produce statistically significant improvements in cognitive test results. Some other strategies may have proved unsuccessful because it has been difficult to attain therapeutic doses owing to unacceptable associated side effects, whereas in others this may indicate a flaw in the hypothesis or the lack of appropriate measures of change. The measurement of such subtle changes in cognition has posed a considerable problem in a disease which, by definition, should be relentlessly deteriorating, though in practice can still fluctuate considerably from month to month, and even year to year (Holmes and Lovestone, 2003).

36.2 TREATMENT STRATEGIES

36.2.1 ACh precursors and releasing agents

One of the first treatment strategies was an attempt to increase ACh production by precursor loading. However, there is really no demonstrable shortage of choline or lecithin in the brain and repeated studies have failed to produce positive results (see Becker *et al.*, 1988 for review), although a Cochrane review of mixed dementias suggested some evidence of positive effect in the short term for choline (Fioravanti and Yanagi, 1998).

A number of drugs have been regarded as ACh releasers. This mode of action is often inferred, largely owing to an inability to demonstrate other actions, although a few pyridine derivatives that are predominantly potassium channel blocking agents appear genuinely in this class. There have been at least two UK phase III studies of ACh releasers, both of which were potassium channel blockers. Linopirdine (DUP 996) showed no advantage over placebo and was later found to have a releasing effect on ACh only in the presence of high potassium concentrations, suggesting a limited use *in vivo*. The other, besipirdine (HP749), was a selective M-channel blocker (a potassium channel inactivated by muscarinic agonists) and was found not to be an effective ACh releaser and trials have been unremarkable.

36.2.2 ACh agonists

The lack of response to ACh precursors and releasing agents has to some degree been mirrored at the other side of the synapse when one looks directly at acting ACh agonists. Whilst precursor loading and cholinesterase inhibition are inevitably dependent on intact presynaptic neurones, the finding that at least two subtypes of central cholinergic receptors were not changed in post-mortem AD brain (Palacios *et al.*, 1986) led to the obvious step of trying to stimulate them directly.

Early attempts with compounds like arecoline, pilocarpine, bethanecol, oxotremorine and RS86, some of which needed to be given by intrathecal infusion, were abandoned due to short half-lives and the central and peripheral side effects. There are now a number of orally active selective muscarinic agonists that have reached clinical trials but, despite initial therapeutic optimism, results have been disappointing.

36.2.2.1 XANOMELINE

Xanomeline is an M1- and M4-selective agonist and the first to show a significant though modest treatment effect on cognition as measured by the ADAS-cog (Bodick *et al.*, 1997). This was the first trial of an M1 agonist to report a cognitive improvement but what was perhaps more interesting was the reported improvement in behaviour, including decreases in hallucinations, agitation, vocal outbursts, delusions, suspiciousness and mood swings. Unfortunately, because of unacceptable side effects (nausea, vomiting and fainting), the oral preparation has been dropped, though phase II trials

using transdermal patches are underway, in the hope of eliminating the troublesome metabolite produced in the gut and thought to be responsible for the side effects. The improvements seen in non-cognitive symptoms have led some to postulate its use as an antipsychotic (Mirza *et al.*, 2003).

36.2.2.2 OTHER MUSCARINIC AND NICOTINIC AGONISTS

Sabcomeline (SB202026), a partial agonist functionally selective for M1 receptors, has a lower affinity for the M2 and M3 sites, which are thought to mediate side effects. A significant improvement on ADAS-cog was seen in a randomized placebo-controlled trial in 364 patients over 14 weeks, but showed a non-statistically significant improvement in CIBIC-plus (Kumar and Orgogozo, 1996).

Milameline is a partial agonist with equal affinity for M1 and M2 receptors. Lack of cognitive efficacy caused the cessation of phase III studies, even though, anecdotally, it seems to have had some beneficial non-cognitive effects.

Talsaclidine, a functionally selective M1 receptor agonist, and AF102B, have both shown small improvements in ADAS-cog and some claim that they may influence amyloid production. This is based on the fact that stimulation of M1 receptors has been shown to increase the 'normal' processing of amyloid precursor protein (APP) through the α -secretase pathway (Nitsch *et al.*, 1992). It may be for this reason that further development of M1 agonists persists, though tolerability appears to be a common limiting factor.

Nicotinic agonists, often thought to be too toxic, are arousing interest, particularly as galantamine, a cholinesterase inhibitor also stimulates nicotinic receptors through allosteric modulation. However, there are only a few such drugs in trials at the preclinical/phase I stage.

36.2.3 Cholinesterase inhibitors

Acetylcholinesterase inhibitors (AChEIs) have shown consistent efficacy and to date are the only class of cholinomimetics to have gained regulatory approval for treating AD. At present four compounds have gained licences – tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon) and galantamine (Reminyl) – with a number of others in development (see Table 36.1).

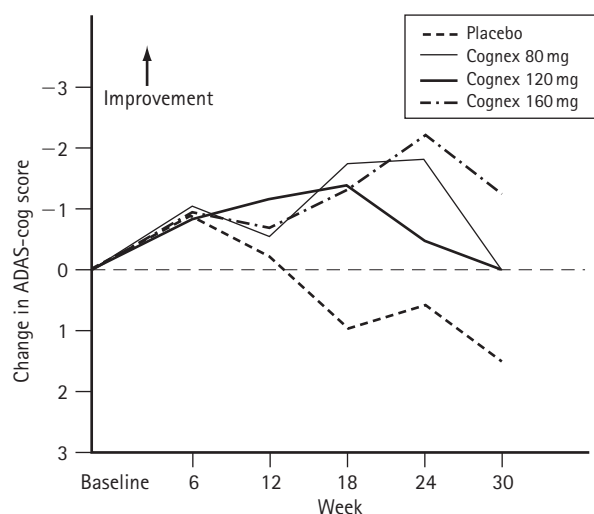

The clinical development of cholinesterase inhibitors (ChEIs) for the treatment of AD started nearly 20 years ago with intravenous administration of physostigmine. The results were encouraging and clearly showed cognitive improvement in AD but the short duration of action and side effects meant it was not suitable for clinical use.

36.2.4 Tacrine (Cognex)

The paper by Summers *et al.* (1986) reporting a trial of tacrine (tetrahydroaminoacridine or THA), although by current standards judged to be very flawed, ignited the blue touch paper and set the AD research community alight, in an attempt to replicate or refute his findings. Numerous trials

Table 36.1 Summary of clinical trial data: the effect of AChEIs on ADAS-cog (ITT)

Drug	Author	No. on active treatment	Dose (mg/day)	Duration of study (weeks) ITT analysis	Placebo/active difference on ADAS-cog points	Difference from baseline
Tacrine	Farlow <i>et al.</i> (1992)	37	80	12	3.8	
	Knapp <i>et al.</i> (1994)	238	160	30	4.1

**Figure 36.1** ADAS-cog change from baseline in patients completing 30 weeks of tacrine trial. (Data from: Knapp *et al.*, 1994.)

took place (e.g. Davis *et al.*, 1992) but the definitive study was the one by Knapp *et al.* (1994), which tested the compound at higher doses than earlier trials and for a longer period, as a result of the Food and Drug Administration (FDA) request for positive evidence on cognition for 6 months. This was a 30-week trial at a time when studies had usually been only of 6 or 12 weeks' duration. Since then the 24–30-week trial has now become standard. What the Knapp study showed was that at high doses, 160 mg/day, there were statistically significant improvements over placebo in ADAS-cog, CIBI and MMSE; that the improvements started to wane after a few months and that placebo patients steadily declined (Figure 36.1). However, what also became clear was that poor tolerability and side effects would limit the usefulness of the drug.

Tacrine was developed as an analeptic and originally used in anaesthesia to potentiate suxamethonium and to alleviate

post-anaesthetic delirium. It is a reversible inhibitor of both acetyl- and butyryl-cholinesterase (BuChE) and requires dosing four times a day. The major side effect was a liver transaminitis, subsequently found to be of little clinical significance in that it resolved on stopping the drug and 80 per cent of patients could be rechallenged with no recurrence. However, combined with the gastrointestinal side effects, this meant that 70 per cent of patients on the 160 mg/day were unable to complete the 30-week study, and as only 27 per cent of those achieved a >4 point improvement on the ADAS-cog, this meant that in fact only about 10 per cent of patients started on tacrine gained a significant benefit over the 7.5-month period. Clearly this figure could be raised by rechallenging those with transaminitis but this is contentious and off-putting for patient and clinician alike. Further evidence from PET scanning on patients before and after treatment with tacrine seemed to demonstrate considerable improvement in brain metabolism, suggesting a functional change that mirrored clinical findings (Plate 14).

36.2.5 Physostigmine and eptastigmine

The race subsequently started to find more acceptable alternatives to tacrine. Early trial results with a long-acting sustained-release preparation of physostigmine suggested similar efficacy with better tolerability than tacrine. As with earlier physostigmine preparations, although there seemed to be no liver problems, nausea remained an issue. A larger study, unfortunately with a complicated enrichment protocol, showed small improvements. The improved cognition occurred only in patients who had also shown a response in a prestudy, dose-titration phase. It had a short, 6-week, double-blind phase and the effect size at the end point was 1.75 points on the ADAS-cog scale (Thal *et al.*, 1997).

Whilst a lot of the early work on AChEIs took place with physostigmine, its short action and poor tolerability prevented

it from becoming an acceptable treatment and as yet it is not licensed. The heptyl analogue of physostigmine, eptastigmine, was found to be more stable, longer lasting, if less potent, and significantly less toxic than the former. In phase III studies it has shown typical AChEI efficacy in terms of improvement in ADAS-cog. One study by Canal and Imbimbo (1996a) showed an effect size of 4.7 points over 25 weeks, which is as good a response as any seen in studies to date. Clinical development, however, has been slow and one company withdrew after a neutropenia developed in two patients (Enz, 1998). There is some suggestion that this drug may be of particular benefit in the middle to late stages of the disease (Canal and Imbimbo, 1996b). A review of the data has been published by Braida and Sala (2001).

36.2.6 Metrifonate

This old drug was for years the mainstay of treatment for bilharzia because of its cholinergic effects. It is in itself, a simple organophosphorus compound, relatively inactive, but it is slowly hydrolysed to dichlorvos in the body, a potent irreversible AChEI. Its slow metabolism and permanent inactivation of the enzyme mean once daily dosing is more than adequate, indeed weekly dosing is used in tropical medicine. Another feature of metrifonate is that, as well as having a completely different mode of action from the other AChEIs, it has excellent tolerability and a rather different range of side effects including rhinitis, leg muscle cramps and diarrhoea. Unfortunately, axial and proximal muscle weakness had been noted in a number of patients in the US, severe enough to cause respiratory failure in a few patients and the trial programme has been halted. Like the other AChEIs it did demonstrate cognitive improvement in AD. Pooled data from US studies (Figure 36.2) showed an effect size of 3.8 ADAS-cog points with an improvement over baseline of 1.8 points, the latter comparable with the best in its class (de Jongh, 1988). The European MALT study (Dubois *et al.*, 1999) showed similar efficacy on cognition, significant changes in behaviour and function and, for the first time in a placebo-controlled study, significant improvements

Figure 36.2 ADAS-cog change from baseline in patients completing 26-week metrifonate trial (pooled data, USA). (Data from de Jongh, 1998.) Patients were those who completed double-blind treatment. $P < 0.05$ (relative to placebo).

in carer burden (Shikiar *et al.*, 2000). Because of side effects, however, this drug is unlikely to be studied further.

36.2.7 Donepezil (Aricept)

Donepezil has had the greatest impact so far on the treatment of AD. It was licensed and subsequently cleared for marketing in the US in November 1996 and in the UK in March 1997. It has a high oral bioavailability, is unaffected by food, and has a long plasma half-life of 70 hours permitting once daily dosing. It has almost total plasma protein binding and is a highly selective reversible inhibitor of AChE. It is 10 times less potent than physostigmine but this has not diminished its efficacy in terms of benefits on cognitive function, global assessment and activities of daily living (Burns *et al.*, 1999). The three pivotal placebo-controlled studies all showed an improvement in cognition over baseline at the end of 6 months of around 1 point on the ADAS-cog with an end point effect size over placebo of just under 3 points (Figure 36.3). There have been two 1 year-long placebo-controlled studies that have shown an advantage for long-term treatment both in preservation of cognition (Winblad *et al.*, 2001) and function (Mohs *et al.*, 2001). A third study provided 1-year data for donepezil comparing the rates of cognitive decline after 1 year in patients with probable AD treated with donepezil and those who remained untreated (Doody *et al.*, 2001). Cognitive decline, based on change from baseline in Mini-Mental State Examination (MMSE) scores, was significantly slower in patients treated with donepezil compared with untreated patients ($P = 0.007$). However, it is important to note that the MMSE may not be the most accurate index of the rate of cognitive decline (Goldblum *et al.*, 1994). In fact in the Aricept Withdrawal and Rechallenge Study (AWARE) it was clear that, even in the 30 per cent of patients initially showing no apparent benefit on open label donepezil treatment (often based on MMSE), significant treatment benefits were observed in

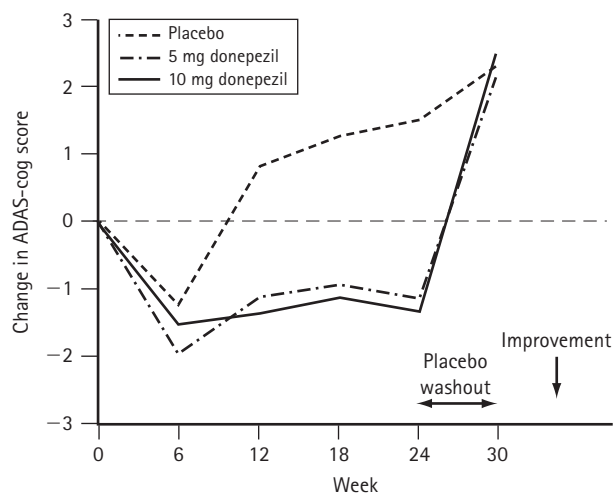

Figure 36.3 ADAS-cog change from baseline in patients completing 30 weeks of donepezil study. (Data from Rogers *et al.*, 1998.)

those continuing treatment versus those switching to placebo (Triau *et al.*, 2003) suggesting it may not be an adequate measure of response.

Long-term follow-up studies seem to suggest (although without a placebo group it is only a suggestion) that the cognitive advantage over placebo is maintained for up to 2 years (Rogers and Friedhoff, 1998), and perhaps even longer (Rogers *et al.*, 2000).

There is now clear evidence from clinical practice that changes in behavioural or non-cognitive symptoms are also a feature of response to donepezil (Gauthier *et al.*, 2002). Whether one regards these effects as separate from the cognitive improvement is a moot point but there is now a large body of evidence demonstrating clear cognitive effects with clinical relevance and extremely good tolerability in very mild, mild to moderate, and severe AD (Rogers and Friedhoff, 1998; Feldman *et al.*, 2001; Seltzer *et al.*, 2003). Naturalistic studies in clinical practice have confirmed these effects and it is clear that the 10 mg dose confers greater efficacy than 5 mg, with tolerability being no different from placebo levels if the dose titration from 5–10 mg is left for 4–6 weeks (Matthews *et al.*, 2000).

36.2.8 Rivastigmine (Exelon)

A carbamate derivative of physostigmine, rivastigmine, which is licensed for the symptomatic treatment of mild to moderate AD, has effects like those of eptastigmine. It does not inactivate ACh by the usual microsomal activity but by attaching a carbamyl residue, which means that, although it has a half-life of 2 hours, cholinesterase inhibition in the brain is thought to last for up to 10 hours. It is therefore classed as a pseudo-irreversible inhibitor and is highly specific for AChE.

The phase III clinical trials indicate broadly similar levels of efficacy to donepezil, although direct comparisons are not possible. For example, in one study the effect size of 3.8 ADAS-cog points is largely made up of deterioration in the placebo group and there is very little improvement over baseline scores (Figure 36.4). The trial was said to include a less

selected population with the placebo group deteriorating at a greater and more naturalistic rate than normally seen in trial patients. These data provide a classical example of why, however tempting it is to do so, it is bad science to compare the results of different trials even if protocols are similar, because trial populations vary so much. In this instance we have to accept that the treatment effect size, of 3.8 ADAS-cog points, however construed, is a clinically significant finding.

Of course, the corollary to the increased rate of decline in the placebo group in this trial is that it could indicate an unusual lack of placebo response. A marked placebo response, is a persistent feature of most other trials. In one phase III study of rivastigmine, for instance, only 16 per cent of placebo patients were better or no worse at 6 months, a much lower percentage than in any other trial (Corey-Bloom *et al.*, 1998). This, considered with the fact that 20 per cent of the high dose group had improved by 7 points or greater on the ADAS-cog, suggests the effect size was a genuine reflection of efficacy in a worsening group of patients (Figure 36.5).

A recent meta-analysis was conducted to show the effects of rivastigmine over 5 years compared with the projected cognitive decline of untreated patients over the same period. Rivastigmine data came from open-label extensions of four 6-month, randomized, placebo-controlled trials. Treatment was continued for up to 5 years with open-label rivastigmine (up to 12 mg/day) and appeared to prevent decline to severe dementia (MMSE <10 points) by at least 2 years compared with the estimated levels of decline, although the few left at the end of the study could arguably be seen as rather atypical patients. These studies, also available for other drugs, are of course not hard evidence, but do suggest a long-term effect (Small *et al.*, 2003).

The main drawbacks of rivastigmine are its short half-life, the consequent twice daily dosing, and the necessity for a slow titration to minimize the cholinergic side effects. The trial data suggest these are not severe but include nausea, vomiting and anorexia. Rivastigmine has also been linked to improvements in non-cognitive symptoms demonstrated by

Figure 36.4 ADAS-cog change from baseline (ITT) in patients completing 26 weeks of rivastigmine study (Data from Corey-Bloom *et al.*, 1998).

Figure 36.5 ADAS-cog change from baseline in patients completing 26 weeks of rivastigmine trial (Data from Corey-Bloom *et al.*, 1998).

the results of a study in patients with dementia with Lewy bodies, which showed that scores on the 10-point Neuropsychiatric Inventory (NPI) were significantly better ($P = 0.01$) after 20 weeks for those on rivastigmine compared with placebo (McKeith *et al.*, 2000).

36.2.9 Galantamine (Reminyl)

The last of the major AChEIs to be licensed for the treatment of mild to moderate AD is by no means the least interesting. Like physostigmine and codeine, this compound is a natural alkaloid and shares with them the potential to allosterically potentiate submaximal nicotinic responses induced by ACh, and competitive agonists. It may well be that this nicotinic effect is the reason why the AChEIs are more effective than other cholinomimetics. Allosteric potentiating ligands like galantamine could therefore enhance nicotinic transmission under conditions of reduced secretion or increased degradation of ACh, or where the ACh sensitivity of nicotinic ACh receptors is reduced. This may well mean they will have a preventive and corrective action on impaired nicotinic transmission and may have more than a symptomatic effect on AD itself (Schrattenholz *et al.*, 1996).

Studies so far have demonstrated consistent evidence of cognitive improvement. An American study with 636 patients showed an effect size of 3.7 points on the ADAS-cog with improvement of 1.7 points from baseline at 6 months (Raskind *et al.*, 2000). An international study showed an effect size of 4.1 points on ADAS-cog, again with improvement over baseline of 1.7 points at 6 months (Wilcock *et al.*, 2000). The data from the US open label continuation study indicate maintenance of this benefit with no decrement from baseline a year later (Lilienfeld and Parys, 2000). Both studies also showed improvements in the global assessment and functional ability.

What is worth noting in many of these trials is the proportion of patients who show quite marked improvements in cognition. In a phase II study of galantamine, 10 per cent of patients on the 30 mg dose of galantamine showed an improvement of 15 points or greater on the ADAS-cog after 12 weeks (Wilkinson and Murray, 2001). No placebo patients ever show this kind of response and this is echoed in other AChEI trials (Figure 36.6).

Galantamine, like all AChEIs, does have tolerability problems unless titrated slowly and, as expected, the side effects are predominantly gastrointestinal. It is, however, over 90 per cent bioavailable so can be given with food. It is a competitive, reversible and specific inhibitor of ACh, with a half-life of about 8 hours. It needs to be given twice daily and has an optimal dose of around 24 mg daily. There are no long-term data from placebo-controlled trials of galantamine but open label continuation studies, now extending to 4 years claim, as with the other AChEIs, that despite a tendency to cognitive decline in the long term there is an advantage to continued treatment compared with the expected decline in patients without treatment.

Figure 36.6 ADAS-cog change from baseline in patients completing 12-week galantamine trial. (Data from Wilkinson and Murray 2001.)

36.2.10 Comparative studies

All the currently available AChEIs seem to have similar cognitive effects with none showing mean improvements on the ADAS-cog of greater than 5 points in 6-month controlled trials. This may be the limit of their efficacy but without comparative studies in the same population it is impossible to make judgements about the relative importance of each compound. Unfortunately, because the differences between the drugs will be small, comparative studies would require enormous numbers to demonstrate statistical significance, consequently to run double-blind trials would be very expensive with the risk of showing no advantage for the company involved.

There equally would be little point in funding such trials by independent bodies unless there were vast differences in cost. Three comparative studies have been conducted for marketing reasons and are all somewhat limited by being open label, albeit with blinded raters. Two sponsored by the makers of donepezil comparing it against rivastigmine and galantamine had similar designs and were run to compare the recommended dosing regimes and tolerability. The first, a 12-week comparison between donepezil and rivastigmine, showed no difference between the two drugs on cognition but many fewer patients were able to be titrated up to the recommended maximum doses of rivastigmine with consequently significantly more gastrointestinal side effects overall compared with donepezil. Unsurprisingly, both clinicians and carers preferred donepezil with its better side effect profile, simpler titration and once daily dosing (Wilkinson *et al.*, 2002).

The second study, between donepezil and galantamine, was also of only 12 weeks duration, which meant that the maximum dose of galantamine was only reached in the last month compared with 2 months for the donepezil group. Tolerability, whilst still in favour of donepezil, was much more acceptable in the galantamine group. However, significant advantages were demonstrated for donepezil over its

comparator in cognition and function and may represent a function of the short duration of the study (Jones *et al.*, 2004).

The third study, sponsored by the makers of galantamine, was somewhat different. Hoping to show some evidence of disease modification as a result of its proposed nicotinic effects, the researchers enrolled a somewhat more severe group (MMSE 9–18) for 1 year and used computerized tests of attention in some centres. They used an activity of daily living scale as the primary outcome measure and this showed no difference between the groups. There were no significant differences in the secondary outcomes of MMSE ADAS-cog, NPI or caregiver burden; however, a subanalysis of those enrolled with MMSE scores from 12–18 did show an advantage on MMSE, one of the secondary outcomes, for the galantamine group (Wilcock *et al.*, 2003). The discrepancy between the two studies of donepezil and galantamine underlines the very small differences between the drugs in relation to outcomes, with all three compounds having broadly similar effects. This was a confirmation of the pivotal trial data with the drugs being separated only by their different side effect profiles and dosing regimes.

36.3 CONCLUSION

This review of the available data on the cognitive effects of all the current cholinomimetic treatments shows that only the AChEIs have a clear statistical and clinical advantage over placebo. The clinical utility may be even greater if one looks at behavioural change, one area where other classes of drug (e.g. M1 agonists) have also shown some positive effects. The averaged outcomes from placebo-controlled studies conceal the fact that, while some patients show little benefit, others show considerable improvements (>15 points on ADAS-cog). Unfortunately, however, all studies to date suggest that predicting response is not possible before treatment starts. The effect appears to be maintained over a number of months and, while it does fade in those who have responded, the advantage over placebo may remain for a number of years. As efficacy fades it may be possible to maintain the cognitive benefits by increasing the dose of AChEIs, as long as the drug is tolerated.

What is not clear is whether intermittent treatment, allowing restitution of neurotransmitter and receptor sensitivity, will sustain the cognitive improvement, a claim made, but as yet unsubstantiated, for rivastigmine, the AChEI with the shortest half life. The numerous interactions with, and modulation of, cholinergic function by other neurotransmitters may explain why cholinomimetics seem to have a ceiling effect and the combination of cholinergic and other strategies may yet show a synergistic effect. One study adding memantine to donepezil in moderately severe AD has shown promise, although a similar study in mild to moderate AD has not (Hartmann and Mobius, 2003; Tariot *et al.*, 2003). Clearly work on oxidative stress, the inflammatory response,

modification of APP processing, tau phosphorylation, the effects of excitatory amino acids and the ion channels will all come to bear on the treatment of AD in due course. However, AChEIs have shown clear clinical benefits in cognition and behaviour and will be the cornerstone of pharmacological treatment in AD for some years to come.

Non-cholinergic therapies of dementia

LON S SCHNEIDER

37.1 Prevention of dementia	474	37.3 Summary	479
37.2 Potential non-cholinergic strategies for Alzheimer's disease	474	References	479

Until recently cholinesterase inhibitors (ChEIs) have been the only approved treatments for Alzheimer's disease (AD). Recently memantine was approved by European, North American and other regulators for the treatment of moderate to severe dementia of the Alzheimer's type. There continue to be no approved treatments in Europe and North America for other dementias, although several trials suggest the feasibility for ChEIs for the vascular dementias (Erkinjuntti *et al.*, 2002; Black *et al.*, 2003; Wilkinson *et al.*, 2003) or dementia with Lewy bodies (McKeith *et al.*, 2000).

In addition there are a range of medications, vitamins or herbs, not explicitly approved for Alzheimer's disease or dementia, that have potential usefulness, that have not been clearly demonstrated in clinical trials to be efficacious, but that can either be prescribed by physicians or purchased by patients. These medications include piracetam, extract of *Ginkgo biloba*, selegiline, vitamin E, multiple B vitamins and the HMG-CoA reductase inhibitors (statins). Notably, medications such as oestrogens and anti-inflammatories have been advocated by some in the recent past, but now need reconsideration in the light of current clinical trials showing no evidence and potential cognitive worsening with these drugs (Aisen *et al.*, 2003b; Rapp *et al.*, 2003; Visser *et al.*, 2003).

37.1 PREVENTION OF DEMENTIA

From a public health point of view, preventing the onset of AD is more important than the treatment of dementia after it develops. In this respect interventions that might decrease the risk of dementia such as reducing blood pressure to prevent cerebrovascular disease, the use of lipid lowering drugs,

or reducing homocysteine with B vitamins will be discussed in this chapter. Other considerations in prevention include improving diet, ceasing smoking, improving exercise, effectively treating diabetes mellitus, and preventing head injury. However, these 'preventative' measures are non-specific for dementia and have salutary effects on a range of conditions.

There is direct clinical trials evidence that vitamins and trace elements supplementation improves cognitive function in elderly subjects who may or may not have had dementia. For example, 86 older subjects were randomized to a 1-year trial of placebo or a supplement containing various vitamins and elemental metals. In this small trial performed in India there were improvements on memory, long-term retrieval, category fluency and digit span, as well as a rather marked improvement on Mini-Mental State Exam (MMSE) scores. However, generalizing such findings to other populations may be difficult considering that diagnosis and baseline nutritional status may be factors in the response, and notably MMSE scores were low in this middle-class Indian cohort, averaging 21–15 (Chandra, 2001). Nevertheless, this trial points to the potential that a variety of non-specific health or physiological interventions could have salutary effects on cognition.

37.2 POTENTIAL NON-CHOLINERGIC STRATEGIES FOR ALZHEIMER'S DISEASE

ChEIs are the only medications currently approved in the US for treating mild to moderate AD. The use of ChEIs for the management of the cognitive and behavioural symptoms of AD is reviewed elsewhere in this book. The overall

effectiveness of ChEIs, modest at best, is manifested generally as stabilization of cognitive symptoms over 6 months to 1 year compared with the continuing cognitive decline in placebo-treated patients. Additionally, only a minority of patients treated benefit over those 6 months. As such, clinicians regularly encounter requests for information on other potential treatments including over-the-counter medications, herbal remedies, vitamins and agents approved for other indications or those which are available only outside the US.

Since the goals of treatment can range from symptomatic improvement to slowing symptom progression, or even to delaying the onset of dementia, potential benefits must be weighed carefully against adverse-effect risks. Moreover, it is particularly important to weigh treatment options with patients diagnosed with mild cognitive impairment (MCI) since only 8–15 per cent of these MCI patients develop dementia on an annual basis, while nearly 40 per cent do not appear to progress to AD and indeed may no longer display any cognitive impairment at 2-year follow up (Larrieu *et al.*, 2002). Some potential or emerging treatment options based on available clinical data are discussed below (see Table 37.1).

37.2.1 Homocysteine reduction and vitamin E

Elevated levels of homocysteine (HC) may contribute to cardiovascular disease (Wilcken and Dudman, 1989; Bellamy and McDowell, 1997), cognitive impairment (Lehmann *et al.*, 1999) and dementia (Seshadri *et al.*, 2002). Plasma concentrations of HC rise when its metabolism to methionine or cysteine is impaired, which may occur under a number of circumstances including natural ageing. Increased plasma levels of HC are associated with damage to vascular endothelial cells (Wilcken and Dudman, 1989) and increased risk for thrombosis (Bellamy and McDowell, 1997), possibly through lipid peroxidation (Voutilainen *et al.*, 1999) and release of endothelium-derived relaxing factor causing vasodilatation (Stamler *et al.*, 1993). More relevant to AD, HC also potentiates the neurotoxic effects of A β *in vitro*, in hippocampal neurones (Ho *et al.*, 2001; Kruman *et al.*, 2002) through an unknown mechanism. It is therefore possible that reducing levels of HC would lead to cognitive benefits in people with cerebrovascular disease or AD, possibly by delaying the onset of dementia, or improving cognitive function. HC plasma levels can be reduced by as much as 30 per cent using a regimen of B vitamins (e.g. B₁₂ 1 mg/day, B₆ 25 mg/day, and folic

Table 37.1 Non-cholinergic approaches for the treatment of AD

Agent*	Possible mode of action	Status
Vitamins B ₆ , B ₁₂ , folate therapy	Combination may lower homocysteine (HC) levels. Elevated HC may raise risks for cardiovascular disease and AD	Unproven effects. Observational studies show decreases in incidence of AD. Clinical trial is ongoing
Vitamin E or selegiline	Antioxidant effects may be neuroprotective	In a single trial each was effective at delaying clinical progression of moderate to severe AD patients, but not effective for improving cognition (Sano <i>et al.</i> , 1997). One trial of vitamin E (compared to donepezil and placebo) for MCI is underway
Oestrogens	Have neurotrophic properties; enhances NGF, synaptogenesis, increase acetylcholine	New evidence is largely negative; no evidence for cognitive improvement; risks outweigh benefits. May be worse than placebo (Mulnard <i>et al.</i> , 2000; Rapp <i>et al.</i> , 2003). Should not be used for treating or preventing dementia or cognitive impairment
Non-steroidal anti-inflammatory drugs (NSAIDs)	Anti-inflammatory mechanism may be neuroprotective	Clinical trials results in AD and MCI generally are negative (Scharf <i>et al.</i> , 1999; Van Gool <i>et al.</i> , 2001; Aisen <i>et al.</i> , 2003b; Visser <i>et al.</i> , 2003). One prevention trial ongoing
HMG-CoA reductase inhibitors (statins)	Inhibits the production of cholesterol, modulates APP processing	Observational studies show decreases in incidence of AD. Two large cardiovascular trials did not show cognitive effects in elderly. At least one ongoing trial in AD
<i>Ginkgo biloba</i>	Possible anti-oxidant and other mechanisms, could be neuroprotective	Some clinical trials in AD are positive. One prevention trial (GEMS) is ongoing
Memantine	NMDA-receptor antagonist; anti-glutamate effects, may protect against calcium-induced neurotoxicity	Clinical trials in moderate to severe AD are positive. Trials in mild to moderate AD are ongoing. Approved for moderately severe to severe AD in EU, Canada and US

*Except for memantine none of the agents is approved for AD in the EU or North America

acid 5 mg/day) and a placebo-controlled clinical trial is underway to determine whether such a regimen will slow the rate of cognitive decline in AD (Aisen *et al.*, 2003a).

37.2.2 Antioxidants

The antioxidant effects of vitamin E (α -tocopherol) might have an impact on reducing clinical progression of illness. In the prototypical antioxidant trial (Sano *et al.*, 1997), vitamin E, selegiline (a monoamine oxidase inhibitor relatively selective for the MAO-B subtype at doses of 10 mg/day) or their combination in moderate to severe AD patients was associated with a delay in either nursing home placement and the loss of activities of daily living, supporting a protective effect for the treatments. Interestingly, despite the delay in the progression of functional impairment, no significant effect on cognition was observed. Further investigation is warranted, including studies in earlier stages of AD and in MCI. At present, a multicentre trial comparing vitamin E and donepezil in MCI patients is ongoing: http://adcs.ucsd.edu/MCI_Protocol.htm.

37.2.3 Anti-inflammatories

Markers of inflammation in the brains of AD patients suggest a potential therapeutic benefit of anti-inflammatory use (Aisen and Davis, 1994; Breitner, 1996; Aisen, 2000). Epidemiological studies with non-steroidal anti-inflammatory drugs (NSAIDs) have indicated that these agents may be potentially effective for reducing the incidence or delaying the onset of AD (Rich *et al.*, 1995; McGeer and McGeer, 1996; in t' Veld *et al.*, 2001). Yet, barring one exception (Rogers *et al.*, 1993), randomized, placebo-controlled studies of NSAIDs in AD patients have failed to show a clinical benefit (Scharf *et al.*, 1999; Aisen 2000; Van Gool *et al.*, 2001; Aisen *et al.*, 2003a, b).

A recently completed 1-year multicentre, placebo-controlled trial involving 351 participants tested the potential of either the cox-2 inhibitor rofecoxib or the non-selective NSAID naproxen to slow the progressive cognitive decline that is characteristic in patients with mild to moderate AD (Aisen *et al.*, 2003b). In this study, there was no difference in change of ADAS-cog score in patients treated with either NSAID compared with the placebo group, indicating that anti-inflammatory drugs may not be effective in slowing cognitive decline in mild to moderate AD.

To investigate the effect of NSAIDs in delaying the onset of AD, an ongoing multisite trial (the Alzheimer's Disease Anti-inflammatory Prevention Trial, ADAPT) (Martin *et al.*, 2002) is enrolling over 2500 patients aged 70+ years with a family history of dementia to be randomized to treatment with naproxen, celecoxib, or placebo, and followed for 5–7 years. Another trial will evaluate subjects 'at risk' for developing AD for short-term effects of ibuprofen on beta-amyloid_{1–42} ($A\beta$) levels in cerebrospinal fluid, which may be an early biomarker for AD. Results from these and similar

trials will be required to assess adequately the clinical benefit of NSAID use in AD.

37.2.4 HMG-CoA reductase inhibitors (statins)

Emerging evidence suggests that cholesterol lowering and the use of HMG-CoA reductase inhibitors may impact the development or progression of AD possibly because cholesterol levels modulate the enzymatic processing of amyloid precursor protein (APP) and the production of $A\beta$, a main component of neuritic plaques in AD brain (Refolo *et al.*, 2000). Cholesterol-fed rabbits demonstrate increased levels of $A\beta$ in the brain, and hypercholesterolaemia induced by a high cholesterol diet results in increased levels of $A\beta$ in the CNS (Sparks *et al.*, 1994, 1995). Furthermore, simvastatin administration *in vitro* reduces intra- and extracellular $A\beta$ levels in neuronal cultures (Fassbender *et al.*, 2001).

Observational studies of patient databases have demonstrated that lovastatin- or pravastatin-treated patients have a 60–73 per cent lower prevalence of AD (Wolozin *et al.*, 2000) and an analysis of a UK clinical practice database suggests a markedly reduced risk for dementia in patients taking statins compared with case-matched controls (Jick *et al.*, 2000). In a case-control analysis of the Canadian Study of Health and Aging, statin use was associated with reduced risk for AD as well (Rockwood *et al.*, 2002).

Large clinical trials, however, thus far have not supported statin use for improving cognition or prevention of dementia. A randomized placebo-controlled trial of pravastatin (the PROSPER study) in 5804 subjects aged 70–82 years with histories or risk factors for vascular disease reported favourable cardiovascular outcomes but no significant effect on cognitive function or disability during the average 3.2 year follow-up period (Shepherd *et al.*, 2002). Further, a randomized, placebo-controlled trial of the effect of simvastatin on cardiovascular outcomes in a subgroup of patients aged 70+ years ($n = 5806$), demonstrated no significant difference in the proportion of patients with cognitive impairment or in the incidence of dementia over the average 5-year follow-up period (Heart Protection Study Collaborative, 2002).

One placebo-controlled clinical trial randomized 44 AD patients to placebo or simvastatin 80 mg/day for 26 weeks, reporting both reduced CSF $A\beta$ and less decline on MMSE in patients on simvastatin (Simons *et al.*, 2002). An ongoing clinical trial of 400 patients with mild to moderate AD will evaluate the effects of simvastatin in slowing the clinical decline of AD patients.

37.2.5 *Ginkgo biloba*

The ability of an extract from the leaves of *Ginkgo biloba* to improve cognitive function in AD patients is the subject of ongoing work. Preclinical evidence suggests the components in *Ginkgo* might have neuroprotective effects, including scavenging of oxygen free radicals, protection of membranes

against lipid peroxidation, inhibition of A β formation and aggregation, and protection against A β toxicity, as well as putative anti-apoptotic effects via inhibition of caspase-3 activation (Luo *et al.*, 2002). A number of clinical studies support the relatively common use in some European countries of *Ginkgo biloba* as a cognitive enhancer (Weitbrecht and Jansen, 1986; Mancini, 1993; Hofferberth, 1994; Kanowski *et al.*, 1996; Le Bars *et al.*, 1997; Maurer *et al.*, 1997; Birks *et al.*, 2002). However, a clear role for *Ginkgo biloba* either as a symptomatic agent or as prevention for AD has not been determined.

A 52-week, placebo-controlled, double-blind trial of 309 patients with either AD or vascular dementia demonstrated that 120 mg/day standardized *Ginkgo biloba* extract (EGb 761) conferred a statistically significant improvement on ADAS-cog scores compared with placebo, indicating a stabilization of cognitive decline (Le Bars *et al.*, 1997). The results of this trial are controversial since it included a mixed patient population of AD and vascular dementia, and very little deterioration was observed in the placebo group compared with other AD trials of similar length.

A Cochrane meta-analysis also supports a positive effect of *Ginkgo biloba* (Birks *et al.*, 2002). Interestingly, studies in normal elderly subjects have been contradictory (Mix and Crews, 2002; Solomon *et al.*, 2002), presenting a confusing picture for *Ginkgo biloba* extract use, perhaps partly owing to variations in dose, duration and methodological issues such as lack of blinding. It is speculative that *Ginkgo biloba* extract may be more effective in the cognitively impaired, where it is typically used, than in healthy subjects.

A 6-month placebo-controlled trial of two doses of *Ginkgo biloba* extract, EGb 761, 240 mg/day and 120 mg/day, in patients with mild to moderate AD has been completed. A 5-year placebo-controlled, randomized trial of approximately 3000 subjects aged 75+ years (the GEMS trial), funded by the US National Institute for Complementary and Alternative Medication (NICAM), is currently underway to evaluate *Ginkgo biloba* in prevention of AD. Another prevention study, also sponsored by the US National Institutes of Health, is underway to determine the effect of 240 mg/day EGb 761 in preventing (or delaying) the conversion of 200 healthy subjects 85 years or older to MCI. Results of these trials will lead to a better understanding of a role for *Ginkgo biloba* extract as a potential AD therapeutic agent.

37.2.6 NMDA-receptor antagonism

Part of the consequent pathology in AD involves neurotoxicity; overstimulation of NMDA receptors by glutamate has been implicated as a cause of neurotoxicity (Greenamyre *et al.*, 1988). Inhibiting the excitotoxic impact of glutamate is problematic, since its normal action on its various receptors is necessary for learning and memory. In preclinical studies, a non-competitive NMDA-receptor antagonist, memantine, protected against the effects of glutamate and calcium-mediated neurotoxicity due to influx of calcium (Parsons *et al.*, 1999).

It has been available in Germany for the treatment of Parkinson's disease and various other neurological disorders since 1982, and was approved in 2002 by the European Union and in 2003 by the FDA for treating moderately severe to severe AD. Memantine's effects appear subtler than a range of NMDA antagonists that have not proven to be clinically successful.

37.2.6.1 MECHANISM OF ACTION

Memantine is an open channel blocker that does not have appreciable activity until increased glutamate levels trigger the receptor and cause the ion channel to open. Then it enters the channel and occupying a site 'downstream', preventing calcium influx and preventing the depolarization/hyperactivation of the neurone. Since it is cleared from its site of action quickly, memantine might provide partial blocking of the channel depending on intrasynaptic levels of glutamate. As glutamate increases, causing channels to open, memantine appears to block more. As glutamate decreases, memantine blocks less, allowing greater neuronal activity. In some respects memantine can be viewed as a modulator of glutamatergic activity (Rogawski and Wenk, 2003).

37.2.6.2 PHARMACOKINETICS

The absorption of memantine is not affected by food intake; bioavailability is 100 per cent. Plasma protein binding is 45 per cent and peak plasma concentrations occur 3–7 hours after oral intake. It is widely distributed and rapidly diffuses across the blood–brain barrier. The majority of the parent compound (57–82 per cent) is excreted unchanged in the urine; there is minimum hepatic metabolism; elimination half-life ($t_{1/2}$) is 60–80 hours. There are potential interactions with hydrochlorothiazide resulting in a potentially reduced diuretic effect. There are no known interactions with ChEIs (Namenda prescribing information, Forest Laboratories Inc., 2003).

37.2.6.3 CLINICAL TRIALS

The effect of memantine on cognition generally has been positive in clinical trials (Gortelmeyer and Erbler 1992; Winblad and Poritis 1999; Wilcock *et al.*, 2000; Larrieu *et al.*, 2002; Aisen *et al.*, 2003b; Reisberg *et al.*, 2003) (Table 37.2). Memantine (20 mg/day) was investigated for the treatment of moderate to severe AD in a 28-week placebo-controlled trial of 252 patients (Reisberg *et al.*, 2003). The decline of cognitive function, as measured by the change in Severe Impairment Battery (SIB) score, was lessened in memantine patients compared with the deterioration observed in placebo patients (Figure 37.1).

A 26-week randomized, placebo-controlled trial of memantine in moderate to severe AD also showed greater improvement in cognition, global assessment and function compared with placebo (Tariot *et al.*, 2004). In this trial memantine or placebo was administered double-blinded to

Table 37.2 Placebo-controlled trials of memantine

Authors	Dose (mg/day)	N	Diagnosis/severity	Length (weeks)	Main measures

**Figure 37.1** Memantine in moderate to severe AD patients. Mean change from baseline in Severe Impairment Battery (SIB) score (\pm SE) in the observed-cases analysis is shown for each time point, and for the end point using a last observation carried forward analysis (Reisberg *et al.*, 2003).

patients who had been maintained on stable doses of donepezil for at least 6 months. In fact, the average time on donepezil was approximately 2.5 years, with nearly 90 per cent on donepezil for over 1 year before being randomized. Notably, the placebo-treated patients, i.e. patients who continued on donepezil throughout the 6 months of the trial, continued to decline at a rather rapid rate, suggesting that memantine substantially stabilized symptoms over this short period of time, while any effect of the cholinesterase inhibitor may have been lost previously or overcome by the disease course.

Additionally, in nursing home patients with severe dementia (MMSE < 10), probably either AD or vascular dementia, memantine showed significant improvement over placebo in a 12-week trial as measured by global and functional measures (Winblad and Poritis, 1999).

There have been two trials in patients with vascular dementia (Orgogozo *et al.*, 2002; Wilcock *et al.*, 2002). These patients tended to have ischaemic vascular dementia. In these trials there were salutary effects on cognition using the ADAS-cog and adverse events were mild (Orgogozo *et al.*, 2002; Wilcock *et al.*, 2002). Lastly, at least three clinical trials assessing the efficacy of memantine in mild to moderate AD have been completed but not published. News releases from Forest Laboratories and Lundbeck in January 2004 stated that one of two placebo-controlled trials in patients not on ChEIs was statistically significantly in favour of memantine.

37.2.6.4 ADVERSE EFFECTS

Adverse events were noticeable in the moderate to severe monotherapy trial (Reisberg *et al.*, 2003) in that agitation was

less frequent in patients on memantine without there being significant increases in other adverse events. In the memantine add-on trial (Tariot *et al.*, 2004), confusion, generally rated as mild, occurred four times more frequently in the memantine group, and headache twice as frequently. Of note gastrointestinal symptoms were less frequent with diarrhoea or faecal incontinence occurring half as frequently in the memantine group, suggesting that the actions of memantine may mitigate some of the cholinergic effects of donepezil.

37.3 SUMMARY

Of the treatments discussed only *Ginkgo biloba* extract (EGb 761) and memantine have a measure of regulatory approval. Memantine is specifically approved for moderate to severe AD. The evidence base for both these treatments is better developed. By contrast there is insufficient evidence to inform clinical practice on the use of homocysteine reduction or statins for either the treatment of dementia or its prevention. The evidence is also insufficient for vitamin E. There has been only one underpowered clinical trial assessing vitamin E effects in moderate to severe Alzheimer's disease that showed analysis-dependent results for either vitamin E alone or vitamin E combined with selegiline. The trial had substantial dropouts over the several year follow up and, importantly, there is no clear effect on improvement of cognition. Although not detailed in this chapter, the evidence for the use of selegiline is somewhat greater including the vitamin E trial and earlier short-term trials in elderly individuals with non-specific dementias or cognitive impairment.

The use of hormone replacement therapy, specifically oestrogens or oestrogens combined with a progestin, cannot be endorsed. In fact the bulk of the evidence is that their use is associated with greater cognitive impairment in people with AD and are not effective in preventing or delaying the onset of dementia. Similarly, overall, anti-inflammatories have not been shown to be effective and in fact may be harmful in patients who have AD. One true prevention trial is ongoing, however, and may provide information on its preventative uses (Martin *et al.*, 2002).

In view of memantine's effects in moderate to severe patients (typically patients with MMSEs < 15 or so) and with some suggestion of potential efficacy in heterogeneous vascular dementia, it may be considered as a symptomatic treatment. Clinical considerations involve either using it alone, perhaps in people who had been on ChEIs in the past and who are either intolerant or who found the medication not effective, or using it in patients who are being maintained on ChEIs for rather long periods. At the moment there is no evidence on whether memantine should be started prior to or simultaneously with a cholinesterase inhibitor, whether the two treatments together are better than either one alone.

Dosing is fairly straightforward with a titration to 10 mg b.i.d. over the course of 3 weeks. Adverse events appear

particularly mild with memantine; however, post-introductory experiences and further clinical trials will allow for better estimates.

Merriam *et al.* (1988) asserted that Alzheimer's disease (AD) is 'the most widely encountered cause of psychiatric pathology associated with a specific neuropathological substrate'. This is consistent with phenomenological studies and literature reviews, which generally converge on the conclusion that roughly 90 per cent of patients with dementia will develop significant behavioural problems at some point in the course of illness (Tariot and Blazina, 1993). The 'behavioural and psychological signs and symptoms of dementia' (Finkel *et al.*, 1996) do not typically meet criteria for discrete psychiatric disorders. They do, however, tend to occur in clusters of signs and symptoms that may vary among patients and over time (Tariot and Blazina, 1993). Examples of these clusters are provided in Table 38.1, based upon a review of published studies regarding psychopathological changes in dementia that was performed in 1993. With experience, these clusters of signs and symptoms can be both predicted and recognized, and can be used as guideposts in the selection of appropriate therapy.

This chapter will focus on agitation, which Cohen-Mansfield and Billig (1986) defined as 'inappropriate verbal, vocal, or motor activity unexplained by apparent needs or confusion'. Cohen-Mansfield and Billig (1986) empirically categorized agitated behaviours into three key groups:

- disruptive but not aggressive (e.g. attempts to leave, robes and disrobes, repeated complaints or questions);

Table 38.1 Summary of literature regarding psychopathology of dementia* (per cent of patients affected among studies reviewed)

	Range	Median
1. Disturbed affect/mood	0–86	19
2. Disturbed ideation	10–73	33.5
3. Altered perception

8. Vegetative behaviours		
• Sleep	0–47	27
• Diet/appetite	12.5–77	34

*Adapted from Tariot and Blazina, 1993

- socially inappropriate (e.g. disrobing or urinating in public); and
- aggressive (e.g. physical, such as hitting or slapping, or verbal, such as obscenities or name-calling).

As Table 38.1 indicates, half or more of patients with dementia will show some feature of agitation at some point in the course of illness.

38.1 A RATIONAL APPROACH

This chapter proposes a systematic general approach to the evaluation and management of agitation that is based on an elaboration of prior work (Leibovici and Tariot, 1988; Tariot *et al.*, 1995a; Tariot, 1996, 1999; Tariot and Schneider, 1998; Loy *et al.*, 1999); key aspects are described below:

- *Define target symptoms.* Review the available evidence and delineate the patient's behaviour pattern, e.g. 'wanders without an apparent destination, calls out repeatedly, bites and kicks during care'.
- *Establish or revisit medical diagnoses.* It is almost a truism in geriatrics that delirium is a frequent cause of incident agitation, and must always be suspected. Common culprits include respiratory or urinary infections, dehydration, occult trauma, electrolyte disturbances, or side effects of medications. Such medical problems should be treated specifically and the patient monitored carefully, ideally without the need for other medications.
- *Establish or revisit neuropsychiatric diagnoses.* It is also possible that the disturbed behaviour may reflect a long-standing, recurrent, or new onset discrete psychiatric disorder. When a specific disorder is identified, it should be specifically treated and monitored.
- *Assess and reverse aggravating factors.* Examples might include deficits in hearing or vision, or an environment that is too dark, noisy, or cold. Disrupted daily routines may present a remediable factor. It is important to look hard for environmental triggers.
- *Adapt to specific cognitive deficits.* Some patients may be able to respond to verbal reassurance and redirection, whereas others may not. Pain or distress may need to be inferred from behaviour or facial expression. Some may need constant environmental cueing to organize their behaviour. It is important to identify each patient's cognitive strengths and weaknesses, attempting to capitalize on residual strengths and avoid weaknesses.
- *Identify relevant psychosocial factors.* It can be easy to overlook the fact that a patient with dementia may be suffering anxiety, sadness, denial, or fury in response to major and minor life events. In some long-term care facilities, for instance, moving from one unit to another can be associated with perceived loss of status as well as contact with familiar people. It is easy to overlook this as a precipitant of 'agitation'.
- *Educate caregivers.* Caregivers can learn that change in behaviour usually has meaning, and that the behaviours can occur in discernible patterns. This helps caregivers interact in a more supportive manner. In the process, caregivers can be taught to employ essential behaviour

management principles, learning, for instance, that their own behaviour is a major determinant of the patient's behaviour. Caregivers can be trained to identify common triggers as well as consequences of agitated behaviour, and work with health professionals to attempt to minimize the triggers and maximize more positive circumstances.

If the behavioural disturbance is grossly aggressive or disruptive, and frankly dangerous, it may be necessary to use antipsychotics or benzodiazepines on an emergency basis, preferably by mouth but sometimes parenterally. In rare cases, hospitalization is needed. Once the emergency is under control, it is imperative to pay attention to the basics outlined above.

38.2 DEVELOPMENT OF THE PSYCHOBHAVIOURAL METAPHOR

For persisting non-emergent problems where non-pharmacological interventions have been exhausted, we adopt an approach that begins with a definition of a target symptom pattern that is at least roughly analogous to a drug-responsive syndrome. We refer to this as the 'psychobehavioural metaphor' (Leibovici and Tariot, 1988). We then match the dominant target symptoms (the metaphor) to the most relevant drug class. For example, in the case of a verbally and physically agitated patient who is also irritable, negative, has become socially withdrawn, and appears dysphoric, we might well first undertake a trial of an antidepressant. Conversely, if the patient showed 'agitation' in the context of increased motor activity, loud and rapid speech, and lability of affect, we might consider early use of a mood stabilizer. The 'aggressive' patient whose hostile actions are associated with delusions is likely to be treated first with an antipsychotic. Although this approach to drug selection is face-valid, there is limited empirical support for it thus far (Devanand, 2000; Lyketsos *et al.*, 2000; Tariot *et al.*, 2001a, 2002a; De Deyn *et al.*, 2003). Thus, the validity of the approach that we have endorsed for some years, and that reflected in most consensus guidelines (Rabins *et al.*, 1997; Alexopoulos *et al.*, 1998; Doody *et al.*, 2001), has not been established empirically.

The approach adopted in this chapter more or less reflects the position of the American Geriatrics Society and American Association for Geriatric Psychiatry consensus statement (2003) with respect to the use of target symptoms to guide selection of drug class. We emphasize selection of a medication with at least some empirical evidence of efficacy and with the highest likelihood of tolerability and safety. We observe some general rules such as starting with low doses and escalating slowly, assessing target symptoms as well as toxicity, and discontinuing the medication if it is harmful or ineffective. Even when a medication is helpful at subtoxic doses, an empirical trial is often performed in reverse and the patient monitored for recurrence of the problem. This type of approach is actually mandated in the nursing home setting

in the USA by Federal regulations created in 1987. Sometimes several medications need to be tried in series before a successful one is identified; sometimes combinations are warranted; sometimes no medication is found that is helpful. We hold the view that best practice includes routine use of cholinesterase inhibitors in most patients with AD as well as certain other dementias, meaning that psychotropic use occurs against this backdrop. The recent emergence of memantine as an antidementia agent will mean that a substantial proportion of patients may receive psychotropics in addition to this, alone or in combination with cholinesterase inhibitors, as well. The trials conducted with these agents were aimed toward obtaining regulatory approval and not informing clinical practice regarding issues such as the advantages or disadvantages of one agent versus the other for relief of behavioural symptoms, or of using psychotropics in combination with these agents. Practice will outstrip evidence for the foreseeable future.

38.3 SPECIFIC CLASSES OF PSYCHOTROPICS

The remainder of this chapter reviews the most relevant classes of agents and specific agents within those classes, focusing on information from about the last 5 years and on older studies that remain as crucial guides to practice. Much of the older literature was reviewed previously in the prior edition of this textbook (Rosenquist *et al.*, 2000); this chapter builds on that as well as some of our earlier work (Tariot, 1999, Loy *et al.*, 1999, Profenno and Tariot, 2004). Table 38.2 provides an overview of individual agents and typical starting doses proposed, based upon a mixture of data and clinical experience.

38.4 CONVENTIONAL ANTIPSYCHOTICS

Within the context of the 'metaphor' approach, antipsychotics would be used first for treatment of agitation that included psychotic features (Tables 38.3 and 38.4). In reality, antipsychotics have been used and studied in patients with a wide range of psychopathology. There are two main classes of antipsychotics: so-called conventional antipsychotics and the newer atypical agents. Prior reviews of the conventional agents have concluded that the effects of these agents were consistent but modest, and that no single agent was better than another (Wragg and Jeste, 1989; Schneider *et al.*, 1990).

Lanctot *et al.* (1998) performed a meta-analysis including some studies that were less rigorous than those included in the Schneider *et al.* (1990) meta-analysis. These authors also concluded that type and potency of agent did not influence response. They reported an average therapeutic effect (antipsychotic versus placebo) of 26 per cent, with placebo response rates ranging from 19 to 50 per cent. Side effects were reported to occur more often on drug than placebo (mean difference 25 per cent). These meta-analyses did not include five more recent studies (Devenand *et al.*, 1998;

Table 38.2 Selected current pharmacological treatments for agitation in dementia*

Drug and class	Suggesting starting** and (maximal) daily dose (mg/day)
Antipsychotics	
<i>Traditional:</i>	
• Haloperidol	0.25–0.5 (2–4)
• Thioridazine	12.5–25 (50–100)
• Thiothixene	0.5–1 (2–4)
<i>Atypical:</i>	
• Clozapine	6.25–12.5 (25–100)
• Olanzapine	2.5 (5–10)
• Quetiapine	25 (50–200)
• Risperidone	0.5 (1–2)
• Aripiprazole	5 (15)
• Ziprasidone	unknown
Anxiolytics and sedatives	
<i>Benzodiazepines:</i>	
• Alprazolam	0.5 (1–2)
• Lorazepam	0.5 (2–4)
• Oxazepam	10 (40–60)
<i>Non-benzodiazepines:</i>	
• Zolpidem	2.5 (5)
• Buspirone	10 (30–60)
Antidepressants	
• Trazodone	25–50 (200–300)
<i>SSRIs:</i>	
• Citalopram	10 (20)
• Fluoxetine	10 (20)
• Sertraline	25–50 (100–200)
Anticonvulsants	
• Carbamazepine	50–100 (300–500)
• Divalproex	125–375 (500–1500)
β-blockers	
• Propranolol	20 (50–100)
Others	
• Selegiline	10
• Oestradiol/progesterone	0.625/2.5

* Adapted from Loy *et al.*, 1999

** Suggestions are based on published data as well as anecdotal experience, and should be regarded accordingly

De Deyn *et al.*, 1999; Allain *et al.*, 2000; Teri *et al.*, 2000; Tariot *et al.*, 2002a). The data from these newer studies generally conform to the results of the meta-analyses.

Reviews regarding conventional agents cite side effects including akathisia, parkinsonism, tardive dyskinesia, sedation, peripheral and central anticholinergic effects, postural hypotension, cardiac conduction defects and falls (Lanctot *et al.*, 1998). Most of these data come from short-term controlled trials; evidence regarding long-term safety is generally lacking. Data available from other elderly populations, however, indicate that caution is warranted. For instance, rates of tardive dyskinesia are 5–6-fold greater in older than in younger populations after treatment with conventional agents (Jeste

Table 38.3 Conventional antipsychotics

Study	Diagnosis	N	Design	Dose (mg/day); duration	Response	Adverse effects
Haloperidol Schneider <i>et al.</i> , 1990	Dementia	252 (in 7 DB, PC trials in primary dementia)	Meta-analysis of 33 neuroleptic trials	2.5–4.6, haloperidol; 3–8 weeks	Little benefit beyond placebo across all neuroleptics; average effect 18% greater than placebo	Not reported
Devanand <i>et al.</i> , 1998	AD	71	Randomized DB, PC, parallel group	2–3 or 0.5–0.75; 6 weeks	Decreased psychosis, aggression, agitation with higher dose only, 55–60% response versus 25–35% low dose response versus 25–30% placebo	Moderate–severe EPS at high dose (20%)
Christensen and Benfield, 1998	Organic mental syndrome	48	Randomized cross-over to alprazolam	Mean 0.64; 6 weeks	No difference between treatments on CGI, CAG	None seen at this low dose
De Deyn <i>et al.</i> , 1999	AD, vascular, mixed	344	Randomized, MC DB, parallel group risperidone or placebo	Mean 1.2; 13 weeks	Significantly greater improvement for haloperidol versus placebo on BEHAVE-AD and CMAI, decreased physical and verbal aggression (72% risperidone versus 69% haloperidol versus 61% placebo on BEHAVE-AD)	EPS 22%, somnolence (18% haloperidol versus 4% placebo)
Allain <i>et al.</i> , 2000	AD, VaD, mixed	306	Randomized MC, DB, PC, parallel group	100–300 tiapride or 2–6 haloperidol; 21 days	Significantly improved CGI and MOSES irritability/aggressiveness subscore for both drugs compared to placebo, no differences between drugs	Less EPS with tiapride than haloperidol
Teri <i>et al.</i> , 2000	AD	149	Randomized DB, PC, parallel group	1.8 haloperidol, 200 trazodone, or behaviour management techniques; 16 weeks	Reduced agitation not significantly different between treated and placebo groups	Less EPS with behaviour management techniques
Tariot <i>et al.</i> , 2002a	Probable AD with psychosis	284	Randomized, PC, DB versus quetiapine (n = 94 on haloperidol)	Mean 1.89; 8 weeks	No change in psychosis, some decrease in agitation	EPS, sedation

AD, Alzheimer's disease; BEHAVE-AD, Behavioral Pathology in Alzheimer's Disease Rating Scale; CGI, Clinical Global Impression; CMAI, Cohen-Mansfield Agitation Inventory; DB, double-blind; EPS, extrapyramidal symptoms; MC, multicentre; MOSES, Multidimensional Observation Scale for Elderly Subjects; PC, placebo-controlled; SCAG, Sandoz Clinical Assessment-Geriatric Scale; VaD, vascular dementia

et al., 1995). For practical purposes, side effects typically guide selection of these agents when they are used in patients with dementia. A clinical issue that is of particular importance is dementia with co-occurring extrapyramidal disorders such as dementia with Lewy bodies, where occasional extraordinary sensitivity to conventional agents is seen (Ballard *et al.*, 1998). For all these reasons, atypical antipsychotics may have special utility in patients with dementia. This may account for the enthusiasm expressed by 'experts' toward use of atypicals in this population (Alexopoulos *et al.*, 1998).

38.5 ATYPICAL ANTIPSYCHOTICS

These are listed in Table 38.4.

38.5.1 Clozapine

Only anecdotes and case reports are available; none is new since our previous chapter was written. Individual patients showed partial improvement in agitation or psychosis, whereas others developed side effects including sedation and anticholinergic effects. Whilst not mentioned specifically in these reports, agranulocytosis and seizures have been reported in other populations, the former requiring regular haematological testing for months. Dose-response issues are unresolved. In using this medication, we err on the side of caution by starting at 6.25 or 12.5 mg/day. Based on the relative lack of motor toxicity encountered with clozapine, a case can be made to select this agent preferentially in patients with dementia and extrapyramidal disorders. However, in view of the lack of information regarding dose-response, the risk of side effects in the elderly and the lack of controlled data regarding efficacy and tolerability, most clinicians are likely to choose from among the newer atypical agents first.

38.5.2 Risperidone

The earliest exploratory studies indicated that doses in the range of 0.5–2 mg/day might be best tolerated, with dose-related risk of motor toxicity (especially in patients with extrapyramidal disorders). Sedation, peripheral oedema, and orthostatic hypotension were sometimes reported. Use of risperidone can result in increased prolactin levels in other populations, although the clinical significance of this in patients with dementia is uncertain. We do not routinely check serum prolactin levels, and would only take action in response to elevated levels associated with symptoms associated with its use (e.g. galactorrhoea in women, sexual dysfunction in men) or with symptoms indicative of a possible hypothalamic tumour (e.g. diplopia). The earlier open trials and case series indicated that risperidone may decrease agitation, aggression or psychosis in patients with dementia, spawning more definitive trials. Three large multicentre trials of risperidone

have been completed in nursing home patients with relatively severe dementia (De Deyn *et al.*, 1999; Katz *et al.*, 1999; Brodaty *et al.*, 2003).

In the aggregate, these risperidone studies comprise the largest placebo-controlled, multicentre studies ever conducted of any form of treatment for agitation or aggression associated with dementia. A conservative interpretation of the available evidence would be that the efficacy of risperidone is roughly equivalent to that of haloperidol. The tolerability of risperidone appears to be better, with low to moderate risk of dose-related parkinsonism and sedation and numerically higher rates of peripheral oedema and sedation in patients treated with risperidone versus placebo. As more data have emerged from the large clinical trials with risperidone, there has been more opportunity to examine possible side effects that might not be discernible in single clinical trials.

In October 2002, HealthCanada issued a letter to health-care professionals stating that risperidone use may be associated with cerebrovascular events in elderly patients with dementia (Wooltorton, 2002). In April 2003, the FDA issued a similar warning of cerebrovascular events with risperidone in patients with dementia and noted that risperidone has not been shown to be safe or effective in treating dementia-related psychosis.

38.5.3 Olanzapine

Recent studies suggest benefit of olanzapine in treating agitation in patients with dementia. A 6-week, randomized, parallel-group, multicentre study of olanzapine in 206 nursing home residents with dementia and agitation and/or psychosis has been completed using fixed doses of 5, 10 and 15 mg/day versus placebo (Street *et al.*, 2000). In patients receiving 5 and 10 mg/day, significant improvement in agitation and aggression compared with placebo was seen, and patients receiving 5 mg/day also demonstrated significant improvement compared with placebo in broader assessments of psychopathology. Sedation and postural instability were observed at all doses in at least 25 per cent of subjects. Some of the patients from this trial received follow-up open-label, flexible-dose treatment for 18 weeks; results were consistent with the findings from an earlier paper (Street *et al.*, 2001).

Meehan *et al.* (2002) studied acute treatment of agitation with intramuscular olanzapine in 272 inpatients or nursing home residents with AD and/or vascular dementia. Olanzapine was found to be superior to placebo in treating agitation at 2 and 24 hours. Adverse events were not significantly different between groups. At present, this formulation has not been marketed in the US.

However, a cautionary note is warranted when considering using this agent in patients with dementia. In January 2004, Eli Lilly issued a warning of increased incidence of cerebrovascular adverse events in patients with dementia who were treated with olanzapine.

Table 38.4 *Atypical antipsychotics*

Study	Diagnosis	N	Design	Dose (mg/day); duration	Response	Adverse effects
Olanzapine						
Satterlee <i>et al.</i> , 1995	AD	238	Randomized MC, PC, DB	1–8; 8 weeks	No benefit versus placebo	None reported versus placebo
Street <i>et al.</i> , 2000	AD, moderate-severe	206	Randomized, MC, PC, DB, parallel group	5, 10 and 15; 6 weeks	Decreased agitation, delusions, hallucinations on NPI-NH at 5 and 10 (but not 15) mg/day versus placebo	Dose-dependent sedation, abnormal gait
Street <i>et al.</i> , 2001	AD	105	Open as f/u to previous 6-week DB trial	Flexible 5–15; 18 weeks	Significantly improved agitation and other symptoms by NPI/NH and other scales	Somnolence, accidental injury, rash
Meehan <i>et al.</i> , 2002	AD, VaD, or mixed with acute agitation	272	Randomized, MC, PC, DB	IM 5, 2.5, or 1 lorazepam; 2 hours and prn x 2	Decreased agitation at 2 and 24 hours within 20 hours	No significant difference between placebo and any active treatment
Quetiapine						
Tariot <i>et al.</i> , 2000a	Various psychotic disorders	184	Open, MC	12.5–800 (median 137.5); 52 weeks	Significant decreases in BPRS total and CGI severity	Somnolence (31%), accidental injury (24%), dizziness (17%)
Scharre and Chang, 2002	AD	10	Open	50–150 (mean = 100); 12 weeks	Improved NPI for delusions and agitation or aggression	Drowsiness (40%), weight gain (40%)
Davis and Baskys, 2002	DLB	10	Open	25–150 (50 mg modal); 12 weeks	Significant reduction in total NPI and agitation subscales of NPI and BPRS	No significant increase in EPS
Tariot <i>et al.</i> , 2002a	Probable AD with psychosis	284	Randomized, DB, PC versus haloperidol (n = 91 on quetiapine)	Mean 100; 8 weeks	No change in psychosis, some decrease in agitation	Sedation
Risperidone						
Herrmann <i>et al.</i> , 1998	AD, vascular, Lewy body	22	Case reports	Mean 1.5; 1 week–10 months	Improvement CGI (17)	EPS (11), sedation (1), drooling (1)
Lavretsky and Sultzer, 1998	AD, vascular, PD, PSP, mixed	15	Open (concurrent psychotropics allowed)	0.5–3; 9 weeks	Decreased agitation (in all 15)	Sedation (5), akathisia (1)

(Continued)

Table 38.4 (Continued)

Study	Diagnosis	N	Design	Dose (mg/day); duration	Response	Adverse effects
Risperidone De Deyn <i>et al.</i> , 1999	AD, vascular, mixed dementia	344	Randomized MC, DB, parallel group versus placebo or haloperidol	Mean 1.1; 13 weeks	Decreased physical and verbal aggression (72% risperidone versus 69% haloperidol versus 61% for placebo)	EPS not different from placebo, somnolence (12% risperidone versus 4% placebo)
Katz <i>et al.</i> , 1999	AD, vascular, mixed dementia	625	Randomized MC, PC, DB, parallel group (lorazepam, benztropine and chloral hydrate allowed PRN)	0.5, 1.0, 2.0; 12 weeks	Dose-dependent decrease in aggression and psychosis, significant at 1 and 2 (but not 0.5) mg/day	Somnolence, EPS 21% (on 2 mg/day, compared to 12% on placebo), mild peripheral oedema in some
Brodaty <i>et al.</i> , 2003	AD, VaD, mixed	345	Randomized, MC, PC, DB	Mean 1.0; 12 weeks	Significant reductions in CMAI total aggression score and BEHAVE-AD aggressiveness	Somnolence, UTI

AD, Alzheimer's disease; BEHAVE-AD, Behavioral Pathology in Alzheimer's Disease Rating Scale; CMAI, Cohen-Mansfield Agitation Inventory; DB, double-blind; EPS, extrapyramidal symptoms; DLB, Dementia with Lewy bodies; MC, multicentre; NPI-NH, Neuropsychiatric Inventory – Nursing Home version; PC, placebo-controlled; PD, Parkinson's disease; PSP, progressive supranuclear palsy; UTI, urinary tract infection; VaD, vascular dementia

38.5.4 Quetiapine fumarate

Two open trials and a case series with quetiapine within a dose range of 25–800 mg/day suggested possible behavioural benefits for agitation (Tariot *et al.*, 2000a; Davis and Baskys, 2002; Scharre and Chang, 2002). A 10-week multicentre placebo-controlled trial of quetiapine versus haloperidol was conducted in elderly nursing home patients with psychosis that was operationally defined. These criteria were implemented prior to the development of clinical criteria for the psychosis of AD proposed recently (Jeste and Finkel, 2000). This trial is notable in that it may have been the first large placebo-controlled study of antipsychotics in patients with dementia selected because of the presence of psychotic symptoms. The results from the analysis of the subgroup ($n = 284$) with AD have been presented in abstract form (Tariot *et al.*, 2002a) and a manuscript is under review. Flexible doses of the medication were permitted; the mean daily dose of haloperidol was 2 mg/day at end point, while that of quetiapine was about 120 mg/day. None of the treatment groups differed with respect to reduction in measures of psychosis, which was the primary outcome of the trial, whereas there was evidence of reduced agitation on some measures with both haloperidol and quetiapine treatment but not placebo. Tolerability of quetiapine was superior to that of haloperidol. A more critical review of the data will be possible once the trial results are published.

The broad dose range in which quetiapine has shown efficacy means that clinicians should titrate the dose upward to find the optimally effective range for a given individual. Because a high-dose study of quetiapine in dogs showed evidence of cataract formation, appropriate evaluation for this is recommended at present (e.g. via slit lamp examination or direct ophthalmoscopy). A causal link has not been shown in humans, and it is worth noting that a similar recommendation has been made for other psychotropics (e.g. carbamazepine, thioridazine). Definitive studies conducted in humans should resolve the issue of whether this caution is necessary.

38.5.5 Ziprasidone and aripiprazole

There are no geriatrics-specific studies of ziprasidone in the elderly and none in patients with dementia. Results from a placebo-controlled trial of aripiprazole in 208 outpatients meeting new clinical criteria for psychosis of AD (Jeste and Finkel, 2000) have been presented in abstract form (De Deyn *et al.*, 2003). The medication was generally well tolerated, with numerically more frequent sedation in the active treatment group. The primary outcome, a measure of psychosis, did not show a difference between drug and placebo, although there was some behavioural benefit on secondary measures. A better understanding of this trial will be possible after the results are published.

38.5.6 Atypicals: summary

The data indicate that atypical antipsychotics as a class are likely better tolerated than typical antipsychotics and at least as efficacious. There appear to be modest differences within the class of atypicals in terms of effectiveness, but the significance of these differences is unclear. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) protocol for AD, a trial developed in collaboration with the National Institute of Mental Health (NIMH), will be the first head-to-head study of these agents in dementia patients. This 36-week placebo-controlled study compares the effectiveness of the atypical antipsychotics olanzapine, quetiapine and risperidone, as well as citalopram, for psychosis and agitation occurring in outpatients with AD (Schneider *et al.*, 2001).

At present, there are only limited data regarding the long-term safety and efficacy of these agents. Jeste *et al.* (2000) recently reported a cumulative incidence rate for tardive dyskinesia of 2.6 per cent in 330 patients with dementia treated openly with risperidone (mean dose about 1 mg/day) for a median of 273 days. This figure is much lower than that reported in older people treated with conventional agents (Jeste *et al.*, 1995), and is consistent with data reported in a recent prospective longitudinal study of risperidone and haloperidol in older subjects with mixed psychiatric disorders (Jeste *et al.*, 1999). There are, however, no placebo-controlled data addressing these issues, and no studies employing withdrawal manoeuvres.

Evidence of increased incidence of cerebrovascular accidents in patients with dementia who have been treated with two members of this class of medications, i.e. risperidone and olanzapine, suggests need for increased caution in selecting and using this class of medication in patients with dementia. A preliminary meta-analysis of clinical trials of atypical antipsychotics in dementia by Schneider and Dagerman (2003) suggests a trend for death to be associated with randomization to any antipsychotic. It is possible that patients with existing cerebrovascular disease, or with risk factors, might be most susceptible. However, this has yet to be definitively addressed with studies designed to assess side effects or efficacy as a function of baseline medical condition. All in all, the risk/benefit ratio of any treatment must be borne in mind: the risk of not treating a morbid complication of the illness has to be weighed against the small perceived or real risk of active treatment. That is, if an alternative agent is to be used, how convincing are the data about its safety and efficacy?

38.6 BENZODIAZEPINES

According to the ‘metaphor’ approach adopted in this chapter, we would consider these agents first for patients with prominent anxiety. Since features of anxiety and depression overlap extensively in any case, and particularly in patients

with dementia, many physicians opt to use an antidepressant rather than a benzodiazepine if medication is needed. Benzodiazepines have been used for agitation associated with dementia, in several studies that have been reviewed previously (Patel and Tariot, 1991; Loy *et al.*, 1999). Most of these showed, on average, a reduced level of agitation with short-term therapy. There have been very few studies in the past 10 years, none of which was placebo-controlled. In the aggregate, as reviewed in the previous version of this chapter, these studies suggest that agitation associated with anxiety, sleep problems and motor tension might be most likely to respond. Some of the earlier studies in which benzodiazepines were compared with traditional antipsychotics suggested that antipsychotics might be superior.

Prior reviews indicate that side effects occur commonly with benzodiazepines, including sedation, ataxia, falls, confusion, anterograde amnesia, lightheadedness, paradoxical agitation, as well as tolerance and withdrawal syndromes (Patel and Tariot, 1991). It is because of this safety profile that we reserve use of benzodiazepines for situational disturbances, such as dental procedures, for as-needed use, or situations where routine use has been attempted and found to be convincingly safe. Drugs such as lorazepam and oxazepam tend to be selected first because they have straightforward metabolism and relatively short half-lives.

38.7 BUSPIRONE

There have been no randomized, placebo-controlled, double-blind studies of this agent. Reduced agitation has been reported in some open trials that we have summarized previously (Loy *et al.*, 1999; Rosenquist *et al.*, 2000), using doses in the range of 10–60 mg/day. The medication has the advantage of generally good tolerability, with the exception of headache, nervousness and dizziness in a modest percentage

of patients. There is no evidence regarding tolerance or paradoxical effects in this population.

38.8 ANTIDEPRESSANTS

These are listed in Tables 38.5 and 38.6.

We would consider using this class of agents first in patients with agitation accompanied by evidence of depressive features as described in the introduction. There is some evidence linking impulsivity to disordered serotonergic function (Coccaro, 1996), lending support to the use of serotonergic agents. They have also probably been more widely assayed because of their good tolerability profile and widespread use in other psychiatric disorders.

Trazodone was one of the first studied (Table 38.5). There has been only one published double-blind, placebo-controlled study, showing no relative benefit of trazodone over haloperidol or placebo in outpatients with dementia and agitation (Teri *et al.*, 2000). The trial also included a non-blinded behaviour management arm; this also showed no relative benefit. Among the non-placebo-controlled studies, doses typically reported ranged from 50 to 400 mg/day, occasionally higher. Irritability, anxiety, restlessness and depressed affect have been reported to improve, along with sleep disturbance. Reported side effects have included sedation, orthostatic hypotension and delirium. The most rigorous among these compared trazodone (mean dose about 220 mg/day) with haloperidol (mean dose 2.5 mg/day) (Sultzer *et al.*, 1997). Agitation improved equally in both patient groups, although tolerability was reported to be better in the trazodone group. The Expert Consensus Guideline (Alexopoulos *et al.*, 1998) favours use of trazodone to treat sleep disturbance primarily, relegating it to second- or third-line use for 'mild' agitation. A typical starting dose would be 25 mg/day, with maximum doses usually of 100–250 mg/day.

Table 38.5 Antidepressants

Study	Diagnosis	N	Design	Dose (mg/day); duration	Response	Adverse effects
Trazodone Sultzer <i>et al.</i> , 1997	Dementia	28	Randomized DB parallel haloperidol	50–250; 9 weeks	Decreased agitation for both; trazodone better for verbal aggression, oppositional and repetitive behaviours	Sedation (1), imbalance (1); one-third; fewer dropouts in trazodone group
Teri <i>et al.</i> , 2000	AD	149	Randomized DB, PC, parallel group	1.8 haloperidol, 200 trazodone, or behaviour management techniques; 16 weeks	Reduced agitation not significantly different between treated and placebo groups	Less EPS with behaviour management techniques

Data regarding selective serotonin reuptake inhibitors (SSRIs) are summarized in Table 38.6. Nyth and Gottfries (1990) performed a review of controlled studies of citalopram, which suggest some beneficial behavioural effects. Results from two open trials support this conclusion (Ragneskog *et al.*, 1996; Pollock *et al.*, 1997).

Recently, a double-blind, placebo-controlled study compared citalopram and perphenazine with placebo in patients with various dementia diagnoses, probable AD and dementia

with Lewy bodies being the more common diagnoses, who had at least one symptom of psychosis or behavioural disturbance: 85 hospitalized patients were treated after 3 days of dose escalation with doses of 20 mg/day citalopram or 0.1 mg/kg/day of perphenazine for up to 14 days. Both citalopram and perphenazine demonstrated significant improvement compared with placebo for agitation, lability and psychosis. Side effects were similar in the three treatment groups (Pollock *et al.*, 2002).

Table 38.6 Antidepressants: selective serotonin reuptake inhibitors

Study	Diagnosis	N	Design	Dose (mg/day); duration	Response	Adverse effects
Citalopram						
Nyth and Gottfries, 1990	AD, vascular	98	DB, PC	10–30; 4 weeks	Decreased emotional blunting, confusion, irritability, anxiety, mood, restlessness	Confusion (2), dizziness (1), sedation (1)
Nyth <i>et al.</i> , 1992	Dementia (29)	149	DB, PC	10–30; 6 weeks	Decreased anxiety, fear-panic, depressed mood in all	Tiredness (18), problem concentrating (9), apathy (8), dizziness (7), sedation (11), tension (11)
Ragneskog <i>et al.</i> , 1996	AD (55), vascular dementia (30), alcoholic dementia (5), NOS (3)	123	Open, 2 centres	20–40; 1–12 months	Decreased CGI or GBS for irritability, depression (60%), restlessness, anxiety	Tiredness (15); dizziness (14); drowsiness, sleep disturbances, restlessness (4), aggression (3), anxiety (2)
Pollock <i>et al.</i> , 1997	AD	15	Open	20; 2 weeks	Decreased agitation, hostility, delusions, disinhibition	Dropouts from nausea (1), myoclonus (1)
Pollock <i>et al.</i> , 2002	Inpatient AD, VaD, mixed, or other not specified	85	Randomized DB, PC, parallel group	20 citalopram or 6.5 mean perphenazine, up to 17 days	Significantly improved agitation for citalopram versus placebo	Similar scores among all groups
Fluoxetine						
Auchus and Bissey-Black, 1997	AD	15	DB, PC parallel group versus haloperidol	20; 6 weeks	Neither more effective than placebo for agitation	Anxiety, nervousness, confusion, tremor
Sertraline						
Burke <i>et al.</i> , 1997	AD, NOS dementia	19	Chart review	50; variable duration (10/11 AD; 4/8 NOS)	Improved on CGI	None reported
Paroxetine						
Ramadan <i>et al.</i> , 2000	AD or VaD	15	Open	10–40; 3 months	Verbal agitation reduced	Weight gain (5), diarrhoea (1), worsened EPS (1)

AD, Alzheimer's disease; CGI, Clinical Global Impression; DB, double-blind; GBS, Gottfried-Bråne-Steen; NOS, not otherwise specified; PC, placebo-controlled; VaD, vascular dementia

No benefit of administration has been reported yet for fluoxetine or fluvoxamine, and only anecdotes have been published regarding other serotonergic agents (e.g. sertraline), all suggesting possible benefit at least in individual patients. Gastrointestinal distress, loss of appetite and weight, sedation, insomnia, sexual dysfunction and occasional paradoxical agitation can occur with serotonergic agents, although, as a group, they tend to be well tolerated. Results from large placebo-controlled studies will be critical to clarify the optimal role of this class of agents.

38.9 ANTICONVULSANTS

These are listed in Tables 38.7 and 38.8.

We might consider use of anticonvulsants first in patients with features of mania, as well perhaps in those with prominent impulsivity, lability, or episodic aggression. Evidence regarding these agents was summarized previously: we will review it briefly here.

Chambers *et al.* (1982) performed an 8-week cross-over study of carbamazepine in 19 women with mild agitation who also received antipsychotics: this brief report was negative. Tariot *et al.* (1994) performed a 12-week placebo-controlled pilot cross-over study of carbamazepine in 25 patients, showing encouraging effects on agitation and not other aspects of psychopathology. A more recent confirmatory parallel group study of 6 weeks' duration in 51 patients also found a significant reduction in agitation using a mean dose of 300 mg/d (Tariot *et al.*, 1998). Tolerability in these studies was generally good, with evidence of sedation and ataxia (Tariot *et al.*, 1995b).

A 6-week, randomized, double-blind, placebo-controlled, parallel group trial of carbamazepine 100 mg q.i.d. was conducted in 21 patients with probable AD with agitation and mild psychotic or mood disturbances who had failed

previous treatment with antipsychotics (Olin *et al.*, 2001). Secondary analysis suggested improvement in agitation-related symptoms. Adverse events were reported as mild. Side effects seen in other populations, such as rashes, sedation, haematologic abnormalities, hepatic dysfunction and altered electrolytes, would be more likely to be evident with widespread use of carbamazepine in the elderly (Tariot *et al.*, 1995b). Further, it has considerable potential for significant drug-drug interactions. The carbamazepine studies provide evidence to support the concept that anticonvulsants have anti-agitation efficacy. The question of whether alternative agents may be equally or more effective, or at least safer and better tolerated, remains open.

Valproic acid, also available as the enteric-coated derivative, divalproex sodium, is approved by the US FDA for treatment of acute mania associated with bipolar disorder. There are at present 18 case reports or case series in patients with dementia addressing efficacy, safety and tolerability (Tariot, 2004). There was wide variation in the daily dose (240–4000 mg/day) and plasma levels of valproate (14–107 µg/mL); approximately two-thirds of patients showed clinically evident improvement in agitation, chiefly reported in descriptive terms. Side effects were consistent with Package Insert information. The preliminary data suggested that valproate may be effective and safe for the treatment of agitation associated with dementia and supported further studies.

The first randomized, placebo-controlled, parallel group study of this agent was 6 weeks in duration (Porsteinsson *et al.*, 2001). The 'best dose' of divalproex sodium (mean = 826 mg/day, mean level 46 µg/day) was assessed in 56 nursing home residents with dementia complicated by agitation. The primary measure of agitation showed a nearly significant reduction with valproate versus placebo. Serious adverse events occurred at a rate of 10 per cent in both the drug and placebo groups, with milder side effects occurring more frequently in the drug group, chiefly consisting of sedation,

Table 38.7 Anticonvulsants: carbamazepine

Study	Diagnosis	N	Design	Dose (mg/day); duration	Response	Adverse effects
Tariot <i>et al.</i> , 1994	AD, VaD	25	Cross-over PC (some other psychotropics permitted)	300 modal; 5 weeks	Decreased agitation (16 versus 4 placebo)	Tics (1), sedation
Tariot <i>et al.</i> , 1998	Dementia	51	Randomized PC (no psychotropics except chloral hydrate as needed)	300 modal; 6 weeks	Improved on CGI (20/26); also improved on OAS, BPRS, BRSD	Ataxia (9 vs. 3 placebo), disorientation (4 versus 0 placebo), tics (1), sedation
Olin <i>et al.</i> , 2001	AD	21	Randomized, DB, PC	388; 6 weeks	Improved BPRS hostility item	Diarrhoea more common with active treatment

AD, Alzheimer's disease; BPRS, Brief Psychiatric Rating Scale; BRSD, CERAD Behavioral Rating Scale for Dementia; DB, double-blind; OAS, Overt Aggression Scale; PC, placebo-controlled; VaD, vascular dementia

gastrointestinal distress, and ataxia, typically rated as mild, and the expected decrease in average platelet count (about 20 000/mm³). Forty-six of these participants were subsequently treated for 6 weeks in an open fashion with clinically optimal doses of divalproex sodium (range 250–1500 mg/day, mean 851 mg/day) (Porsteinsson *et al.*, 2003). The results confirmed and extended those from the placebo-controlled phase of the trial.

A randomized, double-blind, placebo-controlled, cross-over study of valproate 480 mg/day for 3 weeks was conducted in patients with dementia and aggressive behaviour (Sival *et al.*, 2002). No significant differences in aggressive behaviour in this short-term trial were seen between placebo and active treatments according to the primary outcome measure. However, there was a trend to improvement in measures of aggression that correlated with serum valproate levels, and sodium valproate showed significant effects on restless, melancholic and anxious behaviours, interpreted as generally consistent with anti-agitation results seen previously, as well as trends for improvement for dependent and suspicious

behaviours. There were no drug-placebo differences in rate or type of adverse events.

A multicentre, randomized, placebo-controlled, 6-week, study of divalproex sodium conducted in 172 nursing home residents with dementia and agitation who also met criteria for secondary mania incorporated an aggressive dosing and titration protocol resulting in a target dose of 20 mg/kg/day for 10 days (Tariot *et al.*, 2001a). This titration rate and dose resulted in sedation in about 20 per cent of the drug-treated group and a relatively high dropout rate, leading to premature discontinuation of the study (n = 100 completers). There were no significant drug-placebo differences in change in manic features, but there was a significant effect of drug on agitation. Sedation occurred in 36 per cent of the drug group versus 20 per cent of the placebo group, and mild thrombocytopenia occurred in 7 per cent of the drug group and none of the placebo treated patients.

The results from this trial were used to amend the Package Insert information, cautioning against use of similar doses and/or titration rates in the elderly. If valproate is used, the

Table 38.8 *Anticonvulsants: divalproex*

Study	Diagnosis	N	Design	Dose (mg/day); plasma level (µg/mL); Duration	Response	Adverse effects
Herrmann, 1998	AD, LB, vascular dementia	16	Open	750–2500 (mean = 1331); mean level = 459 µM; 5–34 weeks	Improved on CMAI, BEHAVE-AD (11)	Sedation, ataxia, diarrhoea (1)
Kunik <i>et al.</i> , 1998	Dementia	13	Retrospective review (concurrent BDZs, antipsychotics)	500–1750 (mean = 846); mean level = 48; duration variable	Decreased physical not verbal agitation and aggression on CMAI (10)	None reported; drug interaction with phenytoin noted (1)
Porsteinsson <i>et al.</i> , 2001	AD, vascular dementia, mixed dementia	56	Randomized PC (no psychotropics except chloral hydrate as needed)	375–1375 (mean = 826); mean level = 45; 6 weeks	Decreased agitation by BPRS and CGI	Sedation and nausea, vomiting or diarrhoea
Tariot <i>et al.</i> , 2001a	AD and/or vascular dementia with secondary mania	172	Randomized, DB, PC, parallel-group	1000 median	Significant improvement on CMAI verbal agitation subscale	Somnolence, thrombocytopenia
Sival <i>et al.</i> , 2002	AD, vascular dementia, other and mixed dementia	42	Randomized, DB, PC, cross-over	480; mean level = 41; 3 weeks active treatment	No change in aggressive behaviour compared to placebo	Small increase in incidence of adverse events compared to placebo
Porsteinsson <i>et al.</i> , 2003	AD, vascular dementia, mixed dementia	46	Open extension	250–1500 (mean = 851); mean level = 47; 6 weeks	Decreased agitation by BPRS and CGI	Fall, sedation, and nausea, vomiting or diarrhoea

AD, Alzheimer's disease; BPRS, Brief Psychiatric Rating Scale; CGI, Clinical Global Impression; CMAI, Cohen-Mansfield Agitation Inventory; DB, double-blind; LB, Lewy body; PC, placebo-controlled

available evidence would suggest a starting dose of about 125 mg p.o. b.i.d., increasing by 125–250 mg increments every 5–7 days, with a maximal dose determined by clinical response, or where there is uncertainty, a serum level of about 60–90 µg/mL. In our hands, the typical target dose is about 10–12 mg/kg/day. The usefulness of the new once-daily extended release formulation is not established in this population.

There are no controlled studies of which we are aware of the newer anticonvulsants including lamotrigine, gabapentin and topiramate. There are a few case reports and case series suggest benefit with gabapentin (Regan and Gordon, 1997; Hawkins *et al.*, 2000; Herrmann *et al.*, 2000; Roane *et al.*, 2000; Megna *et al.*, 2002).

There are emerging biological data addressing the mechanism of action of mood stabilizers suggesting in particular that lithium and valproate, but not other agents, may have clinically relevant neuroprotective properties (Manji *et al.*, 2000; Tariot *et al.*, 2002b). Further understanding of these issues may differentiate among available agents and also lead to the identification of new targets for therapy.

38.10 SELEGILINE

Also known as L-deprenyl, selegiline relatively selectively inhibits monoamine oxidase (MAO) type B at doses up to 10 mg/day, while non-selectively inhibiting MAO A and B at higher doses. It has primarily been used in the treatment of motor dysfunction patients with Parkinson's disease but there are a surprising number of clinical reports in patients with dementia. In many cases, the agent was looked at as a possible disease modifier or cognition-enhancing agent, rather than as treatment for behaviour *per se*. In a meta-analysis, Tolbert and Fuller (1996) reported that all uncontrolled studies of this agent in dementia that addressed behavioural changes indicated beneficial behavioural effects of selegiline, whilst two of the five double-blind, placebo-controlled studies reported somewhat positive behavioural effects. A different meta-analysis of 11 randomized placebo-controlled double-blind trials found that four trials indicated positive behavioural effects (Birks and Flicker, 1998). Since the overall evidence of behavioural efficacy is limited, selegiline is not likely to be a first, or even second, choice for the treatment of agitation. Its role as a neuroprotective agent or cognitive enhancer in dementia has yet to be fully clarified.

38.11 β-ADRENERGIC RECEPTOR BLOCKERS

This class of agents has not been subject to rigorous study. Most of the evidence comes from open trials conducted more than 10 years ago (Rosenquist *et al.*, 2000). Doses used are typically below 100 mg/day for propranolol.

Adverse reactions of β-blockers include bradycardia, hypotension, potential worsening of congestive heart failure or asthma, reduced adrenergic response to hypoglycaemia in patients with diabetes, sedation, increased confusion, psychosis, depression and increased atrioventricular block. It is unclear what role this class of medication has in the treatment of agitation associated with dementia at this point. If it is to be attempted at all, we would argue that it should occur only after safer and more conventional therapies have failed, and only with careful monitoring for side effects.

38.12 LITHIUM

There are no controlled studies of this agent for agitation in dementia; there are at most some case series published in the 1980s (Rosenquist *et al.*, 2000). The limited literature suggests that occasional patients showed improvement, but toxicity was common, including worsening of extrapyramidal syndromes, ataxia and confusion. Since the therapeutic index is so narrow, we find it hard to justify using this agent in a patient lacking a syndromal diagnosis of bipolar disorder. Even then, we are more inclined to use anticonvulsants first. If we choose lithium, close monitoring is in order.

38.13 CHOLINERGIC THERAPIES

We completed a previous review of studies with cholinergic therapies (Rosenquist *et al.*, 2000).

As summarized by Cummings (2000), there is mounting evidence that cholinergic agents, especially cholinesterase inhibitors, may have modest clinically relevant psychotropic effects in some patients with dementia. For the most part, the studies were not designed to address behavioural outcomes as the primary goal. A prospective clinical trial of metrifonate versus placebo found modest reduction in average neuropsychiatric symptoms in the drug group versus placebo group (Morris *et al.*, 1998). A retrospective analysis of two 26-week double-blind, placebo-controlled multicentre trials of metrifonate found a behavioural effect size of 15 per cent, with significant improvement observed in measures of agitation/aggression and aberrant motor behaviour as well as hallucinations, dysphoria and apathy (Raskind *et al.*, 1999; Cummings *et al.*, 2001). Although these data support the potential behavioural impact of cholinergic treatment, development of metrifonate has been abandoned because of toxicity.

Tariot *et al.* (2000b) showed reduced incidence of neuropsychiatric symptoms on drug versus placebo in outpatients who generally lacked psychopathology at baseline in a 5-month study of galantamine. A secondary analysis of behavioural data from a 6-month, placebo-controlled trial of donepezil in nursing home residents with probable AD complicated by behavioural symptoms showed reduced agitation (Tariot *et al.*, 2001b). In a case series, 28 patients with AD

treated with donepezil 5 mg/day for 1 month followed by a mean dose of 10 mg/day for 5 months showed improvement in symptoms of agitation (Paleacu *et al.*, 2002).

38.14 MEMANTINE

Memantine is a non-competitive inhibitor of *N*-methyl-*D*-aspartate (NMDA) receptors that may permit normal memory formation but blocks their excitotoxic activation (Winblad *et al.*, 2002). The FDA recently approved memantine for treatment of moderate to severe AD. A placebo-controlled study of memantine 10 mg/day for 3 months in patients with severe dementia showed significant clinical improvements in memantine-treated patients (Winblad and Poritis, 1999). In a more recent double-blind, placebo-controlled study, 252 patients with moderate to severe AD were randomized to treatment with memantine 20 mg/day or placebo for 7 months (Reisberg *et al.*, 2003). There were significant improvements among memantine-treated patients in the primary global and functional end points. The behavioural data indicated a trend to less worsening in memantine-treated patients in psychopathology, without agitation effects. Agitation was more common as an adverse event in the placebo group.

38.15 HORMONAL THERAPY

There are no definitive studies of hormonal agents, which are sometimes used when more conventional therapies fail. The available literature was summarized previously (Rosenquist *et al.*, 2000). The anecdotal evidence is by no means conclusive, and only suggests that these agents might occasionally be helpful. Controlled studies would be extremely useful.

38.16 SUMMARY

Humane treatment of patients with dementia includes vigorously addressing the kinds of behavioural and psychological signs and symptoms that are likely to occur. The main emphasis should be on non-pharmacological approaches, including carefully investigating for possible delirium and searching hard for social or environmental interventions that capitalize on the patient's residual strengths. It is indeed this process of attempting to 'find what works' that makes treatment in this population so fascinating, as well as challenging.

Psychotropics should be reserved for cases where other, simpler interventions have been attempted and deemed inadequate. We advocate a target symptom-based approach, which matches the most salient target symptoms to a relevant drug class. Although there is no compelling empirical support for this approach, it has the advantage of being face-valid and

logical, which are reassuring features when one is a consultant in a confusing situation.

Much of the available data do in fact indicate that antipsychotics as a group can show benefit for agitation associated with psychotic features. Further, evidence also is mounting that this class of agents may also show benefit for agitation or aggression not associated with psychotic features. As indicated, the side effects of the typical antipsychotics are protean. The data are emerging regarding safety and potentially greater effectiveness of atypical antipsychotics. The available literature regarding non-antipsychotic medication includes antidepressants, anticonvulsants, anxiolytics and a variety of other agents with less foundation. As data accrue regarding these therapeutic approaches, we will have a clearer sense of exactly how and when they should be deployed. In the meantime, clinicians are obliged to deal as thoughtfully as possible with patients on a case-by-case basis, attempting first and foremost to avoid toxicity of therapies intended to help.

A predominantly psychosocial approach to behaviour problems in dementia: treating causality

MICHAEL BIRD

39.1 Conceptual background: the nature of challenging behaviour	499	39.4 Conclusion	506
39.2 Assessment	500	Appendix	507
39.3 Interventions	502	References	507

This chapter describes an approach to behaviour problems in dementia and concentrates on identifying both the causes of the behaviour in the individual case, and why it is defined as a problem. It begins with a conceptual discussion. Section 39.2 outlines the variables that must be assessed in order to uncover the causes of the problem. Section 39.3 discusses treatment options, including three case studies by way of illustration. Finally, there is a short conclusion on the nature of psychosocial approaches and their relationship with psychopharmacology.

39.1 CONCEPTUAL BACKGROUND: THE NATURE OF CHALLENGING BEHAVIOUR

Over the last decade, what may be called the *behaviour syndrome – standard therapy model* has predominated in the psychogeriatric literature. This model sees the person with dementia as the identified patient and the behaviour as the syndrome to be treated, usually with a standardized treatment such as antipsychotic medication.

The conceptual basis of this model underpins and can be seen in the large number of classification instruments where a named behaviour is the syndrome, or where behaviours are clustered into broader syndromes. Examples are: ‘Pacing up and down’ from the Dementia Behaviour Disturbance Scale (Baumgarten *et al.*, 1990); ‘cognitive abulia’ in the BEHAV-AD (Reisberg *et al.*, 1989); or, ‘irritability/lability’ in the Neuropsychiatric Inventory (Cummings *et al.*, 1994). It can also be seen in the many journal articles appearing each year

advocating a standard and usually pharmacological treatment for a mysterious syndrome called ‘agitation’. Though agitation does have a meaning in psychiatry, it is often used indiscriminately in dementia research for just about any behaviour that causes problems, and is therefore clinically meaningless.

Standardized treatments for specific behaviours or syndromes are not the focus of this chapter, which is based on a different conceptualization of problem behaviour in dementia. This assumes that, regardless of its nature, the behaviour is actually the end symptom of multiple and case-specific biopsychosocial causality. Rather than simply trying to suppress or manage the symptom, the behaviour, treatment in most cases is much more effectively targeted at causality. Causality will be idiosyncratic to the case, and will include not only causes of behaviour but also why it is perceived as a problem. Treatment may be directed at the person with dementia and/or family carers or care staff. This model is supported by two broad classes of evidence and a controlled clinical trial:

- Though brain impairment associated with dementia is usually a necessary condition for behaviour which may be seen as ‘challenging’, the same behaviour in different cases will usually be caused by an interaction of that impairment with many case-specific factors. These factors can include medical/physical problems, the environment – including the way care is carried out, mental illness or personal history. For example, many factors can contribute to vocal disruption in dementia, including pain or understimulation (e.g. Cohen-Mansfield and Werner, 1997), overstimulation

(e.g. Meares and Draper, 1999), anxiety (e.g. Hallberg *et al.*, 1993), the nature of social interaction with care staff (Edberg *et al.*, 1995), post-traumatic stress disorder (Bird *et al.*, 2002) or hallucinations (Tsai *et al.*, 1996).

- There is abundant evidence that factors other than the behaviour determine whether it is seen as a problem. An obvious example is wandering, which may only be classified as problem behaviour where there is no perimeter fence. However, many other factors influence emotional response to patient behaviour, for example depression in home carers (e.g. Hinchliffe *et al.*, 1995), and organizational or staff variables in residential care (Baillon *et al.*, 1996; Moniz-Cook *et al.*, 2000). Bird *et al.* (2002) found that different care staff exposed to the same behaviour by the same patient exhibited great variability in distress levels about the behaviour (ranging from none to very high). There was also strikingly low agreement amongst senior staff about severity of the problems caused by these residents.

So, what constitutes ‘challenging’ behaviour is often determined by the eye of the beholder; any definition must therefore include the effects of the behaviour. The definition used for this chapter is ‘any behaviour associated with the dementing illness which causes distress or danger to the person with dementia or others, or is a manifestation of distress’ (Bird *et al.*, 1998).

If this conceptualization is correct, it follows that there is no easily defined syndrome based on the behaviour, nor a standard treatment. The nature of the behaviour does not even predict whether intervention is required. Where intervention is required because the behaviour is a manifestation of distress or is causing significant distress, treatment will be mainly directed at causes, including the reasons why it causes distress.

Support for the effectiveness and efficacy of this approach may be found in a controlled trial by Bird *et al.* (2002), where a small clinical team treated a series of cases ($n = 44$) of behavioural disturbance, many severe, and concentrated on causality. There was a 43 per cent post-intervention reduction in frequency of the main referred behaviour, with the effect still evident 3 months later. Interventions were predominantly psychosocial, but medication was used as an adjunct in a significant minority of cases. In a few cases it was the primary modality, for example where the cause was depression or pain or distressing hallucinations. There was no relationship between the nature of the behaviour and the type of treatment. The interventions required initial time-intensive engagement (a mean of 5.5 visits per case) while the case was assessed and a tailored treatment package devised and implemented. However, overall, they took no more clinical visits than a control group ($n = 22$), which used the more usual predominantly pharmacological approach. Both groups produced equivalent improvements in behaviour and carer/nursing staff emotional response, but the causality-focused approach had far fewer medication changes, drug side effects, and hospitalizations for the behaviour.

39.2 ASSESSMENT

If challenging behaviour is the end product of an interaction between many case-specific variables, multidimensional assessment is essential. Each case must be approached with questions rather than preconceived answers in the form of standard treatments. Multiple sources of information are required, in particular the people who know the patient best. In nursing homes it is essential to include hands-on care staff, often ignored, as well as more senior staff and family. Another essential source is the person with dementia, using direct discussion where possible, focused attention (for example, to the content of screaming), and behavioural observation. The primary assessment questions may be encapsulated under the questions below.

39.2.1 Is the behaviour causing distress or danger to the patient or others?

If the behaviour is a manifestation of distress by the patient, there is clearly an obligation to treat regardless of whether it is causing distress to others. If it is not a manifestation of distress and it is not causing distress or danger, the behaviour, by definition, is not ‘challenging’, and not a legitimate target for clinicians. Bizarre behaviour is not necessarily the same as challenging behaviour. A common example is benign hallucinations or delusions (Peisah and Brodaty, 1994), though investigation may be necessary to determine whether these phenomena are symptoms of treatable physical illness, especially if there is relatively sudden onset. However, there are many other behaviours associated with dementia that are often classified as aberrant or agitated, such as pacing or repeatedly sorting clothing, where it is essential to first assess whether it is a problem for anybody. ‘Treating’ a behaviour simply because it challenges the clinician’s perception of what is normal risks producing non-benign outcomes, especially with the side effects associated with psychotropic medication (Katona, 2001).

Even if there is distress amongst carers or nursing staff, it is important to discover who is distressed, and the source and severity of that distress, in order to determine whether home carer or nursing staff concerns are a more appropriate target than the behaviour (see Section 39.3, pp. 502–503).

39.2.2 What is the patient actually doing, and what is the context?

Labels like agitation carry almost no clinical information. It is essential to determine what the person with dementia is actually doing to cause distress, and the context in which it occurs (when, where, or to whom?). Even the term aggression carries little information. It could range from frequent dangerous physical violence to occasional verbal abuse or innocuous pushing away, in which case dealing with carer

concerns is likely to predominate in any intervention. The context even of severe aggressive behaviour could range from a response to hallucinations (Tsai *et al.*, 1996) to its very common occurrence during intimate personal care in nursing homes (Bridges-Parlet *et al.*, 1994; Bird *et al.*, 2002), though even here it often occurs only with some staff.

39.2.3 Aetiology – what is causing or exacerbating the behaviour?

Beyond the brain impairment itself, important within-patient variables include past history and character, pattern of cognitive and sensory impairment, physical health and comfort, and mental health. External variables are the vast complex of physical and social phenomena that form the patient's immediate world. The role of assessment is to develop evidence-based hypotheses about the factors that produce the behaviour and, of those, which are realistically adjustable. The following comments provide only a flavour of the critical importance of this information.

39.2.3.1 WITHIN-PATIENT VARIABLES

The most common adjustable patient characteristics relate to medical/physical problems, including pain or discomfort, constipation, drug interactions and infections (Peisah and Brodaty, 1994; Cohen-Mansfield and Werner, 1999; Bird *et al.*, 2002). Depression can also precipitate behaviour problems, and must be assessed (Menon *et al.*, 2001). For example, Elmståhl *et al.* (1998) reported that nursing home residents with dementia who were depressed or in physical pain were more likely to be on antipsychotics than the appropriate medication. Though interventions for these phenomena will be primarily medical, psychosocial methods can be used as adjuncts (see Case 2 in Section 39.3, pp. 504–505).

Beyond this, even non-adjustable factors such as past history can provide vital information when an intervention is planned. For example, learning that a woman who screamed and was violent during bathing was a probably manifesting panic based on known premorbid trauma helped staff to change their approach and largely eliminate the behaviour (Woods and Bird, 1998). In Case 1 below (Section 39.3, pp. 503–504), learning that a resident resisting personal care suffered from obsessive-compulsive disorder related to cleanliness meant that the behaviour was unlikely to change, so the intervention was directed at improving staff skills and confidence.

39.2.3.2 EXTERNAL VARIABLES

Many texts concentrate on the physical environment in dementia care (e.g. Day *et al.*, 2000) and it can be an important causal and, by adjustment, ameliorating factor in challenging behaviour. This applies to either the presence or absence of stimuli. For example, incontinence has been reduced by visual, auditory or situational cues (Hanley, 1986; Bird *et al.*, 1995);

screaming by room relocation (Meares and Draper, 1999); wandering by visual barriers (Hussian and Brown, 1987); and self-harm by removal of cues precipitating it (Bird *et al.*, 1998). The patient described in the previous paragraph who screamed in the bathroom because of panic could have her hair washed without incident in a local salon (Woods and Bird, 1998).

It is, however, more often the care environment that is critical in assessment. The association between violence and care interactions has already been noted. In other examples, Cohen-Mansfield and colleagues (1992) found a relationship between disturbed behaviour and staff schedules; Edberg *et al.* (1995) showed that the nature of nurse-patient interactions was associated with vocal disruption; Rogers *et al.* (2000) that carer practices increased patient dependence; and Schnelle *et al.* (1999) that night-time disturbance occurred because staff behaviour woke residents up.

These findings are unsurprising. Most people with dementia live, by necessity, in dependent and dynamic relationships either at home or in institutions. What the patient does and feels affects carers, whose actions and emotions in turn affect the patient. Assessment must therefore include the way care is carried out. Even if carer practices are not causing the behaviour, it is often easier to change what they are doing than patient behaviour direct. Working with home or institutional carers to adapt their attitudes and approach predominated in the intervention study by Bird *et al.* (2002) (see Appendix at the end of the chapter, p. 507).

39.2.4 What realistically can be done? Case-specific constraints and possibilities

Detailed assessment of causality frequently suggests obvious solutions – for example, alleviating loneliness by having someone socialize with the resident several hours a day. However, interventions must also be feasible. To do this, the final key component of assessment is to determine the constraints and potentialities of the situation on the ground. This involves both the person with dementia and the care environment in which the intervention must take place.

39.2.4.1 PATIENT POSSIBILITIES

Assessment of residual capacity of the person with dementia is essential. For example, highly structured counselling is possible in early dementia (e.g. Teri, 1994; Woods and Bird, 1998); learning to respond to cues is still possible in the moderate stages (Bird, 2001). Conversely, assessment may show that nothing can be done directly with the patient because he or she is too impaired or too difficult, or because the behaviour is not going to change.

Formal neuropsychological assessment can provide guidance, but a more direct method is behavioural experiment. For example, operant conditioning was used in a case of gross sexual assault of female staff during showering because, though it is often ineffective in dementia, assessment showed some

insight and a capacity to learn simple associations (Bird *et al.*, 1998). The experiment of having a novel 'no nonsense' nurse shower the patient showed that the behaviour was at least partially under his control, and a further experiment that the reinforcer for abstaining from assault (reading the newspaper with a carer) was genuinely pleasurable.

The number of visual cues one sees in nursing homes that are illegible even to the young cognitively intact clinician underlines how rarely assessing the patient's capacity to respond to an intervention is considered before it is put in place. Cues are useless in dementia unless the patient can see them, learn to attend to them and, having done so, remember what they mean and, having done that, act on them (Bird, 2001).

39.2.4.2 ENVIRONMENTAL POSSIBILITIES

Assessment in order to become familiar with the possibilities and limitations of the care environment is equally essential. For example, with a fit younger patient whose violent behaviour was partially related to 'living in this prison' (a nursing home with no outside access), it was necessary to engage a volunteer to take him out jogging because assessment showed clearly that staff were insufficiently motivated to perform this task regularly (Bird *et al.*, 2002). In Case 3 (Section 39.3, pp. 505–506), provision of care at timed intervals was implemented as part of the intervention with a woman who shouted and pressed the buzzer frequently. It was only attempted because assessment showed flexible organization and because staff were sufficiently motivated to carry it out. This would not have been possible in a nursing home with a rigid structure, nor in one where management regarded psychotropic medication as the universal panacea.

As this implies, part of the assessment must include capacity for change within a given care setting. To assess this, clinicians must rely on clinical judgement. For example, depression or anger in home carers often inhibits them from looking at behaviour objectively. The author's rough rule of thumb is that, if even minimal objectivity is impossible, an intervention requiring a change in carer behaviour is not possible until carer distress is addressed. In residential facilities, the closer the institution approximates the acute hospital medical model, the more difficult it will be to implement non-pharmacological interventions. In certain facilities only a masochist would attempt complex psychosocial interventions, though sometimes even a small core of committed staff is sufficient to start the ball rolling. The clinician must look for flexibility of approach and the presence of, or potential to develop, some kind of dementia literacy. In this respect, an empathic understanding of how the patient experiences the world is more important than theoretical knowledge of brain-behaviour relationships.

There is a small but growing literature on the problems of gaining compliance from staff in undertaking psychosocial interventions in residential dementia care (e.g. Schnelle *et al.*, 1998), though it remains an unresolved issue (Allen-Burge *et al.*, 1999).

39.3 INTERVENTIONS

39.3.1 Carer distress as the clinical target

As already discussed, the emotional response of those exposed to a behaviour is often the most important factor in determining whether intervention is required. Restricting treatment to the behaviour alone is, therefore, an absurd limitation of options. In a significant minority of cases, addressing carer concerns is sufficient. Beyond this, even if patient behaviour change is necessary, the most common method will probably involve working with home carers or nursing staff to change their attitude or approach (see Appendix, p. 507). Interventions aimed at carer or care staff attitudes or practices require the same rapport as normal psychotherapy though, in institutions, multiple staff of varying levels of skill, insight, flexibility and motivation makes the task more complex. Equally, as in one-to-one psychotherapy, if carer/care staff concerns are not at least listened to, there can be little rapport and little chance of compliance. Work in progress (Edberg and Bird, 2003), involving focus groups of staff in a number of countries, suggests that, in aged care institutions, listening to and responding to staff distress remains relatively rare.

At least two intervention studies that have included a strong psychosocial component and carer measures (Hinchliffe *et al.*, 1995; Bird *et al.*, 2002), have shown a relationship between reduced problem behaviour and alleviation of carer distress, but causal direction is impossible to attribute. In both studies, in some situations carer distress was alleviated such that, though the behaviour remained, it ceased to be seen as a significant problem (see Case 1 below).

It is often necessary to reduce carer distress before attempting an intervention requiring their input. For example, it was necessary to work first on the anger of a home carer whose confrontational response to her husband's obsessive toileting was exacerbating the problem (Bird, 2003). Emotional support, education on dementia, and learning that her husband was genuinely anxious enabled her to respond with empathy, physical comfort and gentle assertion – reducing the behaviour to more manageable proportions and improving her own mental health.

Many factors influence whether carers or care staff are distressed by patient behaviour. Known examples include: appraisal – not the reality – of physical threat (Rodney, 2000); nursing home organizational factors (Baillon *et al.*, 1996); interpretation of the behaviour (Harvath, 1994); depression in carers (Hinchliffe *et al.*, 1995; Teri, 1997); low dementia literacy (Hagen and Sayers, 1995); level of support provided (Moniz-Cook *et al.*, 2000); and morale and attitude to care (Jenkins and Allen, 1998).

These are variables which can be addressed directly. Though controlled clinical intervention studies are astonishingly rare within the vast home carer burden literature, a few structured support and education programmes have demonstrated clear benefits, including more effective management

of behaviour problems and concomitant delayed entry into residential care (Teri, 1999). In institutions, programmes that have addressed staff attitude and care practices have produced not only improved staff morale (Berg *et al.*, 1994) but also: reduced problem behaviour (Hagen and Sayers, 1995; Rovner *et al.*, 1996; Bird *et al.*, 2002); reduced patient dependence (Baltes *et al.*, 1994); reduced patient anxiety and depression (Bråne *et al.*, 1989); improved staff–patient cooperation and therefore reduced problems in personal care (Edberg *et al.*, 1996); and reduced use of physical restraint and antipsychotic drugs (Ray *et al.*, 1993; Levine *et al.*, 1995).

So, there is abundant evidence that the clinician called to ‘treat’ a case of challenging behaviour who ignores carer distress about that behaviour as the primary clinical target, or as a critical ancillary to dealing with the behaviour, is working with a grossly circumscribed repertoire; 20 per cent of cases reported by Bird *et al.* (2002) were ameliorated without addressing patient behaviour.

39.3.2 Addressing the causes of the behaviour

When physical/medical or mental health contributory factors that can be treated pharmacologically have been addressed, and where the intervention requires more than addressing carer/care staff distress, the clinician must develop a psychosocial package that addresses other causes.

The literature on psychosocial approaches was plagued for many years by scarcely believable assertions, uncontaminated by evidence, of benefits from various generic or proprietary therapies. More recently, there has been movement in a scientific direction. For example, the first controlled trial of aromatherapy, undertaken by a prestigious psychogeriatric team in the UK has now been published. It showed positive effects of massage with melissa oil on generalized agitation (Ballard *et al.*, 2002).

Opie *et al.* (1999) remains one of the best literature reviews of psychosocial approaches. The majority of the 44 studies incorporated had study designs classified as ‘weak’ but effects were consistent and strong enough for the reviewers to advocate a strong coordinated research effort.

Examples are:

- ‘white noise’ (waterscape sounds) reducing verbal disruption in that proportion of the subjects who would tolerate headphones (Burgio *et al.*, 1996);
- social interaction reducing verbal disruption (Cohen-Mansfield and Werner, 1997);
- bright light reducing nocturnal disturbance (Colenda *et al.*, 1997) or motor restlessness (Haffmans *et al.*, 2001);
- music tailored to the patient’s tastes reducing generalized agitation (Gerdner and Swanson, 1993) or physical aggression (Clark *et al.*, 1998);
- social stimulation reducing physical aggression (Wystanski, 2000);

- personalized tapes made by family members reducing agitation (Woods and Ashley, 1995);
- cued recall of more adaptive behaviour for a variety of problems (Bird, 2001; Bird *et al.*, 1995) and
- cue cards for repetitive questions (Bird *et al.*, 1995; Bourgeois *et al.*, 1997).

As these examples show, most research evaluating psychosocial interventions has followed the same *behaviour syndrome – standard treatment* conceptualization as pharmacological research, though it tends to focus more at the level of treatments for specific behaviour. It is valuable because it adds more techniques to the tool-kit, in the same way as drug trials suggest formulations that can be applied with minimal risk to the patient. These generic or behaviour-specific techniques are especially useful where there is no identifiable cause of the behaviour, or there are no other options and the behaviour is still significantly distressing.

However, standardized interventions are not the focus of this chapter. If the cause of vocal disruption is treatable pain, treatable infection, or treatable depression, rote application of baroque music or white noise or melissa oil, though potentially less harmful, is as ludicrous and unprofessional as rote prescription of antipsychotic medication. If disturbed sleep/wake cycles are caused by nurses waking patients at night, training staff to exhibit common sense is likely to be more relevant than bright-light therapy.

39.3.3 Three case studies

In the controlled trial by Bird *et al.* (2002), by far the most common psychosocial interventions, apart from alleviating carer/care staff distress, were not the application of standardized interventions. They were to change the care practices and responses of carers/care staff or the environmental features that were contributing to the behaviours or exacerbating them to unmanageable proportions. These methods are summarized in the Appendix (p. 507). Brief descriptions of the psychosocial and/or pharmacological interventions for all cases undertaken in the trial can be found in the study report.

Three cases from the trial are reported here to give a more general flavour of the causality-based approach described in this chapter. Behaviour intensity measures (duration or frequency) reported in Figure 39.1 are based on direct observation and recording. Validated staff response measures reported are:

- individual staff stress caused by the behaviour;
- individual ability to cope with the patient’s behaviour; and
- problem severity assessing overall degree of disruption to the facility.

39.3.3.1 CASE 1

L, 87 years, had progressive dementia of undiagnosed aetiology. She had lived in a hostel since well before onset of

Figure 39.1 (a-c) Pre- and post-intervention behaviour intensity outcomes of three typical cases.

impairment and was much loved by senior staff. She was dysphasic and not testable on the Mini-Mental State Exam (MMSE) of Folstein *et al.* (1985). She was in the moderate range on the Clinical Dementia Rating (CDR) of Morris (1993). Otherwise pleasant and easy to manage, she was referred for violent resistance and swearing and yelling during toileting and showering. Low-dose antipsychotic medication had been tried by the general practitioner but it resulted in chronic unsteadiness and a severe fall. Most staff had given up, leaving her personal care for two older staff, who could usually accomplish the task using a mix of chocolate bribes and knowing when to back off or be assertive (i.e. dementia-specific nursing skills). Because L was doubly incontinent, she sometimes had to wait for several hours covered in urine and faeces until one of the experts came on.

At assessment, we followed up on a statement by L's 93-year-old sister: 'She's always been as mad as a hatter'. It became clear that L had suffered most of her life from obsessive-compulsive disorder related to cleanliness. Though she had been in the hostel for 15 years, no member of staff knew this. We assessed the chances of care staff knowing, understanding and applying all L's rituals as nil and the behaviour, accordingly, as unlikely to change. We discussed the situation with staff and, though L was clearly appropriate for nursing home placement, they were adamant they wanted to keep her. The intervention therefore consisted of the two experts showing the others how they undertook personal care and, equally important, providing encouragement to keep going. Figure 39.1a shows no decrease in the total amount of staff time taken to provide personal care to L, but a decrease after 2 months and a total cessation after 5 months of unsuccessful attempts (i.e. where staff gave up). They all now felt confident to accomplish the task. Though mean stress scores did not decline because L continued to resist, the mean coping score post-intervention reflected significantly increased personal self-efficacy. The hostel manager downgraded the problem from severe to moderate on the problem severity scale.

In this case, the cause of the behaviour was known, but nothing could be done to change it. The task was always likely to be stressful but part of the reason it was a problem was a sense of hopelessness and lack of support for staff. The intervention addressed this. The staff regarded it as a success and they were able to realize their wish of continuing to care for L.

39.3.3.2 CASE 2

P, 84 years, lived in an excellent nursing home. She scored 7 on the MMSE and was graded in the severe range on the CDR. She was referred for barging into other resident's rooms and 'tidying up', including stripping or making beds still occupied by other residents. Fights and confrontations were common. Family history showed that she had always been a busy well-organized person, and somewhat bossy. P was easy to move on in the morning but became increasingly disturbed as the day progressed, physically resisting or directly assaulting staff trying to redirect her. Escalation of her behaviour through the day was put down to 'sundowning', a syndrome like many others in dementia that simply labels a pattern of behaviour but does not explain it. Discussions with staff suggested that, if she could be induced to take a rest in the middle of the day, problems were minimal. Perusal of her medical notes revealed both a hip and knee reconstruction, and later in the day she could clearly be seen grimacing when using the affected leg.

The primary cause of the behaviour therefore was escalating pain, interacting with her premorbid character. However, because of cognitive impairment, it did not occur to P to rest; the worse the pain, the busier she became. She was only on analgesics 'as required'.

The intervention was systematic pharmacological and psychosocial pain relief. For the psychosocial component we

tried a bath in the middle of the day to relax her limbs but this created more problems than it solved because P had strong opinions on when one should be bathed. However, once they understood the cause and what was required, the staff developed their own intervention. This was to place a water chair in the staff room and invite P to their 'meeting' over the 2 hours when they took turns to have lunch. Exhausted, she would quickly fall asleep, often for more than an hour. The behaviour dropped from 8.4 room intrusions daily involving physical confrontation to 2.86 (Figure 39.1b). She was also easier to redirect. We were unable to obtain valid frequency data at 5-month follow up as P was bed-bound at that time and easily manageable but, once she was active again, the problem did not resume. Mean staff stress levels dropped from very high to the middle of the scale and senior staff downgraded problem severity from extreme to mild. There was no movement on the coping measure.

39.3.3.3 CASE 3

K was an 82-year-old woman of non-English speaking background who was causing major problems in a nursing home. She could no longer walk following a severe stroke and also because she had refused all physiotherapy. One member of staff was experiencing symptoms of post-traumatic stress disorder, including nightmares about K, and agency staff refused to come to the nursing home if they had to care for her. Because of language problems, she could not validly be tested with the MMSE. CDR assessment placed her in the mild range of cognitive impairment. She was referred for:

- violent resistance in personal care, especially dangerous because she was a very large woman, and staff had been injured transferring her to the shower trolley;
- pressing the buzzer and calling out hundreds of times a day;
- assaulting staff and other residents;
- refusing to let other residents be in her room, though she was in a shared room;
- having physical fights with her daughters, one at least of whom was in the nursing home from early morning to late at night;
- refusing to be attended by anybody other than the director of nursing or a current favourite;
- family aggressively and frequently demanding that someone do something for their mother.

Staff distress was manifested as fear, resentment and anger, frustration and helplessness. It was caused by a strong sense of duty of care, unawareness of their own rights, lack of knowledge about K, and lack of appreciation of the level of family guilt for not looking after their mother. The behaviour was caused by abdominal pain, anger that she was in the nursing home rather than being cared for by her family, fear in bed-to-commode or shower trolley transfers, feeling that she had lost control of all aspects of her life, family conflict whilst in the nursing home, and, possibly, depression.

The intervention was to, first, hold a meeting at which every staff member attended, including those off-duty, where we allowed them to air their considerable distress in a non-judgemental atmosphere. A consensus decision was taken about the limits of acceptable behaviour. Staff were also given a lot of information about K's remarkable life by two of her daughters, and we facilitated a discussion about how she might be feeling. We held a separate meeting with the family to discuss their concerns, establish rapport, and also to advise them that part of the intervention would involve them paying for a single room.

Thereafter, we devised a programme collaboratively with staff for each feature of her behaviour. For morning care, staff were not to struggle with K. If she resisted they were to make her safe and comfortable, and withdraw showing no anger and promising to come back when she felt better. They practised safe bed transfers with each other, and practised looking and sounding calm even if they did not feel it. When she did finally comply, they were to provide positive reinforcement in the form of effusive thanks and massage after the shower. When she called out and pressed the buzzer repeatedly, it was usually because she was in pain. Staff would go to her three times to relieve the pain as much as possible, then explain on the fourth visit that they could do no more, and would come back at an agreed interval. A staff member was delegated to be K's carer each shift so that the job was rotated. They were given count-down timers to ensure that they did attend her at roughly the agreed time. The buzzer was disconnected but registered on personal pagers carried by staff. K was given regular rather than as-required pain relief, and antidepressants were also tried, though they had no discernable effect. The family were advised that they could only attend between 11.00 and 17.00 hours. This clearly relieved them.

The intervention began formally on a specified day, and staff had access to telephone support for the first week thereafter. This was especially important for the first 2 days when K sat for several hours covered in faeces and urine but refusing to be showered. Figure 39.1c shows that, at 2-month follow up, time devoted to personal care of K had dropped from a mean of 7.3 staff hours a day to 4.8; at 5-month follow up it was 2.2 hours a day. This was still excessive but staff were extremely happy about their achievement. Staff stress associated with K dropped from the maximum to the middle of the scale, and the coping measure showed modest but consistent improvement. Senior staff downgraded problem severity from extreme to moderate. Occasional booster sessions were required for staff but K remained manageable until she died.

Most of this intervention addressed the causes both of staff distress and the behaviour. Putting K in a single room and ensuring that the family were not present when morning and evening care took place reduced factors that significantly exacerbated the problem. K learned that she could trust the staff to come at regular intervals and did not need to continuously press the buzzer or shout, and that it was in any case a waste of time doing so. Control of when she was showered and toileted was returned to her. Staff learned that they were

not alone in their feelings about K, and that they did not have to stay when being assaulted and shouted at, so they too were in control of the situation. They learned a lot more about K and were able to see her point of view, and respect her and be less angry. Anger on both sides was further reduced because relations between staff and K improved dramatically. This was partly because staff attended her at timed intervals rather than when they were exasperated or frightened, so they were calmer and interactions were less confrontational. Anger was also reduced by the massage, initially conceived as reinforcement for compliance. It is almost impossible to give or receive massage in an agitated state, and it became an important social interaction between K and staff, where they learned more about each other.

39.4 CONCLUSION

The multifactorial nature of behaviour problems, in aetiology and other contextual variables that determine treatment choice, make the *behaviour syndrome – standard treatment* model completely inappropriate for psychosocial interventions. It is probably not particularly useful for pharmacological approaches either. The development and evaluation of standard techniques, pharmacological and psychosocial, is important but only as a means of adding to the tool-kit from which the health worker can select the most appropriate combination of techniques after holistic assessment – not before it. Unfortunately, both clinical experience and the high rate of inappropriate prescribing for behaviour problems suggests that many clinicians think only of answers, often in a kind of scattergun approach. If enough pellets are fired, something may hit the target.

It is essential to go into a case with a bagful of questions before even beginning to consider what the answer may be. For a given behaviour in a given case, these answers will be selected from an astonishingly diverse range, entirely dependent on the information uncovered by assessment. For a screaming case, for example, the range might include but certainly not be restricted to:

- doing nothing about the behaviour and instead addressing carer issues;
- transferring the patient to a facility sensible enough to have a sound-proof room or installing double-glazing;
- changing rosters so that only certain nurses perform intimate personal care;
- transmitting soothing sounds through headphones;
- engaging a volunteer to sit holding the patient's hand;
- or adjusting medication, for example rationalizing polypharmacy or prescribing antidepressants, analgesics or antipsychotics.

So, psychosocial and pharmacological approaches are not mutually exclusive; both need to form part of the tool-kit.

The relationship between them is not one of competition. According to the conceptualization presented in this chapter, recommendations to always use psychosocial methods first (e.g. Peisah and Brodaty, 1994; Herrmann, 2001) are incorrect, and are in any case infinitely more honoured in the breach than the observance. Studies such as the randomized controlled trial of Teri *et al.* (2000), where antipsychotics, antidepressants, and behavioural treatment were compared for treatment of challenging behaviour, though methodologically sound, are asking the wrong questions. The question is not whether one treatment is superior to the other. The question is: what combination of methods, psychosocial and/or pharmacological, which can realistically be implemented on the ground, will best address the causes of the referred problem – including why it is a problem.

Trials for such a conceptualization, where there is no easily labelled syndrome based on the behaviour and no easily identified standard treatment, require development of methodologies that fit the phenomena. Trials where a standard treatment is applied to a diffuse range of behaviours labelled as 'agitation', though they have merit in adding the therapeutic tool-kit, may be regarded as an example of making the phenomena fit the methodology.

Results of studies that have grappled with this issue and applied and measured case-specific interventions (e.g. Hinchliffe *et al.*, 1995; Bird *et al.*, 2002; Opie *et al.*, 2002) do, however, beg the question as to why there is such an imbalance in favour of psychopharmacology, in particular antipsychotics. In our trial, we used a predominantly psychosocial approach directed at causality, and obtained equivalent reductions in behaviour and carer/staff distress at no more time per case, and less costs in medications, side effects, and hospitalizations, than a group where treatment was primarily pharmacological and directed at the behaviour (Bird *et al.*, 2002).

Although there has been some decline in antipsychotic use in the USA (Svarstad *et al.*, 2001) following publication of the Beers criteria (Beers, 1997) and legislation to enforce them, the predominant use of antipsychotics for challenging behaviours in dementia continues (e.g. Dhalla *et al.*, 2002; Sloane *et al.*, 2002; van Reekum *et al.*, 2002). This is despite abundant evidence of only moderate efficacy at best, high risks of side effects (e.g. Lanctot *et al.*, 1998; Katona, 2001), and risks of missing pharmacologically treatable causes of behaviour such as pain, infections or depression (Nygaard *et al.*, 1994; Peisah and Brodaty, 1994; Elmståhl *et al.*, 1998; Menon *et al.*, 2001). In some cases, antipsychotics may be the treatment of choice, for example where hallucinations are causing distress and neuroleptic malignant syndrome is not present, or where there is simply no other alternative.

Usually, however, there are alternatives and they are much more likely to be visible when the clinician looks beyond the behaviour to its causes. When there is a focus on causality, psychosocial methods are much more likely to come into play. Unfortunately, despite frequent calls for more research into psychosocial alternatives or adjuncts to psychopharmacology

for behaviour problems in dementia (e.g. Teri *et al.*, 2000; Herrmann, 2001; Margallo-Lana *et al.*, 2001), the research effort remains fragmented. It is largely undertaken by a finite number of enthusiasts around the world, largely dependent upon charitable and government grants because, by definition, psychosocial research is never going to be funded by the pharmaceutical industry.

APPENDIX

Examples of psychosocial methods used in a case series ($n = 44$) where they were the primary modality (Bird *et al.*, 2002). Seventy-five per cent of interventions took place in residential care facilities and, for most cases, several methods were combined:

A. Working primarily with carers/nurses (categories in order of frequency of use)

- 1) *Changing nursing care practices to fit the problem*
Examples: Increasing sensitivity in intimate personal care; letting patient sleep to natural waking time; not waking patient at night even when wet; structured patient-specific activity at key times; selection of a 'specialized team' for care of certain patients.
- 2) *Attitude change*
Examples: Presentation of the patient as a person as well as a problem (often includes history and accomplishments); education in the fact that behaviour usually has identifiable causes, and what those causes might be in this particular case; reframing behaviour in the context of the disease.
- 3) *Education in basic dementia care skills*
Examples: Going with the flow wherever possible and avoiding confrontation and logic; minimizing abrupt or noisy approaches to the patient; 'going slow is quicker'; planning excursions ahead (including location and appropriateness of public toilets), learning to read signs of patient emotional arousal
- 4) *Changing the physical or social environment (other than changing carer practices)*
Examples: Restricting means to undertake the behaviour; decreasing social interaction at known trouble times (e.g. meals); hiding or restricting access to cues that precipitate the behaviour; music at strategic times.
- 5) *Support*
Examples: Supportive counselling, cognitive-behavioural therapy, or referral to carer agencies to do this; listening to and validating care staff distress; validation what carers/care staff are already doing; showing carers/care staff that they have rights too.
- 6) *Others*
Examples: Differential reinforcement (only three stroke-related cases; not normally effective in dementia); personal electronic sensor to alert staff that a patient has wandered; negotiating limits for a family where visits are exacerbating the behaviour.

B. Working with the patient direct

- 1) *Dealing with physiological precipitants of behaviour*
Examples: Managing physical discomfort (especially pain) more systematically; close monitoring of fluid intake and prompt response to urinary tract infections; reducing patient's alcohol intake.
- 2) *Using spared memory*
 Using spaced retrieval and fading cues to teach patient to associate tangible cues with desired behaviour; having only toilet lit at night and all other doors closed.
- 3) *Direct negotiation and discussion of issues with patient*
 Three cases only of mild impairment, but backed up by simple large-print letter to be read repeatedly by patient and carer and/or large-letter cue cards in strategic places (e.g. back of toilet door).

Psychological approaches for the management of cognitive impairment in Alzheimer's disease

ANNE UNKENSTEIN

40.1 Factors influencing management of cognitive impairment in Alzheimer's disease	510	40.5 Middle stage – working with carers	513
40.2 Assessment	511	40.6 Later stage – environmental adaptation	513
40.3 Feedback	511	40.7 Conclusion	514
40.4 Early stage – memory strategies	511	References	514

There is currently no curative medical treatment available to reverse the cognitive impairment that occurs in Alzheimer's disease (AD). A psychological approach aims to promote the best possible quality of life for both people with AD and their carers, by offering positive, individualized and effective management. With the growing emphasis on early diagnosis of dementia, there are increasing opportunities to provide psychological interventions from the earliest stages of AD. This chapter outlines factors influencing the choice of practical management strategies, discusses assessment and feedback and describes specific techniques for managing cognitive impairment in the early, middle and late stages of AD.

40.1 FACTORS INFLUENCING MANAGEMENT OF COGNITIVE IMPAIRMENT IN ALZHEIMER'S DISEASE

Each person who has AD is unique. The way the person presents results from a complex interaction of brain disease, personality, biography, health and social psychology (Kitwood, 1993). Each person needs to be treated as an individual. An approach that might prove successful for one person may prove ineffective for another (Woods and Bird, 1999). There is no single correct approach to the management of cognitive impairment in AD. The help that is relevant can vary considerably.

There is a great deal of variation in cognitive function in AD according to the stage of dementia and different patterns of brain pathology. AD does not necessarily imply global

impairment of brain function. There will nearly always be some retained abilities. It is important to identify these cognitive strengths and use them positively. Interventions can draw on retained skills in order to bypass weaknesses.

Cognitive impairment is just one aspect of AD. People with this disease also experience changes in behaviour, emotional control, personality and self-care. These changes need to be taken into account when working on strategies for cognitive impairment. A team approach with agreement about realistic goals and consistent strategies is recommended. Carers need to be included in management planning. Wherever the person with AD lives, carers will be involved. They may be relatives, friends, neighbours or health professionals.

Not all of the person's symptoms are directly due to brain disease. People with AD are very sensitive to their physical and psychological environment. The first diagnosis of dementia is often made when a person experiences a change to his/her usual environment such as the death of a spouse or moving to a new house. It is important to be aware of environmental factors that can be altered in order to enhance cognitive function.

Health factors can exacerbate any cognitive impairment. Sensory impairment, especially of vision and hearing, can adversely affect cognitive function. People with AD commonly experience anxiety, distress and depression. Confusion can also be increased during acute or chronic illness and with any physical discomfort or pain. Alcohol, some medications and fatigue may cause transient exaggeration of cognitive impairment (Robinson *et al.*, 2001). It is necessary to be alert to any superimposed health problems and to control these to help people maintain maximum function.

Progressive decline in cognitive function is characteristic of AD. Management strategies need to be flexible and adapted over time. Assessment at regular intervals will allow for the development of realistic expectations. The aim of any strategies employed is to maintain as high a level of function as possible by helping the individual to better utilize remaining function.

40.2 ASSESSMENT

A thorough assessment is required in order to design an individualized approach to management of cognitive impairment. This should include assessment of the person's medical and psychological status and assessment of cognition. Assessment of the person's health is important, as there may be additional treatable medical conditions.

It is beneficial to interview the carers to gain information about the person's personality, interests, home environment and the history of events leading up to the assessment. Information about strategies that the carers have already tried and their willingness to provide support can also be gathered.

A neuropsychological assessment provides a basis for individual intervention. It allows for a focus on strengths by outlining abilities that remain unaffected, and also outlines areas of cognitive impairment to be managed. Serial neuropsychological assessment can be used to monitor progression of symptoms over time. It can provide an objective viewpoint to the carers and to the person with AD with regard to the progression of symptoms. Part of the assessment is to check the attitude of the person to their symptoms, as this will influence choice of strategies.

The assessment phase will identify the problem but it is important to go beyond this phase for better management of cognitive impairment. It is beneficial to share the information gathered with the person with AD and the carers.

40.3 FEEDBACK

A feedback session following assessment can serve many purposes. It provides information about how the disease is affecting various aspects of cognitive function in order to improve understanding. Whilst it is important to acknowledge areas of loss, a positive approach can be maintained by highlighting what the person can still do.

The carers are often the people who provide ongoing management of the person with cognitive impairment. Feedback can empower carers by acknowledging the success they have had with strategies that they have already tried. It can also provide emotional support and practical help and assistance. Carers can access a great deal of general information about AD (e.g. Tappen 1997; Kuhn 2003). However, specific information that is more relevant to their particular situation can be provided in a feedback session.

Feedback can be given to carers alone or including the person with dementia where appropriate. A description of the person's cognitive strengths and weaknesses is given. This information is then used to help carers make sense of behaviour that otherwise would seem to suggest that the person is purposefully being annoying. For example, by outlining the different types of memory and how each is affected, it becomes easier to understand why a person can recall information from their remote past but not what was said two minutes ago. Furthermore, if carers know that the person has memory impairment they are more likely to understand why the person persistently repeats the same question or forgets to pass on a phone message. It can be reinforced that this is not something that is done deliberately. Behaviour is thus reinterpreted as related to brain disease and not purposeful or intended. This information is also useful when it comes to management of cognitive impairment. For example, if carers know that forgetfulness is due to memory loss from brain disease they are more likely to understand that the person is unlikely to learn by repetition. They are also more likely to use strategies that avoid reliance on intact memory ability.

A feedback session offers an opportunity to ask the person with dementia and the carers how the cognitive problems manifest themselves in everyday life. This information can be used to make strategies realistic and relevant to the life of the person with dementia (Wilson, 1995).

A written reminder of what was discussed during the feedback session can be useful. Both the person with dementia and the carers may forget what was discussed, especially if they are just coming to terms with the diagnosis.

An initial discussion of strategies to help manage cognitive impairment can be included in a feedback session. The types of strategies employed will vary according to the person's individual situation and the stage of AD.

40.4 EARLY STAGE – MEMORY STRATEGIES

In early stage AD the most significant cognitive impairment is in memory function. Impairment of new learning is most prominent, including acquisition and retention of new information. At this stage, people with AD may forget what you have just told them, forget where they have put something, repeat the same thing as if they haven't said it before or have difficulty learning how to use something new.

At this stage the person often remains aware of cognitive losses and may be motivated to seek methods to compensate for them. The person is usually living in the family home. Initial strategies therefore focus on the individual with increasing involvement of family carers over time. The aim is to maintain as much independence as possible. Family members and friends need to avoid taking over responsibilities too soon.

Many of the strategies that are used by people experiencing normal memory change with ageing are useful at this stage (see Sargeant and Unkenstein, 2001, for a detailed

description of memory strategies). It is important to ask people whether they are already using any memory aids before explaining the use of memory strategies. People should be encouraged to draw on strategies that they have used in the past. They will be more likely to use strategies if they are already familiar with them (Kotler-Cope and Camp, 1990). Everyone has different preferences. For instance, some people like to use diaries whilst others prefer a noticeboard.

People need not just one technique, but a whole range of strategies. It is important to find out the typical things a person tends to forget and work out some strategies that will suit these specific situations and be usable for that person. Strategy use will vary according to differing interests, lifestyles and home environments. A home visit is sometimes useful to help tailor strategies to particular situations.

The emphasis is on practical compensatory techniques rather than attempting to restore lost cognitive function by direct retraining. People with early AD and their relatives and friends often ask if repetitive practice is helpful. Attempting to relearn lost skills can unnecessarily confront the person with an experience of repeated failure and there is no evidence that specific training improves memory in general (Bird, 2000).

A more practical approach is to avoid challenging the person's lost memory function. For example, rather than asking a question that relies on intact memory function such as 'What show did you watch on television last night?', rephrase the question to 'Did you enjoy the show that you watched last night?' If people become repetitious it may be best to try distracting them with another topic of conversation. Enhancing familiarity is also beneficial. Developing a regular routine and doing things at a set time of the day or week will reduce the load on memory.

Memory strategies can be thought of as internal or external. Internal strategies involve some form of internal mental manipulation, for example, mentally retracing one's steps to remember where an object was left. External strategies involve using some sort of external aid, for example a note pad for writing a list, or a diary. They can also involve making changes to the environment, for instance, having designated locations in which to store particular items.

Internal strategies focus on enhancing encoding and retrieval processes. The emphasis is on making more efficient use of current cognitive capacity. A motivated individual may employ simple internal strategies in the early stage of AD. These strategies typically involve one of three main features: focusing attention, adding meaning to the information to be remembered, or reducing the amount of information to be remembered. Simple internal strategies such as ensuring understanding, associating new information with information that is known well and visualization may be useful for motivated individuals in the earliest stages of AD.

Internal strategies or mnemonic techniques can also be quite complex. Well known mnemonic techniques include the method of loci and peg word systems. These techniques require training and considerable remaining cognitive capacity including new learning and motivation for success.

Even in the early stage of AD, people usually do not have the motivation or learning ability required to use these techniques (Camp and McKittrick, 1992). More recently, researchers have investigated the use of other learning methods for those with AD. With specific training techniques it has been shown that people with AD can learn new information under certain conditions. See De Vreese *et al.* (2001) and Grandmaison and Simard (2003) for a review of the efficacy of memory stimulation in AD.

External strategies aim to compensate for memory impairment by reducing the demand on a person's memory. They are generally easier to use and more suitable for everyday remembering than internal strategies. They may involve written reminders, storage of objects in specially designated places, technical memory devices and reminders from other people.

Written reminders assist with remembering locations of objects, a task that has to be done, appointments, shopping items, messages, names and instructions. Calendars, diaries, notebooks, notepads, noticeboards, sticky notes and computers are all useful. Having a pen or pencil attached reduces the load on memory even further. Such written aids should not only be readily visible and accessible but should also be in close proximity to the to-be-remembered activity. For example, a shopping list pad on refrigerator door, or instructions for how to operate a piece of equipment permanently displayed on that equipment.

External memory strategies can assist with orientation in early stage AD. It is helpful to mark off the days as they pass on a calendar, or use a flip-top desk calendar and turn each day over as it passes. Newspapers can also serve as prompts. Clocks should be positioned in places where they are readily seen and ideally should have day and date built in.

Storing objects in specially designated places can help with remembering the location of objects, a task that has to be done or something to be taken out. For example, keys can be stored near the front door of the house. This makes it easy to pick up the keys when leaving the house and to get into the habit of putting them back when returning.

Leaving objects in visible locations can act as a reminder to do something. Medications can be left somewhere obvious in the kitchen if they are to be taken with meals. A special place near the front door, such as a hall table, can be used to put objects that are to be taken out with a person.

A useful storage device for managing medications is a dosette box. The box is divided into compartments that relate to the day of the week or time of the day into which a set number of tablets can be placed. The box has to be filled at weekly or other intervals, but it is simple to use and lets people know whether they have taken the necessary tablets.

Basic alarms are useful to help people remember something they have to do. A common example is an oven timer used as a reminder to turn the oven off. Many household objects have built in memory aids. For instance, many telephones have a system that enables storage of frequently used numbers that can then be dialled by pressing only one appropriately

labelled button. Automatic shut-off devices on electrical and gas appliances, such as stovetops, kettles or lights can be installed. These devices will turn the power off after a period of time if the appliances are left on accidentally. More complex electronic memory aids can be useful for motivated and insightful individuals but may require training to know how to operate them. They usually rely on other cognitive processes remaining intact and may not suit the person with even early AD.

Reminders from other people can provide an excellent memory back-up system. Family members can provide telephone reminders or leave notes in a regular and prominent location. Reminders need to be specific. For example, a note saying 'back in 5 minutes' does not provide enough information. The person with AD needs to know at what time the person will return (Twining, 1991).

40.5 MIDDLE STAGE – WORKING WITH CARERS

In middle stage AD people experience increasing memory loss, language difficulties and specific disorders such as apraxia. They may be unable to function independently outside the home and require increasing assistance with tasks of personal care. They could be living in their own home or supported accommodation. By this stage the person's insight into their cognitive losses usually has diminished.

With little awareness of their difficulties and increased cognitive impairment, it becomes difficult to work on strategies with the person with AD alone. The management of cognitive impairment therefore becomes focused on working in collaboration with family members or other carers. Carers know the person best and often come up with strategies that work well for that person. Carers can provide reminders for the person, encourage the person to use external memory aids and make appropriate changes to the environment. Without this assistance the person is unlikely to make use of memory strategies. By this stage strategies for other areas of cognitive impairment are also required. Providing support and information to the carers can help to further tailor strategies to make them suit the individual's current cognitive strengths and weaknesses.

Carers will need to become increasingly involved in the use of external memory strategies and can assist with setting up a designated 'memory centre' in a visible location in the home environment (Sargeant and Unkenstein, 2001). Here the carer could hang a whiteboard on which the day, date and daily schedule is written or a clock with the day and date on it. A pin board next to this can be used to display other important information. The carer may need to keep reminding the person to check the memory centre. Carers can also develop 'communication books'. For this a notebook is left in a special location where visitors can write messages. The person can be encouraged to check this book regularly as a reminder of who has visited recently.

These strategies are a form of reality orientation, an approach that emphasizes the use of external cues and structures to assist the person in maintaining contact with the environment (see Woods, 2002 and Spector *et al.*, 2000a for a review of reality orientation). An individual approach to reality orientation is required. Carers can help identify to which realities the person needs or desires to be oriented.

Carers can continue to encourage a regular routine of familiar activities. Sudden unexplained changes or unfamiliar activities could cause the person distress (Tappen, 1997). Carers can help the person focus on activities that are familiar and based on previous interests, such as gardening, walking the dog or other household tasks. Drawing on the continued strength of procedural and lifetime memories can provide meaningful activity. Carers at accommodation facilities can find out about the person's past likes, dislikes, lifestyle and life interests from family members. This information and any old photos available can be recorded in a book that can be used as a cue for discussion and reminiscence (see Spector *et al.*, 2000b for a review of reminiscence).

A familiar environment will reduce the demand on the person's memory. Unnecessary changes such as rearranging furniture should be avoided. If changes have to be made, they should be introduced slowly, with explanation.

Carers may need assistance with strategies for other areas of cognitive impairment. For example, the person at this stage may experience apraxia, an inability to carry out routine patterns of voluntary movement. A common problem caused by apraxia is difficulty with dressing. Helping the carer to understand that a person can sometimes dress automatically, but has difficulty when the movement comes under conscious control is useful. To remove the degree of voluntary focus from the action, avoid giving the person direct instructions about performing the task. Specific techniques include distracting the person's attention from the task, imitation, laying the clothes out in the order in which the person likes to put them on and giving reassurance and praise for each successful step. See Holden (1995) for strategies for other specific cognitive disorders.

40.6 LATER STAGE – ENVIRONMENTAL ADAPTATION

In the later stages of AD people experience marked confusion and widespread cognitive disturbance. Most people with this stage of AD are living in supported accommodation with professional carers. Strategies for management of cognitive impairment need to be focused more heavily on the environment in which the person is living. Adaptations are made to the environment rather than expecting the individual to change. Visiting the person's residence allows one to observe environmental cues, how they might best be used and/or changed and how new ones might be introduced (Kapur, 1995).

At this stage people become dependent on their environment to support them. Making adaptations to the environment

can enhance people's feelings of security and help them cope with their confusion and disorientation. When people first move into a new residence there is often a settling in period. An unfamiliar and new environment can increase confusion. It helps to make the environment as familiar as possible. Familiar possessions, such as photos, objects and furniture can be put in the person's room.

A routine and daily timetable should be emphasized. Orientation information or cues can lessen confusion. For example, having access to a window helps a person to tell the time of the day and the weather. A good sensory environment with adequate light is important. Making each part of a large place unique in some way is useful for orientation to the environment. Colour and furniture can highlight difference. Smaller spaces are less confusing than large.

Clear labelling throughout the accommodation facility can further lessen confusion. Direction can be marked on the floor or walls with coloured lines or arrows. Individual rooms can be clearly labelled. Large uppercase print with black against white is often best for older people (Kapur, 1995). Pictures may be more easily understood than written labels. For example, a picture of a toilet on the toilet doors. Carers can wear name badges, with their first name only, that are large enough to read. People will require continued instruction as to how to use these orientation aids.

To maximize cognitive function it helps to simplify the environment to avoid the person becoming overwhelmed. If there is excessive stimulation then confusion may be exacerbated. It helps to remove distractions, keep noise levels down and not have too many people around (Robinson *et al.*, 2001).

It is often difficult to communicate with the individual with this stage of dementia. Using an empathic, validating approach that displays respect and sensitivity to feelings can help to ensure understanding.

40.7 CONCLUSION

Better management of cognitive impairment in AD using a psychological approach is just one part of the challenge to maintain maximum function throughout the course of the illness (Kitwood, 1993). For any symptom of the disease, the first step involves investigating what may be causing the person to present in that particular way. Multidisciplinary assessment will establish whether there are any environmental factors that can be altered or health factors that can be treated in order to enhance the individual's function. Effective management strategies that are relevant to the stage of AD and other individual variables can be developed using a collaborative approach involving the person with dementia, carers and health professionals.

Prevention of Alzheimer's disease

NITIN B PURANDARE, CLIVE BALLARD AND ALISTAIR BURNS

41.1 Control of risk factors for cerebrovascular disease	515	41.5 Target populations	520
41.2 Control of subclinical inflammatory processes	518	41.6 Conclusion	520
41.3 Control of oxidative stress and free radicals	519	References	520
41.4 Improving functional neuronal capacity	519		

Primary prevention of Alzheimer's disease (AD) is the ultimate goal of therapeutic intervention. The prevalence of dementia would be reduced by 50 per cent if risk reduction strategies were successful in delaying the onset of dementia by 5 years (Jorm *et al.*, 1987). Our selective review focuses on four key areas that are particularly amenable to therapeutic intervention: control of risk factors for cerebrovascular disease, anti-inflammatory drugs, anti-oxidants, and increasing functional neuronal capacity.

41.1 CONTROL OF RISK FACTORS FOR CEREBROVASCULAR DISEASE

41.1.1 Hypertension

41.1.1.1 EPIDEMIOLOGICAL EVIDENCE

Epidemiological studies have established hypertension in mid-life (systolic and diastolic) as a risk factor for AD and vascular dementia (VaD) in later life (Guo *et al.*, 2001; Peila *et al.*, 2001, Murray *et al.*, 2002). The Honolulu Asia Aging Study (HAAS) followed over 3500 Japanese-American men over 25 years, and found hypertension to increase the risk of dementia by 4–5-fold in those who were never treated with antihypertensives. The risk was greatest in those with systolic hypertension and apolipoprotein E (ApoE) ϵ 4-allele after controlling for other risk factors (odds ratio, OR = 13.0) (Peila *et al.*, 2001). In HAAS the OR for dementia in patients with systolic hypertension and ApoE ϵ 4 decreased from 13.0 to 1.9 in those receiving antihypertensives. Murray *et al.* (2002) followed 1900 African-Americans over 5 years and found use of antihypertensives to be associated with 38 per cent (OR = 0.62) reduction in incident AD and VaD.

41.1.1.2 RANDOMIZED CONTROLLED TRIALS

Six randomized controlled trials (RCTs) of antihypertensives have been published with cognition and or dementia as one of the outcomes (see Table 41.1). Earlier trials using diuretics or beta-blockers did not demonstrate a lower risk of incident dementia (Applegate *et al.*, 1994; Prince *et al.*, 1996). The results of more recent trials using calcium channel blockers (Syst-Eur trial: Forette *et al.*, 1998 and 2002) or angiotensin-converting enzyme (ACE) inhibitors (HOPE trial: Bosch *et al.*, 2002; PROGRESS trial: Tzourio *et al.*, 2003) have been mixed but more encouraging. The Syst-Eur trial (Forette *et al.*, 1998) reported that nitrendipine (calcium channel blocker) reduced the risk of AD by 50 per cent over 2 years. The PROGRESS (2003) trial, which included both normotensive and hypertensive patients with previous history of cerebrovascular disease, found a significant reduction in stroke related dementia in patients treated with perindopril (ACE inhibitor) as the main antihypertensive. The SCOPE trial (Lithell *et al.*, 2003) included a much older (70–89 years) patient group and excluded those with stroke or myocardial infarction in previous 6 months. Candesartan (angiotensin II type 1 [AT1] receptor blocker) was not found to have any positive effect on progression of cognitive impairment over 3.7 years. However, antihypertensives were used in 84 per cent of the controls and the mean blood pressure difference achieved between active and placebo groups was very small.

The statistical power of these studies is limited by the low incident risk of dementia in these studies because of the young age and modest study durations. In all RCTs, incident dementia has been a secondary outcome, heart disease or stroke being the primary outcomes, and generally brief assessment instruments lacking sensitivity to subtle changes have been employed. Also, epidemiological evidence suggests that the time lapse between diagnosis of hypertension and

Table 41.1 Effect of antihypertensive treatment on cognitive function and dementia

Randomized controlled trials	Sample size	Participants (characteristics, age in years)	Duration	Treatment	Impact on dementia or cognition
Forette <i>et al.</i> , 1998 (Syst-Eur)	2418	>60 systolic hypertension	2 years	Nitrendipine	50% reduction in the incidence of dementia (7.7 to 3.8 cases per 1000 patient-years, $P = 0.05$)
Forette <i>et al.</i> , 2002 (Extended follow-up of Syst-Eur)	2902	>60 systolic hypertension	3.9 years	Nitrendipine, enalapril maleate, hydrochlorothiazide	55% reduction in the risk of dementia (7.4 to 3.3 cases per 1000 patient-years, $P < 0.001$)
Applegate <i>et al.</i> , 1994 (Systolic Hypertension in the Elderly)	2034	>60 systolic hypertension	5 years	Chlorthalidone	No significant impact of cognition or incident dementia
Prince <i>et al.</i> , 1996 (MRC Older people with HT)	2584	65–74 systolic BP: 160–209 mmHg	4.5 years	Atenolol, hydrochlorothiazide, amiloride	No significant impact on cognition or incident dementia
Bosch <i>et al.</i> , 2002 (HOPE)	9297	>55 left ventricular dysfunction	4.5 years	Ramipril, vitamin E	Significantly better outcome with respect to cognition and function
The PROGRESS Collaborative Group (Tzourio <i>et al.</i> , 2003)	6105	mean age 64; stroke or TIA with and without hypertension	4 years	Perindopril, indapamide	Significant reduction in cognitive decline and incident dementia associated with recurrent stroke
Lithell <i>et al.</i> , 2003 (SCOPE)	4964	70–89 systolic and or diastolic hypertension	3.7 years	Candesartan (antihypertensive used in 84% of controls)	No difference on progression of cognitive impairment

onset of dementia can be over 15 years, and it is not known whether the protective effect of starting antihypertensives on incident dementia extends throughout this period.

The treatment issues may be slightly different in established VaD. One study has indicated that maintaining systolic blood pressure (BP) within upper limits of normal (135–150 mmHg) was more beneficial in preserving cognitive functions than reducing systolic BP below this level (Meyer *et al.*, 1986). Another issue which needs further clarification is whether the risk reduction is related to actual reduction in the BP and/or some other neuroprotective action of the individual hypertensive, such as calcium channel antagonists, ACE inhibitors or AT1 receptor blockers. In animal studies, angiotensin II has been shown to inhibit acetylcholine release while AT1 receptor blockers improve cognitive performance (Barnes *et al.*, 1989; Fogari *et al.*, 2003).

41.1.2 Hypercholesterolaemia

41.1.2.1 BIOLOGICAL BASIS FOR IMPORTANCE IN PREVENTION OF AD

Hypercholesterolaemia, especially increased low density lipoproteins, is a known risk factor for coronary heart disease,

atherosclerosis and stroke, which are all associated with increased risk of dementia. The ApoE $\epsilon 4$ allele affects stabilization of membrane lipoproteins and is a risk factor for hypercholesterolaemia, as well as AD. Lowering of cholesterol promotes the non-amyloidogenic α -secretase pathway (Kojro *et al.*, 2001). Statins reduce cholesterol levels by inhibiting the enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA). In addition, statins have an antioxidant action, they decrease pro-inflammatory process and improve cerebral blood flow. Lovastatin was shown to reduce amyloid beta protein 42 ($A\beta_{42}$) in cultured hippocampal neurones (Simons *et al.*, 1998) and simvastatin had a similar effect in cerebrospinal fluid (CSF) and brain tissue of guineapigs (Fassbender *et al.*, 2001).

41.1.2.2 CLINICAL EVIDENCE

A number of case-control and epidemiological studies have reported hypercholesterolaemia as a risk factor for dementia, including AD. For example, Moroney *et al.* (1999) followed over 2000 older people in New York City over 2 years and found those with cholesterol levels in the highest quartile to be at increased risk of dementia, especially VaD (OR = 3–4) compared with those in the lowest quartile. A similar sized study but with much longer follow up (21 years), from eastern Finland, reported that raised cholesterol in mid life

(>6.5 mmol/L) to more than double the risk of dementia, including AD, independently of other risk factors such as hypertension and ApoE ϵ 4 (Kivipelto *et al.*, 2002).

There are some important inconsistencies in the epidemiological evidence. For example, some studies have found risk reduction with lipid lowering agents (LLAs) in general, while others suggest the risk reduction to be more specifically associated with use of statins. A recent meta-analysis of seven observational studies indicated risk reduction in cognitive impairment to be significant for only statins (OR = 0.43) and not other LLAs (Etminan *et al.*, 2003). Other inconsistencies may relate to differential effect in certain age groups (statins and lower risk of AD in those <80 years, Rockwood *et al.*, 2002) and specific actions of individual statins. For example, simvastatin acts directly on processing of amyloid precursor protein (APP) by inhibiting both α - and β -secretase (Sjogren *et al.*, 2003).

The results of intervention trials, with cognition as one of the many secondary outcomes, have been disappointing. MRC/BHF Heart Protection Study (Heart Protection Study Collaborative Group, 2002), comparing simvastatin versus placebo, found simvastatin to reduce the risk of major vascular events by one-third. The study examined a potential effect on cognition using a modification of the Telephone Interview for Cognitive Status (TICS). There was no difference between two groups in either proportion of patients scoring below the cut-off of 22 out of 39 or in the mean TICS score. The PROSPER study (Shepherd *et al.*, 2002), an RCT of pravastatin (n = 2891) versus placebo (n = 2913) over 3 years, found pravastatin to significantly reduce mortality from coronary disease but to have no effect on cognition. The statistical power of both studies was limited by the low incident dementia in study subjects (0.3 per cent in active or placebo group in the Heart Protection Study).

41.1.3 Elevated homocysteine

Plasma or serum homocysteine, or total homocysteine (tHcy), refers to the sum of the sulfhydryl amino acid homocysteine and the homocysteinyl moieties of the disulfides homocysteine and homocystein-cysteine, whether free or bound to plasma proteins. A number of factors such as age, diet, vitamin B₁₂ and folate, plasma albumin, use of diuretics and renal function influence homocysteine levels in the blood. Elevated tHcy may lead to an excessive production of homocysteic acid and cysteine sulfinic acid, which act as endogenous agonists of NMDA receptors. In addition to this excitotoxic effect, homocysteine is also known to cause damage to vascular endothelium.

41.1.3.1 PREVALENCE AND IMPORTANCE IN CVD

Elevated tHcy is found in 61 per cent of hospitalized older patients (Ventura *et al.*, 2001). Gottfries *et al.* (2001) identified elevated tHcy in 31 per cent of patients with mild cognitive impairment (MCI), 45 per cent of patients with AD, and 62 per cent of patients with VaD. Elevated tHcy is known to increase the risk of coronary artery disease, peripheral vascular

disease, and cerebrovascular disease. Elevated tHcy is also associated with increased risk of silent brain infarcts and white matter lesions (Vermeer *et al.*, 2002). A case-control study from Northern Ireland, reported moderately high tHcy levels to be associated with stroke, VaD and AD, independent of vascular risk factors and nutritional status (McIlroy *et al.*, 2002). A meta-analysis from Homocysteine Studies Collaboration group (2002), which included individual participant data from 30 prospective or retrospective studies, indicated that after adjusting for known cardiovascular risk factors low tHcy levels ($3.0 \pm 0.41 \mu\text{mol/L}$) were associated with 11 per cent lower risk of ischaemic heart disease and 19 per cent lower risk of stroke.

41.1.3.2 ROLE IN COGNITION AND AD

In older people without dementia, elevated tHcy is associated with more subtle cognitive impairment. Dufouil *et al.* (2003) followed up 1241 subjects aged 61–73 years over 4 years and found higher concentrations of tHcy to be associated with poor performance on all neuropsychological tests with the odds of cognitive decline 2.8-fold ($P < 0.05$) higher in subjects with tHcy levels above $15 \mu\text{mol/L}$ compared with those with levels below $10 \mu\text{mol/L}$. Fasting tHcy levels were shown to predict cognitive decline in a follow-up study of 32 healthy elderly people over 5 years ($P < 0.001$), especially word recall, orientation and special copying skills (McCaddon *et al.*, 2001). Case-control studies have shown elevated tHcy to be associated with AD after adjusting for age, sex, nutritional status and ApoE ϵ 4 allele (Clarke *et al.*, 1998). A large epidemiological study in Framingham, USA, involving 1092 older residents in the community (mean age 76 years, median follow up 8 years) reported that the risk of AD nearly doubled (relative risk, RR 1.8; confidence intervals, CI 1.3–2.5) with one standard deviation increase in tHcy levels at baseline (Seshadri *et al.*, 2002).

41.1.3.3 CAN LOWERING HOMOCYSTEINE PREVENT COGNITIVE DECLINE?

Although elevated tHcy has been shown to be associated with cognitive impairment in AD, the effect of reducing homocysteine levels on cognition and global functioning has not been adequately investigated. In a small prospective study involving 33 patients, Nilsson *et al.* (2001) reported an improvement in cognitive function after 2 months of cobalamin (B₁₂) and folate treatment in individuals with mild to moderate dementia who had elevated tHcy. Patients with severe dementia and those who had normal tHcy did not, however, show clinical improvement.

Intervention trials to lower homocysteine levels need to consider three things:

- first, whether to target people with tHcy levels in the highest quartile of local population or use an arbitrary cut-off of such as $> 15 \mu\text{mol/L}$;
- second, the best treatment combination to lower tHcy from various forms of B₁₂ and folate needs to be

determined, also considering merits of additional nutrients such as n-acetyl cysteine;

- third, a better understanding is required of factors affecting tHcy levels and their response to vitamin supplementation. Age, plasma albumin, use of diuretics and renal function are just some of them (Ventura *et al.*, 2001).

C677T mutation of methylenetetrahydrofolate reductase (MTHFR) gene, present in about one-fifth of people with AD, may be yet another important factor that affecting treatment response. MTHFR acts as a methyl donor for homocysteine methylation and hence reduces homocysteine levels. C677T mutation is common in the Caucasian population (30 per cent), which results in lower MTHFR activity and elevated tHcy (Bottiglieri *et al.*, 2001; Frosst *et al.*, 1995).

41.1.4 Other cardiovascular risk factors

Diabetes, carotid atherosclerosis, heart disease and smoking are risk factors for stroke, VaD and AD. Their control reduces the occurrence of cerebrovascular disease and one would expect a similar risk reduction in AD, but so far there is no RCT. Nonetheless, understanding underlying pathophysiological mechanisms may open new avenues for prevention. For example, mutations in insulin degrading enzyme (IDE) that induce diabetes, also impair degradation of β -amyloid (Farris *et al.*, 2004). Similarly, spontaneous cerebral microemboli (SCE), common in carotid disease but thought to be asymptomatic, have been associated with cognitive impairment following carotid and heart bypass surgery. We examined the frequency of SCE in AD and VaD by transcranial Doppler monitoring of middle cerebral arteries over 1 hour. Among 85 AD-control and 85 VaD-control pairs, we found SCE in 37–38 per cent of patients with AD or VaD compared with 13–14 per cent of their controls ($P < 0.001$; Purandare *et al.*, 2003). SCE are potentially treatable and if they are found to be predictive of cognitive decline then they could be a target in prevention of dementia, both AD and VaD.

Yet another example would be smoking. Whilst smoking overall appears to be associated with a doubling of the risk of AD (presumably because of cardiovascular factors), nicotine itself may have neuroprotective properties and possibly reduce amyloid burden (Nordberg *et al.*, 2002).

41.2 CONTROL OF SUBCLINICAL INFLAMMATORY PROCESSES

41.2.1 Biological basis

The importance of inflammatory processes in causation of dementia is established with evidence from biochemical, neuropathological and epidemiological studies. Primary inflammatory cytokines such as interleukins 1 β (IL-1 β), IL-6, and α 2-macroglobulin are increased in brains of

patients with AD. The neuropathological features of AD include accumulation of microglia and astrocytes around senile plaques. Both express HLA antigens and are involved in activation of the complement cascade. These inflammatory changes are thought to lead to further amyloid deposition and neuronal damage.

Non-steroidal anti-inflammatory drugs (NSAIDs) differ in their mechanisms of action and as yet we do not know the mechanism that is most important in offering neuroprotection in AD. Traditional NSAIDs such as ibuprofen, indomethacin affect both cyclo-oxygenases (Cox-1 and Cox-2). Newer NSAID such as celecoxib and rofecoxib specifically inhibit Cox-2 and hence have less propensity to cause gastrointestinal side effects. Cox-1 is prominent in CA-1 of hippocampus and is involved in microglial activation surrounding senile plaques. Cox-2 is prominent in dendrites of pyramidal neurones and is increased in many areas of brains in AD. Cox-2 levels correlate with A β -amyloid levels in the AD brains. Cox-2 is required in neurones with NMDA receptors responsible for glutamate-induced excitotoxicity in AD. NSAIDs also exhibit actions other than suppression of inflammation. NSAIDs inhibit Cox in platelets (resulting in reduced platelet aggregation and reduced A β -amyloid in blood) and in vascular endothelium (protecting the endothelium from free radicals). The importance of non-inflammatory actions of NSAIDs is highlighted by observations that both 'low' and 'high' doses offer neuroprotection. It is also possible that some NSAIDs influence amyloid deposition by inhibiting γ -secretase, independent of cyclo-oxygenase activity (Weggen *et al.*, 2001).

41.2.2 Clinical evidence

A number of epidemiological studies have shown long-term use of NSAIDs to be associated with 2–4-fold reduced risk of AD, but some have been inconclusive (McGeer *et al.*, 1996). A more recent systematic review and meta-analysis of nine observational studies concluded that NSAIDs do offer some protection against AD (Etminan *et al.*, 2003). In't Veld *et al.* (2001) suggest that the conflicting evidence may be related to inaccurate recording and reliance on patients'/relatives' memory or incomplete medical records. They examined computerized pharmacy records in the follow-up study of almost 7000 residents of Rotterdam over 7 years. NSAIDs were associated with reduced risk of AD depending on the duration of the use (<1 month: RR 0.95; 1–24 months: RR 0.83; >24 months: RR 0.20). Zandi and Breitner (2001) suggest that to be protective in AD, NSAIDs would need to be taken several years before the disease onset, and secondary or tertiary prevention trials were unlikely to show a positive effect. This is in keeping with a very modest effect observed in RCTs of low-dose prednisone and NSAIDs in AD, including a recent trial of rofecoxib (Cox-2 inhibitor) or naproxen versus placebo with negative results (Aisen *et al.*, 2000, 2003). The results of the Alzheimer's Disease Anti-inflammatory

Prevention Trial (ADAPT) should be interesting as it is examining efficacy of celecoxib and naproxen in older people (over 70s with family history of AD), and is attempting to exclude people with prodromal AD.

41.3 CONTROL OF OXIDATIVE STRESS AND FREE RADICALS

41.3.1 Biological basis

Oxidative stress can cause lipoprotein oxidation, A β polymerization and generation of excessive free radicals. *In vitro* studies suggest that ApoE ϵ 4 reduces anti-oxidant capacity of neurones. Vitamins E and C along with alcohol (in moderation) scavenge these free radicals.

41.3.2 Clinical evidence

A number of epidemiological studies have found higher dietary intake of vitamins E and C, and moderate alcohol consumption to lower risk of dementia. In the Rotterdam study (Ruitenberg *et al.*, 2002), which followed over 5000 people for an average 6 years, a moderate alcohol consumption (1–3 drinks per day) was associated with reduced risk of dementia including both AD and VaD (hazards ratio, HR 0.58). Orgogozo *et al.* (1997) found 250–500 mL daily consumption of wine to reduce risk of dementia even further (OR 0.19). Additional studies are needed to examine the effect of type of alcohol on risk reduction, as micronutrients in red wine, especially resveratrol, may offer specific protection against β -amyloid toxicity, an effect also observed with green tea extracts and curry spice, curcumin.

There are no specific clinical trials examining the prevention of dementia with anti-oxidants. The key RCT, in which 341 patients with moderate to severe AD were randomized to receive selegiline (monoamine oxidase inhibitor) and vitamin E (either alone or in combination) or placebo found all active treatments, including vitamin E alone, to slow progression of AD over 2 years, as measured by time to occurrence of death, institutionalization, loss of ability to perform basic activities of daily living or severe dementia, but with no effect specifically on cognition (Sano *et al.*, 1997).

41.4 IMPROVING FUNCTIONAL NEURONAL CAPACITY

41.4.1 Role of cognitive, physical and social activities

A number of cross-sectional and retrospective studies have found an inverse relationship between activities (cognitive, physical or leisure) in mid-life and latter risk of dementia.

The repetition of cognitive skills may improve processing skills such as working memory and perceptual speed by possibly increasing dendritic plasticity. Physical exercise can increase insulin-like growth factor (IGF-1) and somatostatin levels, which are decreased in AD. IGF-1 has been shown to reduce tau phosphorylation and have an anti-apoptotic effect. In experiments on rats, environmental enrichment has been shown to inhibit spontaneous apoptosis, increase neurogenesis in dentate gyrus and improve spatial memory (Nilsson *et al.*, 1999; Young *et al.*, 1999). This may suggest a possible link between environment/social stimulation and regenerative brain processes.

41.4.2 Clinical evidence

There are no RCTs, but four large observational studies have shown reduced activities as an independent risk factor for AD. Wilson *et al.* (2002) followed 801 older clergy over 4 years and found 111 developed AD. They recorded seven common activities involving information processing as a core component (e.g. reading, watching TV, doing crosswords, etc.). The frequency of each activity was rated on a 5-point scale (1 = once a year, 5 = everyday) and responses to each item averaged to calculate a composite score (range: 1–5). The authors in their previous work had shown this to be a reliable method compared with differential weighing of each item depending on the perceived cognitive demand. After controlling for age, sex and education, a 1-point increase in cognitive activity was associated with 33 per cent reduction in risk of AD (HR 0.67). The epidemiological evidence for physical activity in prevention of dementia is mixed. Wilson *et al.* (2002) and Verghese *et al.* (2003) suggested that risk reduction was specifically due to cognitively stimulating activities. Friedland *et al.* (2001) found that reduced activity (intellectual, passive or physical) in mid-life increased the risk of developing AD by 250 per cent. The mixed results could be partly explained by how each study divided activities into physical, cognitive or social. For example, ‘dancing’ (Verghese *et al.*, 2003) or ‘going to museum’ (Wilson *et al.*, 2002) often included as cognitive activities include a strong physical component. Activities, either cognitive or physical, often include social aspects and are done as leisure activities. The social aspect of the activities or rich social network itself may be beneficial in reducing risk of dementia. Wang *et al.* (2002) in their analysis of the Kungsholmen project found that engagement in stimulating activities (mental, social or productive) reduced the risk of developing dementia over 6 years by 50 per cent (RR 0.54–0.58).

However, care has to be taken with interpretation of these studies as activities may be a proxy to some other factors such as education, socioeconomic status and generally healthy lifestyle. Although reduced activities have been shown to exist many years prior to onset of dementia, one cannot completely rule out the possibility of a prolonged prodrome.

41.5 TARGET POPULATIONS

Many of the risk factors for AD and the beginning of losses in key neuronal receptor systems (Perry *et al.*, 2001) come into play in mid-life, 15 to 20 years prior to onset of AD. This would suggest targeting prevention strategies at people with risk factors in their mid-life, who may not have any identifiable cognitive impairment. The economics of such trials make them impractical, due to low incident dementia and prolonged follow up over two decades. Identification of surrogate markers of subclinical disease progression is crucial for their viability.

Another approach would be to target older people who have developed some cognitive impairment but which is not severe enough to cause functional impairment and warrant diagnosis of dementia. A somewhat loose and controversial term 'mild cognitive impairment' (MCI) is most widely used to describe this population, which has community prevalence of 17–34 per cent with annual 'conversion' to dementia of between 3 and 15 per cent depending upon the population (Burns and Zaudig, 2002). Mild 'vascular cognitive impairment' (mVCI), which describes people with early cognitive impairment related to cerebrovascular disease, may be a more specific target owing to importance of vascular risk factors in causation of AD.

41.6 CONCLUSION

The epidemiological evidence suggests that it is possible to delay, if not prevent, the onset of dementia, both AD and VaD. The RCT evidence is building up for antihypertensives but remains sparse for other strategies. Most of the ongoing RCTs focus on one or two vascular risk factors and assess dementia only as a secondary outcome. There is a need for RCTs that will target multiple risk factors in at risk people with MCI or mVCI with incident dementia as a primary outcome. The design of such RCTs should be guided by the up-to-date basic research on pathophysiological mechanisms involved in causation of common dementias.

42.1 Natural history of Alzheimer's disease	522	42.4 Future strategies to delay emergence of Alzheimer's disease	525
42.2 Symptomatic clinical trials using cholinesterase inhibitors and memantine	523	References	525
42.3 Disease modification strategies	524		

Any therapy, whether pharmacological or not, requires proof of safety and efficacy. This chapter will outline the various trial design issues that have been encountered in the modern pharmacological treatment of Alzheimer's disease (AD). The experience gained so far has been predominantly in the symptomatic treatment of AD, using parallel group designs over 3–12 months. A number of randomized clinical studies attempting to modify progression of AD are under way, using parallel groups or survival designs over 1 year or longer.

The natural history of AD will be described first, introducing the concepts of disease stages, disease milestones and symptomatic domains that fluctuate in intensity as the disease runs through its course. Lessons from the symptomatic studies using cholinesterase inhibitors and memantine will be summarized. Current disease modification study designs will be outlined.

42.1 NATURAL HISTORY OF ALZHEIMER'S DISEASE

The natural history of AD can be broadly considered as a presymptomatic stage, during which a number of pathological events take place (see Chapters 28–30), an early symptomatic or prodromal stage with affective and/or cognitive manifestations, and symptomatic mild, moderate and severe stages. Each of these stages could be targeted for specific treatments, requiring different trial designs and outcomes (Table 42.1).

Disease milestones can also be defined in AD (Box 42.1). Some of these can be a target for treatment, with considerable face validity and impact on care (Galasko *et al.*, 1995). For example, studies in mild cognitive impairment (MCI) of the amnesic type may demonstrate that the diagnosis of dementia (predominantly AD) is delayed by 6 months or

Table 42.1 Examples of trial design and outcomes for each stage of Alzheimer's disease

Stage	Target population	Trial design	Primary outcome
Presymptomatic	Healthy elderly	Survival over 5 years	Incident dementia
Prodromal	Mild cognitive impairment; amnesic subtype	Survival over 3 years	Conversion to dementia
Mild to moderate	AD in the community	Six months parallel groups	Cognition and global impression of change
Moderate to severe	AD in the community or in assisted-living	Six months parallel groups	Global impression of change
Severe	AD in institution	Six months parallel groups	Behaviour

Box 42.1 *Clinical milestones in Alzheimer's disease*

- Emergence of cognitive symptoms
- Progression from amnesic mild cognitive impairment to diagnosable dementia
- Loss of instrumental activities of daily living (ADL)
- Emergence of behavioural and psychological symptoms of dementia
- Nursing home placement
- Loss of self-care ADL
- Death

longer. Delaying loss of autonomy for self-care and even death in moderate to severe stages of AD using α -tocopherol in only one study by the Alzheimer Disease Cooperative Study group (Sano *et al.*, 1997) has influenced clinical practice to use vitamin E in all stages of AD, at least in the USA. Delaying the loss of autonomy for instrumental activities of daily living (ADL) or the need for nursing home care would reduce the need for supportive care. Delaying emergence of some of the behavioural and psychological symptoms of dementia (BPSD) would reduce caregiver burden and later need for nursing home placement.

Symptomatic domains in dementia include cognition, ADL and behaviour. One can even add a domain of changes in motricity, since patients with AD will manifest some features of parkinsonism late in the disease. In many patients early changes in mood and anxiety precede the formal diagnosis of AD, sometimes with spontaneous improvement as insight into the disease is lost. Cognitive and functional ADL decline are relatively linear over time, whereas BPSD peak midway into the disease course and resolve spontaneously through the severe stage as motricity becomes impaired (Gauthier *et al.*, 2001). These natural fluctuations in the intensity of individual symptomatic domains through the stages of AD have an impact into trial design and outcomes (Table 42.2). It should be noted that studies can be of shorter duration and/or of smaller numbers of subjects in moderate compared with mild

stages of AD because of the faster rate of decline in the moderate stage, which may be related to the sensitivity of measurement scales, or to the progression of AD.

42.2 SYMPTOMATIC CLINICAL TRIALS USING CHOLINESTERASE INHIBITORS AND MEMANTINE

The modern treatment for AD was initiated by the report that tacrine improved some aspects of cognition and daily life. The follow-up confirmatory studies used cross-over and parallel group designs. The FDA published 'guidelines' (Leber, 1990), which greatly influenced the choice of outcomes for proof of efficacy of drugs improving symptoms in AD: a cognitive performance-based scale such as the ADAS-cog and an interview-based impression of change became the primary outcomes in mild to moderate AD, usually defined operationally as scores between 10 and 26 on the Mini-Mental State Examination (MMSE; Folstein *et al.*, 1975). Unfortunately, as these FDA guidelines cautioned against the 'pseudospecificity' of measurable benefits on neuropsychiatric manifestations in AD, they delayed research in this symptomatic domain. More recent discussions and publications from the FDA and other regulatory agencies have been more accepting of ADL and behaviour as important outcomes.

The following study designs have been used in the proof of efficacy for cholinesterase inhibitors (ChEIs): parallel groups over 3–12 months, and survival to a predefined clinical end point over 1 year or longer.

The parallel groups offer the possibility of short-term (minimum of 3 months) studies comparing the efficacy of different doses of the drug versus placebo. The primary analysis is done on outcomes at the end of the study using the last observation carried forward (LOCF) or intent to treat (ITT) analyses, which compensate for missing values in case of dropouts. Although LOCF/ITT has been favoured by the FDA, investigators and other regulatory agencies are now suggesting that for studies of 12 months or longer duration,

Table 42.2 *Examples of impact of symptoms through stages of AD on trial design and outcomes*

Stage	Prominent features	Types of outcomes	Examples
Mild	Depression may be present; few BPSD; cognitive decline slow but predominant feature; some instrumental ADL losses	Cognition; instrumental ADL	ADAS-cog, ADCS-ADL, DAD
Moderate	Cognitive decline more rapid; functional decline more rapid; BPSD emerge	Cognition; instrumental and basic ADL; behaviour	ADAS-cog, DAD, ADCS-ADL, NPI, BEHAVE-AD
Severe	Cognitive losses harder to measure (floor effect); few self-care ADL remaining; BPSD abating; parkinsonism emerging	Cognition; self-care ADL; behaviour; parkinsonism	SIB, ADCS-ADL, NPI, UPDRS

ADAS-cog, Alzheimer Disease Assessment Scale – cognitive subscale (Rosen *et al.*, 1984); ADCS-ADL, Alzheimer Disease Cooperative Study ADL scale (Galasko *et al.*, 1997); BEHAVE-AD, Behavioral symptoms in Alzheimer's disease (Reisberg *et al.*, 1987); DAD, Disability Assessment in Dementia (Gélinas *et al.*, 1999); NPI, Neuropsychiatric Inventory (Cumplings *et al.*, 1994); SIB, Severe Impairment Battery (Panisset *et al.*, 1994); UPDRS, United Parkinson Disease Rating Scale (Fahn and Elton, 1987)

the primary analysis should be done on observed cases (OC), i.e. completers. For practical purpose both types of analysis will usually be performed. Although 'cognitive enhancement' was the main hope for ChEIs as a therapeutic class, the reality that has emerged from 6 months studies with open-label extensions and the one-year placebo-controlled Nordic study (Winblad *et al.*, 2001) is that, although there is a small but statistically significant improvement in cognition peaking at 3 months with the ChEIs, the most clinically relevant finding has been the stabilization of cognitive decline with 'return to baseline' at 9–12 months for the actively treated groups at the higher therapeutic doses, compared with placebo treated groups who decline steadily. It should be noted that this natural decline varies greatly between studies in AD, and is even less evident in AD with cerebrovascular disease or in vascular dementia (VaD), where control of vascular risk factors appear to modify progression, at least in studies of 6 months' duration (Schneider, 2003).

Survival studies have primarily targeted loss of ADL, and have successfully demonstrated a delay in the loss of autonomy for patients on ChEIs compared with placebo. Parallel group studies of 6 months' duration in patients ranging from mild to moderately severe AD (MMSE 5–26) have also established that ADL are stable on treatment, but show no benefit on instrumental ADL (so called 'tutoring effect').

The most difficult domain to study, although very significant clinically, has been behaviour. The availability of general BPSD scales such as the NPI and BEHAVE-AD, as well as specific scales such as Cohen-Mansfield Agitation Inventory (Cohen-Mansfield *et al.*, 1989), has not yet allowed unequivocal demonstration of benefit in severe stages of AD. New methods of analysis of behaviour have been proposed (Gauthier *et al.*, 2002), and will likely be more successful in defining categories of BPSD symptoms most responsive to ChEIs (anxiety, hallucinations), memantine (agitation) and other drugs.

Memantine as a new therapeutic class has been found to be effective in a range of studies using parallel groups, in moderate to severe AD (Doody *et al.*, 2004). Scales appropriate for this stage of disease, such as the SIB, the ADCS-ADL and the NPI have been used and accepted by the FDA and other regulatory agencies. Of great importance is the novel design of adding memantine or placebo to a stable dose of a ChEI used successfully, paving the way to a number of studies where novel drugs or placebo are added to 'standard treatment'.

42.3 DISEASE MODIFICATION STRATEGIES

Although no trial design has yet led to a successful treatment for disease modification, many attempts have been made using parallel groups >1 year. Recent refinements of this design include adding the novel drug or a placebo to standard treatment over 1 year, selection of outcomes that demonstrate relatively linear changes over time such as the Clinical Dementia Rating sum of boxes (Hughes *et al.* 1982),

Box 42.2 Add-on design for disease modification

- One year is the minimum period for meaningful clinical observations in mild to moderate AD considering natural decline (may need to be longer in mild AD)
- Ethically long duration studies without 'standard treatment' are not possible
- There are scales with relatively linear changes over 1 year, such as the CDR sum of boxes, the ADAS-cog, the DAD and the ADCS-ADL, allowing analysis for slopes of decline
- A randomized wash-out from active treatment at the end of the study could demonstrate a lack of return to placebo
- A demonstrable reduction in rate of brain atrophy associated with differences in clinical decline would offer great face validity

randomized wash-out at the end of the year, and volumetric brain measurements using magnetic resonance imaging at beginning and end of year (Mohr *et al.*, 2004). The reasoning behind this 'add-on design' is summarized in Box 42.2.

Although this design appears promising, there are uncertainties and limitations. For instance the difference in rate of brain atrophy may be absent or opposite to expectations, with accelerated atrophy in the actively treated group. Wash-out from an active treatment will not be acceptable to all institutional review boards, and a previous attempt in using this design with patients treated with propentofylline failed to convince regulatory agencies (Whitehouse *et al.*, 1998).

One of the most difficult issues in disease modification strategies is the decision of the stage of disease where the proposed drug is most likely to work. On this 'proof-of-concept' phase II/III efficacy and safety study hinges the entire future of the drug. For example, numerous attempts at treating patients with AD in mild to moderate stages using non-steroidal anti-inflammatory drugs have failed, despite the weight of evidence from epidemiological research and the biological plausibility of an inflammatory response to β -amyloid deposition. It may be that treatment in the late presymptomatic or in the prodromal stages would be the most appropriate time. On the other hand studies in these stages of AD would require 3–5 years, a very long time for a 'proof-of-concept'. Alternative patients groups could be considered, such as presenilin mutation carriers or amnesic MCI, perhaps with additional risk factors for rapid conversion to AD such as apolipoprotein E.

A survival design is currently being tested extensively in order to delay progression from amnesic MCI to diagnosable dementia, predominantly AD (Geda and Petersen, 2001). These studies are unlikely to be considered as 'disease modifying', but rather as early symptomatic treatment in the prodromal stage of AD.

42.4 FUTURE STRATEGIES TO DELAY EMERGENCE OF ALZHEIMER'S DISEASE

As hypotheses on the pathophysiology of AD emerge from epidemiological research in human populations, post-mortem and biomarkers studies in patients, and animal models, we will need to establish whether new therapies can delay the onset of symptoms in asymptomatic people at varying degrees of risk of AD. The prototype of trial design to establish the safety and efficacy of such therapies is an ongoing 5-year survival study comparing *Ginkgo biloba* to placebo in elderly subjects, with incident dementia as primary end point. Variations of this design may be possible, by enriching the study population with different levels of risk, such as a positive family history of AD and/or selected gene markers, although it should be remembered that any enrichment of a study population may limit the applicability of findings to the population as a whole.

43.1 HISTORICAL BACKGROUND

As early as 1896 ‘arteriosclerotic dementia’ (referring to vascular dementia – VaD) was separated from ‘senile dementia’ (referring to Alzheimer’s disease – AD) (Berchtold and Cotman, 1998). Alzheimer together with Binswanger recognized the heterogeneity of VaD by describing four clinicopathological variants of VaD (Román, 2001), as well as vascular lesions in the Alzheimer brain. Nevertheless, until the 1960s and 1970s, cerebral atherosclerosis by causing chronic strangulation of blood supply to the brain was thought to be the commonest cause of dementia, and AD was regarded as a rare cause affecting only younger patients. Tomlinson *et al.* (1970) reinvented AD as the more frequent cause of dementia than that of arteriosclerotic dementia. In 1979 Hachinski and colleagues used the term multi-infarct dementia (MID) to describe the mechanism by which they considered VaD was produced (Hachinski *et al.*, 1974). As the pendulum swung in the direction of AD, vascular forms of dementia became relegated to a position of relative obscurity (Brust, 1988).

Despite until 1990s the concept of VaD has been that it is a dementia caused by small or large brain infarcts, that of MID (Hachinski *et al.*, 1974; Erkinjuntti and Hachinski, 1993), VaD has come full circle with the resurgence of interest of the whole spectrum of vascular causes of cognitive impairment and dementia (Hachinski, 1990). The new term is vascular cognitive impairment (VCI), which reflects the reinvention of the importance of vascular burden of brain and cognition (Bowler and Hachinski, 1995; O’Brien *et al.*, 2003a, b). The

original findings of Alois Alzheimer have been ‘reinvented’. Important are new data highlighting complex interactions between vascular aetiologies, changes in the brain, host factors and cognition (Chui, 1989; Tatemichi, 1990; Desmond, 1996; Pasquier and Leys, 1997; Skoog, 1998). Also reinvention of the heterogeneity of VaDs has fuelled the discussion, and subcortical vascular disease and dementia is seen the cardinal subtype (Erkinjuntti *et al.*, 2000; Erkinjuntti and Pantoni, 2000; Román *et al.*, 2002). Further the facts that vascular factors relate and coexist with AD have strengthened interest in the vascular burden of cognition (Kalaria and Ballard, 1999; Skoog *et al.*, 1999).

43.2 VASCULAR BURDEN OF THE BRAIN AND COGNITION

The VaDs are the second most common single causes of dementia (Rocca *et al.*, 1991; Hebert and Brayne, 1995; Lobo *et al.*, 2000; Rockwood *et al.*, 2000; Doody *et al.*, 2001). Cerebrovascular disease (CVD) relates to a high risk of cognitive impairment and dementia (Tatemichi *et al.*, 1992; Tatemichi *et al.*, 1994a). In addition, vascular factors such as coexisting stroke and white matter lesions (WMLs) relate also to AD (Snowdon *et al.*, 1997). Thus vascular causes are an important cause of cognitive impairment worldwide (Hachinski, 1992; O’Brien *et al.*, 2003b).

CVD and ischaemic brain injury have been seen as the primary cause of clinical deficits in VCI and the VaDs (Erkinjuntti, 1999). The multiplicity of vascular causes,

associated risk factors and clinical manifestations of dementia related to CVD makes VCI and VaD a complex area of research (Wallin and Blennow, 1993; Erkinjuntti, 1999; Pohjasvaara *et al.*, 2000). Even though a number of sets of diagnostic criteria have been produced for epidemiological studies of VaD, opinions are divided over the definition of VaD subtypes. How wide should the definition of the cognitive syndrome and the vascular cause be, and which patients should be excluded from a diagnosis of VCI and VaD?

Also, debate centres on difficulties in distinguishing between dementia owing to AD and that arising from CVD, as there are large overlaps in clinical signs and symptoms. Both result in cognitive, functional and behavioural impairment. There are also similarities in pathophysiological mechanisms (e.g. WMLs, delayed neuronal death and apoptosis) (Pantoni and Garcia, 1997; Snowden *et al.*, 1997; Skoog *et al.*, 1999), associated risk factors (e.g. age, education, arterial hypertension; Skoog, 1994; Skoog *et al.*, 1999) and neurochemical deficits (e.g. cholinergic dysfunction) (Togi *et al.*, 2002; Wallin *et al.*, 2002) shared with these two dementia causes.

More important, however, is the fact that AD and VaD coexist in a large proportion of patients (Kalaria and Ballard, 1999; Rockwood, 1997; Rockwood *et al.*, 2000). AD with CVD (referred also to as mixed dementia) could present clinically either as AD with evidence of cerebrovascular lesions in brain imaging, or with features of both AD and VaD (Rockwood *et al.*, 1999). Based on the findings from the Nun Study, it has been suggested that CVD may play an important role in determining the presence and severity of clinical symptoms of AD (Snowden *et al.*, 1997). Either way, the prevalence of AD with CVD has previously been underestimated (Kalaria and Ballard, 1999).

43.3 VASCULAR COGNITIVE IMPAIRMENT

The recognition of AD as the commonest cause of dementia resulted in criteria of dementia based on the clinical picture of AD (Bowler and Hachinski, 1995; Erkinjuntti *et al.*, 1997). Features of dementia included early and prominent memory loss, progression, irreversibility and a level of cognitive impairment sufficient to affect normal activities of daily living (ADL). Unexplained different definitions of dementia required different combinations of impairment in different domains of cognition (Erkinjuntti *et al.*, 1997).

In AD involvement of the medial temporal lobe results with dense episodic memory impairment. By contrast, patients with vascular lesions have no such predilection (Rockwood *et al.*, 1999, 2000). The emphasis on dementia underestimates the vascular burden of cognition, as well as distracts focus on prevention and treatment. Accordingly, it has been suggested to abandon the 'alzheimerized' dementia concept in the setting of CVD, and substitute it with a broader category of VCI (Hachinski, 1992; Bowler and Hachinski, 1995; Bowler *et al.*, 1999; O'Brien *et al.*, 2003a, b).

In VCI, vascular refers to all causes of ischaemic CVD, and cognitive impairment encompasses all levels of cognitive decline, from the earliest step to a more severe and broad dementia-like cognitive syndrome (Bowler *et al.*, 1999; O'Brien *et al.*, 2003a, b). VCIs that do not meet the criteria of dementia have been labelled also as vascular cognitive impairment with no dementia, vascular CIND (Rockwood *et al.*, 1999, 2000). VCI is expected to include cases with cognitive impairment related to CVD (transient ischaemic attack [TIA], stroke), multiple cortico-subcortical infarcts, silent infarcts, strategic infarcts, small vessel disease with WMLs and lacunae, as well as AD pathology with coexisting CVD lesions. The concept and definition of VCI or CIND is still in evolution. The two main factors to be defined include the level of severity of cognitive impairment and the pattern of cognitive impairment (O'Brien *et al.*, 2003a, b); in particular identification of a cognitive syndrome signalling a high risk of further cognitive decline, vascular mild cognitive decline (VMCI), a group of patients similar to that of amnesic MCI as a risk state for AD (Petersen *et al.*, 2002), is a challenge.

43.4 EPIDEMIOLOGY

Our understanding of the population distribution of VCI and its outcomes are subject to the variety of definitions used to identify it (Rocca *et al.*, 1991; Lobo *et al.*, 2000). For example, if mixed AD/VaD is included, then VCI may even be the most common cause of chronic progressive cognitive impairment in elderly people (Rockwood *et al.*, 2000).

The prevalence of VCI has been estimated at 5 per cent of people over age 65 in a Canadian Study (Rockwood *et al.*, 2000). This included patients with CIND. The prevalence of vascular CIND was 2.4 per cent; that of AD with CVD 0.9 per cent and that of VaD 1.5 per cent. By contrast, in the same study, the prevalence of AD without a vascular component was 5.1 per cent, and at all ages up to age 85 was less common than VCI.

As traditionally conceived, VaD is the second most common single cause of dementia accounting for 10 and even up to 50 per cent of the cases, depending on the geographic location, patient population and clinical methods used (Rocca *et al.*, 1991; Hebert and Brayne, 1995; Lobo *et al.*, 2000). The prevalence of VaD has been higher in earlier studies in China and Japan, compared with Europe and United States. The prevalence of VaD has ranged from 1.2 to 4.2 per cent in persons aged 65 years and older (Hebert and Brayne, 1995). In a European collaborative study using population-based studies of people aged 65 years and older conducted in the 1990s the age-standardized prevalence of dementia was 6.4 per cent (all causes), 4.4 per cent for AD and 1.6 per cent for VaD (Lobo *et al.*, 2000). In this study 15.8 per cent of the cases had VaD and 53.7 per cent AD.

The incidence of VaD has varied between 6 and 12 cases per year in 1000 persons aged 70 years and older (Hebert and Brayne, 1995). The incidence of VaD increases

with increasing age, without any substantial difference between men and women in a European collaborative study (Fratiglioni *et al.*, 2000).

In the Canadian study, the mean duration of survival in VCI was 41 months (Rockwood *et al.*, 2000). The highest impact on mortality arose from VaD in women (Ostbye *et al.*, 2002). In general, survival from VaD is around 5 years (Hebert and Brayne, 1995), less than that for the general population or those with AD (Mölsä *et al.*, 1995; Skoog *et al.*, 1993). Also post-stroke dementia is an independent predictor of mortality (Tatemichi *et al.*, 1994b).

The cognitive outcome of patients with VaD may be as severe as in AD but their morbidity and mortality are usually worse. Chui and Gonthier (1999) reviewed studies showing shorter survival in VaD than in AD; also, those who survived VaD had a more variable course. Survival variability may produce a length bias whereby patients whose disease progresses too rapidly are usually excluded in prevalence surveys (Wolfson *et al.*, 2001).

Although natural history studies have found poor cognitive outcome in patients with VaD, this has not been seen in clinical trials in VaD. In such trials, patients in the placebo groups have had little progression of impairment – the so-called ‘stable placebo response’ (Kittner *et al.*, 1997; Kittner for the European/Canadian Propentofyllin Study Group, 1999). The most likely explanation is the degree of exclusion of cases with mixed AD plus CVD, since these mixed patients usually have a progression mid-way between AD and VaD cases (Erkinjuntti *et al.*, 2002). Other explanations have been proposed, including selection bias since patients enrolled in trials are generally more fit than patients studied in natural history settings, expectation bias, placebo effect and co-intervention, resulting in better control of vascular risk factors, that might also explain both less disease progression and lower mortality rates. Finally, outcome measures used in these trials and adopted from AD trials may be relatively less unresponsive to decline.

43.5 DISEASE MECHANISMS

VCI and VaDs as a general entity include many syndromes, which themselves reflect a variety of vascular mechanisms and changes in the brain, with different causes and clinical manifestations. The pathophysiology incorporates interactions between vascular aetiologies (CVD and vascular risk factors), changes in the brain (infarcts, WMLs, atrophy), and host factors (age, education) (Chui, 1989; Tatemichi, 1990; Desmond, 1996; Pasquier and Leys, 1997; Skoog, 1998).

43.5.1 Aetiologies

Aetiologies of VCI include both CVDs and risk factors (Box 43.1). The main CVDs include large artery disease, cardiac embolic events, small vessel disease and haemodynamic

Box 43.1 Aetiologies of vascular dementia

Cerebrovascular disorders

- Large artery disease
 - artery-to-artery embolism
 - occlusion of an extra- or intracranial artery
- Cardiac embolic events
- Small vessel disease
 - lacunar infarcts
 - ischaemic white matter lesions
- Haemodynamic mechanisms
- Specific arteriopathies
- Haemorrhages
 - intracranial haemorrhage
 - subarachnoidal haemorrhage
- Haematological factors
- Venous diseases
- Hereditary entities

Risk factors

- Vascular
 - arterial hypertension
 - atrial fibrillation
 - myocardial infarction
 - coronary heart disease
 - diabetes
 - generalized atherosclerosis
 - lipid abnormalities
 - smoking
- Demographic factors
 - high age
 - low education
- Genetic factors
 - family history
 - specific genetic factors
- Stroke-related factors
 - type of CVD
 - site and size of infarcts

mechanisms (Brun, 1994; Wallin and Blennow, 1994; Pantoni and Garcia, 1995; Amar and Wilcock, 1996; Erkinjuntti, 1996).

Risk factors related to VCI (Box 43.1) include risk factors for CVD, stroke, WMLs, but, at the same time, also those of any cognitive decline and AD (Skoog, 1998). They can be divided into vascular factors (e.g. arterial hypertension, atrial fibrillation, myocardial infarction, coronary heart disease, diabetes, generalized atherosclerosis, lipid abnormalities, smoking), demographic factors (e.g. age, education), genetic factors (e.g. family history and specific genetic features), and stroke-related factors (e.g. type of CVD, site and size of stroke) (Skoog, 1998; Gorelick, 1997). Hypoxic ischaemic events (cardiac arrhythmias, congestive heart failure, myocardial infarction, seizures, pneumonia) may be an important risk factor for incident dementia in patients with stroke (Moroney *et al.*, 1996).

43.5.2 Brain changes

The changes in the brain related to VaD include both ischaemic and non-ischaemic factors (Chui, 1989; Tatemichi, 1990; Brun, 1994; Erkinjuntti, 1996) (Box 43.2). The static ischaemic lesions include arterial territorial infarct, distal field (watershed) infarct, lacunar infarct, ischaemic WMLs and incomplete ischaemic injury. Incomplete ischaemic injury include, for example, focal gliosis and incomplete white matter infarctions in areas of selective vulnerability (Englund *et al.*, 1988; Pantoni and Garcia, 1997). The functional ischaemic changes include both focal (around the ischaemic lesion) and remote (disconnection, diaschisis) effects. The volume of functionally inactive tissue exceeds that of static ischaemic lesions in VaD (Mielke *et al.*, 1992). Current technologies in clinical work-up have limitations in detection of incomplete ischaemic injury and functional ischaemic changes. Also distinction between ischaemic and degenerative origin of atrophic changes awaits discovery (Vinters *et al.*, 2000).

43.5.3 Brain mechanisms

Pathophysiological mechanisms related to VaD include: volume of brain infarcts (size reaching a critical threshold), number of infarcts (additive, synergistic), site of infarcts (bilateral, strategic cortical or subcortical sites), WMLs (extent, site, type, density), other ischaemic factors (incomplete ischaemic injury, delayed neuronal death, functional changes), atrophy (location, extent), and additive effects of other pathologies (AD, Lewy body dementia) (Chui, 1989; Tatemichi, 1990; Desmond, 1996; Erkinjuntti, 1996). Relationship between vascular factors and cognition is essential: whether the identified vascular factors cause, compound or only coexist with the VaD syndrome (Box 43.3) (Tatemichi *et al.*, 1994a; Erkinjuntti *et al.*, 1988). Another important question is, whether they contribute to the risk and clinical picture of AD (Pasquier and Leys, 1997; Snowden *et al.*, 1997). Questions of type, extent, side, site and tempo of vascular

Box 43.2 Brain changes in vascular dementia

Static lesions

- Arterial territorial infarct
- Distal field (watershed) infarct
- Lacunar infarct
- Ischaemic white matter lesions
- Incomplete ischaemic injury
- Atrophy

Functional ischaemic changes

- Focal (around the ischaemic lesion)
- Remote (disconnection, diaschisis)

lesions in the brain relating to different types of VaD have no firm answers (Chui, 1989; Tatemichi, 1990; Desmond, 1996; Erkinjuntti, 1996).

43.5.4 Anatomical brain imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) studies on VaD indicate that bilateral ischaemic lesions are of importance (Erkinjuntti and Hachinski, 1993; DeCarli and Scheltens, 2002). Regarding locations some emphasize deep infarcts in the frontal and limbic areas, other cortical ones, especially in the temporal and parietal areas. There are also controversies in regard to the number and volume of the infarcts, as well as the extent and location of atrophy. The diffuse WMLs have been offered as an important factor leading to functional disconnection of cortical brain areas.

Generalizations and summary in regard to lesion and cognition interaction in VaD can be made (Erkinjuntti *et al.*, 1999; Román *et al.*, 2002; O'Brien *et al.*, 2003a, b):

- Not a single feature, but a combination of infarct features, extent and type of WMLs, degree and site of atrophy, and host factors characterizations are correlates of VCI/VaD.
- Infarct features favouring VaD include: bilaterality, multiplicity (>2), location in the dominant hemisphere and location in the fronto-subcortical and limbic structures.
- WML features favouring VaD are extensive WMLs (extending periventricular WMLs and confluent to extending WMLs in the deep white matter).
- It is doubtful that only a single small lesion could support an imaging evidence for a diagnosis of VaD. However, exceptions are rare cases with strategic infarcts.
- Absence of CVD lesions on CT or MRI are against a diagnosis of VaD.

43.6 MAIN SUBTYPES OF VASCULAR DEMENTIAS

The subtypes of VaD included in current classifications are the cortical VaD or MID also referred to as post-stroke VaD, the subcortical ischaemic vascular disease and dementia (SIVD) or the small vessel dementia, and the strategic infarct dementia (Box 43.4) (Erkinjuntti, 1987b; Román *et al.*, 1993; Brun, 1994; Cummings, 1994; Wallin and Blennow, 1994; Loeb and Meyer, 1996; Konno *et al.*, 1997; Wallin *et al.*, 2003) and many include also the hypoperfusion dementia (Sulkava and Erkinjuntti, 1987; Román *et al.*, 1993; Brun, 1994; Cummings, 1994). Further subtypes suggested include haemorrhagic dementia, hereditary vascular dementia, and AD with CVD (also labelled as combined or mixed dementia).

43.6.1 Cortical VaD

Cortical VaD, post-stroke VaD (MID) relates to large vessel disease, cardiac embolic events and also hypoperfusion. It shows predominantly cortical and cortico-subcortical arterial territorial and distal field (watershed) infarcts. Typical clinical features are lateralized sensorimotor changes and abrupt onset of cognitive impairment and aphasia (Erkinjuntti, 1987b; Erkinjuntti *et al.*, 1988). In addition, some combination of different cortical neuropsychological syndromes are present in cortical VaD (Mahler and Cummings, 1991).

43.6.2 Strategic infarct dementia

In strategic infarct dementia focal, often small, ischaemic lesions involving specific sites critical for higher cortical functions have been classified separately. Of the cortical sites, the hippocampal formation, angular gyrus and gyrus cinguli are examples. The subcortical sites include thalamus, fornix, basal forebrain, caudate, globus pallidus and the genu or anterior limb of the internal capsule (Tatemichi, 1990; Erkinjuntti and Hachinski, 1993; Erkinjuntti, 1996). Depending on the strategic location in question, the time-course and clinical features vary greatly.

Box 43.4 Subtypes of vascular dementia

- Cortical VaD, multi-infarct dementia (MID), post-stroke VaD
- Subcortical VaD, subcortical vascular disease and dementia (SIVD), small vessel dementia
- Strategic infarct dementia
- Hypoperfusion dementia
- Haemorrhagic dementia
- Hereditary vascular dementias
- Other vascular dementias
- Alzheimer's disease with CVD ('combined or mixed dementia')

43.6.3 Subcortical VaD

Subcortical ischaemic vascular dementia (SIVD), the small vessel dementia, incorporates two entities 'the lacunar state' and 'Binswanger disease' (Román *et al.*, 2002). It relates to small vessel disease and is characterized by lacunar infarcts, focal and diffuse ischaemic WMLs, and incomplete ischaemic injury (Erkinjuntti, 1987b; Román, 1987; Mahler and Cummings, 1991; Wallin *et al.*, 2003). The ischaemic lesions in SIVD affect the prefrontal subcortical circuit and the subcortical syndrome is the cardinal clinical manifestation (Cummings, 1993; Erkinjuntti *et al.*, 2000). Clinically, small vessel dementia is characterized by pure motor hemiparesis, bulbar signs and dysarthria, gait disorder, depression and emotional lability, and, especially, deficits in executive functioning (Ishii *et al.*, 1986; Babikian and Ropper, 1987; Román, 1987; Mahler and Cummings, 1991; Wallin *et al.*, 1991).

The patients with the SIVD having multiple lacunes and extensive WMLs on neuroimaging often give only a clinical history of 'prolonged TIA' or 'multiple TIAs' (which mostly are minor strokes) without residual symptoms and only mild focal findings (e.g. drift, reflex asymmetry, gait disturbance), which supports the importance of neuroimaging requirements in the criteria (Erkinjuntti *et al.*, 2000).

43.7 CLINICAL FEATURES

Early cognitive syndrome of SIVD is characterized by dysexecutive syndrome including slowed information processing, memory deficit (may be mild), and behavioural and psychological symptoms (Román *et al.*, 2002). The dysexecutive syndrome in SIVD includes impairment in goal formulation, initiation, planning, organizing, sequencing, executing, set-sifting and set-maintenance, as well as in abstracting (Mahler and Cummings, 1991; Cummings, 1994; Desmond *et al.*, 1999). The memory deficit in SIVD may be milder than, for example, in AD, and is specified by impaired recall, relative intact recognition, less severe forgetting, and better benefit from cues (Desmond *et al.*, 1999). Behavioural and psychological symptoms in SIVD include depression, personality change, emotional lability and incontinence, as well as inertia, emotional bluntness and psychomotor retardation (Mahler and Cummings, 1991; Román *et al.*, 1993; Cummings, 1994).

The early cognitive syndrome of cortical VaD includes some memory impairment (by definition), which may be mild, some heteromodal cortical symptom(s) such as aphasia, apraxia, agnosia, visuospatial or constructional difficulty. In addition most patients have some degree of dysexecutive syndrome.

Clinical neurological findings (Box 43.5) especially early in the course of SIVD include episodes of mild upper motor neurone signs (drift, reflex asymmetry, incoordination), gait disorder (apractic-atactic or small-stepped), imbalance and falls, urinary frequency and incontinence, dysarthria, dysphagia, as well as extrapyramidal signs (hypokinesia, rigidity)

Box 43.5 *Clinical features of vascular dementia***Course**

- Frequently an insidious onset and progressive deterioration
- Often stepwise deterioration (some recovery after worsening) and fluctuating course (e.g. difference between days) of cognitive symptoms
- May be relatively abrupt onset (days to weeks) of cognitive impairment

Symptoms and signs

- Clinical neurological findings indicating focal brain lesion early in the course:
 - mild motor or sensory deficits, decreased coordination, brisk tendon reflexes, Babinski's sign, field cut
- Bulbar signs including dysarthria and dysphagia
- Gait disorder: hemiplegic, apractic-atactic, small-stepped
- Unsteadiness and unprovoked falls
- Urinary frequency and urgency
- Psychomotor slowing, abnormal executive functioning
- Depression, anxiety, emotional lability
- Relatively preserved personality and insight in mild and moderate cases

Comorbid findings

- History of cardiovascular diseases (not always present), e.g. arterial hypertension, coronary heart disease, atrial fibrillation

CT or MRI

- Focal infarcts (70–90%). Diffuse or patchy white matter lesions (70–100%), often more extensive

SPECT or PET

- Often patchy reduction of regional blood flow and decreased white matter flow

EEG

- Compared to Alzheimer's disease, more often normal. If abnormal, more focal findings. Overall, abnormality increases with more severe intellectual decline

Laboratory

- No known specific tests. Often findings related to concomitant diseases, e.g. hyperlipidaemia, diabetes, cardiac abnormality

(Ishii *et al.*, 1986; Babikian and Ropper, 1987; Erkinjuntti, 1987a; Román, 1987; Román *et al.*, 1993, 2002). However, often these focal neurological signs are subtle only (Fischer *et al.*, 1990; Skoog, 1997).

Patients with cortical VaD, having multiple cortico-subcortical infarcts often show field cut, lower facial weakness, lateralized sensorimotor changes and gait impairment (hemiplegic, apractic-atactic) (Erkinjuntti, 1987a).

In SIVD the onset is variable. For example in the series of Babikian and Ropper (Babikian and Ropper, 1987), 60 per cent of the patients had a slow, less abrupt onset, and only 30 per cent an acute onset of cognitive symptoms. The course was gradual without (40 per cent) and with (40 per cent) acute deficits (Babikian and Ropper, 1987).

Traditionally cortical VaD (MID, post-stroke VaD) has been characterized by a relative abrupt onset (days to weeks), a step-wise deterioration (some recovery after worsening), and fluctuating course (e.g. difference between days) of cognitive functions (Román, 1987; Erkinjuntti, 1987b; Fischer *et al.*, 1990; Chui *et al.*, 1992; Román *et al.*, 1993; Skoog, 1997).

43.8 CLINICAL CRITERIA

Since the 1970s several clinical criteria for VaD have been used (Erkinjuntti, 1994; Rockwood *et al.*, 1994; Wetterling *et al.*, 1996). The most widely used criteria for VaD include the DSM-IV (American Psychiatric Association, 1994), the ICD-10 (World Health Organization, 1993), the ADDTC criteria (Chui *et al.*, 1992), and the NINDS-AIREN criteria (Román *et al.*, 1993).

The two cardinal elements implemented in the clinical criteria for VaD are the definition of the cognitive syndrome of dementia (Erkinjuntti *et al.*, 1997), and the definition of the vascular cause of the dementia (Erkinjuntti, 1994; Wetterling *et al.*, 1994, 1996). Variation in defining these two critical elements has created different definitions giving different point prevalence estimates, identifying different groups of subjects, and consequently also identifying different types and distribution of brain lesions (Skoog *et al.*, 1993; Wetterling *et al.*, 1996; Erkinjuntti *et al.*, 1997, 1999; Pohjasvaara *et al.*, 1997). Further, this heterogeneity may have been a factor for negative results in prior clinical trials on VaD (Inzitari *et al.*, 2000). All the clinical criteria used are consensus criteria, which are neither derived from prospective community-based studies on vascular factors affecting the cognition, nor based on detailed natural histories (Chui *et al.*, 1992; Román *et al.*, 1993; Erkinjuntti, 1994, 1997; Rockwood *et al.*, 1994). All the cited criteria are mainly based on the ischaemic infarct concept and designed to have high specificity, although they have been poorly implemented and validated (Rockwood *et al.*, 1994; Erkinjuntti, 1997).

The NINDS-AIREN criteria:

- emphasize heterogeneity of VaD syndromes and pathologic subtypes including not only ischaemic stroke but also other causes of CVD including cerebral hypoxic-ischaemic events, WMLs, and haemorrhagic strokes;
- recognize the variability in clinical course, which may be static, remitting, or progressive;
- highlight the question of the location of ischaemic lesions and the need to establish a causal relationship between vascular brain lesions and cognition;

- recognize the need to establish a temporal relationship between stroke and dementia onset;
- include specific findings early in the course that support a vascular rather than a degenerative cause;
- emphasize the importance of brain imaging to support clinical findings; and
- give value of neuropsychological testing to document impairments in multiple cognitive domains.

The NINDS-AIREN criteria handle VaD as a syndrome with different aetiologies and different clinical manifestations and not as a single entity, and they list possible subtypes to be used in research studies. The focus is on consequences of CVD, but the criteria takes also into account different aetiologies. These criteria incorporate also different levels of certainty of the clinical diagnosis (probable, possible, definite).

In a neuropathological series, sensitivity of the NINDS-AIREN criteria for probable and possible VaD was 58 per cent and specificity 80 per cent (Gold *et al.*, 1997). The criteria successfully excluded AD in 91 per cent of cases, and the proportion of combined cases misclassified as probable VaD was 29 per cent. Compared with the other modern criteria, the ADDTC criteria (Chui *et al.*, 1992), the NINDS-AIREN criteria are more specific and they better exclude combined cases (54 per cent versus 29 per cent). In a more recent series the sensitivity of NINDS-AIREN criteria for probable VaD was 20 per cent and specificity 93 per cent; the corresponding figures for probable ADDTC were 25 and 91 per cent (Gold *et al.*, 2002). The interrater reliability of the NINDS-AIREN criteria is moderate to substantial (kappa 0.46 to 0.72) (Lopez *et al.*, 1994).

43.9 DIFFERENTIAL DIAGNOSIS

Differential diagnosis of VaD include besides differentiation between VaD and AD a number of other conditions (Box 43.6). We focus here on AD and AD + CVD.

Box 43.6 Differential diagnosis of vascular dementia

- Alzheimer's disease
- Alzheimer's disease with cerebrovascular disease (CVD)
- Normal pressure hydrocephalus (NPH)
- Non-ischaemic white matter lesions and dementia
- Frontal lobe tumour
- Intracranial mass
- Vascular dementia and Alzheimer's disease (mixed)
- Lewy body dementia
- Frontotemporal dementia
- Parkinson's disease and dementia
- Progressive supranuclear palsy
- Multisystem atrophy

43.9.1 Alzheimer's disease

AD has typical neuropathological stages (transentorhinal, limbic and neocortical) corresponding to clinical stages (preclinical, early and mild dementia) (Braak and Braak, 1991). Accordingly, AD is a typical stage concurrent disorder, progressing from mild cognitive impairment (MCI), to early predementia AD and then to stages of AD dementia (Petersen, 1995), and is not a diagnosis of exclusion. Taken the clinical series on differential diagnosis between AD and VaD, the main limitations have included definition of the cognitive syndrome, the dementia syndrome, definition of the cause/aetiology of the dementia syndrome, and heterogeneity of patient populations, especially that of VaDs. The traditional concept of dementia has been based on the typical clinical features of AD (McKhann *et al.*, 1984; Erkinjuntti *et al.*, 1997). The definition has been the prison of AD, as the focus has been early episodic memory impairment, more or less global cognitive syndrome, with progressive course, and major restrictions of ADL. These are features different from that in early cases of VaD, and these criteria merely detect an endstage of VaD.

The most widely used definition of the cause of these cognitive syndromes includes the NINDS-AIREN for probable VaD (Román *et al.*, 1993) and the NINCDS-ADRDA for probable AD (McKhann *et al.*, 1984). These criteria define a stereotyped set of patient groups: probable VaD characterized by abrupt onset, or fluctuating and stepwise course with clinical signs of CVD and relevant CVD on brain imaging. On the contrary AD is characterized by insidious onset, progressive course, without clinical signs of CVD and without signs of CVD in brain imaging. Accordingly, in typical cases the differentiation between probable VaD and AD using common clinical tools is direct (Erkinjuntti *et al.*, 1988).

Hachinski Ischaemic Score has been widely used to differentiate patients with VaD and AD (Hachinski *et al.*, 1975) (Table 43.1). In most clinical series the majority of the items differentiate VaD from probable AD – as a matter of fact this is based on the clinical definitions used. However, in a large

Table 43.1 Hachinski Ischaemic Score

Item	Score value
Abrupt onset	2
Stepwise deterioration	1
Fluctuating course	2
Nocturnal confusion	1
Relative preservation of personality	1
Depression	1
Somatic complaints	1
Emotional incontinence	1
History of hypertension	1
History of strokes	2
Evidence of associated atherosclerosis	1
Focal neurological symptoms	2
Focal neurological signs	2

neuropathologically confirmed series by Moroney *et al.* (1997), the independent correlates of VaD were stepwise deterioration (OR 6.1), fluctuating course (OR 7.6), history of hypertension (OR 4.3), history of stroke (OR 4.3) and history of focal neurological symptoms (OR 4.4).

43.9.2 Alzheimer's disease with CVD

AD and CVD (mixed dementia) is a challenge. Increasing evidence shows that different vascular factors are related to AD, and frequently CVD coexist with AD (Kalaria and Ballard, 1999; Skoog *et al.*, 1999). This overlap is increasingly important in older populations. Clinical recognition of patients with mixed dementia or AD with CVD, however, is a problem. As detailed in the neuropathological series of Moroney *et al.* (1997) these patients have a clinical history and signs of CVD, being clinically more close to VaD. In fact, in this series fluctuating course (OR 0.2) and history of strokes (OR 0.1) were the only items differentiating AD from the mixed cases.

Problematic clinical examples include stroke unmasking AD in patients with post-stroke dementia, insidious onset and/or slow progressive course in VaD patients, and cases where difficulty exists in assessing the role of less extensive WMLs or of distinct infarcts on neuroimaging. AD with CVD (referred also as mixed dementia) could present clinically either as AD with evidence of cerebrovascular lesions in brain imaging, or with features of both AD and VaD (Rockwood *et al.*, 1999). In a Canadian study, typical AD presentations with one or more features pointing to 'vascular aspects', derived from the Hachinski Ischaemia Scale score, were used successfully to diagnose AD + CVD in combination with neuroimaging of ischaemic lesions (Rockwood *et al.*, 2000). Vascular risk factors, and focal neurological signs and symptoms were present more often in AD with CVD than in 'pure' AD. Other visible clinical clues for a diagnosis of AD with CVD were gained from analyses of disease course characteristics, and presentations of patchy cognitive deficits, early onset of seizures or gait disorder.

A solution to recognize patients with AD + CVD could be to find reliable biological markers of clinical AD. Potential markers include, for example, early prominent episodic memory impairment, early and significant medial temporal lobe atrophy on magnetic resonance imaging (MRI), bilateral parietal hypoperfusion on single photon emission computed tomography (SPECT), change in cerebrospinal fluid (CSF) β -amyloid and tau-protein, or presence of ApoE ϵ 4 allele.

43.10 CLINICAL EXAMINATION

Clinical evaluation of patients with memory impairment has two diagnostic approaches: first, the symptomatic diagnosis,

i.e. evaluation of the type and extent of cognitive impairment; and second, the aetiological diagnosis, i.e. evaluation of vascular cause(s) and related factors. The prevalent symptomatic categories besides dementia include delirium, circumscribed neuropsychological syndromes, e.g. aphasia, and functional psychiatric disorders, e.g. depression (Erkinjuntti, 1997). Steps in the aetiological diagnosis include diagnosis of the specific causes, especially the potentially treatable conditions, evaluation of secondary factors able to affect the cognitive functioning and more detailed differentiation between specific causes, especially that between VaD and AD.

Elements in the clinical examination of the patients with suspected vascular dementia have been detailed in Box 43.7. The cornerstone in the evaluation are traditional clinical skills to perform detailed clinical and neurological history and examination, including interview of a close informant. These patients are challenging and we should allocate enough time for the consultation, often 40–60 minutes.

Beside mental status examination include the Mini-Mental State Examination (Folstein *et al.*, 1975); it has limitations as it emphasizes language, does not include timed elements and recognition portion of the memory tests, is insensitive to mild deficits, and is influenced by education and age. Other proposed screening instruments for VaD include a 4–10 word memory test with delayed recall, cube

Box 43.7 Clinical examinations of patients with suspected vascular dementia

Symptomatic diagnosis (type and extent of cognitive impairment)

- Interview of the patient and caregiver
- Bedside mental status examination
- Neuropsychological examination
- Assessment of social functions and activities of daily life
- Assessment of psychiatric and behavioural symptoms

Aetiological diagnosis (vascular cause[s] and related factors)

- Clinical and neurological history and examination
- Ischaemic scores
- Brain imaging: computed tomography (CT) or preferably magnetic resonance imaging (MRI) of the brain
- Routine laboratory investigations
- Chest X-ray
- Electrocardiography (ECG)
- Single photon emission computed tomography (SPECT)
- Electroencephalography (EEG)
- Extended laboratory investigations including coagulation studies
- Doppler ultrasonography/magnetic angiography of the carotid arteries
- Echocardiography
- 24-hour ECG and blood pressure monitoring

drawing test for copy, verbal fluency test (number of animals named in 1 minute), and Luria's alternating hand sequence or finger rings and letter cancellation test (neglect) (Román *et al.*, 1993). This has given rise to proposals to incorporate such testing in future clinical trials, and to the development of the vascular equivalent of the ADAS-cog, the VaDAS-cog (Ferris and Gauthier, 2002).

Often more detailed neuropsychological tests and test batteries are needed. The test battery should cover the main cognitive domains including memory functions (short- and long-term memory), abstract thinking, judgement, aphasia, apraxia, agnosia, orientation, attention, executive functions, and speed of information processing (Erkinjuntti *et al.*, 1997; Pohjasvaara *et al.*, 1998; Hietanen *et al.*, 2003; Tingus *et al.*, 2003). Assessment of a person's social and emotional functioning is also part of basic evaluation.

Clinical evaluations to define the aetiological diagnosis include clinical and neurological history and examination (Box 43.7).

Brain imaging should be performed at least once during the initial diagnostic workout; because of its higher sensitivity and ability to demonstrate medial temporal lobe and basal fore-brain areas MRI is preferred. Chest X-ray, electrocardiography and screening laboratory tests are part of the basic evaluation (Erkinjuntti and Sulkava, 1991; Amar and Wilcock, 1996; Orrell and Wade, 1996; DeCarli and Scheltens, 2002). In selected cases extended laboratory investigations, analysis of the CSF, electroencephalography (EEG), quantitative

EEG and SPECT are done, as well as examinations of the extra- and intracranial arteries and detailed cardiological investigations.

43.11 PREVENTION

Primary prevention aims to reduce incident disease by eliminating its cause or the main risk factors (Last, 1988) (Table 43.2). In primary prevention, the target is the person with a 'brain at risk' of CVD before cognitive impairment or stroke occur. The intent is to treat putative risk factors and to promote protection. In this contexts the effect of primary prevention in populations free of cognitive impairment still remains less well known. Most cardiovascular and cerebrovascular studies on primary prevention have missed the opportunity to study cognition as an end point. The Medical Research Council's treatment trial of hypertension in older adults did not show an effect on subsequent cognitive function (Prince *et al.*, 1996). In contrast, the SYST-EUR Study demonstrated that the treatment of isolated systolic hypertension in the elderly with a calcium-channel agent decreased significantly the incidence of dementia (Forette *et al.*, 1998, 2002). Other inferences about the positive effects of primary prevention are based on cumulative experience with the treatment of vascular risk factors in the primary prevention of stroke.

Table 43.2 *Prevention and treatment of vascular dementia*

Type of therapy	Main target	Degree of cognitive impairment	Action
Prevention			
<i>Primary</i>	Brain at risk of CVD and any cognitive impairment	Normal	Treatment of and action on risk factors; promotion of protective factors
<i>Secondary</i>	CVD brain at risk of VCI and VaD	Normal; mild diffuse in several; significant in one domain	Diagnosis of the type of CVD; acute intervention on ischemic brain changes; treatment according to CVD type; intensifying treatment of risk factors
Treatment			
<i>Slowing progression</i>	Risk of progression of VCI and VaD	Significant in several domains; dementia	Intensifying primary and secondary prevention
<i>Symptomatic</i>			Targeted medications to: increase cerebral blood flow; support neuronal metabolism; modify neurotransmission; neuroprotection
<i>Secondary factors</i>	Risk of intensifying VCI and VaD		Treatment of secondary factors affecting the cognition
<i>AD strategies</i>			AD treatments to prevent, slow progression and treat symptoms of impairment of cognition and behaviour

AD, Alzheimer's disease; CVD, cerebrovascular disease; VaD, vascular dementia; VCI, vascular cognitive impairment

Secondary prevention aims to prevent disease progression by means of early detection and appropriate treatment. In secondary prevention, the target is CVD in the brain at risk of VCI and VaD. The basis of secondary prevention therefore includes diagnosis and treatment of acute stroke in order to limit the extent of ischaemic brain changes and to promote recovery, prevention of recurrence of stroke, according to the type of CVD, slowing the progression of brain changes associated with VaD (e.g. ischaemic white matter lesions, management of risk factors of incident dementia), as well as intensifying treatment of risk factors. There have been significant advances in acute stroke therapy, particularly in regard to antiplatelet agents, thrombolysis and acute stroke care (Wardlaw, 2001), although neuroprotection has been disappointing (Gorelick, 2000). Treatments for recurrent stroke prevention are also well defined (Gorelick, 2002). Selection of treatment is guided by the aetiology of CVD such as large artery disease (e.g. antiplatelet agents, carotid endarterectomy), cardiac embolic events (e.g. anticoagulation), small-vessel disease (e.g. aspirin), and haemodynamic mechanisms (e.g. control of hypotension and cardiac arrhythmias) (Gorelick, 2002). Hypoxic ischaemic events (cardiac arrhythmias, congestive heart failure, myocardial infarction, seizures, pneumonia) are important risk factors for incident dementia in patients with stroke (Moroney *et al.*, 1996). There is a dearth of knowledge on the effects of secondary prevention of VaD. Most trials on acute stroke and secondary prevention of stroke have missed the opportunity to study cognition as an end point.

Perindopril, an angiotensin-converting enzyme inhibitor used in a trial of secondary prevention of stroke (PROGRESS Collaborative Group, 2003), showed a beneficial effect (usually coupled with the diuretic indapamide) in patients who had a previous stroke. Lowering of blood pressure was associated with a reduction in the risk of dementia and severe cognitive impairment among patients who experienced recurrent stroke.

Given that HMG Co-A reductase inhibitors (statins) are important in the secondary prevention of stroke (Callahan, 2001), there are incentives to undertake trials in patients with mild VaD.

In general, drugs initiated for the treatment of CVD and prevention of its adverse outcomes should be continued even as cognitive impairment manifests itself. Often, the drugs that modify vascular risk factors are used less frequently as the dementia becomes more severe. As dementia progresses lower blood pressure is often seen with severe disease. In small series, patients with VaD benefited from blood pressure control and cessation of smoking (Meyer *et al.*, 1986). Routine use of acetylsalicylic acid in VaD is controversial (Molnar *et al.*, 1999). Effects of vitamins to reduce plasma homocysteine levels await randomized controlled trials (Welch and Loscalzo, 1998). Further, the absence of progressive cognitive decline in patients receiving placebo in symptomatic treatment trials of VaD may also reflect an effect of intensified risk factor control (Rother *et al.*, 1998).

43.12 TREATMENT

A vascular aetiology underlay the use of several compounds purported to be useful in the symptomatic treatment of VaD. These included antithrombotics, ergot alkaloids, nootropics, TRH-analogue, *Ginkgo biloba* extract, plasma viscosity drugs, hyperbaric oxygen, antioxidants, serotonin and histamine receptor antagonists, vasoactive agents, xanthine derivatives and calcium antagonists (Erkinjuntti, 1999; Doody *et al.*, 2001; Erkinjuntti and Rockwood, 2001; Rockwood *et al.*, 2002; Inzitari *et al.*, 2003). These studies have mostly had negative results, were based on small numbers, short treatment periods, variations in diagnostic criteria and tools, often included mixed populations, and have had variations in the application of clinical end points. Currently there is not a widely accepted standard symptomatic treatment of VaD (Doody *et al.*, 2001). Two drugs which were carefully studied are propentofylline (Rother *et al.*, 1998) and nimodipine (Pantoni *et al.*, 1996; Lopez-Arieta 2001).

Propentofylline, a glial modulator, is no longer under study despite observed beneficial effect on learning and memory (Mielke *et al.*, 1998). Unpublished results of several European and Canadian double-blind, placebo-controlled, randomized, parallel group trials on the efficacy and safety of long-term treatment with propentofylline, compared with placebo, in patients with mild to moderate VaD according to NINDS-AIREN criteria (Román *et al.*, 1993) have been shown as a poster (Pischel, 1998). This 24-week study showed a significant symptomatic improvement and long-term efficacy in ADAS-Cog and CIBIC-plus up to 48 weeks. In addition, sustained treatment effects for at least 12 weeks after withdrawal were present suggesting an effect on disease progression.

Nimodipine, a dihydropyridine calcium antagonist was used in subcortical VaD. Nimodipine is held to effect vasodilatation, without a steal effect, so as to reduce the influx of calcium ions into depolarized neurones. In consequence, it is held to have a neuroprotective effect that is not directly related to changes in cerebral blood flow. In addition the drug has a specific effect on small vessels. Encouraging results from an open-label trial (Pantoni *et al.*, 1996) led to a subgroup analysis of a larger double-blind, placebo-controlled study known as the Scandinavian Multi-Infarct Dementia Trial. Patients were divided between MID and subcortical VaD groups, according to CT findings and were blindly assessed. Nimodipine had a beneficial effect on attention and psychomotor performances in the subcortical group, although, no clear advantage was seen in the combined sample (Pantoni *et al.*, 2000a, b). These preliminary results are currently being tested in an international, multicentre, randomized, double-blind trial enrolling patients with subcortical VaD, defined on a clinical-radiological basis (Erkinjuntti *et al.*, 2000). For the moment, the Cochrane Collaboration review concluded that there is no convincing evidence that nimodipine is a useful treatment for the symptoms of vascular dementia (Lopez-Arieta, 2001).

43.12.1 Current treatment of VaD

At present, there is evidence-based data that two types of drugs modulating neurotransmission abnormalities appear to be useful in VaD; these neurotransmitter abnormalities are acetylcholine deficit (acetylcholinesterase inhibitors, AChEIs) and glutamate excess (memantine).

Memantine is a moderate-affinity, voltage-dependent, uncompetitive NMDA receptor antagonist with fast receptor kinetics (Görtelmeyer and Erbler, 1992). Initial data from a double-blind, placebo-controlled nursing home trial in severe dementia of mixed aetiology (51 per cent of patients had VaD), showed that memantine (10 mg/day) was well tolerated, improved function, and reduced care dependency in treated patients with severe dementia, compared with patients on placebo (Winblad and Poritis, 1998). Based on the hypothesis of glutamate-induced neurotoxicity in cerebral ischaemia, two randomized, placebo-controlled 6-month trials have studied memantine (20 mg/day) in patients with mild to moderate probable NINDS-AIREN VaD (Orgogozo *et al.*, 2002; Wilcock *et al.*, 2002).

The study MMM 300 randomized 147 patients on memantine and 141 on placebo (Orgogozo *et al.*, 2002). After 28 weeks, the mean ADAS-cog scores were significantly improved relative to placebo: the memantine group mean score had gained an average of 0.4 points, whereas the placebo group mean score declined by 1.6, i.e. a difference of 2.0 points ($P = 0.0016$). The response rate for CIBIC-plus, defined as improved or stable, was 60 per cent with memantine compared with 52 per cent with placebo ($P = 0.227$). The Gottfries-Bråne-Steen (GBS) Scale and the Nurses' Observation Scale for Geriatric Patients (NOSGER) total scores at week 28 did not differ significantly between the two groups. However, the GBS Scale intellectual function subscore and the NOSGER disturbing behaviour dimension also showed a difference in favour of memantine ($P = 0.04$ and $P = 0.07$, respectively).

The study MMM 500 randomized 277 patients on memantine and 271 on placebo (Wilcock *et al.*, 2002). At 28 weeks the active group had gained 0.53 and placebo declined by 2.28 points in ADAS-cog, a significant difference of 1.75 ADAS-cog points between the groups ($P < 0.05$). The global assessment CGIC, the MMSE, GBS or NOSGER did not reveal differences between the groups. Memantine was well tolerated in the two studies. In a *post hoc* pooled subgroup analysis of these two studies by baseline severity as assessed by MMSE, the more advanced patients obtained a larger cognitive benefit than the mildly affected patients did. The subgroup with an MMSE score < 15 at baseline showed an ADAS-cog improvement of 3.2 points over placebo (Möbius and Stöfler, 2003). Subgroup analyses by radiological findings at baseline showed that the cognitive treatment effect for memantine was more pronounced in the small vessel type group of patients who had no signs of cortical infarctions in their brain scans (CT or MRI). In addition, the placebo decline in this group was clearly more pronounced than in

patients with (cortical) large-vessel type VaD (Möbius and Stöfler, 2002).

43.12.2 Cholinergic dysfunction in VaD

Cholinergic deficit in VaD, independently of any concomitant AD pathology, has been documented. Cholinergic structures are vulnerable to ischaemic damage. Indeed, hippocampal CA1 neurones are particularly susceptible to experimental ischaemia, and hippocampal atrophy is common in patients with VaD in the absence of AD (Vinters *et al.*, 2000). Selden *et al.* (1998) described two highly organized and discrete bundles of cholinergic fibres in human brains that extend from the nucleus basalis to the cerebral cortex and amygdala. Both pathways travel in the white matter, and together carry widespread cholinergic input to the neocortex. Localized ischaemic focal lesions or white matter lesions may interrupt these cholinergic bundles. Mesulam *et al.* (2003) demonstrated cholinergic denervation from pathway lesions, in the absence of AD, in a young patient with CADASIL, a pure genetic form of VaD.

In experimental rodent models, such as the spontaneously hypertensive stroke-prone rat, there is a significant reduction in cholinergic markers including acetylcholine (ACh) in the neocortex, hippocampus and CSF (Togashi *et al.*, 1994). White matter infarction in rodent models results in substantial decreases in cholinergic markers, presumably through an impact on cholinergic projection fibres (Freidle, 1967). In human disease there is a reported loss of cholinergic neurones in 70 per cent of AD cases and in 40 per cent of VaD patients examined neuropathologically, and reduced ACh activity in the cortex, hippocampus, striatum and CSF (Court *et al.*, 2002).

43.12.3 Cholinesterase inhibitors in VaD

Four cholinesterase inhibitors (ChEIs) have been approved for use in AD: tacrine, donepezil, rivastigmine and galantamine. In controlled trials, secondary outcomes have varied, but often included ADL and behavioural scales. Studies have shown a modest improvement of cognition peaking at 3 months and decline below the baseline or starting point at 9–12 months. There is good evidence for stabilization of ADL decline for at least 6 months, and improvement of some behaviours associated with AD (predominantly apathy and hallucinations). A description of reasonable therapeutic expectations was published by Winblad *et al.* (2001).

By 2004 pivotal randomized clinical trials with ChEIs had been conducted in patients with probable and possible VaD (donepezil) and in probable VaD or AD + CVD (galantamine). A smaller series on SIVD with rivastigmine has been published. Large clinical trials on VaD are ongoing with galantamine (GAL-INT-26) and rivastigmine (Vantage).

Donepezil's safety and efficacy has been studied in the largest clinical trial of pure VaD to date (Pratt *et al.*, 2002). A

total of 1219 subjects were recruited for a 24-week, randomized, placebo-controlled, multicentre, multinational study divided in two identical trials, 307 and 308 (Black *et al.*, 2003; Wilkinson *et al.*, 2003). The patients were randomized to one of three groups: placebo, donepezil at a dosage of 5 mg/day or donepezil 10 mg/day. The group receiving 10 mg/day initially received 5 mg/day for 4 weeks; the dosage was then titrated up to 10 mg/day. Patients with a diagnosis of either possible or probable VaD according to the NINDS-AIREN criteria were eligible for inclusion in the study (Román *et al.*, 1993). All patients had brain imaging prior to the study (CT or MRI) with demonstration of relevant cerebrovascular lesions. Patients with pre-existing AD were excluded, as were patients with the so-called 'mixed dementia', better defined as AD + CVD. Although patients with concomitant AD may not be totally excluded, the NINDS-AIREN criteria are able to classify patients into probable or possible VaD categories (Erkinjuntti *et al.*, 1988; Gold *et al.*, 2002).

Probable VaD was present in 73 per cent of the patients in the two studies. Probable VaD was diagnosed by the presence of mild to moderate dementia, clinical and brain imaging evidence of relevant CVD, and a clear temporal relationship between stroke and cognitive decline, with onset of dementia within 3 months of a clinically eloquent stroke or a stepwise course. Possible VaD was diagnosed in cases with indolent onset of the cognitive decline, and accounted for 27 per cent of the cases. Possible VaD included patients with silent stroke, extensive white matter disease or an atypical clinical course. There were no differences in trial results between these two subgroups.

The end points included cognition measured with the ADAS-cog, MMSE, global function as measured with the Clinicians' Interview-Based Impression of Change – Plus (CIBIC-plus), the Sum of Boxes of the Clinical Dementia Rating (CDR-SB) and ADL as measured with Alzheimer's Disease Functional Assessment and Change Scale (ADFACS).

In the study 307 (Black *et al.*, 2003), the donepezil treatment group showed statistically significant improvement in cognitive functioning measured by ADAS-cog; the mean changes from baseline score was: donepezil 5 mg/day, -1.90 ($P = 0.001$); donepezil 10 mg/day, -2.33 ($P < 0.001$). The MMSE also showed statistically significant improvement versus placebo. The treated group showed as well significant improvement in global function on the CIBIC-plus in the 5 mg/day group ($P = 0.014$), which did not reach significance in the 10 mg/day group ($P = 0.27$). CDR-SB showed non significant benefit in the 5 mg/day group, but was significant in the 10 mg/day group ($P = 0.022$). The ADL showed significant benefits in donepezil-treated patients over placebo using the ADFACS in both treatment groups ($P < 0.05$).

In the study 308 (Wilkinson *et al.*, 2003), the donepezil treatment group showed statistically significant improvement in cognitive functioning measured with the ADAS-cog; the mean changes from baseline score was: donepezil 5 mg/day, -1.65 ($P = 0.003$); donepezil 10 mg/day, -2.09

($P = 0.0002$). The MMSE also showed statistically significant improvement versus placebo. The treated group showed as well significant improvement in global function of the CIBIC-plus in the 5 mg/day day group ($P = 0.004$), which did not reach significance in the 10 mg/day group ($P = 0.047$). CDR-SB showed non-significant benefit in the 5 mg/day group, but was significant in the 10 mg/day group ($P = 0.03$). The ADL showed superiority in the donepezil-treated patients over placebo using the ADFACS in both treatment groups, which, however, did not reach significance at the end of the study compared with placebo.

Of interest, cognitive decline in untreated patients with VaD in this trial was less severe than in placebo-treated patients with AD during 24 weeks of study, using similar instruments. These differences were also noted for global effects, measured by the CIBIC-plus version; and, in contrast with AD, patients with VaD showed actual improvements in global function. In contrast with AD trials, these VaD studies enrolled more men than women (58 per cent versus 38 per cent), their mean age was older (74.5 ± 0.2 versus 72 ± 0.2 years), their HIS score more elevated (6.6 ± 0.2 versus < 4), with higher percentages of subjects with hypertension, cardiovascular disease, diabetes, smoking, hypercholesterolaemia, previous stroke and TIAs, suggesting that the two populations are clearly different (Pratt *et al.*, 2002).

Donepezil was generally well tolerated, although more adverse effects were reported in the 10 mg group than in the 5 mg or placebo groups. The adverse effects were assessed as mild to moderate and transient, and were typically diarrhoea, nausea, arthralgia, leg cramps, anorexia and headache. The incidence of bradycardia and syncope was not significantly different from the placebo group. The discontinuation rates for the groups were 15 per cent for placebo, 18 per cent for the 5 mg group, and 28 per cent for the 10 mg group. There was no significant interaction with the numerous cardiovascular medications and antithrombotic agents used by this population. Donepezil was demonstrated to be effective and well tolerated in the treatment of patients with VaD.

Galantamine is a cholinesterase inhibitor that also modulates central nicotinic receptors to increase cholinergic neurotransmission. In a multicentre, double-blind, 6-month randomized controlled trial patients diagnosed with probable VaD, or with AD combined with CVD, received galantamine 24 mg/day ($n = 396$) or placebo ($n = 196$) (Erkinjuntti *et al.*, 2002). Eligible patients met the clinical criteria of probable VaD of the NINDS-AIREN (Román *et al.*, 1993), or possible AD according to the NINCDS-ADRDA (McKhann *et al.*, 1984). They also showed significant radiological evidence of CVD on CT or MR (i.e. they had AD and CVD). Evidence of CVD on a recent (within 12 months) scan included multiple large-vessel infarcts or a single, strategically placed infarct (angular gyrus, thalamus, basal forebrain, territory of the posterior or anterior cerebral artery), or at least two basal ganglia and white matter lacunae, or white matter changes involving at least 25 per cent of the total white matter. They

had to score 10–25 on the MMSE and 12 or more in the ADAS-cog/11, and had to be between ages of 40 and 90 years.

Primary end points were cognition, as measured using the ADAS-cog/11, and global functioning, as measured using the CIBIC-plus. Secondary end points included assessments of activities of daily living, using the Disability Assessment in Dementia (DAD), and behavioural symptoms, using the Neuropsychiatric Inventory (NPI) (Erkinjuntti *et al.*, 2002).

Analysing both groups as a whole, galantamine demonstrated efficacy on all outcome measures. Galantamine showed greater efficacy than placebo on ADAS-cog (2.7 points, $P \leq 0.001$) and CIBIC-plus (74 per cent versus 59 per cent of patients remained stable or improved, $P \leq 0.001$). Activities of daily living and behavioural symptoms were also significantly improved compared with placebo (both $P < 0.05$). Galantamine was well tolerated (Erkinjuntti *et al.*, 2002).

In an open label extension the original galantamine group of patients with probable VaD or AD + CVD showed similar sustained benefits in terms of maintenance of or improvement in cognition (ADAS-cog), functional ability (DAD) and behaviour (NPI) after 12 months (Erkinjuntti *et al.*, 2003).

Although the study was not designed to detect differences between subgroups, the subgroup of patients with AD + CVD on galantamine ($n = 188$; 48 per cent) showed greater efficacy than placebo ($n = 97$; 50 per cent) at 6 months on ADAS-cog ($P \leq 0.001$) and CIBIC-plus ($P = 0.019$) (Erkinjuntti *et al.*, 2002). In the open-label extension patients with AD + CVD continuously treated with galantamine maintained cognitive abilities at baseline for 12 months (Small *et al.*, 2003).

Probable VaD was diagnosed in 81 (41 per cent) of the placebo patients and in 171 (43 per cent) of the patients on galantamine. In the probable VaD group, ADAS-cog scores improved significantly (mean change from baseline, 2.4 points, $P < 0.0001$) in patients treated with galantamine for 6 months, but not in the patients treated with placebo (mean change from baseline, 0.4; treatment difference versus galantamine 1.9, $P = 0.06$) (Erkinjuntti, 2002; Erkinjuntti *et al.*, 2002). More patients treated with galantamine than with placebo-maintained or improved global function (CIBIC-plus, 31 per cent versus 23 per cent); however, it was not statistically significant. In these patients, the cognitive benefits of galantamine were maintained at least up to 12 months, demonstrating a mean change of -2.1 in the ADAS-cog score compared with baseline (Small *et al.*, 2003) and the active group was still close to baseline at 24 months (Kurz *et al.*, 2003).

Rivastigmine is an acetylcholinesterase and butyrylcholinesterase inhibitor. The effects of rivastigmine in the treatment of cognitive impairment associated with general VaD remain to be established. It has been shown in a small study of patients with subcortical VaD that rivastigmine improved cognition (clock drawing test), reduced caregiver stress and improved behaviour (Moretti *et al.*, 2001). AD patients with vascular risk factors showed relatively larger effect size in cognitive response (ADAS-cog) than those

without vascular risk factors (Kumar *et al.*, 2000; Erkinjuntti *et al.*, 2002).

44.1 LEUKOARAIOSIS: HISTORICAL NOTES, DEFINITION AND RADIOLOGICAL–PATHOLOGICAL CORRELATES

44.1.1 Historical notes

A possible relation between cerebral white matter changes and impairment in cognitive functions was first suggested by Binswanger. In 1894, in a lengthy manuscript dealing with the differential diagnosis of general paresis of the insane, Binswanger described the case of a syphilitic man in his mid-50s, who had developed a progressive decline in mental functions characterized by speech and memory disorders, depression and personality changes (Binswanger, 1894; Blass *et al.*, 1991). At autopsy, the dura mater at the base of the skull showed granular deposits; there was minimal intracranial atherosclerosis, considerable enlargement of the lateral ventricles, marked atrophy of the cerebral white matter, and multiple ependymal thickenings (Binswanger, 1894; Blass *et al.*, 1991). Binswanger neither provided microscopic descriptions nor illustrated any findings of this single case, which remained the sole publication in which he dealt with the topic of white matter disease (Schneider and Wiczorek, 1991). In 1902, Alzheimer referred to the case described by his mentor Otto Binswanger, added a short histological description of what he considered was an analogous case and, intuitively, attributed the white matter changes to arteriosclerosis of the long penetrating vessels (Alzheimer, 1902; Schorer, 1992).

In 1962, Olszewski was the first to doubt that Binswanger's original report contained sufficient data to define a new disease, and suggested that the lesions in the dura mater and in

the ependyma, together with the history of syphilis, made Binswanger's a likely case of neurosyphilis. Accordingly, Olszewski proposed the term subcortical arteriosclerotic encephalopathy to describe 'a form of cerebral arteriosclerosis in which vessels of the white matter and subcortical grey matter are affected predominantly' (Olszewski, 1962). In subsequent years, the diagnosis of 'Binswanger's disease' remained restricted to rare descriptions, and careful revision of previous cases shows that many of them were ascribable to heterogeneous pathological processes (Pantoni *et al.*, 1996b; Pantoni and Garcia, 1996).

The diagnosis of 'Binswanger's disease' acquired new popularity after the introduction of computed tomography (CT) and the first reports based exclusively on clinical-radiological findings (Rosenberg *et al.*, 1979) that led many to assume that 'Binswanger's disease' could be diagnosed premortem (Loizou *et al.*, 1981; Tomonaga *et al.*, 1982; Young *et al.*, 1983; Bradley *et al.*, 1984a; Kinkel *et al.*, 1985, 1986; Gerard and Weisberg, 1986). However, it soon became apparent that alterations of the hemispheric white matter, detected by either CT or magnetic resonance imaging (MRI), were common both in symptomatic and asymptomatic subjects.

Careful discussion about the historical appropriateness and usefulness of the eponym 'Binswanger's disease' is beyond the scope of this chapter and has been already dealt with in a collection of papers (Bogousslavsky *et al.*, 1996). Nowadays, many authors still use the eponym to describe a form of vascular dementia with prevalent damage of subcortical structures. Bennett *et al.* (1990) have proposed clinical criteria for 'Binswanger's disease' which, unfortunately, were validated against pathological criteria on which no consensus exists. In the NINDS-AIREN criteria for vascular dementia

'Binswanger's disease' somehow overlaps with the more general definition of 'small-vessel disease with dementia' (Román *et al.*, 1993). Therefore what is by some still considered as a well-defined disease entity ('Binswanger's disease') probably represents only the most severe expression of a pathological process–radiological picture encompassing normal and pathological states without a clear cut-off.

44.1.2 Definition of leukoaraiosis

The term leukoaraiosis (originally leuko-araiosis) (LA) is a neologism coined in the 1980s to describe the radiological alterations detected by CT in the brains of elderly neurologically normal subjects and, more frequently, in demented patients (Hachinski *et al.*, 1986, 1987). The term derives from the Greek *leuko* (white) and *araiosis* (rarefaction), and was intentionally meant to be descriptive in an attempt to overcome the diffuse tendency to identify these neuroimaging abnormalities of uncertain origin and unclear clinical significance with a disease. LA designates areas of hypodensity on CT in the periventricular or subcortical white matter. The lesions can be focal, initially confluent, or diffuse according to the severity; are usually symmetric in the two hemispheres; and can be differentiated from other cerebrovascular processes such as territorial infarcts. In the original group of papers that reported on the new term and on the clinical correlates of LA, only CT-detected lesions were considered (Hachinski *et al.*, 1987; Inzitari *et al.*, 1987; Steingart *et al.*, 1987a, b). However, in the following years the term leukoaraiosis was also used to describe the MRI white matter lesions of analogue significance. On MRI these lesions appear as areas of hyperintensity on T2-weighted images and, given the better spatial resolution of this technique, can be differentiated into those in the periventricular region and those in the deep white matter of the corona radiata or centrum semiovale. A number of studies then pointed out differences, similarities and correlations between the lesions detected by CT and MRI (Brant-Zawadzki *et al.*, 1983; Bradley *et al.*, 1984b; Salgado *et al.*, 1986; Zimmerman *et al.*, 1986; Erkinjuntti *et al.*, 1987a; Johnson *et al.*, 1987; Lechner *et al.*, 1988). Recently, a systematic approach to the harmonization of CT and MRI LA rating has also been proposed (Pantoni *et al.*, 2002).

Over the following years, a large number of visual scales have been developed to rate and classify LA mainly in order to detect a cut-off score to define a pathological status. These scales are described in detailed in a review paper (Scheltens *et al.*, 1998). Being based on visual evaluation, many scales are prone to high interrater variability. The complexity of different scales is very variable. The scales based on MRI evaluation are usually more complex than those based on CT. Based on the above mentioned collaborative work by the European Task Force on Age-Related White Matter Changes, harmonization of the scales has been proposed. The main results of this collaboration are the creation of a new visual

rating that can be used for both CT and MRI (Wahlund *et al.*, 2001), the development of methods to convert the score of one visual rating scale into that of another (Pantoni *et al.*, 2002), and definition of the agreement between visual and volumetric assessment of white matter changes (Kapeller *et al.*, 2003).

In recent years, computer-assisted volumetric evaluation of LA as detected by MRI has been used and proposed as a more valuable tool to assess the impact of these changes on clinical functions (Schmidt *et al.*, 1993). Volumetric assessment techniques are time consuming but likely more reliable than visual rating for the assessment of the progression of LA that is to be considered a rather slow but measurable process (Kapeller *et al.*, 2003). One of the most relevant advances in the field is the recent demonstration of the progression of white matter changes in a group of patients with severe degrees of LA (Schmidt *et al.*, 2003). Also based on the experience gathered in other neurological diseases such as multiple sclerosis, the volumetric assessment of LA has thus been proposed as an outcome measure for clinical trials focused on small vessel-related diseases that are characterized by prominent LA, such as subcortical vascular dementia (Schmidt *et al.*, 2004).

44.1.3 Radiological–pathological correlates of leukoaraiosis

The pathological correlates of LA are not definitely established. At the histological level, heterogeneous changes may all result in radiological pictures of white matter hypodensity on CT and hyperintensity on MRI. A number of studies have investigated the radiological–pathological correlates of LA, performing either neuroimaging and pathological studies after a short interval or post-mortem MRI examination.

LA in the periventricular white matter correlates with decreased myelin content (Sze *et al.*, 1986; Leifer *et al.*, 1990; Fazekas *et al.*, 1991; Grafton *et al.*, 1991; van Swieten *et al.*, 1991a; Chimowitz *et al.*, 1992; Scarpelli *et al.*, 1994; Moody *et al.*, 1995), loss of ependymal cell layer, reactive gliosis (the combination of the two above is also called granular ependymitis) at the tip of the frontal horns (Sze *et al.*, 1986; Jungreis *et al.*, 1988; Fazekas *et al.*, 1991; Grafton *et al.*, 1991; Chimowitz *et al.*, 1992; Scarpelli *et al.*, 1994), as well as with increased content of periependymal extracellular fluid, and with smaller and fewer number of axons per unit area (Sze *et al.*, 1986). Some authors also have described enlarged perivascular spaces at these periventricular locations (Grafton *et al.*, 1991) but, because small lesions in the periventricular white matter exist in all age groups (Sze *et al.*, 1986; Moody *et al.*, 1995), many authors do not consider these as indicative of true pathology.

The histological correlates of subcortical white matter changes, detectable by MRI, are less consistent than those reported for periventricular white matter changes. In these MRI studies, tiny focal abnormalities correspond to enlarged perivascular spaces (Chimowitz *et al.*, 1992; Scarpelli *et al.*,

1994), small cavitory infarcts (or lacunes) (Braffman *et al.*, 1988a; Marshall *et al.*, 1988; Muñoz *et al.*, 1993), demyelinating plaques, brain cysts and congenital diverticuli of the lateral ventricles (Braffman *et al.*, 1988b). MRI methods seem adequate to distinguish between enlarged perivascular Virchow–Robin spaces and lacunar infarcts (Braffman *et al.*, 1988b; Jungreis *et al.*, 1988). The more typical diffuse lesions in the centrum semiovale have been related to myelin rarefaction that in most instances spares the U fibres (Révész *et al.*, 1989; Chimowitz *et al.*, 1992). Sometimes these diffuse lesions are accompanied by astrogliosis (Fazekas *et al.*, 1991, 1993) and diffuse vacuolization of the white matter (Muñoz *et al.*, 1993). The white matter rarefaction corresponds to loss of myelinated axons, decreased number of oligodendrocytes, and vacuolation without clear aspects of necrosis (Awad *et al.*, 1986b; Lotz *et al.*, 1986; Janota *et al.*, 1989; Révész *et al.*, 1989). Thickening of the wall of the small vessels (arteriolosclerosis) is commonly found in areas of white matter rarefaction (Lotz *et al.*, 1986; Marshall *et al.*, 1988; Révész *et al.*, 1989; Leifer *et al.*, 1990; Fazekas *et al.*, 1991; van Swieten *et al.*, 1991b).

44.2 LEUKOARAIOSIS: PATHOGENIC ASPECTS

The pathogenesis of LA is still under investigation although the most recent data all point to a possible vascular (i.e. related to vessel disease) origin of these changes. Which vascular mechanism is involved cannot be considered, however, as definitively clarified.

Since the original, although largely incomplete and anecdotal, reports by Binswanger (Binswanger, 1894; Blass *et al.*, 1991) and Alzheimer (Alzheimer, 1902; Schorer, 1992), the white matter changes seen in demented patients were intuitively linked with vessel abnormalities. More recently, a number of clues suggest that vascular, and more specifically ischaemic, mechanisms are responsible for these alterations (Pantoni and Garcia, 1997). Among these are:

- The higher frequency of LA in patients with cerebrovascular diseases and in subjects with vascular risk factors (arterial hypertension, heart disease, diabetes mellitus, etc.) (Liao *et al.*, 1996; Longstreth *et al.*, 1996);
- The higher frequency of cardiovascular events at follow up in patients with LA (Inzitari *et al.*, 1995, 1997; Longstreth *et al.*, 2002; Wong *et al.*, 2002; Yamauchi *et al.*, 2002; Henon *et al.*, 2003; Vermeer *et al.*, 2003a);
- Some preliminary observations by positron emission tomography showing an ischaemic state of areas of LA (Yao *et al.*, 1992);
- The recent demonstration of the high susceptibility of white matter components to ischaemia (Pantoni *et al.*, 1996a; Petito *et al.*, 1998; Pantoni, 2000).

Central to the vascular theory is the role played by deep small vessel alterations. Changes of the arteriolosclerotic type

in the small vessels (loss of smooth muscle cells, fibrohyalinization of the tunica media, thickening of the wall) are commonly seen in areas of white matter alterations and have been associated particularly with ageing, arterial hypertension and diabetes mellitus (Alex *et al.*, 1962; Furuta *et al.*, 1991; Ostrow and Miller 1993). These changes may result in stenosis or occlusion of the vessels with consequent sudden or more chronic oligoemia of the parenchyma. Moreover, the arteriolosclerotic changes lead the small arteries and arterioles located in the deep white matter and basal ganglia to lose their physiologic capacity to dilate and constrict in response to variations of systemic blood pressure (autoregulation). Accordingly, the areas supplied by these vessels may suffer from cerebral blood flow fluctuations (either drops or increases) in response to changes of systemic blood pressure.

Both these types of mechanism may be particularly harmful to the brain parenchyma since the blood supply of the deep cerebral structures is of the terminal type with scarce, if any, anastomoses (Rowbotham and Little, 1965; Van den Bergh and van der Eecken, 1968). This vascular damage to the white matter would not be sufficient to provoke complete necrosis of the tissue (with the exception of some areas where true lacunar infarcts are recognizable) but could cause selective damage to some histological components. Brun and Englund were among the first to propose that the diffuse changes of the white matter seen in demented patients were to be considered a form of incomplete infarction (Brun and Englund, 1986). Although this remains a hypothesis, there are now experimental data showing that white matter components are extremely vulnerable to ischaemia and can be damaged in the absence of neuronal injury (Pantoni *et al.*, 1996a; Petito *et al.*, 1998).

As far as the pathogenesis of LA in Alzheimer's disease (AD) is concerned, there are a few hypotheses that have been put forward. The majority of AD patients show cerebral amyloid angiopathy, another type of small vessel disease. Cerebral amyloid angiopathy is histologically characterized by thickening of the wall of small- and medium-size subarachnoid and cortical arteries and arterioles caused by the deposition in the media and adventitia of an amorphous, eosinophilic material that shows typical yellow-green birefringence when stained with Congo Red and viewed under polarized light (Vinters, 1987). The hypothesis that amyloid angiopathy in AD patients may be causally linked to white matter alterations is supported by the observation that subcortical leukoencephalopathy was demonstrated in patients with cerebral amyloid angiopathy who lacked changes characteristic of AD (Gray *et al.*, 1985; Tabaton *et al.*, 1991).

The hypothesis that white matter damage in patients with AD might simply reflect Wallerian changes secondary to cortical loss of neurones (Leys *et al.*, 1991) seems less likely. The histological markers of Wallerian changes, such as abundant lipid-laden macrophages, are in fact missing in most areas of leukoencephalopathy. Moreover, it is difficult to understand why many AD patients with severe cortical atrophy and loss of neurones lack demonstrable white matter changes at

autopsy (Brun and Englund, 1986). Magnetic resonance spectroscopy data confirm that decreases in myelin phospholipids exist in areas of LA, in the absence of changes in the concentration of *N*-acetyl-aspartate, a marker for neuronal perikarya (Constans *et al.*, 1995). This reinforces the hypothesis that the changes in the white matter can occur independent of the alterations involving the grey matter. A second possible cause of white matter damage in AD patients are changes affecting the tunica media and tunica adventitia of the white matter vessels, the extent and frequency of which is higher than in age-matched controls (Brun and Englund, 1986; Scheltens *et al.*, 1995). A third possible cause could be changes in the permeability of the blood–brain barrier to proteins and the accumulation of fluid in the extracellular space. This leakiness might be the result of structural alterations, such as thickening of the basal lamina and pericapillary gliosis affecting the precapillary arterioles (Buée *et al.*, 1994).

As alternatives to the possible ischaemic origin of LA, other hypotheses have been raised. In our view, these mechanisms are not mutually exclusive and may concur to the development of the final pathological picture. The small vessel alterations also could lead to damage of the blood–brain barrier and chronic leakage of fluid and macromolecules in the white matter. White matter changes characterized by pallor sparing the U fibres, accompanied by reactive astrogliosis and small vessel thickening have been described in conditions with antecedent brain oedema (Feigin and Popoff, 1963). This suggests that transient cerebral oedema might be an additional cause of white matter changes. The increased interstitial fluid concentration in abnormal white matter may be also a consequence of arterial hypertension. The blood–brain barrier may be leaky, and the capillary permeability to proteins may be increased in patients with systemic hypertension (Nag, 1984). Abnormalities in the blood–brain barrier, in the form of increased concentration of cerebrospinal fluid proteins, have been described in a group of patients with LA (Pantoni *et al.*, 1993) and in a pathological series of patients with subcortical vascular encephalopathy (Akiguchi *et al.*, 1998). In addition to the effects of sustained hypertension, hypertensive bouts of short duration could cause fluid transudation and protein leakage.

In addition to acquired vascular risk factors and conditions, genetically determined factors also could play an important role in the development of white matter alterations in the elderly. At least one form of vascular leukoencephalopathy exists that is genetically determined. It is called CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) and has been recently recognized and genetically characterized (Joutel *et al.*, 1996). It is caused by a point mutation in the Notch3 gene located on chromosome 19p13.1. The clinical features of CADASIL are similar to those encountered in patients with sporadic age-related LA (cognitive deterioration, mood and gait disorders, recurrent subcortical strokes), but the age of onset of these disturbances is classically in the fourth and fifth decades and the course is usually very severe (Chabriet

et al., 1995; Dichgans *et al.*, 1998; Desmond *et al.*, 1999; Sarti and Pantoni, 2000). Moreover, migraine in young ages is another hallmark of the disease. From the radiological point of view, CADASIL patients present with diffuse cerebral white matter alterations associated with small focal lesions of the lacunar type. Histological studies have shown a degeneration of small vessel smooth muscle cells with deposition of granular osmiophilic material in the vessel wall (Ruchoux and Maurage, 1997; Sarti and Pantoni, 2000). The epidemiological relevance of CADASIL is under evaluation. Once reputed a rare disease, the number of described patients is now continuously increasing with cases reported at older ages and with more benign course raising the possibility of different patterns of transmission or penetrance (Pantoni *et al.*, 2004).

Genetic factors may also contribute, by interaction with conventional risk factors, to the development of white matter injury in non-familial cases. The heritability of LA has been shown by two studies in a consistent extent of about 65–70 per cent (Carmelli *et al.*, 1998; Turner *et al.*, 2004). Among possible genetic factors, angiotensinogen gene promoter haplotype (Schmidt *et al.*, 2001) and paraoxonase specific polymorphisms (Schmidt *et al.*, 2000) already have been found to be associated with LA. Another genetic factor with possible influence on the presence an extension of LA could be apolipoprotein (ApoE). The ApoE ϵ 4 allele (Skoog *et al.*, 1998) has been associated with damage of cerebral subcortical structures in one CT-based community survey, while the ϵ 2- ϵ 3 ApoE genotype has been found to be associated with white matter changes among population subjects free of neuropsychiatric disease (Schmidt *et al.*, 1997). While the possible specific role of these genetic factors in the origin of LA remains to be explored, their influence could explain why not all the patients with vascular risk factors, for example hypertension, develop white matter alterations at follow up.

44.3 LEUKOARAIOSIS: EPIDEMIOLOGICAL ASPECTS

LA is frequently detected by CT and MRI both in asymptomatic people older than 60 years and in cognitively impaired individuals, especially those who have evidence of either cerebrovascular disease or risk factors associated with stroke (Pantoni and Garcia, 1995). Among series of patients with dementia of presumed vascular origin, LA is detected by CT with a frequency ranging from 41 to 100 per cent (London *et al.*, 1986; Inzitari *et al.*, 1987; Erkinjuntti *et al.*, 1987a, b; Aharon-Peretz *et al.*, 1988; Jayakumar *et al.*, 1989; Wallin *et al.*, 1989; Kobari *et al.*, 1990a, b; Parnetti *et al.*, 1990; Rähkä *et al.*, 1993), and by MRI in 64 to 100 per cent of the cases (Erkinjuntti *et al.*, 1987a; Fazekas *et al.*, 1987; Hershey *et al.*, 1987; Kertesz *et al.*, 1990; Kobari *et al.*, 1990b; Mirsen *et al.*, 1991; Almkvist *et al.*, 1992; Liu *et al.*, 1992; Schmidt, 1992; Wahlund *et al.*, 1994). Although the frequency of LA is

the highest in patients with cerebrovascular diseases, with or without dementia, a large proportion of AD patients, ranging from 19 to 78 per cent in CT-based studies have LA (George *et al.*, 1986a; London *et al.*, 1986; Erkinjuntti *et al.*, 1987a; Inzitari *et al.*, 1987; Rezek *et al.*, 1987; Steingart *et al.*, 1987b; Aharon-Peretz *et al.*, 1988; Erkinjuntti *et al.*, 1989; Fazekas *et al.*, 1989; Wallin *et al.*, 1989; Kobari *et al.*, 1990a, b; Blennow *et al.*, 1991; Diaz *et al.*, 1991; Lopez *et al.*, 1992; R ih a *et al.*, 1993), and from 7.5 to 100 per cent in MRI studies (George *et al.*, 1986b; Erkinjuntti *et al.*, 1987a; Fazekas *et al.*, 1987; Bondareff *et al.*, 1988; Wilson *et al.*, 1988; Fazekas *et al.*, 1989; Kertesz *et al.*, 1990; Kobari *et al.*, 1990b; Kozachuk *et al.*, 1990; McDonald *et al.*, 1991; Mirsen *et al.*, 1991; Almkvist *et al.*, 1992; Schmidt, 1992; Wahlund *et al.*, 1994; Waldemar *et al.*, 1994). However, the changes in white matter density are usually less severe in AD patients than in those with cerebrovascular disorders (Fazekas *et al.*, 1987; Steingart *et al.*, 1987b; Bowen *et al.*, 1990; Kertesz *et al.*, 1990; Almkvist *et al.*, 1992; Wahlund *et al.*, 1994).

LA in normal controls is usually less severe than in demented patients (Harrell *et al.*, 1991; Schmidt, 1992; Waldemar *et al.*, 1994), but is, however, frequent, occurring in up to 21 per cent of asymptomatic subjects evaluated with CT (London *et al.*, 1986; Inzitari *et al.*, 1987; Steingart *et al.*, 1987a; Kobari *et al.*, 1990b; R ih a *et al.*, 1993; George *et al.*, 1986a; Rezek *et al.*, 1987; Fazekas *et al.*, 1989) and up to 100 per cent among those evaluated with MRI (George *et al.*, 1986b; Fazekas *et al.*, 1987, 1988; Fazekas, 1989; Hendrie *et al.*, 1989; Hunt *et al.*, 1989; Rao *et al.*, 1989; Bowen *et al.*, 1990; Kertesz *et al.*, 1990; Kobari *et al.*, 1990b; Kozachuk *et al.*, 1990; Zubenko *et al.*, 1990; McDonald *et al.*, 1991; Mirsen *et al.*, 1991; Schmidt *et al.*, 1991, 1993; Almkvist *et al.*, 1992; Boone *et al.*, 1992; Schmidt, 1992; Tupler *et al.*, 1992; Waldemar *et al.*, 1994). The prevalence of MRI-detected LA in the general population has been evaluated in some recent community-based studies (Breteler *et al.*, 1994b; Lindgren *et al.*, 1994; Schmidt *et al.*, 1995; Ylikoski *et al.*, 1995; Liao *et al.*, 1996; Longstreth *et al.*, 1996). The figures are shown in Table 44.1.

Although figures are variable, the frequency of LA in these studies generally is very high. When any degree of white matter alterations was considered, almost all the subjects in the sample proved to have LA (Liao *et al.*, 1996; Longstreth *et al.*, 1996). In all these studies the severity and the extent of hyperintense images in the white matter increased with age.

One of these studies (Liao *et al.*, 1996) evaluated the possible difference in frequency of white matter alterations and risk factors between white and African American subjects. The higher prevalence of LA among African Americans was explained by the higher prevalence of hypertension in this racial group. No data exist so far on the prevalence of white matter changes among Asians among whom hypertension is highly prevalent.

Only one study has used CT to estimate the prevalence of white matter changes in the population. The study performed in Sweden in a cohort of very old (85-year-old) subjects reported an over-30 per cent prevalence of moderate to

Table 44.1 Frequency of MRI-detected white matter changes in population based studies

Author	Age	Number of subjects evaluated by MRI	Prevalence of white matter changes

severe LA among non-demented subjects of this age group (Skoog *et al.*, 1994). In the same Swedish community an ongoing survey has recently reported the presence of LA of any degree to be present in about 55 per cent of the subjects with a mean age of 74 years (Simoni *et al.*, 2003).

Discrepant data on the frequency of LA across studies can be attributed to the inclusion of subjects of different ages or with different frequency of associated vascular risk factors. In addition, in MRI studies, the diverse strengths of magnetic field and variations in pulse sequence may lead to different results. Other possible reasons are the different criteria used for defining LA, including whether minimal periventricular lesions are considered or not.

44.4 RELEVANCE OF LEUKOARAIOSIS TO COGNITIVE IMPAIRMENT

44.4.1 Specificity of the association between leukoaraiosis, dementia and dementia type

The first reports of radiologically detected white matter changes regarded anecdotal cases of patients with dementia and other neurological deficits consistent with the diagnosis of 'Binswanger's disease'. In ensuing studies of series of patients collected for presenting with white matter abnormalities on CT, dementia or intellectual impairment was not invariably present (Valentine *et al.*, 1980; Goto *et al.*, 1981; Loizou *et al.*, 1981). The prevalence of demented patients varied across these series according to the different study settings and selection. The frequency of mental deterioration appeared to increase with the extension of white matter disease in a study performed in two Japanese geriatric hospitals (Goto *et al.*, 1981). All 15 patients in the series of Loizou *et al.* selected for fulfilling diagnostic criteria for a diagnosis of subcortical arteriosclerotic encephalopathy were mildly to

moderately demented (Loizou *et al.*, 1981). Mental abnormalities included mostly impaired visual-motor skills and executive functions, mood and other frontal lobe disturbances related to white matter disease predominantly located in the frontal lobes. In the same study, a second small series of clinically unselected patients with white matter changes comprised subjects who were not demented, and, who, according to the authors, could exemplify early stages of subcortical arteriosclerotic encephalopathy (Loizou *et al.*, 1981).

LA was then examined in series of demented patients compared with non-demented controls. These studies provided conclusive evidence that the mere presence of LA was not synonymous with dementia. George *et al.* (1986a) were the first to indicate that what they called 'brain lucencies' were observable in demented patients as well as in normal aged individuals and a strict correlation with age was observed. They also suggested that in their AD patients the presence of lucencies seemed to worsen the dementing disorder. MRI soon proved to be more sensitive than CT in revealing changes in white matter. Awad *et al.* (1986a) investigated 'incidental subcortical lesions' on MRI scans of elderly individuals. Prevalence of these lesions was definitely correlated with increasing age, history of hypertension and ischaemic cerebrovascular disease, but was independent of any particular clinical entity, including dementia. However, George *et al.* (1986b) found that in demented patients the extent of white matter involvement on MRI was greater than in normal controls.

A similar finding was reported by others (Rezek *et al.*, 1987). In a study of demented patients compared with age-matched controls, Inzitari *et al.* (1987) addressed the question to what extent LA was linked with dementia, adjusting for factors associated with both conditions. Prevalence of LA was 35 per cent among 140 demented patients and about 11 per cent among 110 aged controls, a difference that was statistically highly significant. However, the strong association between dementia and LA disappeared in a multivariate statistical model including vascular risk factors and history of stroke as possible confounding factors, and the association between dementia and LA turned out mainly to be explained by the effect of stroke. In this study, history of stroke proved to be the major independent predictor of LA and deep lacunar infarct was the stroke type most frequent among demented patient with stroke history. Regarding dementia types, 100 per cent of patients classified as having multi-infarct dementia had LA. However, 33 per cent of the patients classified in the AD subgroup also showed LA.

This last finding, while confirming previous observations, was in contrast with the very low prevalence (1.5 per cent) of LA in AD patients found by Erkinjuntti *et al.* (1987b) in a study of the same period. The difference appeared less marked, but still significant, when MRI was used to replicate the study (Erkinjuntti *et al.*, 1987a); all the 29 vascular dementia patients had white matter changes in this second study, as opposed to 8 of 22 (36 per cent) in the AD group. These findings induced the authors to indicate imaging techniques as a tool for discriminating between different dementia types.

Schmidt (1992) made similar observations comparing MRI scans of 31 patients with vascular dementia with those of 27 patients with AD type dementia and those of 18 normal controls. Almost all the vascular dementia patients had white matter changes; these consisted in irregular periventricular halos in 94 per cent of patients, whereas large confluent subcortical lesions were observable in only half of these patients. AD patients showed almost exclusively punctate lesions which, however, were present in the large majority (78 per cent) of the patients. These findings suggest that between the two types of dementia, besides difference in the absolute prevalence of white matter lesions, there are quantitative differences and different morphological patterns, possibly expressing different pathological substrates.

The study by Hershey *et al.* (1987) found no statistically significant difference in the prevalence of white matter lesions between cerebrovascular patients with and without dementia, confirming that cerebral vascular disease is more important than dementia in relation to these lesions. Ventricular enlargement was the only abnormality discriminating between demented and non-demented patients in this study. Tanaka *et al.* (1989) performed a similar study in the setting of lacunar infarction. Demented patients had more severe white matter disease, but also a greater degree of brain atrophy.

From the evaluation of these first cross-sectional and observational data all the difficulties and uncertainties linked with the interpretation of the pathophysiological role of LA in relation to dementia emerge, even in relation to the vascular dementia setting where LA is most frequently observable, and where the current view considers white matter changes an important factor to be taken into account. Regarding LA associated with AD, we have seen that, after the first observations, this rather surprising finding has been reported repeatedly, although with a wide variation in the observed prevalence.

44.4.2 Effect of leukoaraiosis on severity of dementia and on pattern of cognitive impairment

Several early studies attempted to evaluate the impact of white matter abnormality on the severity of dementia or on pattern of cognitive impairment (Table 44.2). Patients included in these studies were for the large majority AD patients. Concerning neuropsychological measurements, there were studies that employed screening tools for dementia or dementia scales, and studies that used comprehensive test batteries or tests of selective cognitive functions.

From the evaluation of the results reported in Table 44.2, the following conclusions may be made. First, CT studies are not numerous and their results seem to be much influenced by the effect of age. In one population-based study examining a fairly wide patient sample in the oldest age group, demented patients compared with and without LA, proved

Table 44.2 Studies examining the impact of leukoaraiosis on severity of dementia, or type of cognitive impairment in demented patients

more impaired in both global and selective cognitive functions (Skoog *et al.*, 1996). It is noteworthy that subcortical functions were the ones found to be selectively affected. Second, in MRI studies, discrepant results are apparent. Data may be influenced by small sample sizes, different age groups, patient selection, and use of different tools for measuring cognition. In this last connection, abnormalities of global cognitive function seem less prone to be associated with the presence of LA, in comparison with those of selective functions.

However, in one study, measuring quantitatively abnormal white matter volume, Stout *et al.* (1996) were able to find a correlation between this volume and scores of tests of global cognition such as the Mini-Mental State Examination (MMSE) and the Mattis Dementia Rating Scale. MRI study results may be influenced by different lesion patterns of white matter abnormalities (i.e. differently located and shaped lesions, periventricular halos, punctate or confluent focal deep or subcortical lesions).

Fazekas *et al.* (1996), confirming a finding previously reported by others (Mirsen *et al.*, 1991), have shown that computer-measured, rather than visually rated, periventricular hyperintensity was significantly greater in AD patients than in controls matched for risk factors. They also observed a significant association between periventricular hyperintensity thickness and lateral ventricular enlargement. Based on these observations, it has been suggested that the more likely explanation for the discrepancy of reports on the association between MRI assessed LA and dementia may be due to difference in brain atrophy across the various groups of patients investigated (Fazekas *et al.*, 1998). This may explain the lack of difference in brain hyperintensities between early AD and control subjects reported by Erkinjuntti *et al.* (1994).

A positive association between ventricular dilatation and cognitive impairment has been observed in numerous, both cross-sectional and longitudinal, studies on LA and cognitive decline, and in the setting of either vascular or AD dementia. Studies using detailed and comprehensive tests batteries tended to discover more abnormalities linked with presence and severity of LA than those using global screening tools for dementia assessment. Again, functions found consistently to be impaired in many studies were those linked to subcortical-frontal connections. For example, attention and visual construction proved to be selectively impaired in some studies (Bondareff *et al.*, 1988; Kertesz *et al.*, 1990; Almkvist *et al.*, 1992).

44.4.3 Leukoaraiosis as a predictor of dementia progression

Longitudinal studies examining the prognostic significance of LA in relation to dementia development or progression are very scanty. Morris *et al.* (1990) followed up 12 AD patients with and 26 AD patients without LA over a period of 66 months (Morris *et al.*, 1990). At the end of the follow up, AD patients with LA had not experienced greater dementia progression or mortality. No progression of LA was observed during the study period, but in patients with LA ventricular size tended to increase. The rate of disease progression was examined by Lopez *et al.* (1992) in 22 patients with probable AD and LA compared with 22 AD patients without LA. Executive/attention, lexical/semantic, memory/learning, and visuospatial functions did not differ between the two groups at baseline or at the 1-year follow-up examination. However, patients with AD and LA were more likely to develop cerebrovascular disease during follow up than AD controls without LA.

Bracco *et al.* (1993) examined MRI features as possible predictors of cognitive decline in 24 patients with cerebrovascular disease and LA. All the patients underwent an extensive clinical and neuropsychological assessment on admission, and 19 patients were followed with repeated cognitive examinations for an average of 48 months. Neither extent nor location of LA predicted the development or the

progression of mental deterioration in patients who were mentally healthy or already cognitively impaired at entry.

44.4.4 Leukoaraiosis and dementia onset after acute stroke

In the last few years a number of studies have focused on the frequency, characteristics and determinants of dementia occurring in patients with an acute stroke. In this sense, efforts have been made in order to characterize the structural correlates of this frequent condition from the radiological point of view (Erkinjuntti *et al.*, 1999; Pantoni *et al.*, 1999), and LA has been hypothesized to be one potential radiological substrate of post-stroke dementia. This hypothesis is based on the evaluation of some studies.

Liu *et al.* (1992) compared clinical and MRI features in 24 patients who became demented after having a stroke and 29 patients who did not. The total area of LA was 10 times larger among patients who developed dementia. LA was the factor that best discriminated between the two groups of patients among several others, including age, total area of infarction and location in the dominant hemisphere. Out of 146 patients with a first-ever stroke, examined for dementia 3 months after the event by Censori *et al.* (1996) 15 were found to have become demented. LA was present in one-third of patients with post-stroke dementia as opposed to one-sixth of those without dementia, a difference that was not statistically significant owing to low statistical power. Patients who developed post-stroke dementia more frequently had diabetes mellitus, atrial fibrillation, aphasia, large middle cerebral artery infarction and more severe neurological deficits at entry and at 3 months than did non-demented patients, underlining the fact that the onset of post-stroke dementia is likely to be a multifactorial process.

The most comprehensive data about LA as predictor of dementia in stroke patients come from studies that have followed up patients with lacunar stroke: 95 of 215 Japanese patients with a first-ever lacunar stroke had LA on admission CT scan (Miyao *et al.*, 1992). One month after stroke, 15.1 per cent of patients with LA were found to be demented compared with 1.7 per cent of patients without LA, rates that, at the end of the 25-month follow up, had increased to 22.1 per cent and 2.5 per cent, respectively (Miyao *et al.*, 1992). The new onset dementia was attributed to stroke recurrence (mostly recurrent lacunar stroke) in all but one patient with LA.

In another study performed in Italy and aimed at investigating the risk and determinants of dementia among patients with lacunar stroke, 25 of 108 patients (23.1 per cent) developed dementia over a period of 4 years (Loeb *et al.*, 1992). The frequency of LA did not differ between patients who became demented and those who did not, while the recurrence of stroke was by far the most important determinant of subsequent dementia.

The discrepancy on the role of LA in predicting dementia between these two studies (Loeb *et al.*, 1992; Miyao *et al.*, 1992) may be due to the different case-mix. In fact, in the Italian study, patients had more severe disease at baseline, all presenting multiple lacunar infarcts on entry CT scan.

A parallel progression of LA and lacunar infarct was clearly demonstrated by Van Zagten *et al.* (1996) who examined by CT scanning repeated over 3 years the evolution of LA and associated vascular lesions in 63 patients with a first-ever symptomatic lacunar stroke, and in 44 patients with cortical territorial stroke. Progression of LA occurred in 27 patients (26 per cent) and was strongly associated with symptomatic or silent lacunar stroke at entry. Although no evaluation of evolution of functional, including cognitive, deficits was performed in this study, the results indirectly support the hypothesis that in patients with stroke, even if LA progresses over time, this is accompanied by progression of lacunar lesions, which may be the primary determinant of cognitive decline in these patients.

In a smaller study, Tarvonen-Schröder *et al.* (1995) did not find any association between progression of LA and a selective infarct type: 11 (29 per cent) of the 38 patients with either pure LA or LA combined with radiological evidence of infarction proved to have significant and rapid progression of LA during a 3-year follow-up period, irrespective of whether the infarct was small, deep, or cortical on baseline CT scan. No difference in the occurrence or type of dementia was detected at the end of the follow-up period between patients with progressive and non-progressive LA, but progressive LA was paralleled by the increase in cortical atrophy.

More recently, the presence of LA in stroke patients has been related to the occurrence of executive dysfunction reinforcing the idea that the type of cognitive change associated with LA is likely to be of the frontal type (Vataja *et al.*, 2003).

44.4.5 The role of leukoaraiosis in criteria for vascular dementia

Despite the controversies existing about the effect of the presence or the severity of white matter changes on cognition, current consensus criteria for vascular dementia and vascular dementia subtypes list LA as one of the radiological correlates of the disease. The ICD-10 criteria require the presence of dementia, hypertension, and LA to reach a diagnosis of subcortical vascular dementia (Wetterling *et al.*, 1994). According to the NINDS-AIREN criteria, LA involving at least one-fourth of the cerebral white matter is one of the radiological correlates supporting the clinical diagnosis of vascular dementia (Román *et al.*, 1993). These latter radiological criteria have been more recently operationalized (van Straaten *et al.*, 2003). The presence of extensive LA finally has been taken as one of the two radiological hallmarks of subcortical vascular dementia (the other one is the presence of multiple lacunar infarcts) in the set of clinoradiological criteria specifically developed to define this subtype of

cerebrovascular dementia in research settings (Erkinjuntti *et al.*, 2000).

44.4.6 Leukoaraiosis and cognitive functions in non-demented subjects

The possibility that LA, frequently observed in elderly subjects, produces subtle or selective cognitive deficits not sufficient for a clinical definition of dementia was first suggested by Steingart *et al.* (1987a). They observed that elderly volunteers participating in a dementia study as non-demented controls and showing LA on CT scan scored lower on an extended scale for dementia than control subjects without LA, and had difficulties in selective tasks involving time orientation, construction of sentences and memory. This finding put forward important questions about the role of LA in contributing to cognitive decline in the elderly to a level not severe enough to imply a diagnosis of dementia but still able to produce difficulties in everyday life. Neuropsychological tools to be used in this case have of course to be much more sensitive and selective than those commonly used to screen out patients with dementia. Studies in this setting have been numerous, but the results, as for the dementia setting, are discrepant. Table 44.3 lists such studies.

From the evaluation of Table 44.3 there are difficulties in drawing unequivocal conclusions. Conflicting results were obtained even by studies using similar instruments to measure cognitive functions and examining subjects comparable in age (the lack of effect was not surprising when the mean age of the sample was low, as in the study of Schmidt *et al.* [1991]). Studies exploring selective functions in a more or less detailed fashion tended to achieve more positive results compared with studies evaluating global cognitive functions. The reasons for discrepancy are again, besides age, size and mode of selection of investigational cohorts, different MRI equipment (varying from 0.02 to 1.5 Tesla), and different lesion patterns considered for their correlation with cognitive test scores. Moreover, the effect of age and other vascular risk factors was not taken into account in all the studies. The fact that two out of the three CT studies found an effect of LA on cognitive performance may be explained by the greater severity of white matter lesions as expressed by CT-evidenced LA. This may suggest that, if only confluent large changes were considered in MRI-assessed LA, an association with cognitive impairment could have been demonstrated.

Only some of the studies reported in Table 44.3 took into account concomitant structural lesions such as brain atrophy or silent infarcts. For example, a more strict association was found between cognitive deficits and ventricular enlargement than with white matter lesions in the one study, which considered cognitive impairment as possibly related to either structural abnormality (Breteler *et al.*, 1994a). Regarding the cognitive domains affected, results are rather consistent in indicating a predominant involvement of functions linked with fronto-subcortical circuits. Impairments of attention,

Table 44.3 Effect of leukoaraiosis on cognitive functions in non-demented subjects

Author, Year	Number of patients with LA/total sample	Mean age of patients with LA/patients without LA or of total sample	Association (\pm) of cognitive impairment with LA and type of impairment
CT studies			
Steingart <i>et al.</i> , 1987	9/105	75.3/70.8	Lower score on extended scale for dementia, especially items 12 (sentences construction and memory) and 13 (orientation to time)
Masdeu <i>et al.</i> , 1989	40	83.3	No effect on Blessed and Mattis dementia scales
Skoog <i>et al.</i> , 1996	46/134	85	Subjects with LA scoring lower in MMSE and in tests of verbal ability, spatial ability, perceptual speed, secondary memory, and basic arithmetics
MRI studies			
Rao <i>et al.</i> , 1989	10/50	47.1/42.8	Lack of association with any test of a comprehensive battery
Hendrie <i>et al.</i> , 1989	16/27	76.4/67.5	No variation of MMSE, CAMCOG and WAIS digit symbol
Hunt <i>et al.</i> , 1989	34/46	78.2	Lack of association with any test of a comprehensive battery after controlling for age
Mirsen <i>et al.</i> , 1991	39	73.2	No association between any pattern of LA and performance on Extended Scale for Dementia
Harrell <i>et al.</i> , 1991	25	65.6	No correlation between severity of either periventricular or deep hyperintensities and MMSE and MDRS
Schmidt <i>et al.</i> , 1991	12/32	43.3/35.8	No difference between subjects with and without white matter lesions on a computerized test of vigilance and reaction time, a test of visual attention and a test of learning and memory
Tupler <i>et al.</i> , 1992	48/66	69.9/64.3	No difference between subjects with and without subcortical white matter hyperintensities in Benton Facial Recognition Test and WAIS digit symbol after controlling for age and education
Boone <i>et al.</i> , 1992	54/100	62.8	Subjects with extensive (>10 cm ²) white matter lesions more impaired in basic attention and selected frontal lobe skills
Matsubayashi <i>et al.</i> , 1992	60/73	70	Correlation with MMSE and Hasegawa score, and visuospatial cognitive performance test
Schmidt <i>et al.</i> , 1993	74/150	61.3/58.5	Difference between subjects with and without white matter hyperintensities in form B of Trail Making Test, a complex reaction time task, and the assembly procedures of the Purdue Pegboard test
Ylikoski <i>et al.</i> , 1993	48/120	Range 55–85	Significant association of total LA and results of Trail Making Test A, Stroop test (words/time and difference/time) and compound score of speed and attention
Fukui <i>et al.</i> , 1994	38/43	66.1/55.3	No direct correlation between white matter hyperintensities score and any cognitive test. Periventricular hyperintensity associated with reduced performance in the Stroop test
Breteler <i>et al.</i> , 1994b	29/111	Range 65–84	Borderline correlation between degree of white matter lesions and CAMCOG score. White matter lesions significantly associated with subjective mental decline
Breteler <i>et al.</i> , 1994a	23/96	73.6	White matter lesions associated with word fluence (letter B), Trail Making Test A and B, Word List Learning (delayed recall)
Baum <i>et al.</i> , 1995	16/41	50.8	White matter foci related to performance on immediate visual memory/visuoperceptual skills, visuomotor tracking/psychomotor speed and, to a lesser degree, learning capacity and abstract and conceptual reasoning skills
Longstreth <i>et al.</i> , 1996	3301	75	Association of white matter lesions and modified MMSE, and Digit Symbol Substitution Test

visuospatial memory, visuospatial skills and frontal skills were the abnormalities most frequently reported.

That specific rather than general cognitive tasks are affected by the severity rather than by the mere presence of LA has been shown by other more recent surveys (de Groot *et al.*, 2000; Leaper *et al.*, 2001). Moreover, even in subjects who score high on neuropsychological tests, the severity of LA can be reflected by subjective cognitive dysfunction and reporting of progression of these dysfunctions (de Groot *et al.*, 2001).

Studies examining only subjects with vascular risk factors were not included in Table 44.3 since they cannot be considered strictly normal. Three studies have investigated hypertensive subjects compared with non-hypertensive controls (Schmidt *et al.*, 1991, 1995; van Swieten *et al.*, 1991a). In the study of van Swieten *et al.* (1991a), 10 of 42 hypertensive elderly subjects had confluent white matter lesions on MRI versus only one from an equal number of controls. The performances on MMSE, Stroop colour-word test, Trail Making test, and the visual subtest of the Wechsler Memory Scale were worse among hypertensive patients with confluent lesions. In the 1991 study of Schmidt *et al.*, 35 hypertensive subjects performed worse than non-hypertensive controls on verbal memory, total learning and memory capacity, although there was no difference in cognitive performance between hypertensives with and without punctate white matter lesions on MRI (Schmidt *et al.*, 1991). In a second study by Schmidt *et al.* (1995), 89 hypertensives tended to perform worse than 89 non-hypertensive controls when assessed for attentional and visuopractic skills. Twenty-seven out of 43 non-demented patients with history of stroke, different vascular risk factors and periventricular white matter CT hypodensity were studied with a detailed neuropsychological examination by Gupta *et al.* (1988). Even in patients with the lowest degree of white matter abnormalities there was a defect in sustained mental concentration and attention. Slowness in acquisition, difficulty in organizing material to be learned, lack of consistency in recall, and difficulties in spontaneous recall were also reported in the investigated patients.

Similar patients were studied by Junquè *et al.* (1990). Among functions explored by a comprehensive test battery, the main cognitive abnormality was a reduced speed of information processing, especially complex processes, an abnormality that was independent of age. The authors concluded that slowness of thought was the main characteristics of cognitive functioning in patients with LA (Junquè *et al.*, 1990). This slowness could affect encoding and retrieval processes in memory, although the overall results of the study tended to exclude the presence of an encoding deficit.

In none of the reported studies of the effect of LA in non-demented subjects have behavioural aspects been taken into account. Mood disorders, including depression and irritability, possibly concurring with cognitive deficits in affecting behaviour, can be substantiated by several observations in either non-demented or demented subjects with LA (O'Brien *et al.*, 1996a, b, 1998).

44.4.7 Leukoaraiosis as predictor of dementia in normal subjects and in subjects with mild cognitive impairment

Because subtle cognitive deficits are found frequently in non-demented patients with LA, the question arises whether these subjects are particularly prone to develop a more severe cognitive impairment or even overt dementia over time. Until very recently, the answer was not available and only very preliminary observations were accessible (Fein *et al.*, 1990; Guerriero Austrom *et al.*, 1990; Wohl *et al.*, 1994). Data from a large cohort of community-dwelling normal subjects, sequentially studied with MRI and detailed neuropsychological testing, have been more recently reported (Schmidt *et al.*, 1999). After 3 years, progression of LA was noted in 22 (8.1 per cent) of the 273 subjects but was not associated with cognitive decline. However, the recently published results from a large population-based study enrolling more than 700 subjects demonstrated that the presence of LA (together with that of silent lacunar infarcts) significantly predicts dementia onset (Vermeer *et al.*, 2003b). The relative risk of becoming demented over a 3.6-year follow up was about 1.6 for subjects with periventricular LA at baseline MRI.

In the National Heart, Lung and Blood Institute Twin Study, higher LA volume together with increasing age, ApoE $\epsilon 4$ genotype, elevated mid-life blood pressure, and lower alcohol consumption, significantly increased the risk of mild cognitive impairment (DeCarli *et al.*, 2001).

Many open questions in relation to the role of LA in the development of cognitive impairment or dementia may find an answer only from the results of longitudinal studies. The LADIS (Leukoaraiosis And DISability) study is an international collaborative study that aims to assess the predictive values of different severity degrees of LA on the transition to disability in a group of 639 normally functioning subjects enrolled in 12 European centres (www.ladis.unifi.it). While disability is the main outcome of the 3-year follow up, relevant information will be also collected as far as cognition is concerned, and dementia and mild cognitive impairment will be relevant secondary outcome measures (Pantoni *et al.*, 2005). The preliminary cross-sectional data show that subjects with more severe degrees of LA have poorer cognitive performance and are subjected to a higher risk of transition to a disabled functional status (Inzitari *et al.*, 2003) than subjects with mild LA. If confirmed at the end of the follow up, these data will provide a clear answer on the independent effect of LA on cognition.

Linked with the above mentioned question there is another one that concerns the possible role of LA in the transition from mild cognitive impairment to dementia. A preliminary study aimed at testing possible radiological markers of this transition found that CT-detected LA and temporal lobe atrophy were significant predictors of AD in a small group of 27 patients with mild cognitive impairment (Wolf *et al.*, 2000). These findings have been corroborated by the results of another study performed in a Japanese

sample of 46 patients with mild cognitive impairment defined on the basis of a MMSE score <24 and the lack of fulfilment of DSM-IV criteria for dementia (Koga *et al.*, 2002); in this study, larger quantities of LA were found to be one of the factors predicting cognitive impairment together with cerebral atrophy and lower education level (Koga *et al.*, 2002).

44.4.8 Comments on the role of leukoaraiosis in predicting cognitive impairment

In the previous edition of this book, we concluded that ‘The reported evidence does not support LA as an independent prognostic factor for future development of dementia in healthy subjects ...’. Four years later, the scenario appears changed and the last reported studies advocate modification of that statement. Not only the presence (and the severity) of LA is associated with dysfunction of specific cognitive tasks that depend on the frontal lobes, but it also predicts the development of cognitive impairment and dementia. The effect of LA in specific disease conditions requires some comments.

In patients with stroke, particularly in those with the lacunar type, the presence of LA at stroke onset seems to predict an evolution towards dementia. However, in this setting, the effect of LA seems to be strictly interrelated with that of other lesions with common underlying pathological substrates such as deep lacunar infarcts. In patients with established vascular dementia the net contribution of LA to dementia progression remains to be determined, as it does in relation to other commonly associated lesions (i.e. infarcts, atrophy and ventricular enlargement). However, it appears inappropriate to make a general conclusion on the role of LA in vascular dementia considering that the latter cannot any longer be considered as a homogeneous entity. In fact, the role of LA is likely more prominent in contributing to the clinical picture of patients with the subcortical type of vascular dementia (Erkinjuntti *et al.*, 2000; Román *et al.*, 2002) while its role is probably less prominent in forms characterized by large cortical infarcts. The clinical significance of LA in patients with AD remains instead less clear and the presence of LA does not appear to determine a greater cognitive decline (Hirono *et al.*, 2000). However, the inference from follow-up studies performed with cognitively healthy subjects or AD patients is limited by the small sample sizes, and by observation periods that always are too short.

Another major limitation appears to be the type of cognitive assessment used to define the mental status and the requirement of current criteria for diagnosis of dementia. As LA is unlikely to cause prominent memory problems, being instead more related to frontal lobe executive dysfunctions, it will be difficult to find it associated with forms of dementia such as AD, the essential requirement of which are memory dysfunctions.

44.4.9 Possible mechanisms by which leukoaraiosis may cause or contribute to cognitive impairment

Pathophysiological mechanisms by which LA may cause or contribute to cognitive impairment remain predominantly hypothetical. The hypotheses may be grouped into two main categories discussed below.

44.4.9.1 DIRECT EFFECT

The main question is whether LA is able to produce cognitive impairment *per se*, in other terms what is its exclusive or net contribution, considering risk factors including age, associated with both dementia and LA, or concomitant structural lesions, such as focal (lacunar) infarcts or neurodegenerative changes, that frequently are associated with LA. In the case of a direct effect of LA on cognition, the alteration of myelinated fibres and accompanying tissue abnormalities (e.g. gliosis) known to underlie LA could disconnect functionally-related cortical and subcortical structures (Cummings, 1993). Unfortunately, according to Fazekas *et al.* (1998) ‘such estimate is complicated by our ignorance about the actual severity of damage to connecting fiber tracts based on CT or routine MRI findings’. Hints may proceed from studies of dementia and white matter changes in diseases, such as multiple sclerosis, in which lesions are almost exclusively limited to white matter (Fazekas *et al.*, 1998). For a long time it has been recognized that cognitive dysfunctions frequently occur in multiple sclerosis, but only recently has the use of extensive neuropsychological testing provided accurate information about prevalence and type of cognitive attainment (Rao *et al.*, 1991). Deficits involve predominantly attention, visuospatial functions, memory retrieval and abstraction. The same functions proved to be affected in many of the above reported studies on LA.

Concerning the clinical expression of LA on cognitive grounds, several factors have to be taken into account:

- *Lesion pattern.* What is seen as LA on CT is usually resolved by MRI into differently seated and shaped lesions including periventricular caps, rims, or haloes; deep focal punctate lesions; large confluent or diffuse subcortical lesions. Different pathological processes are now thought to underlie each type of lesion. While focal punctate lesions, a very frequent finding in normal ageing and present even at younger ages, are generally considered of small importance in relation to cognitive impairment, there is evidence that large confluent areas of LA are involved more directly in cognitive decline. Unfortunately, in patients presenting with this type of lesion, the number of lacunar infarcts is also elevated, making it difficult to evaluate the respective role of each. Regarding periventricular abnormalities, we have reported data showing a role in relation to dementia in AD patients, but the effect

of this abnormality can be hardly considered independent since it is also associated with brain atrophy.

- *Location and volume.* Scattered evidence exists as to whether the location of LA is important in relation to the expression of cognitive impairment. Intuitively, lesions predominantly seated in the frontal white matter may sustain the typical pattern of cognitive dysfunction reported in subjects with LA. There are also clues suggesting that location in the posterior white matter is associated with selective dysfunction of areas and tracts involved in visuospatial cognitive performance (Fukui *et al.*, 1994). Although not invariably, changes affecting the entire subcortical white matter, are likely to produce global cognitive dysfunction that are more easily measurable, even with unrefined instruments such as dementia rating scales. Regarding volume of LA (area on CT or MRI scan), there are theories and some evidence that suggest a possible threshold volume above which dementia becomes evident. In one study of healthy elderly patients, the threshold area for cognitive dysfunction was 10 cm² (Boone *et al.*, 1992), consistent with the findings of Erkinjuntti *et al.* (1987b) who observed that a white matter lesion area exceeding one-fourth of the total white matter area discriminates between multi-infarct and AD patients, and that of Liu *et al.* (1992) who found that the mean white matter lesion area in demented stroke patients was 26.7 cm², as compared with 2.5 cm² in non-demented patients.
- *Metabolic status of the tissue.* One positron emission tomography (PET) study (Yao *et al.*, 1992) has demonstrated low flow and increased oxygen extraction in the areas of white matter changes in non-demented subjects, while in patients who were demented the blood flow was decreased and oxygen extraction was normal, indicating a low metabolic rate. The possibility that the threshold for dementia associated with LA is metabolic or functional has been scarcely explored as yet. Some more information in this regard may derive from recently developed MR techniques. Diffusion MRI allows the determination of the directionality of free water in brain tissues. In normal cerebral white matter, diffusion is highly related to the direction of the myelinated axonal bundles (this directionality is called 'anisotropy'). If damage to the white matter occurs, diffusion is increased but to a lesser extent than in the centre of cavitated large infarcts, and anisotropy is lost. Diffusion MRI might detect signal changes (i.e. loss of anisotropy) in the case of disruption of the white matter architecture at very early stages when conventional MRI does not show any signal change (O'Sullivan *et al.*, 2001). These diffusion alterations in the normal-appearing white matter were found to correlate with a test of executive dysfunctions in a small group of patients (O'Sullivan *et al.*, 2001) and with the degree of LA in other white matter areas (Helenius *et al.*, 2002).

44.4.9.2 INTERACTION WITH OTHER PROCESSES INVOLVED IN COGNITIVE IMPAIRMENT

Subcortical infarcts, especially lacunar infarcts, and atrophy, either cortical or subcortical (of which ventricular dilatation may be an expression), are commonly seen in association with LA in aged patients and in those with vascular risk factors. From the reviewed evidence, lacunar infarcts remain the main confounder for the association between LA and cognitive impairment in patients with vascular risk factors, in particular arterial hypertension. However, at least two other morphologic aspects are to be taken into account, corpus callosum atrophy (Yamauchi *et al.*, 2000) and hippocampal atrophy (Mungas *et al.*, 2001; Wu *et al.*, 2002) as they may interact with LA in determining cognitive impairment. It should be noted that what is seen on MRI as hippocampal atrophy may also be the results of ischaemic, not necessarily degenerative, insults. The pathological nature of LA in AD is not well understood. Wallerian degeneration (Leys *et al.*, 1991), incomplete infarction linked with systemic hypoperfusion (Brun and Englund, 1986), and amyloid angiopathy (Gray *et al.*, 1985) are among the advocated causes. Recent MRI studies have shown that LA in AD patients is due mainly to periventricular changes and that these are associated with the degree of brain atrophy. This evidence further supports a marginal role of LA in relation to dementia in pure AD dementia cases. In patients with a mixed type of dementia, particularly frequent at older ages, the role of subcortical lesions of ischaemic origin may be substantial. The Nun Study has convincingly demonstrated that at old ages, in the presence of AD changes, vascular lesions play a crucial role in the manifestation of dementia (Snowdon *et al.*, 1997). In post-stroke dementia the role of LA has to be seen as synergistic with that of other vascular lesions such as volume and site of infarction (Pohjasvaara *et al.*, 2000).

44.5 CONCLUSIONS

Although not synonymous with dementia, LA is potentially involved in cognitive impairment in elderly individuals. Given the pathogenesis, very likely predominantly ischaemic, linked with small vessel disease, the setting in which LA is more closely associated with dementia is that of vascular dementia, particularly of the subcortical type. LA has been described in a noticeable proportion of patients with AD, although, from either retrospective or prospective studies, besides the pathophysiology, the contribution to cognitive deterioration is still unclear. In non-demented elderly individuals it is very likely that LA is associated with subtle cognitive changes, involving predominantly subcortical functions, like attention and speed of mental processes. Its presence is moreover associated with an increased risk of developing cognitive impairment or dementia at follow up.

Regarding mechanisms by which LA causes dementia, they are for large part conjectural, although disconnection

among areas involved in cognition appears the most probable one. Damage to the white matter pathways connecting subcortical structures to the frontal lobes is one of the most likely causes. However, since LA is almost invariably associated with concomitant lesions such as brain atrophy, ventricular dilatation and multiple focal ischaemic lesions, all known possibly to have a role in cognitive impairment, the net contribution of LA is difficult to establish. Future studies, including volumetric MRI techniques, functional imaging (spectroscopy, diffusion-weighted and perfusion images), and other cerebral blood studies, may help to clarify several issues on the relationship between LA and cognitive impairment.

Vascular dementia: neuropathological features

RAJ N KALARIA

45.1 Introduction	565	45.4 Familial vascular dementia and genetic factors	571
45.2 Cerebrovascular disease, vascular dementia and mixed dementia	566	45.5 Conclusions	571
45.3 Brain vascular lesions and vascular dementia	567	References	572

Cerebrovascular disease is distinctly heterogeneous but may lead to vascular cognitive impairment or vascular dementia (VaD). Previous autopsy series of dementia cases have reported frequencies of VaD to vary widely (0.03–58 per cent) but use of current clinical diagnostic criteria suggests worldwide prevalence to be 10–15 per cent. Atherothromboembolism and intracranial small vessel disease are the main causes of brain infarction. Consistent with the subclassification of VaD lacunar infarcts or multiple microinfarcts in the basal ganglia, thalamus, brain stem and white matter are associated with more than 50 per cent of the cases. White matter changes including regions of incomplete infarction are usually widespread in VaD but their contribution to impairment is not explicit. Other pathologies including remote hippocampal injury, neocortical neuronal demise and Alzheimer type of lesions may modify the course of dementia. While most of VaD occurs sporadically, only a small proportion of cases bear apparent familial traits. CADASIL is likely the most common form of hereditary VaD, which arises from small vessel disease. Relative to other common dementias, the neuropathological substrates of VaD need unambiguous definition to impact on preventative and treatment strategies, and are critical for selective recruitment to clinical trials.

45.1 INTRODUCTION

Thomas Willis (1672) deserves the credit for advancing the obvious link between the cerebral circulation and dementia before the twentieth century. However, Alois Alzheimer and Emil Kraepelin among other neuropsychiatrists had specifically

ascribed arteriosclerotic dementia resulting from gradual strangulation of the blood supply to the brain as the main cause of dementia (Berrios and Freeman, 1991). The clear concept of subclasses of VaD was introduced by Otto Binswanger when he described subcortical arteriosclerotic encephalopathy upon pathological verification of cerebral white matter disorder in a group of eight patients (Berrios and Freeman, 1991). Today we accept that cerebrovascular disease causes the second most common form of age-related dementia. VaD may, however, result from all forms of cerebrovascular lesions that sometimes includes post-stroke syndromes (O'Brien *et al.*, 2003). The challenge of defining the pathological substrates of VaD is complicated by the heterogeneous nature of cerebrovascular disease and coexistence of other pathologies including Alzheimer type of lesions. Blood vessel size, origin of vascular occlusion and genetic factors are critical factors in defining subtypes of VaD (Box 45.1). Multi-infarct dementia is caused by large vessel disease whereas Binswanger type of VaD involving subcortical regions including the white matter results from small vessel changes. Subcortical ischaemic VaD appears the most significant subtype of VaD (Román *et al.*, 2002). Other factors that may define the subtype and degree of impairment include multiplicity, size, anatomical location, laterality and age of the lesion (Box 45.1). Several brain regions including the territories of the anterior, posterior and middle cerebral arteries, the angular gyrus, caudate and medial thalamus in the dominant hemisphere, the amygdala and hippocampus as well as the hippocampus have been implicated in VaD (Markesbery, 1998). For purposes of prevention and treatment it is imperative to recognize subtypes of VaD yet not devise numerous categories to make the task overly complicated (Román *et al.*, 1993).

Box 45.1 *VaD subtypes defined by blood vessel size and pathological process*

- Large vessel dementia (multiple infarcts)
- Small vessel dementia (small vessel disease and microinfarction)
- Strategic infarct dementia (infarcts in strategic locations)
- Hypoperfusive dementia
- Dementia related to angiopathies (hypertension, amyloid)*
- Haemorrhagic dementia
- Other causes of VaD (vasculitis)
- Hereditary VaD (CADASIL, CARASIL, HERNs)

*Hereditary forms of cerebral amyloid angiopathy involving ischaemic strokes and intracerebral haemorrhages may also lead to cognitive impairment and stroke (Natte *et al.*, 2001)

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (Kalimo *et al.*, 2002b); CARASIL, cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (Yanagawa *et al.*, 2002); HERNs, hereditary endotheliopathy, retinopathy, nephropathy and stroke (Jen *et al.*, 1997)

45.2 CEREBROVASCULAR DISEASE, VASCULAR DEMENTIA AND MIXED DEMENTIA

There is now a general consensus that the clinical diagnosis of VaD in demented patients with evidence of cerebrovascular lesions applies only when other causes of dementia are ruled out (Erkinjuntti, 1994; see Chapter 43 in this volume). As with diagnosis of other causes of dementia, criteria may be derived from a range of investigations including a detailed clinical history, timing of event, neuropsychometric tests, neuroimaging and neuropathological reports in accord with the DSM criteria. Perhaps inevitably like in the Alzheimer's disease (AD) model, diagnostic criteria based on the pathological findings should be quantified and related to the progression of cognitive impairment (Mirra, 1997). The frequencies of VaD in autopsy series range from as low as 0.03 per cent to as high as 58 per cent with an overall mean rate of 17 per cent (Markesbery, 1998; Jellinger, 2002). In cases where currently accepted criteria have been applied, the frequencies are even lower with a mean of 7 per cent. Perhaps not surprisingly in Japanese studies the incidence of VaD cases was found to be 35 per cent (Seno *et al.*, 1999) and 22 per cent (Akatsu *et al.*, 2001). Taking this into account the worldwide frequency of VaD in autopsy verified cases might be estimated to be between 10 and 15 per cent.

In addition to VaD the diagnosis of mixed dementia (AD and VaD or less frequently dementia with Lewy bodies and VaD) particularly among the oldest old (>85 years of age) is a challenge. Clinical and pathological evidence indicates that combined neurodegenerative and vascular pathologies worsen presentation and outcome of dementia (Snowdon *et al.*, 1997;

Figure 45.1 *Pathological outcome of clinically diagnosed Vascular dementia (VaD). Mixed type 1 revealed large infarcts whereas mixed type 2 predominantly exhibited small vessel disease with microinfarction. 'Other' includes dementia with mild Parkinson's disease and depression. AD, Alzheimer's disease; DLB, dementia with Lewy bodies.*

Esiri *et al.*, 1999; Rossi *et al.*, 2004). A high proportion of individuals fulfilling the neuropathological diagnosis of AD have significant cerebrovascular lesions including silent infarcts upon imaging and extensive white matter disease (Premkumar *et al.*, 1996; Heyman *et al.*, 1998; Nagy *et al.*, 1998; Kalaria and Ballard, 1999). Conversely, clinically diagnosed VaD patients frequently show extensive AD-type neuropathological changes (Hulette *et al.*, 1997; Erkinjuntti *et al.*, 1988; Kalaria and Ballard, 1999). Nolan *et al.* (1998) reported that 87 per cent of the patients enrolled in a prospective series to examine VaD in a dementia clinic were found to have AD either alone (58 per cent) or in combination with cerebrovascular disease (42 per cent) at post mortem. All of the patients with signs of cerebrovascular disease were also found to have some concomitant neurodegenerative disease (Figure 45.1). Similarly, another study indicated that large numbers of VaD cases without coexisting neuropathological evidence of AD suggests that 'pure' VaD is very uncommon (Hulette *et al.*, 1997). Thus current clinical diagnostic criteria serve to detect pathology but not 'pure' pathology. Early validation studies indicated that while mixed dementia could be distinguished from AD, it could not be separated from VaD (Rosen *et al.*, 1980). Recent studies suggest that 30–50 per cent of mixed AD and VaD cases are misclassified as VaD (Gold *et al.*, 1997, 2002) and the neuroimaging component of the NINDS AIREN criteria does not distinguish between people with and without dementia in the context of cerebrovascular disease (Ballard *et al.*, 2003). The potential overlap of pathologies is therefore complex, with different types of cerebrovascular lesions including cortical and subcortical infarction and small vessel disease (Esiri *et al.*, 1997; Ballard *et al.*, 2000), and different types and severity of neurodegenerative changes involving tau, amyloid and α -synuclein pathology. While evidence-based pathological criteria for the diagnosis of mixed dementia remains to be perfected, the diagnosis should be made when a primary neurodegenerative disease known to cause dementia exists with one or more of the pathological lesions

Box 45.2 Key variables to define pathology of VaD

- Identify as ischaemic or haemorrhagic infarct(s)
- Presence of lacunes and lacunar infarcts: *état lacunaire* (grey) and *état criblé* (WM)
- Location of infarcts: cortex, WM, basal ganglia, brain stem (pontine), cerebellum
- Circulation involved: arterial territories – anterior, middle or posterior
- Laterality: right or left anterior and posterior
- Sizes and number of infarcts = dimension: 0–4 mm, 5–15 mm, 16–30 mm, 31–50 mm and >50 mm; if size < 5 mm determine as small or microinfarcts
- Presence and location of small vessel disease: lipohyalinosis; fibroid necrosis; CAA
- Presence of white matter disease: rarefaction or incomplete infarction
- Degree of gliosis: mild, moderate or severe
- Presence of Alzheimer pathology (incl. NFT and neuritic plaque staging). If degree > stage III, the case is mixed AD and VaD
- Presence of hippocampal sclerosis

For reporting purposes each of above features can be scored numerically to provide a summary. For example, 0 is absent and 1 means present. Less frequent lesions including watershed infarcts and laminar necrosis. Increasing numerical value may also be assigned to the infarcts

CAA, cerebral amyloid angiopathy; NFT, neurofibrillary tangles; WM, white matter

defining the VaD subtypes (Box 45.2). Therefore a combination of the nominal three or more infarctions and Alzheimer pathology above stage III may warrant such a diagnosis.

From the essential information derived at autopsy (Box 45.1), we have proposed the neuropathological diagnosis of probable VaD or less popular ‘pure VaD’ be based on the exclusion of a primary neurodegenerative disease known to cause dementia and the presence of cerebrovascular pathology that defines one or more of the VaD subtypes (Box 45.2). These would include dementia among post-stroke survivors who fulfil the NINDS-AIREN (Román *et al.*, 1993) criteria for probable VaD. Those stroke survivors with mild cognitive impairment could be classed as exhibiting vascular cognitive impairment but the criteria for this extension are not widely accepted (O’Brien *et al.*, 2003). The diagnosis of possible VaD may be used when the brain contains vascular pathology, which does not fulfil the criteria for one of the subtypes but where no other explanation for dementia is found.

45.3 BRAIN VASCULAR LESIONS AND VASCULAR DEMENTIA

The majority of arterial territory infarctions, which may be admixed in cortical and subcortical regions, result from

Table 45.1 Dementia associated with different cerebrovascular pathologies

VaD subtypes related to:	Subtype
Large infarct or several infarcts (≥ 50 mL loss of tissue); MID	I
Multiple small or microinfarcts (>3 with minimum diameter 5 mm); Small vessel disease* (involving ≥ 3 coronal levels; hyalinization, CAA, lacunar infarcts, perivascular changes)	II
Strategic infarcts (e.g. thalamus, hippocampus)	III
Cerebral hypoperfusion (hippocampal sclerosis, ischaemic-anoxic damage, cortical laminar necrosis, borderzone infarcts involving 3 different coronal levels)	IV
Cerebral haemorrhages (lobar, ICH or SAH)	V
Cerebrovascular changes with AD pathology (above Braak III); mixed dementia	VI

In all of above, the age of the vascular lesion(s) should correspond with the time when disease began. The proposed Newcastle categorization includes six subtypes (Polvikoski T and Kalaria RN, unpublished observations). The post-stroke cases are usually included in subtypes I–III. While these may not be much different from other published subtypes (Román *et al.*, 1993; Jellinger 2002), they are practical and simple to use. Cases with extensive white matter disease in the absence of significant other features are included under small vessel disease

*Subtype I may result from large vessel occlusion (atherothromboembolism), artery to artery embolism or cardioembolism. Subtype II usually involves descriptions of arteriosclerosis, lipohyalinosis, hypertensive, arteriosclerotic, amyloid or collagen angiopathy. Subtypes I–II and V may result from aneurysms, arterial dissections, arteriovenous malformations and various forms of arteritis (vasculitis)

AD, Alzheimer’s disease; CAA, cerebral amyloid angiopathy; ICH, intracerebral haemorrhage; SAH, subarachnoid haemorrhage; VaD, vascular dementia

atherothromboembolism. This may be responsible for up to 50 per cent of all ischaemic strokes whereas intracranial small vessel disease causes 25 per cent of the infarcts (Kalimo *et al.*, 2002a). Small vessel alternations involve arteriosclerosis and hyalinosis and associated with lacunar infarcts and lacunes predominantly occurring in the subcortical structures. White matter disease or subcortical leukoencephalopathy with incomplete infarction and small vessel disease are common pathological changes in cerebrovascular disease. Others features include border zone (watershed) infarctions, laminar necrosis and amyloid angiopathy (Box 45.2). Complicated angiopathies such as fibromuscular dysplasia, arterial dissections, granulomatous angiitis, collagen vascular disease and giant cell arteritis are rarer causes of cerebrovascular disease (Kalimo *et al.*, 2002a) and VaD.

Previous studies have recorded ischaemic, oedematous and haemorrhagic lesions affecting the brain circulation or perfusion to be associated with VaD (Table 45.1). In four studies where VaD was diagnosed 75 per cent of the cases revealed cortical and subcortical infarcts suggesting other vascular pathologies involving incomplete infarction or border zone infarcts could be important factors. Among other lesions

25 per cent of the cases had cystic infarcts whereas 50 per cent of the cases had lacunar infarcts or microinfarcts. Lacunar infarcts, however, appear to be a common category of infarcts, and currently recognized as the most frequent cause of stroke (dissections, granulomatous angiitis, collagen vascular disease and giant-cell arteritis are rarer causes of cerebrovascular disease (Kalimo *et al.*, 2002a). Severe amyloid angiopathy was present in 10 per cent of the cases. Most interestingly, 55 per cent of the cases revealed hippocampal atrophy in one study (Vinters *et al.*, 2000). One of the studies concluded that ischaemic vascular disease appears to correlate with widespread small ischaemic lesions distributed throughout the central nervous system (CNS) (Vinters *et al.*, 2000).

45.3.1 Large infarction and large vessel pathology

Large infarction or macroinfarction is usually defined as that visible upon gross examination of the brain at autopsy. Stenosis arising from atherosclerosis within large vessels is considered to be the main cause of large infarction, which may sometimes extend beyond the arterial territories. The stages of atherosclerosis may vary from accumulation of foam cells causing fatty streaks to complicated atheromas involving extracellular matrix components and even viral or bacterial infections. Occlusion of the extracranial arteries such as the internal carotid artery and the main intracranial arteries of the circle of Willis including the middle cerebral artery can lead to multi-infarct dementia, which forms approximately 15 per cent of VaD (Brun, 1994). In severe cases medium-sized arteries in the leptomeninges and proximal perforating arteries could be involved. The damage could be worse depending upon the presence of hypertension. Artery-to-artery embolism involves breaking of thrombi from the often ulcerated lesions in the extracranial arteries, e.g. at the bifurcation of common carotid artery or the heart. The thrombi may contain, in addition to coagulated blood and platelets, cholesterol and calcified deposits from the underlying atheromatous plaque. Various types of cardiogenic emboli may also find their way to the anterior or particularly the posterior cerebral circulation, to cause infarcts in the territory of the posterior cerebral artery or superior cerebellar artery.

Arterial territorial infarctions involve four principal areas particularly those supplied by the major arteries: anterior, middle cerebral artery, posterior artery and the territory between the anterior and middle cerebral artery (Kalimo *et al.*, 2002a). The size of these infarctions is determined by assessing the two largest diameters of each lesion (Box 45.2). The typical infarct comprises the central core with complete infarction surrounded by a narrow perifocal hypoperfused (or penumbra) zone of incomplete infarction, which may be oedematous, and leads into normal appearing tissue. The core may involve both the cortex and underlying white matter that is devoid of functional components such as neurones, axons and oligodendrocytes and may in time form cavitated lesions or scars devoid of cells or haemosiderin. Prior to scar formation

between 3 and 14 days, infarct cores attract neutrophils, lipid-laden macrophages or microglia and astrocytes in the lesion, which is easily assessed upon routine staining. The intensity of gliosis, both astrocytic and microgliosis, is an important consideration in judging the degree and age of infarction. Degrees of gliosis or glial scars may be noted in brains subjected to global ischaemia, i.e. after transient cardiac arrest where responses may be observed in vulnerable neuronal groups within the hippocampus or neocortical laminae (Box 45.2).

45.3.2 Microinfarction, lacunar infarcts and lacunes

Microinfarcts have been variably described but widely thought to be small ischaemic lesions visible only upon light microscopy (see Plate 15a, b). These lesions of up to 5 mm diameter may or may not involve a small vessel at its centre but are foci with pallor, neuronal loss, axonal damage (white matter) and gliosis. Sometimes these may include regions of incomplete infarction or rarefied (subacute) change. Microinfarcts have also been described as attenuated lesions of indistinct nature occurring in both cortical or subcortical regions. Such lesions or combination of these should be reported when there are multiple or at least more than three present in any region (Table 45.2). Microinfarcts and lacunar infarcts appear central to the most common cause of VaD and predict poor outcome in the elderly (Esiri *et al.*, 1997; Ballard *et al.*, 2000; Vinters *et al.*, 2000; White *et al.*, 2002). Interestingly, in the autopsied older Japanese-American men the importance of microvascular lesions as a likely explanation for dementia was nearly equal to that of Alzheimer lesions (White *et al.*, 2002). Microinfarction in the subcortical structures has been emphasized as substrate of cognitive impairment, and correlated with increased Alzheimer type of pathology, but cortical microinfarcts also appear to contribute significantly to the progression of cognitive deficits in brain ageing (Kovari *et al.*, 2004). Furthermore microinfarcts even in border zone (watershed) regions may aggravate the degenerative process as indicated by worsening

Table 45.2 Types of vascular and hippocampal lesions reported in VaD

Pathological feature	% Cases
Complete infarctions (cortical and subcortical)	75
Lacunar infarcts (mostly WM and BG)	50
Small or microinfarcts	50
Cystic infarcts	25
Cerebral amyloid angiopathy	10
Intracerebral haemorrhages	2
Hippocampal atrophy and sclerosis	55

Data compiled from 70 cases reported in previous studies (Esiri *et al.*, 1997; Hulette *et al.*, 1997; Vinters *et al.*, 2000; Kalaria *et al.*, unpublished observations). Per cent cases are averaged from two or more reported studies. Cystic infarcts (possibly also lacunar) with typically ragged edges were admixed in both cortical and subcortical structures
BG, basal ganglia; WM, white matter

impairment in AD (Suter *et al.*, 2002). Thus multiple microinfarction appears strongly correlated with dementia indicated by several studies (Jellinger, 2002).

Lacunae are complete or cavitating infarcts as defined above, measuring up to 15 mm in diameter seen radiologically and upon gross examination at autopsy (Box 45.2; Figure 45.2). These lesions are largely confined to the cerebral white matter and subcortical structures including the thalamus, basal ganglia and brain stem. Most lacunae, remnants of small infarcts, are detected in the cystic or chronic stage with no viable central tissue, but could have perifocal regions with incomplete infarction, particularly in the white matter. A few lacunae may represent healed or reabsorbed minute or petechial haemorrhages. Microlacunae have also been described, which essentially should be thought of as large cystic microinfarcts. To distinguish perivascular cavities, it has been suggested that lacunae be classed into three subtypes: lacunar infarcts, lacunar haemorrhages and dilated perivascular spaces (Poirier *et al.*, 1985). Lacunar infarcts usually result from progressive small vessel disease manifested as hypertensive angiopathy that may involve stenosis caused by hyalinosis. Small vessel disease in a perforating artery, for example, may also reveal regions of incomplete infarction, attenuation or rarefaction usually recognized by pallor upon microscopic examination. However, lacunar lesions can also be caused by infections and neoplasms. Lacunae are associated with small perivascular cavities up to 2 mm in diameter often found in the basal ganglia and the white matter. Perivascular cavities or empty spaces resulting from distortion or elongation of small arteries collectively referred to as *état lacunaire* in the grey matter and *état criblé* in the white matter may be numerous in older subjects.

Figure 45.2 Lacunae and small infarcts in a familial VaD. Typical lacunar lesion (arrow) in the thalamus of a 60 year-old-man diagnosed with CADASIL bearing a single missense mutation in the *Notch3* gene. Lacunae in sporadic VaD cases are qualitatively similar.

45.3.3 Small vessel disease

Small vessels including intracerebral end-arteries and arterioles undergo progressive age-related changes (Lammie, 2000), which may result in lacunar or microinfarcts. These range from wall thickening by hyalinosis, reduction or increment of the intima to severe arteriosclerosis and fibroid necrosis (Plate 15b). Uncomplicated hyalinosis is characterized by almost complete degeneration of vascular smooth muscle cells (becomes acellular) with concentric accumulation of extracellular matrix components like the collagens and fibroblasts (Lammie, 2000). These changes are most common in the small vasculature of the white matter (Plate 15b). Small vessel changes likely promote occlusion or progressive stenosis with consequent acute or chronic ischaemia of the tissue behind it. Alternatively, arteriosclerotic changes located in small vessels in the deep white matter and basal ganglia may lose their elasticity to dilate and constrict in response to variations of systemic blood pressure or loss of autoregulation. This in turn causes fluctuations in blood flow response and changes in cerebral perfusion. The deep cerebral structures would be rendered most vulnerable because the vessels are end-arteries almost devoid of anastomoses. Small vessel pathology could lead also oedema and damage of the blood–brain barrier (BBB) with chronic leakage of fluid and macromolecules in the white matter (Ho and Garcia, 1999).

45.3.4 Cerebral amyloid angiopathy (CAA)

While CAA is most common in AD and consistently present in Down's syndrome (Premkumar *et al.*, 1996; Kalaria, 2001) it also occurs in elderly subjects with cerebrovascular disease in the general absence of Alzheimer lesions (Cohen *et al.*, 1997). Amyloid β protein accumulation within or juxtaposed to the vasculature may lead to degeneration of vascular cells in both larger perforating arterial vessels as well as cerebral capillaries that represent the BBB. These likely result in microinfarctions and perivascular cavities similar to those seen in hyalinized vessels in subcortical structures. CAA is an important cause of intracerebral and lobar haemorrhages leading to profound ischaemic damage (Vonsattel *et al.*, 1991). CAA also appears to be causally related to white matter changes described by subcortical leukoencephalopathy in patients with CAA, who lacked changes characteristic of AD (Lammie, 2000). Genetic factors such as the apolipoprotein E (ApoE) $\epsilon 4$ allele associated with severity of CAA may modify or attenuate the perfusion of the white matter (Kalaria, 2001).

45.3.5 Alzheimer-type pathology

Alzheimer lesions including amyloid β plaques and neurofibrillary pathology occur more often in cases of cerebrovascular disease than in normal ageing elderly (Kalaria and Ballard, 1999). We reported that amyloid deposits and tangles were three times greater in VaD cases with small (<15 mL) compared with larger

volume of infarction. However, the burden of Alzheimer lesions was just barely associated with dementia scores (Ballard *et al.*, 2000). While these findings corroborated the importance of microvascular disease rather than macroscopic infarction as the critical substrate in VaD and in AD (Kalaria, 1996), the burden of Alzheimer lesions was just barely associated with dementia scores in VaD (Ballard *et al.*, 2000).

Cerebral amyloid angiopathy is also frequent in VaD even where the amyloid deposits may be rare in the parenchyma. Although conventional histopathological staining methods may not reveal classical amyloid and neurofibrillary pathology the accumulation of amyloid β and tau peptides may be revealed by immunochemical methods. Our preliminary findings suggest that accumulation of soluble amyloid β_{42} in the temporal lobe of VaD patients is almost similar as that in AD subjects by the eighth decade (Kalaria *et al.*, 1999). These observations implied that total amyloid β peptides increase in brains of patients who succumb to cerebral ischaemia and that brains of the very elderly who suffer from stroke produce large amounts of soluble amyloidogenic peptides almost like AD patients.

Amyloid precursor protein accumulation along white matter tracts has also been previously demonstrated in cerebral ischaemia even in middle-aged subjects (Cochran *et al.*, 1991). It may be hypothesized that, concomitant with ageing, small vessel disease along with white matter lesions in the brain causes vascular injury and may induce tissue pH changes, oxidative damage, amyloid precursor protein expression and subsequent aggregation of soluble amyloid β .

A similar argument may be made for parallel changes that induce tau-like pathology and other neuronal changes. This is supported by the demonstration that increases in cerebrospinal fluid (CSF) tau are not restricted to AD but also evident in various forms of VaD (Blennow *et al.*, 1995; Munroe *et al.*, 1995; Skoog *et al.*, 1995). Concentrations of tau in lumbar CSF in patients diagnosed with probable VaD were reported to be comparable to those in AD and were significantly increased compared with those in non-demented elderly controls (Skoog *et al.*, 1995). Similarly, the concentrations of soluble synaptophysin were found to be decreased in VaD as well as in AD (Zhan *et al.*, 1994). These findings not only suggest that axonal degeneration occurs in VaD as evident in AD but support the notion that ischaemic or oligoemic events in the elderly are early events leading to increases in known markers of Alzheimer pathology. Other biological markers for AD such as decreased ApoE levels in CSF have also been reported in VaD (Skoog *et al.*, 1997).

VaD cases may also bear other AD type lesions including cholinergic and monoamine neuronal deficits (Kalaria and Ballard, 1999). Two different groups had previously shown that compared with AD patients choline acetyltransferase activity was also reduced, albeit to a lesser degree, in the temporal cortex and hippocampus in patients diagnosed with multi-infarct dementia or VaD (Perry *et al.*, 1977; Gottfries *et al.*, 1994). However, despite these deficits there do not appear to be pronounced effects in the cholinergic cell bodies of the basal forebrain in VaD (Mann *et al.*, 1986; Keverne *et al.*, 2003).

Subsequent studies had reported deficits in other neurotransmitters particularly 5-hydroxytryptamine (5HT) in the basal ganglia and neocortex of VaD subjects (Gottfries *et al.*, 1994). These findings indicate that a variety of Alzheimer-type of changes are also associated with VaD. The pathological diagnosis of VaD in such cases may be dictated by the degree and location of Alzheimer pathology. If it is restricted to the hippocampus and the density of neuritic plaques or tangles does not exceed stage III of the criteria defined by Thal *et al.* (2002) and Braak and Braak (1995), they could be diagnosed as VaD. This is similar to the notion where dementia cases meeting CERAD criteria for probable AD may exhibit infarctions or white matter changes. However, cases of cerebrovascular disease fulfilling the criteria for VaD (Box 45.2, p. 567) with concomitant Alzheimer pathology above stage III for plaques and tangles may be designated as mixed dementia.

45.3.6 White matter disease

White matter lesions (or subcortical leukoencephalopathy) incorporating myelin loss are considered a consequence of vascular disease. The frequency of white matter changes is increased in patients with cerebrovascular disease and those at risk for vascular disease including arterial hypertension, cardiovascular disease and diabetes mellitus (O'Brien *et al.*, 2003). White matter lesions occur in ≈ 30 per cent of AD and dementia with Lewy body (DLB) cases and may be present irrespective of the focal lesions in VaD (Englund, 1998). It is often argued that white matter damage in patients with AD might simply reflect Wallerian changes secondary to cortical loss of neurones. However, this is unlikely since histological changes characteristic of Wallerian degeneration are not evident as white matter pallor. Conversely, in AD patients with severe loss of cortical neurones similar white matter lesions are not apparent (Englund, 1998).

Lesions in the deep white matter (0.5–1 cm away from ventricle in coronal plane) have been correlated with dementia including VaD (Kalaria and Ballard, 1999; O'Brien *et al.*, 2003). Conflicting data with respect to periventricular lesions may depend on definition of the boundaries between the periventricular and deep white matter if the coursing of the fibres are used as markers. Lacunar infarcts are produced when the ischaemic damage is focal and of sufficient severity to result in a small area of necrosis, whereas diffuse white matter change is considered a form of rarefaction or incomplete infarction where there may be selective damage to some cellular components (Plate 16). While the U-fibres are usually spared, white matter disease comprises several patterns of alterations including pallor or swelling of myelin, loss of oligodendrocytes, axons and myelin fibres, cavitations with or without presence of macrophages and areas of reactive astrogliosis, where the astrocytic cytoplasm and cell processes may be visible with standard stains. Lesions in the white matter also include spongiosis, i.e. vacuolization of the white matter structures and widening of the perivascular spaces.

45.3.7 Hippocampal sclerosis and atrophy

Hippocampal neurones in the Sommer's sector are highly vulnerable to disturbances in the cerebral circulation or hypoxia caused by systemic or cardiovascular disease. Severe loss of hippocampal neurones within the CA fields and infarctions along Ammon's horn are evident in a proportion (10–20 per cent) of usually older (>80 years) VaD cases. The loss of cells should be graded when this is evident, together with any microinfarctions within the hippocampal formation (Dickson *et al.*, 1994). Hippocampal sclerosis is a likely major contributing factor in the hippocampal atrophy described at gross examination. Hippocampal changes remote to ischaemic injury have also been emphasized in subcortical ischaemic vascular dementia (Vinters *et al.*, 2000).

45.3.8 Border zone (watershed) infarcts

Border zone or watershed infarctions mostly occur from haemodynamic events, usually in patients with severe internal carotid artery stenosis. They could occur bilaterally or unilaterally, and disposed to regions between two main arterial territories, deep and superficial vessel systems. Typical border zone infarctions may be 5 mm or more wide as wedge shaped regions of pallor and rarefaction extending into the white matter. Larger areas of incomplete infarction may extend into the white matter (Brun, 1994; Kalimo *et al.*, 2002a). These are characterized by mild to moderate loss of oligodendrocytes, myelin and axons in areas where there may be hyalinized vessels (Brun, 1994). These features may be accompanied by astrogliosis, some microgliosis and macrophage infiltration.

45.3.9 Laminar necrosis

Laminar necrosis is characterized by neuronal ischaemic changes leading to neuronal loss and gliosis in the cortical ribbon. This is particularly apparent in cases where global ischaemia or hypoperfusion has occurred as in cardiac arrest. Typical topographic distribution of spongy form change can be readily apparent with standard stains. They appear more commonly at the arterial border zones (Brun, 1994; Kalimo *et al.*, 2002a) that may fall into the subtype IV of VaD pathology (Box 45.2, p. 567).

45.4 FAMILIAL VASCULAR DEMENTIA AND GENETIC FACTORS

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a small vessel disease that emerges as the most common hereditary form of stroke leading to progressive dementia (Kalaria, 2001; Kalimo *et al.*, 2002b). Several other hereditary conditions presenting with ischaemic strokes or focal infarcts unrelated

to the amyloid angiopathies have been described. These include hereditary multi-infarct dementia (Sourander and Walinder, 1977; Zhang *et al.*, 1994) rare occlusive conditions such as hereditary endotheliopathy retinopathy nephropathy with stroke or HERNs (Jen *et al.*, 1997) and chronic familial vascular encephalopathy (Stevens *et al.*, 1977), which actually proved to be *Notch 3* type CADASIL. In view of the striking pathology (Plate 15, Figure 45.2) including multiple subcortical infarcts, small vessel disease, severe arteriosclerosis, profound white matter rarefaction CADASIL has also been considered a familial form of Binswanger's disease.

Several genes have also been considered to be associated with cerebrovascular disease or stroke risk factors (Kalaria, 2001). The precise functions of the products of these genes, however, in light of the pathogenetic processes remain unclear. The ApoE gene is accepted to be unequivocally linked to late-onset AD but its role in cerebrovascular disease not associated with Alzheimer pathology (i.e. VaD) is not clear. In accord with the implications that ApoE might promote pathological alterations in the vascular wall, the ApoE $\epsilon 4$ allele is a strong factor in the development of CAA but not an independent risk factor in CAA-related intracerebral haemorrhages (Greenberg *et al.*, 1995; Nicoll *et al.*, 1997; Olichney *et al.*, 1996; Premkumar *et al.*, 1996; Zarow *et al.*, 1999). Surprisingly, the ApoE $\epsilon 2$ allele is considered a strong factor for intracerebral haemorrhage in amyloid-laden vessels that may cause rupture of the vessel walls by inducing specific cellular changes (Greenberg *et al.*, 1998; McCarron and Nicoll, 1999). However, a meta-analysis revealed significantly higher ApoE $\epsilon 4$ allele frequencies in patients diagnosed with ischaemic cerebrovascular disease (Kalmijn *et al.*, 1996; McCarron *et al.*, 1999); Frisoni *et al.* (1994) had previously implicated comparably high $\epsilon 4$ allele frequencies in cerebrovascular disease-associated dementia but these observations remain unconfirmed. On the other hand, Traykov *et al.* (1999) showed that the frequency of ApoE $\epsilon 4$ allele in over 70-year-olds with clinically diagnosed VaD or vascular cognitive impairment did not differ from controls. Similarly, pathologically verified studies showed that $\epsilon 4$ allele frequencies did not differ between Binswanger's disease and other forms of VaD (Higuchi *et al.*, 1996).

45.5 CONCLUSIONS

The heterogeneous nature of cerebrovascular disease compels better understanding of the neuropathological substrates of VaD for wide application. Small vessel disease leading to multiple microinfarcts or lacunes in the subcortical structures appear most involved in VaD. White matter pathology is frequent in VaD but it needs evaluation to enable correlation with cognitive decline. Whether hippocampal changes remote from sites of ischaemic injury or Alzheimer pathology contribute to the disease progression is unclear. The systematic classification of VaD pathological subtypes should be

applied universally. The clear definition of the neuropathological correlates of VaD would be useful for preventative and treatment strategies.

46.4 Clinical forms of vascular dementia	578	References	592

The few years elapsed since the publication of this chapter in the Second Edition of *Dementia* (2000) have seen the completion of a number of promising treatment trials in patients with vascular dementia (VaD). Moreover, successful enrolment for these studies demonstrated that by using strict criteria it is feasible to diagnose and identify patients with clinically unmixed VaD, and that the subjects recruited for these trials disclose clinical features and progression patterns that are clearly different from those observed in patient populations selected for clinical trials of Alzheimer disease (AD).

The therapeutic management of VaD is particularly challenging because of the multiple types of cerebrovascular injuries and circulatory events that may lead to vascular cognitive decline and eventual dementia. This multiplicity of pathogenetic mechanisms results in a variety of clinical presentations that hampered in the past the formulation of diagnostic criteria and the ascertainment of cases for controlled clinical trials. In addition, VaD is often complicated with neuropsychiatric symptoms, in particular depression, apathy, aggressiveness and other behavioural changes that require careful management.

In addition to the symptomatic therapeutic trials, a limited number of studies have also shown promise for the prevention of VaD, giving support to the concept that vigorous treatment of vascular risk factors in patients with cognitive decline short of dementia (the so-called vascular cognitive impairment – VCI) could spare the progression to dementia.

46.1 DEFINITIONS

46.1.1 Vascular cognitive disorder (VCD)

VCD is the global category of cognitive decline resulting from cerebrovascular disease (CVD), ranging from VCI to VaD (Román *et al.*, 2004).

46.1.2 Vascular cognitive impairment

VCI was initially coined as an umbrella term to include all forms of vascular cognitive decline (Bowler and Hachinski, 1995; Erkinjuntti and Gauthier, 2002; O'Brien *et al.*, 2003). However, by analogy to mild cognitive impairment (MCI), considered the earliest manifestation of AD (Petersen *et al.*, 1999), the definition of VCI is restricted here to vascular forms of cognitive impairment without dementia.

46.1.3 Vascular dementia

Román (2002b, 2003a) defined VaD as an aetiological category of dementia characterized by acquired intellectual impairment, severe enough to interfere with social and personal independence, resulting from ischaemic or haemorrhagic stroke, as well as from ischaemic hypoperfusive brain injuries, affecting brain regions important for memory, cognition and behaviour. The most common neuropathological lesions capable of producing VaD are hypoperfusive and ischaemic (occlusive)

vascular brain injuries (Brun, 1994; Parnetti, 1999; Mikol and Vallat-Decouvelaere, 2000; Vinters *et al.*, 2000). These include:

- *Hypoperfusion dementia* (Román, 2004): global anoxia, selective vulnerability, border-zone infarcts, and periventricular incomplete white matter ischaemia;
- *ischaemic lesions* involving large vessels: strategic single strokes, multi-infarct dementia (MID); small vessel disease (cortical, subcortical and cortico-subcortical ischaemia), as well as venous occlusions.

46.2 RISK FACTORS FOR VASCULAR DEMENTIA

A number of case-control studies of post-stroke dementia have provided a useful quantification of risk factors for VaD (Tatemichi *et al.*, 1990; Pohjasvaara *et al.*, 1997; Barba *et al.*, 2000). In patients with ischaemic stroke, the most important risk factors for development of post-stroke VaD are older age, lower educational level, recurrent stroke, as well as presence of dysphagia, gait limitations and urinary impairment. The left-sided predominance of lesions in demented patients with large vessel stroke in the territories of the anterior and posterior cerebral arteries has been repeatedly demonstrated (Leys and Pasquier, 2000). Recently, Johnston and colleagues (2004) observed progressive decline in cognitive function among Cardiovascular Health Study participants with stenosis of the left internal carotid artery (ICA), but not in those with stenosis of the right ICA, in the absence of stroke. Possible explanations include the fact that the left hemisphere has larger cholinergic innervation than the right one does; and tests such as the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975), and the CAMCOG, the cognitive portion of the CAMDEX (Cambridge Mental Disorders of the Elderly Examination) (Huppert *et al.*, 1995), rely heavily on language functions.

Other risk factors in patients with post-stroke VaD include current smoking, lower blood pressure, orthostatic hypotension, and larger periventricular white matter ischaemic lesions on brain computed tomography (CT) or magnetic resonance imaging (MRI) (Liu *et al.*, 1991; Gorelick *et al.*, 1992). Orthostatic hypotension is a strong predictor of periventricular white matter ischaemic lesions (Longstreth *et al.*, 1996). Hypoxic and ischaemic complications of acute stroke (e.g. seizures, cardiac arrhythmias, aspiration pneumonia, etc.) are independent risk factors for post-stroke dementia (Moroney *et al.*, 1996); these complications increase more than 4-fold the risk of developing post-stroke dementia (OR 4.3; 95 per cent CI 1.9–9.6, after adjustment for demographic factors, recurrent stroke, and baseline cognitive function). Post-stroke VaD is also a strong predictor of poor outcome (Desmond *et al.*, 1998; Barba *et al.*, 2000; Linden *et al.*, 2004). In Rochester (Minnesota), 10 per cent of 482 incident cases of dementia had onset or worsening of the dementia within 3 months of a stroke (Knopman *et al.*, 2003). Overall, patients with vascular dementia had worse mortality than matched

subjects (relative risk [RR] 2.7), particularly among cases of post-stroke VaD (RR 4.5).

46.3 DIAGNOSTIC CRITERIA AND METHODOLOGY OF CLINICAL TRIALS IN VASCULAR DEMENTIA

46.3.1 Vascular cognitive impairment

There are currently no widely accepted diagnostic criteria for VCI. The Canadian Study on Health and Aging (2000) used the following criteria (Rockwood *et al.*, 2000; Ingles *et al.*, 2002) to classify subjects with VCI without dementia (VCIND):

- The subjects' cognitive impairment did not meet the DSM-III-R criteria for dementia (American Psychiatric Association, 1987); these criteria require impairment of memory and other cognitive domain causing functional deficits.
- Cognitive impairment was judged to have a vascular cause as based on presence of signs of ischaemia/infarction; e.g. sudden onset, stepwise progression, patchy cortical deficits on cognitive testing, other evidence of atherosclerosis, and a high Hachinski Ischaemic Score (HIS) (Hachinski *et al.*, 1975). Presence of vascular risk factors alone was insufficient for a VCIND diagnosis. Global functional impairment was defined as having difficulty in any two of the following domains:
 - performing household chores
 - managing money
 - feeding self
 - dressing and
 - incontinence.

Using these criteria in the Canadian cohort of 10 263 randomly selected persons aged ≥ 65 years, a total of 149 were diagnosed with VCIND (Ingles *et al.*, 2002). Follow-up cognitive diagnoses were available for 102 individuals and after 5 years, 45 patients (44 per cent) developed dementia; the rates of institutionalization and mortality were equivalent to those of AD (Wentzel *et al.*, 2001, 2002). In this study, the progression to dementia was similar to that seen in MCI suggesting that, in all likelihood, the population identified by these criteria was actually a mixture of AD with CVD. Moreover, a number of patients improved their cognitive scores (Wentzel *et al.*, 2002) indicating that VCIND, in contrast with VCI, does not follow a unidirectional progression towards dementia. In summary, valid criteria for VCI are needed at present.

46.3.2 Vascular dementia

The existence of multiple diagnostic criteria for the diagnosis of VaD – and their lack of agreement on patient selection – has been the main argument brandished to deny the existence

of VaD as an independent form of dementia, clinically and pathologically separate from AD. In fact, the criteria differ among themselves since they were designed for different purposes (hospital discharges, research studies, epidemiological surveys, etc.); in addition, they lack sensitivity (particularly when strict imaging criteria are mandatory) since it is virtually impossible to include all forms of VaD within a single set of criteria. Finally, given the importance of CVD in the clinical expression of dementia in patients with lesions of AD, the inclusion of mixed dementia (AD + CVD) is a common occurrence with most criteria.

Román *et al.* (2004) have recently proposed a definition of dementia of vascular origin as characterized by abnormal executive control function, severe enough to interfere with social or occupational functioning. This definition corrects the problem of definitions of dementia that require memory loss as the *sine qua non* for dementia diagnosis. Obligate memory loss in patients with VaD may result in over-sampling of subjects with AD worsened by stroke (AD + CVD).

Existing criteria include the Hachinski Ischaemic Score or HIS (Hachinski *et al.*, 1975); the criteria from the 4th revision of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, better known as DSM-IV (American Psychiatric Association, 1994); the 10th revision of the International Classification of Diseases or ICD-10 (World Health Organization, 1992); the California Criteria for Ischaemic VaD or ADDTC (Chui *et al.*, 1992), and the consensus criteria proposed by Román and colleagues (1993) or NINDS-AIREN criteria. Although all of them are useful in selecting VaD patients with varying degrees of sensitivity and specificity, they are not interchangeable (Verhey *et al.*, 1996; Wetterling *et al.*, 1996; Chui *et al.*, 2000; Pohjasvaara *et al.*, 2000).

The NINDS-AIREN criteria (Román *et al.*, 1993) were developed specifically for research studies in VaD and include a number of vascular aetiologies and clinical manifestations. These criteria have the highest specificity and have been used in most modern controlled clinical trials in VaD (López-Pousa *et al.*, 1997; Kittner, 1999; Erkinjuntti *et al.*, 2002a; Orgogozo *et al.*, 2002; Wilcock *et al.*, 2002; Black *et al.*, 2003; Wilkinson *et al.*, 2003). These criteria recognize patients with multiple forms of stroke and CVD (i.e. ischaemic, haemorrhagic, hypoperfusive) but establish strict requirements to classify patients appropriately. Two cardinal elements of the clinical syndrome of VaD must be identified, namely the cognitive syndrome of dementia and the definition of the vascular cause of the dementia. Cerebrovascular disease is defined by the presence of focal neurological signs and detailed brain imaging showing evidence of stroke or ischaemic changes in the brain. A defining element of the criteria is the need for a temporal relationship between dementia and the cerebrovascular disorder whereby dementia onset should occur within 3 months following a recognized stroke. The temporal relationship may prove to be difficult to fulfil, particularly in patients with silent strokes and in the subcortical form of VaD. These elements are summarized in Box 46.1.

46.3.3 Mixed dementia (AD + CVD)

Specific brain pathological lesions define the two most common forms of senile dementia, AD and VaD. Stroke and cerebrovascular disease are the hallmarks of VaD, while senile plaques and neurofibrillary tangles typify AD. When these two pathologies are combined, the neuropathological diagnosis of AD + CVD or 'mixed dementia' is invoked (Zekry *et al.*, 2002a). Coexistent lesions occur in up to one-third of unselected elderly demented patients (Kalaria and Ballard, 1999; Zekry *et al.*, 2002b, c), or in 10–15 per cent of cases of post-stroke dementia (Hénon *et al.*, 1997, 2001; Barba *et al.*, 2001), but mixed lesions also occur in patients without dementia (Román and Royall, 2004).

Separating AD from VaD may be a frequent problem in patients with pre-existing and progressive memory loss worsened by an acute vascular episode. The NINDS-AIREN criteria (Román *et al.*, 1993) accurately separate VaD from AD or from AD associated to cerebrovascular lesions (AD + CVD) as demonstrated in validation neuropathological studies comparing various sets of diagnostic criteria. The NINDS-AIREN criteria (Román *et al.*, 1993) consistently obtained the highest specificity values, ranging from 0.80 (Gold *et al.*, 1997), 0.86 (Zekry *et al.*, 2002b), 0.93 (Gold *et al.*, 2002) to 0.95 (Holmes *et al.*, 1999). Specificity defines the capacity to identify true negative cases. Therefore, with neuropathology as the gold standard, several studies confirmed that the NINDS-AIREN criteria (Román *et al.*, 1993) successfully exclude AD cases, and have the lowest proportion of mixed cases misclassified. The NINDS-AIREN criteria for VaD (Román *et al.*, 1993) have slightly better specificity than the NINCDS-ADRDA criteria for AD (McKhann *et al.*, 1984; Holmes *et al.*, 1999).

The accuracy of the NINDS-AIREN criteria increases by excluding subjects with pre-existing diagnosis of AD, those with isolated memory impairment (MCI), as well as those with history of obvious progressive cognitive decline prior to a stroke (Hénon *et al.*, 1997, 2001). VaD dementia typically occurs in patients with stroke and multiple vascular risk factors. The HIS quantifies this profile with high interrater reliability ($\kappa = 0.61$). A score >4 in the HIS usually excludes AD.

Using the NINDS-AIREN criteria (Román *et al.*, 1993) along the guidelines described above, two international trials of donepezil in VaD (Black *et al.*, 2003; Wilkinson *et al.*, 2003) were able to recruit more than 1200 patients with relatively pure or unmixed VaD. The VaD population selected was older and had a male preponderance, in agreement with population-based epidemiological data on VaD and in contrast with the female preponderance in AD trials. Furthermore, the 6-month progression of the placebo groups selected in the donepezil VaD studies was different from placebo groups in AD (Román and Rogers, 2004) as well as in mixed AD plus CVD trials (Erkinjuntti *et al.*, 2002a), further indicating the separate identity of the VaD cases selected (Pratt, 2002).

In summary, VaD is a well-defined form of dementia that can be clinically diagnosed with reasonable accuracy. Of all available criteria, the NINDS-AIREN criteria (Román *et al.*,

Box 46.1 *NINDS-AIREN diagnostic criteria for vascular dementia**

I. The criteria for the diagnosis of *probable* VaD include *all* of the following:

1 **Dementia:** Impairment of memory and two or more cognitive domains (including executive function), interfering with ADL and not due to physical effects of stroke alone.

Exclusion criteria: Alterations of consciousness, delirium, psychoses, severe aphasia or deficits precluding testing, systemic disorders, Alzheimer's disease or other forms of dementia.

2 **Cerebrovascular disease:** Focal signs on neurological examination (hemiparesis, lower facial weakness, Babinski sign, sensory deficit, hemianopsia, dysarthria) consistent with stroke (with or without history of stroke, *and* evidence of relevant CVD by brain CT or MRI including *multiple large vessel infarcts* or a *single strategically placed infarct* (angular gyrus, thalamus, basal forebrain, or PCA or ACA territories), as well as *multiple basal ganglia* and *white matter lacunes* or *extensive periventricular white matter lesions*, or combinations thereof.

Exclusion criteria: Absence of cerebrovascular lesions on CT or MRI.

3 **A Relationship between the above two disorders:**

Manifested or inferred by the presence of one or more of the following:

a. onset of dementia within 3 months following a recognized stroke

b. abrupt deterioration in cognitive functions; or fluctuating, stepwise progression of cognitive deficits.

II. Clinical features *consistent* with the diagnosis of *probable* VaD include the following:

a. early presence of gait disturbances (small step gait or *marche à petits pas*, or magnetic, apraxic-ataxic or parkinsonian gait)

b. history of unsteadiness and frequent, unprovoked falls

c. early urinary frequency, urgency, and other urinary symptoms not explained by urological disease

d. pseudobulbar palsy

e. personality and mood changes, abulia, depression, emotional incontinence, or other deficits including psychomotor retardation and abnormal executive function.

III. Features that make the diagnosis of VaD uncertain or unlikely include:

a. Early onset of memory deficit and progressive worsening of memory and other cognitive functions such as language (transcortical sensory aphasia), motor skills (apraxia), and perception (agnosia), in the absence of corresponding focal lesions on brain imaging

b. Absence of focal neurological signs, other than cognitive disturbances

c. Absence of CVD on CT or MRI.

ACA, anterior cerebral artery; ADL, activities of daily living; CT, computed tomography; CVD, cerebrovascular disease; MRI, magnetic resonance imaging; PCA, posterior cerebral artery; VaD, vascular dementia.

*Adapted from Román *et al.* (1993)

1993) have the highest specificity in neuropathology-confirmed cases, effectively ruling out cases of mixed dementia. The population thus selected is different from that of AD and mixed dementia trials. Several controlled clinical trials on VaD have successfully used the NINDS-AIREN criteria, effectively making these criteria the most suitable current choice for VaD studies. In addition, careful interview of relatives and caregivers allows a successful diagnosis of prestroke dementia. In most instances, probable AD is a likely aetiology for the progressive memory loss or MCI occurring prior to the ictus (Jagust, 2001).

46.3.4 Methodological aspects of clinical trials in VaD

The methodological requirements for controlled clinical trials in patients with dementia have been reviewed by the International Working Group on Harmonization of Dementia Drug Guidelines at the Sixth International Congress on AD and Related Disorders in Amsterdam (Whitehouse *et al.*, 1998),

and at the 1998 Osaka Conference on VaD (Erkinjuntti and Sawada, 1999; Erkinjuntti *et al.*, 1999); for more recent reviews see Mills and Chow (2003), Mani (2004), and Erkinjuntti *et al.* (2004). The first and foremost requirement for a valid trial in dementia, and VaD in particular, is the use of appropriate inclusion and exclusion criteria. This requirement is crucial for the selection of a homogeneous population that would allow the generalized application of the trial results. Given the clinical variety of VaD, some authors have suggested limiting the trials to patients with subcortical VaD using various sets of criteria (Pantoni *et al.*, 1996, 2000; Erkinjuntti *et al.*, 2000; Moretti *et al.*, 2001, 2002), or to cases of mixed dementia, including AD + CVD (Erkinjuntti *et al.*, 2002a, b) or AD plus arterial hypertension (Kumar *et al.*, 2000). However, as discussed above, the criteria proposed by Román *et al.* (1993) are appropriate for VaD trials. Several instruments (MMSE, CAMCOG, Clinical Dementia Rating [CDR]) are used to ensure that dementia severity is comparable across the trial.

The next requirement is an appropriate number of participants (sample size). The sample size is a function not only of the effectiveness of the drug, but also of the degree of

responsiveness – or lack thereof – of the measuring instruments, as well as of the accuracy of the end points selected for the trial. Instruments that are relatively insensitive to change, require larger sample sizes in order to demonstrate a statistically significant difference from the placebo or untreated group.

Other requirements include randomization with appropriate group allocation concealment, placebo-controlled, double-blinded design with parallel group, and specific outcome measures, adequate instruments, and well-defined end points. Potential targets for the symptomatic treatment of VaD include:

- symptomatic improvement of the core symptoms (cognition, function and behaviour);
- slowing of progression; and
- treatment of neuropsychiatric symptoms (e.g. depression, anxiety, agitation).

All the current VaD trials have used the same primary outcome measures used in AD trials, as recommended by the United States Food and Drug Administration (FDA). These instruments include the cognitive portion of the Alzheimer's Disease Assessment Scale (ADAS-cog) (Rosen *et al.*, 1984), the Clinician's Interview-Based Impression of change plus caregiver input (CIBIC-plus) (Schneider *et al.*, 1997), or the Clinical Global Impression of Change (CGIC) (Berg, 1988). The European Commission for Medicinal and Pharmaceutical Compounds (CPMC) also requires positive impact on activities of daily living (ADL), using a scale similar to the Alzheimer's Disease Functional Assessment and Change Scale (ADFACS) that provides a measure of instrumental and basic ADL (Mohs *et al.*, 2001). The CPMC also requires a responder analysis; another useful measure is the Disability Assessment for Dementia scale (Gélinas *et al.*, 1999). To the extent that ADAS-cog and CIBIC-plus assess the multiple cognitive domains affected in all forms of dementia, including VaD, it is not unreasonable to use the same measures in both AD and VaD patient populations. However, Quinn and colleagues (2000) showed difficulties with CIBIC-plus ratings in instances of clinical improvement. Physicians fail to recognize successful disease treatment beyond reversal of progression.

Furthermore, current tests are relatively insensitive to frontal/subcortical dysfunction, a key cognitive domain in VaD (Román and Royall, 1999; Pohjasvaara *et al.*, 2002). Future clinical trials should incorporate tests such as the vascular equivalent of the ADAS-cog, the VaDAS-cog (Ferris and Gauthier, 2002), as well as others tests that include formal measurement of executive function. Of interest, ADL are considered a proxy evaluation of executive function. Pohjasvaara *et al.* (2002) confirmed that executive dysfunction was the main determinant of abnormalities in both basic ADL and instrumental ADLs (IADLs) in patients with post-stroke VaD. Executive function tests, including IADLs, may be sensitive tools for the diagnosis of VaD and could accurately measure the effects of potential therapies.

46.4 CLINICAL FORMS OF VASCULAR DEMENTIA

Despite the anatomical and pathophysiological complexity of VaD, Román (1999a, 2002b) has simplified the clinical forms into two groups, acute and subacute, according to the temporal profile of presentation.

46.4.1 Acute forms of VaD

Acute VaD is defined by new onset of dementia after a demonstrated stroke, either a single 'strategic stroke' resulting from occlusion (or rupture) of a large-size vessel, after a symptomatic lacunar stroke caused by ischaemic small vessel disease, or from recurrent strokes (MID). VaD can result from a single stroke located in one of the following three possible areas (Delay and Brion, 1962):

- posterior cerebral artery (PCA) territory, involving ventral-medial temporal lobe, hippocampus, occipital structures and thalamus;
- anterior cerebral artery (ACA) territory and medial frontal lobe lesions, often from an anterior communicating artery aneurysm rupture; and
- basal ganglia and thalamus, usually from small vessel disease; this is the so-called 'thalamic dementia of vascular origin' caused by butterfly-shaped bilateral paramedian thalamic polar infarcts. Some cases of caudate stroke may also result in VaD.

Numerous reports have confirmed the occurrence of true 'lacunar dementia', i.e. acute VaD resulting from a single lacunar stroke involving the inferior genu of the internal capsule and causing ipsilateral blood flow reduction to the inferomedial frontal cortex by a mechanism of diaschisis (Tatemichi *et al.*, 1992, 1995; Chukwudelunzu *et al.*, 2001). This thalamocortical disconnection syndrome is manifested by sudden change in cognitive function, often associated with fluctuating attention, memory loss, confusion, abulia, striking psychomotor retardation, inattention, and other features of frontal lobe dysfunction but with mild focal findings such as hemiparesis or dysarthria.

46.4.2 Subacute-subcortical forms of VaD

Subacute VaD is defined clinically by insidious onset of subcortical dementia with frontal lobe deficits, depressive mood changes – the so-called 'vascular depression' (Alexopoulos *et al.*, 2002), along with psychomotor slowing, parkinsonian features, urinary disturbances and pseudobulbar palsy, usually resulting from small vessel disease (Román *et al.*, 2002f). Symptoms are due to interruption by ischaemic lesions of prefrontal-subcortical circuits for executive control of working memory, organization, language, mood, regulation of attention, constructional skills, motivation, and socially responsive

behaviours (Cummings, 1993). Prefrontal-subcortical loops may be severed by lacunes in the striatum, globus pallidus or thalamus, or by white matter lesions that disconnect prefrontal or anterior cingulate cortexes from their basal ganglia or thalamocortical connections (Swartz *et al.*, 2003; Vataja *et al.*, 2003).

Loss of executive function is a major component of VaD (Román and Royall, 1999), leading to cognitive disability and clinically significant loss of planning capacity, working memory, attention, concentration, discrimination, abstraction, conceptual flexibility, and self-control (Román and Royall, 1999; Vataja *et al.*, 2003). Some patients are unable to initiate the required behaviour, others fail to inhibit irrelevant behaviours, and most can perform individual steps of a complex problem but are unable to provide a correct strategy to solve it. These symptoms often lead to post-stroke depression and functional disability (Pohjasvaara *et al.*, 1998, 2002).

The main clinical forms of subacute VaD are Binswanger's disease (*état lacunaire*), cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), and rare instances of cerebral amyloid angiopathy, including those that present with leukoencephalopathy (Gray *et al.*, 1985; Sarazin *et al.*, 2002). The temporal profile of presentation of these conditions is typically subacute, with a chronic course marked by fluctuations and progressive worsening.

46.4.2.1 BINSWANGER'S DISEASE

Binswanger's disease is characterized by the presence of ischaemic periventricular leukoencephalopathy typically sparing the arcuate subcortical U-fibres (Román, 1987). Brain imaging (CT and MRI) usually correlates well with the pathological features that include diffuse myelin pallor, loss of oligodendrocytes and astrocytic gliosis. Under the microscope, there is loss of myelin and axons resulting in rarefaction, spongiosis and vacuolization without definite necrosis (incomplete white matter infarction); in addition, lesions of arteriosclerosis and other hypertensive lesions (Lammie, 2002), and *état criblé* or widening of perivascular spaces are present. Advanced white matter lesions include focal necrosis and cavitations (lacunes); there are also lacunar infarcts in the basal ganglia and the pons. Román (1985a) suggested the identity of Binswanger's disease and a remarkably similar clinical condition, *état lacunaire* (Marie, 1901), characterized by multiple lacunes, ventricular dilatation and lesions of the white matter with a moth-eaten appearance. The syndrome included mild residual hemiparesis, a peculiar gait with short steps (*marche à petits pas*), dysarthria, pseudobulbar palsy, and extrapyramidal features such as inexpressive facies, slowness of movement, axial rigidity, loss of postural reflexes and frequent falls.

Dementia is not a salient feature of *état lacunaire* (Marie, 1901), but some intellectual deficit is constantly present. However, Fisher (1965) remarked that lacunar strokes typically do not cause disturbances in higher cerebral functions, and when present 'always exclude a lacunar diagnosis'. Among 114 patients with lacunes he examined at necropsy, dementia

was uncommon or mild. Population-based studies of elderly subjects indicate that in the vast majority of cases, lacunes are silent (Longstreth *et al.*, 1998); however, silent lacunes particularly in the thalamus more than double the risk of dementia (hazard ratio 2.26; 95 per cent CI 1.09–4.70) (Vermeer *et al.*, 2003). Hospital-based series of lacunar infarctions show that about 30 per cent of these patients develop dementia (Babikian *et al.*, 1990; Tatemichi *et al.*, 1993). In a clinicopathological review of 100 consecutive autopsies of patients with lacunar strokes at the Hôpital de la Salpêtrière (Román, 1985b), 72 cases with multiple lacunes were found, but only 36 per cent were clinically demented (*état lacunaire*). In six cases, Alzheimer disease and lacunes coexisted and six had Binswanger's disease (Mikol, 1968). In the demented patients, dilatation of the lateral ventricles was the only morphological feature that separated *état lacunaire* patients from cases with multiple lacunes but without dementia, suggesting that either white matter disease or normal pressure hydrocephalus could have contributed to the dementia.

Neuropathological data indicates that up to 60 per cent of patients with AD have Binswanger-type white matter lesions (Brun and Englund, 1986; Englund *et al.*, 1988). These lesions have been postulated as being caused by cerebral hypoperfusion resulting from cardiac disease or orthostatic hypotension; this form could be called AD type B (with Binswanger-type lesions), in contrast with AD type A, with exclusive cortical involvement. Moreover, Snowden and colleagues (1997) in the Nun Study reported that in very old subjects lacunes are an important factor in the clinical expression of AD. Likewise, according to Jellinger and Mitter-Ferstl (2003) the presence of cerebrovascular pathology in patients with AD is significantly higher at autopsy than in controls (48 versus 7.4 per cent). Zekry and co-workers (2002b, c) demonstrated at post-mortem examination the synergistic effect of vascular lesions in patients with dementia of AD. The presence of vascular lesions had a direct correlation with the severity of the dementia. Furthermore, the density of AD lesions (neuritic plaques, focal amyloid β deposits, and neurofibrillary tangles) was significantly lower when vascular lesions were present.

46.4.2.2 CADASIL

CADASIL was described in France in the early 1990s (Bousser and Tournier-Lasserre, 1994); it was originally called 'familial Binswanger' (van Bogaert, 1955) and 'hereditary multi-infarct dementia' (Sourander and Walinder, 1977; Sonninen and Savontaus, 1987). Currently, CADASIL appears to be the most common genetic form of VaD. Recently, Chabriat and Bousser (2003), Dichgans (2002) and Kalimo *et al.* (2002) have provided excellent reviews. This autosomal dominant disorder of cerebral small vessels maps to chromosome 19 and is caused by Notch3 gene mutations. The underlying vascular lesion is a unique non-amyloid non-atherosclerotic microangiopathy involving arterioles (100–400 μm in diameter) and capillaries, primarily in the brain but also in other organs. The diagnosis may be established by skin biopsy with confirmation by

immunostaining with a Notch3 monoclonal antibody. CADASIL offers a natural model for the study of subcortical-subacute forms of VaD, in particular Binswanger's disease. Numerous pedigrees have been described in Europe and North America. Clinical manifestations include transient ischaemic attacks (TIAs) and strokes (80 per cent), cognitive deficits and VaD (50 per cent), migraine with focal deficits (40 per cent), mood disorders (30 per cent) and epilepsy (10 per cent). Onset is usually in early adulthood (mean age: 46 years) in the absence of risk factors for vascular disease, culminating in dementia and death usually about 20 years after onset of symptoms. The dementia is slow in onset, subcortical, frontal in type, accompanied by gait and urinary disturbances, and pseudobulbar palsy clinically identical to that of sporadic Binswanger's disease. MRI reveals a combination of small lacunar lesions and diffuse white matter abnormalities, including, typically, lesions of the corpus callosum; MRI lesions are often present in asymptomatic relatives. Also, cerebral blood flow (CBF) reactivity to inhaled carbon dioxide is impaired. Widespread smooth-muscle cell loss results in decreased regional CBF; these values correlate inversely with cognitive performance. The disease is caused by highly stereotyped mutations in the Notch3 gene that encodes a phylogenetically old transmembrane cell-surface receptor that regulates cell fate during embryonic development. The large extracellular domain of Notch3 contains 34 tandem epidermal growth factor (EGF)-like repeats where the mutations result in gain or loss of a cysteine residue.

46.4.2.3 CEREBRAL AMYLOID ANGIOPATHY

Cerebral amyloid angiopathy or CAA is a heterogeneous group of disorders characterized by deposition of amyloid in the walls of leptomeningeal and cerebral cortical blood vessels, manifested clinically by recurrent or multiple lobar haemorrhages, cognitive deterioration, and ischaemic strokes. Cerebral MRI displays diffuse white matter abnormalities along with ischaemic or haemorrhagic focal brain lesions. On histology, the vessels show amyloid deposition, microaneurysms and fibrinoid necrosis.

There are several autosomal dominant forms of CAA with differences in their clinical, genetic, biochemical and pathologic findings. A β , the major amyloid component in the Dutch, Flemish, and Iowa-type of familial CAA, is also the major amyloid component in sporadic CAA and in AD. Familial British dementia (FBD) with amyloid angiopathy is an autosomal dominant condition characterized by VaD, progressive spastic paraparesis and cerebellar ataxia with onset in the sixth decade (Mead *et al.*, 2000). A point mutation in the BRI gene has been shown to be the genetic abnormality. On brain MRI, Binswanger-type deep white matter hyperintensities and lacunar infarcts are seen, but without intracerebral haemorrhages. The corpus callosum is severely affected and atrophic. Plaques and tangles are present but the amyloid subunit (A β) found in FBD brains is entirely different and unrelated to other amyloid proteins. FBD combines neurodegeneration and dementia with systemic amyloid deposition.

46.5 PHARMACOLOGICAL THERAPY OF VASCULAR DEMENTIA

A review of the history of VaD (Román, 2002c, d) suggests that the prevailing concepts of pathogenesis at a given time influence not only the elaboration of clinical criteria, but also the approach to therapy. Until the 1970s, VaD was believed to be caused by progressive strangulation of blood flow to the brain resulting in chronic cerebral hypoperfusion. Therefore, beginning with nicotinic acid, a number of vasodilating agents were recommended for years for the treatment of non-specific senile symptoms, cognitive decline and dementia. Following the same logic, Walsh (Walsh, 1968; Walsh *et al.*, 1978) claimed significant improvement of symptoms of presenile and senile dementia with a combination of warfarin anticoagulation and psychotherapy. A vascular pathogenesis also underlay the use of antithrombotics, ergot alkaloids, nootropics, thyrotropin-releasing hormone (TRH)-analogue, *Ginkgo biloba* extract, plasma viscosity drugs, hyperbaric oxygen, antioxidants, serotonin and histamine receptor antagonists, vasoactive agents, xanthine derivatives and calcium antagonists (Román, 2000). With increasing recognition of AD and new knowledge of neurotransmitters, neuronal metabolism and biochemical tissue reactions to ischaemia-hypoxia and oxidative stress, more specific medications were developed leading to the current of neuroprotection (Mondadori, 1993). The most recent advance in the treatment of VaD has been the development of medications to enhance specific neurotransmitters, such as acetylcholine. Furthermore, these products have been studied following closely the standard recommendations for controlled clinical trials. The cholinesterase inhibitors will be discussed first, followed by the NMDA-receptor antagonist of glutamatergic neurotransmission, memantine, the calcium channel blockers, the nootropic agents, the xanthines, the ergot derivatives, the vasodilators, and then other various treatments for VaD.

46.5.1 Cholinergic dysfunction in VaD

Cholinergic dysfunction is well documented in VaD, independently of any concomitant AD pathology; these deficits consist of decreased levels of acetylcholine (ACh) in the cerebrospinal fluid (CSF), and reduced cholinergic markers such as choline acetyltransferase (ChAT) in the brain (Szilagy *et al.*, 1987; Wallin *et al.*, 1989; Wallin and Gottfries, 1990; Gottfries *et al.*, 1994; Tohgi *et al.*, 1996). Hippocampal ChAT deficits of up to 60 per cent have been reported in the brains of both AD and VaD patients (Perry *et al.*, 1977; Sakurada *et al.*, 1990; Kalaria *et al.* 2001). The cholinergic basal forebrain nuclei are irrigated by penetrating arterioles and are therefore susceptible to the effects of arterial hypertension. Moreover, ischaemic lesions in the white matter and the basal ganglia can interrupt the cholinergic projections (Swartz *et al.*, 2003). Selden and co-workers (1998) described in the human brain two highly organized and discrete bundles

of cholinergic fibres extending from the nucleus basalis of Meynert (nbM) to the cerebral cortex and amygdala. Mesulam *et al.* (2003) demonstrated cholinergic denervation from ischaemic pathway lesions in CADASIL, a pure genetic form of VaD, entirely unmixed with AD lesions.

Cholinergic mechanisms play a role in the modulation of regional CBF (Sato *et al.*, 2001). Stimulation of the nbM results in increased blood flow in the cerebral cortex (Biesold *et al.*, 1989). This cholinergic vasodilatory system relies upon activation of both muscarinic and nicotinic cholinergic receptors and the response declines with age (Lacombe *et al.*, 1997; Uchida *et al.*, 2000). Therefore, there is loss of cholinergic function in patients with VaD, and this is associated with reductions in CBF (Court *et al.*, 2002).

The above observations provide reasonable arguments to justify the use of cholinesterase inhibitors in VaD (Román, 2005), both unmixed with AD, as well as in patients with AD + CVD. Three of the acetylcholinesterase inhibitors (AChEIs) approved for use in AD – donepezil, galantamine and rivastigmine – have also been studied in VaD and will be reviewed below.

46.5.1.1 DONEPEZIL

Donepezil hydrochloride (E2020, Aricept) is a piperidine-based, reversible, non-competitive AChEI with highly selective central action, approved for treatment of mild to moderate AD (Román and Rogers, 2004). Donepezil is unrelated to other cholinesterase inhibitors, and has greater selectivity for cerebral AChE than for butyrylcholinesterase (BuChE). It reaches peak plasma concentrations 3–4 hours after oral administration. Oral absorption is excellent and is unaffected by food or by time of administration; a single bedtime dose is recommended because of its long half-life. Therapeutic levels are obtained with a dose of 5 mg/day, reaching steady state plasma levels after 15 days. Donepezil is 96 per cent bound to plasma proteins (75 per cent to albumin and 21 per cent to α 1 acid glycoprotein). Donepezil is metabolized primarily by the cytochrome P450 system (CYP 450 isoenzymes 2D6 and 3A4) with extensive first-pass metabolism; it also undergoes glucuronidation (Román and Rogers, 2004).

The safety and efficacy of donepezil has been studied in the largest clinical trial of pure VaD to date (Goldsmith and Scott, 2003). A total of 1219 subjects were recruited for a 24-week, randomized, placebo-controlled, multicentre, multinational study divided in two identical trials, 307 (Black *et al.*, 2003) and 308 (Wilkinson *et al.*, 2003). The patients were randomized to one of three groups: placebo, donepezil at a dosage of 5 mg/day or donepezil, 10 mg/day. The group receiving 10 mg/day initially received 5 mg/day for four weeks; the dosage was then titrated up to 10 mg/day. Most patients (73 per cent) fulfilled diagnosis of probable VaD according to the NINDS-AIREN criteria (Román *et al.*, 1993). All had brain imaging prior to enrolment (CT or MRI) with demonstration of cerebrovascular lesions. Patients with pre-existing AD and those with ‘mixed dementia,’ (AD + CVD) were excluded.

Exclusion criteria also included other neurodegenerative or psychiatric disorders such as schizophrenia or major depression, a MMSE (Folstein *et al.*, 1975) score >26 or <10 , the occurrence of new strokes within the 28 days prior to baseline, or myocardial infarction within 3 months of enrolment. These two VaD studies enrolled more men than women (58 versus 38 per cent) and their mean age was older than in AD (74.5 ± 0.2 versus 72 ± 0.2 years). The more severe vascular pathology of VaD was reflected in the high HIS score (6.6 ± 0.2 versus <4 in AD); most subjects had hypertension, hypercholesterolaemia, cardiovascular disease, diabetes, smoking, previous stroke and TIAs.

There were three main end points:

- cognition, measured with the ADAS-cog (Rosen *et al.*, 1984) and the MMSE (Folstein *et al.*, 1975);
- global function, evaluated with the CIBIC-plus (Schneider *et al.*, 1997) and with the Sum of Boxes of the Clinical Dementia Rating (CDR-SB) scale (Berg, 1988); and
- ADL, measured with the Alzheimer’s Disease Functional Assessment and Change Scale (ADFACS) (Mohs *et al.*, 2001).

In study 307 (Black *et al.*, 2003), both donepezil treatment group showed statistically significant cognitive improvement measured with the MMSE and the ADAS-cog; the mean changes from baseline ADAS-cog scores were: donepezil 5 mg/day, -1.90 ($P = 0.001$); donepezil 10 mg/day, -2.33 ($P < 0.001$). The donepezil 5 mg/day group also showed significant improvement in global function on the CIBIC-plus but this did not reach significance in the 10 mg/day group ($P = 0.27$). The CDR-SB showed non-significant benefit in the 5 mg/day group and statistical significance in the 10 mg/day group ($P = 0.022$). Compared with placebo, there was significant benefit in ADL ($P < 0.05$) in both donepezil groups using the ADFACS.

Similar results were observed in study 308 (Wilkinson *et al.*, 2003); donepezil treatment resulted in significant improvement in cognition measured with the MMSE and the ADAS-cog. For the latter, the mean changes from baseline score were: donepezil 5 mg/day, -1.65 ($P = 0.003$); donepezil 10 mg/day, -2.09 ($P = 0.0002$). Global function on the CIBIC-plus was significantly better in the 5 mg/day group ($P = 0.004$), and was barely below significance in the 10 mg/day group ($P = 0.047$). The CDR-SB showed benefits with 5 mg/day (non-significant), and it reached significance with 10 mg/day ($P = 0.03$). The ADL were improved in patients treated with donepezil when compared with placebo using the ADFACS, but did not reach significance at the end of the study. Comparison of cortical versus subcortical forms of VaD showed no differences in the overall results of the trial (Salloway *et al.*, 2003).

In comparison with AD patients, cognitive decline in untreated patients with VaD during 24 weeks of study in these trials was less severe, using similar instruments. These differences were also noted for global effects, measured by the CIBIC-plus version. Substantial decline of instrumental ADL

was noted in untreated VaD patients. A combined analysis of the total population confirmed the effects on cognition and global function. Of interest, donepezil-treated patients demonstrated statistically significant improvements in instrumental IADLs compared with decline in the placebo group (least squares [LS] mean change from baseline at end point: placebo, 0.60; 5 mg/day -0.09 , $P < 0.05$; 10 mg/day -0.18 , $P < 0.01$). These results suggest that donepezil treatment may improve or maintain the patients' abilities to perform ADL. Executive dysfunction is a major component of disability in patients with VaD and the beneficial effect of donepezil on IADLs may be related to improvement or stabilization of executive function.

Donepezil was generally well tolerated, although more adverse effects were reported in the 10 mg/day group than in the 5 mg/day or placebo groups. The adverse effects were assessed as mild to moderate and transient, and were typically diarrhoea, nausea, arthralgia, leg cramps, anorexia and headache. The incidence of bradycardia and syncope was not significantly different from the placebo group. The discontinuation rates for the groups were 15 per cent for placebo, 18 per cent for 5 mg, and 28 per cent for the 10 mg group. There was no significant interaction with cardiovascular medications or antithrombotic agents. These two large trials offer evidence that donepezil is effective and well tolerated in patients with VaD (Malouf and Birks, 2004).

46.5.1.2 GALANTAMINE

Galantamine (galanthamine, Remynil, Proneurax, Prometax) is a tertiary alkaloid currently approved for the treatment of mild to moderate AD. Galantamine is a reversible specific inhibitor of AChE, and in addition it modulates central nicotinic receptors to increase cholinergic neurotransmission. Galantamine was initially isolated from the bulbs of the snowdrop plant, *Galanthus woronowii*, and from several Amaryllidaceae plants; commercially, galantamine is extracted from *Leucojum aestivum*, the common snowflake (Harvey, 1995; Pearson, 2001). Galantamine has high bioavailability from the oral route; maximum plasma levels are obtained about 1–2 hours after oral administration, with 18 per cent protein binding. Galantamine is metabolized by the CYP2D6 system into three inactive metabolites, *O*-demethyl-galantamine, *N*-demethyl-galantamine, and epigalantamine; elimination half-life is 5–7 hours. Cytochrome CYP2D6 inhibitors will increase the serum concentration of galantamine. The starting daily dose of galantamine is 8 mg/day (4 mg twice daily), but therapeutic levels are reached with 8 mg/day and doses up to 24–32 mg/day are used in AD. The safety and efficacy of galantamine in AD has been studied in randomized, controlled trials recruiting more than 2600 patients. Improvement or stabilization of cognition, function, behaviour and caregiver burden were demonstrated over 6 months; a few 12-month trials confirmed slowing of decline or maintained baseline performance (Corey-Bloom, 2003; Raskind, 2003; Dengiz and

Kershaw, 2004). Galantamine is safe and well tolerated when the dosage is escalated gradually. Galantamine HBr is available in 4 mg, 8 mg and 12 mg tablets.

Galantamine has been studied in VaD in a large phase III, randomized, multicentre, double-blind, placebo-controlled clinical trial in patients with probable VaD, or with AD combined with CVD (Erkinjuntti *et al.*, 2002a). Patients received galantamine 24 mg/day ($n = 396$) or placebo ($n = 196$) for 6 months; the age of the patients ranged from 40 to 90 years. Eligible subjects met either the clinical criteria of probable VaD by NINDS-AIREN criteria (Román *et al.*, 1993), or of possible AD according to the NINCDS-ADRDA criteria (McKhann *et al.*, 1984). Radiological evidence of CVD on brain CT or MR was required (i.e. AD + CVD), including multiple large-vessel infarcts or a single, strategically placed infarct (angular gyrus, thalamus, basal forebrain, territory of the posterior or anterior cerebral artery), or at least two basal ganglia and white matter lacunes, or white matter changes involving at least 25 per cent of the total white matter. Mild to moderate dementia was defined by a score of ≥ 12 in the ADAS-cog/11 (Rosen *et al.*, 1984) and 10–25 on the MMSE (Folstein *et al.*, 1975).

Primary end points were cognition, as measured using the ADAS-cog/11 (Rosen *et al.*, 1984), and global functioning as measured using the CIBIC-plus (Schneider *et al.*, 1997). Secondary end points included assessments of activities of daily living, using the Disability Assessment in Dementia (DAD) (Gélinas *et al.*, 1999), and behavioural symptoms, using the Neuropsychiatric Inventory (NPI) (Cummings *et al.*, 1994). Galantamine demonstrated greater efficacy than placebo on all outcome measures in analyses of both groups of patients as a whole: ADAS-cog (2.7 points, $P \leq 0.001$), on the CIBIC-plus (74 versus 59 per cent of patients remained stable or improved, $P \leq 0.001$). ADL and behavioural symptoms in the NPI were also significantly improved compared with placebo (both $P < 0.05$). Galantamine was safe and well tolerated; however, nausea was reported six times as often by VaD patients on galantamine than those on placebo. In comparison nausea was twice as common in patients with AD treated with galantamine compared with placebo-treated patients (Erkinjuntti *et al.*, 2002a), suggesting lesser tolerability in patients with VaD.

In an open label extension (Erkinjuntti *et al.*, 2003a), the original galantamine group of patients with probable VaD or AD + CVD showed similar sustained benefits in terms of maintenance of or improvement in cognition (ADS-cog), functional ability (DAD), and behaviour (NPI) after 12 months. Although not designed to detect differences between subgroups, the subgroup of patients with AD + CVD on galantamine ($n = 188$, 48 per cent) showed greater efficacy than placebo ($n = 97$, 50 per cent) at 6 months on the ADAS-cog ($P \leq 0.001$) and the CIBIC-plus ($P = 0.019$) (Erkinjuntti *et al.*, 2002a). In the open-label extension, patients with AD + CVD on galantamine maintained cognition at baseline for 12 months (Erkinjuntti *et al.*, 2003a). The subgroup of patients with probable VaD, compared those on placebo

($n = 81$, 41 per cent) with 171 subjects (43 per cent) on galantamine. In the subgroup of patients with VaD treated with galantamine for 6 months, the ADAS-cog scores improved significantly (mean change from baseline, 2.4 points, $P < 0.0001$), compared with no response in placebo group (mean change from baseline, 0.4; treatment difference versus galantamine 1.9, $P = 0.06$) (Erkinjuntti *et al.*, 2003a). More patients treated with galantamine than with placebo maintained or improved global function (CIBIC-plus, 31 per cent versus 23 per cent; not statistically significant). In these patients, the cognitive benefits of galantamine were maintained at least up to 12 months, demonstrating a mean change of -2.1 in the ADAS-cog score compared with baseline, and the active group was still close to baseline at 24 months (Erkinjuntti *et al.*, 2003a). During the 12-month trial, the most frequently reported adverse events were depression (13 per cent), agitation (12 per cent) and insomnia (11 per cent).

46.5.1.3 RIVASTIGMINE

Rivastigmine (Exelon) is a second-generation carbamate slowly reversible AChEI and butyryl-cholinesterase (BuChE) inhibitor currently approved for use in mild to moderate AD (Farlow, 2003). Rivastigmine binds to the AChE molecule in a pseudo-irreversible manner; the acetyl moiety of ACh is dissociated rapidly but the carbamyl moiety remains longer. Rivastigmine is therefore metabolized at the synapse rather than by hepatic cytochrome enzymes; hence, there are no drug–drug interactions (Polinsky, 1998). Rivastigmine has a half-life at the synapse of 9 hours and should be given twice daily. Initial dosage is 3 mg/day and should be slowly escalated to 6 mg/day, 9 mg/day and 12 mg/day. The role of BuChE inhibition in glial cells in AD remains unclear. After treatment of AD with rivastigmine for 12 months, CSF and plasma AChE activity decreased by 46 per cent and BuChE by 65 per cent from baseline (Darreh-Shori *et al.*, 2002). There was a significant correlation between plasma ChE inhibition and cognition, particularly in relation to attention (Almkvist *et al.*, 2004).

The effects of rivastigmine in VaD remain to be determined in phase III, randomized, double-blind, placebo-controlled clinical trials (Moretti *et al.*, 2004). Rivastigmine was used in small open-label studies of patients with subcortical VaD followed for 12 months (Moretti *et al.*, 2001) and 22 months (Moretti *et al.*, 2002); rivastigmine resulted in stabilization of cognition and ADL, with slight improvement of executive function and planning, less caregiver stress and improved behaviour.

Regarding the use of rivastigmine in patients with AD + CVD, Kumar and colleagues (2000) compared the outcomes of AD patients with or without concurrent vascular risk factors; cognitive effects were seen in both groups but patients with AD and vascular risk had greater clinical benefit. These findings were confirmed by Erkinjuntti and colleagues (2002b) in an open-label extension study of 104 weeks. Compared with non-hypertensive patients with AD,

significant treatment differences were observed in the hypertensive subgroup on the Progressive and Global Deterioration Scales (PDS and GDS). Furthermore, Erkinjuntti *et al.* (2003b) stratified 725 patients with AD treated with rivastigmine, according to the presence or absence of arterial hypertension at baseline. Rivastigmine 6–12 mg/day provided better outcomes than placebo on the PDS in the hypertensive ($P = 0.031$) and non-hypertensive ($P = 0.035$) subgroups. All patients receiving rivastigmine 6–12 mg/day had superior CIBIC-plus scores than those receiving placebo. The additional apparent benefits on disease progression detected in patients with AD and hypertension may be linked to drug effects on cerebrovascular risk factors, or to a larger underlying cholinergic deficit in patients with AD and hypertension.

46.5.2 Memantine

Memantine (Namenda, Ebixa, Axura) is a moderate-affinity, voltage-dependent, uncompetitive, potent antagonist of the *N*-methyl-*D*-aspartate (NMDA) receptor (Farlow, 2004). Experimentally, memantine inhibits and reverses the abnormal activity of protein phosphatase (PP-2A) that leads to tau hyperphosphorylation and to neurofibrillary degeneration in AD (Li *et al.*, 2004). Memantine has been shown to be effective and well tolerated in patients with severe AD (Reisberg *et al.*, 2003), and was recently approved by the FDA for the treatment of moderate to severe AD (Möbius, 2003). Furthermore, Tariot and colleagues (2004) showed that, in patients with moderate to severe AD receiving stable doses of donepezil, memantine resulted in significantly better outcomes than placebo in cognition, ADL, global outcome and behaviour. These findings suggest that this dual therapy could be useful.

Memantine has been used also in patients with VaD based on its experimental efficacy in animal models of ischaemia. Memantine acts on potentially contributing factors such as neuronal depolarization, mitochondrial dysfunction, magnesium effects on NMDA receptors and chronic glutamatergic overstimulation; it also has shown positive effects on long-term potentiation and cognitive tests in standard animal models of impaired synaptic plasticity (Möbius, 1999).

Orgogozo and colleagues (2002) and Wilcock and co-workers (2002), recently completed two randomized, placebo-controlled 6-month trials of memantine (20 mg/day) in mild to moderate probable VaD, diagnosed according to the NINDS-AIREN criteria (Román *et al.*, 1993). In study MMM 300 Orgogozo *et al.* (2002) randomized 147 patients to memantine and 141 to placebo. After 28 weeks, the mean ADAS-cog scores were significantly improved relative to placebo: the memantine group gained an average of 0.4 points, versus a decline of 1.6 in the placebo group, a difference of 2.0 points ($P = 0.0016$). The CIBIC-plus improved or stable response, reached 60 per cent with memantine compared with 52 per cent with placebo ($P = 0.227$). The Gottfries-Bråne-Steen (GBS) Scale (Gottfries *et al.*, 1982) and the Nurses' Observation Scale for Geriatric

Patients (NOSGER) (Spiegel *et al.*, 1991) total scores at week 28 did not differ significantly between the two groups. However, the GBS Scale intellectual function subscore and the NOSGER disturbing behaviour dimension also showed a difference favouring memantine ($P = 0.04$ and $P = 0.07$, respectively).

In study MMM 500 Wilcock *et al.* (2002) randomized 277 patients to memantine and 271 to placebo. At 28 weeks the active group had gained 0.53 points and the placebo declined by 2.28 points in ADAS-cog, a significant difference of 1.75 ADAS-cog points between the groups ($P < 0.05$). There were no differences in CGIC, MMSE, GBS or NOSGER between groups. Memantine was well tolerated in both studies. Möbius and Stoffler (2002) performed a *post hoc* pooled analysis of the above two placebo-controlled trials of memantine in VaD. Baseline severity, as assessed by MMSE, showed larger cognitive benefit in patients with more advanced disease. Also, the cognitive treatment effect for memantine was more pronounced in the small-vessel type group without cortical infarctions by CT or MRI. Finally, the placebo subgroup of patients with large vessel disease showed less cognitive decline than the other subgroup.

46.5.3 Calcium channel blockers

The main calcium channels blockers used for the treatment of VaD include nimodipine, lacidipine and fasudil.

46.5.3.1 NIMODIPINE

Nimodipine (Nimotop) is a dihydropyridinic calcium channel blocker used as an antihypertensive agent. Due to its highly lipophilic properties it readily crosses the blood–brain barrier (BBB), affects autoregulation of cerebral blood flow and produces vasodilatation of small cerebral blood vessels (Jansen *et al.*, 1991). Nimodipine has been shown to reduce the severity of neurological outcome in patients after subarachnoid haemorrhage secondary to ruptured aneurysms, probably by decreasing cerebral vasospasm, although this effect has not been demonstrated by angiography or transcranial Doppler (Ohman *et al.*, 1991). In addition to its vascular effects, nimodipine appears to have nootropic properties. There is a high density of nimodipine binding sites in hippocampus, caudate nucleus and cerebral cortex (Traber and Gibsen, 1989). Nimodipine binds to slow L-type calcium receptors, preventing influx of calcium into vascular smooth muscle cells and into ischaemic neurones (Greenberg *et al.*, 1990); experimentally, it provides protection against age-associated microvascular abnormalities in the rat brain (De Jong *et al.*, 1990). Although a neuroprotective effect has been postulated in stroke patients, nimodipine showed only a trend for better outcome when used within the first 12 hours of stroke onset (Gelmers and Hennerici, 1990).

A Cochrane review on nimodipine by Lopez-Arrieta and Birks (2002) concluded that, owing to limitations in the available data, there was no convincing evidence for the efficacy of nimodipine in AD, VaD or mixed forms of dementia.

However, a re-analysis of the Scandinavian Trial of Nimodipine in MID (Pantoni *et al.*, 2000) showed a beneficial effect in tests of attention and psychomotor performance in the subgroup of patients with subcortical small vessel VaD, but not in patients with post-stroke dementia of the MID type.

A pilot open label trial of nimodipine in patients with small vessel VaD was positive (Pantoni *et al.*, 1996). In this study, subcortical VaD was defined according to ICD-10 criteria (World Health Organization, 1992), and inclusion criteria required the patients to have mild to moderate dementia (MMSE, 12–24; Global Deterioration Scale, 3–5), as well as CT evidence of extensive leukoaraiosis and at least one lacunar infarct. The primary measure of efficacy was the Sandoz Clinical Assessment – Geriatric (SCAG) scale (Shader *et al.*, 1974). Using similar criteria and outcome measures, a large multicentre, randomized, double-blind, placebo-controlled trial of nimodipine in subcortical VaD is being conducted in Italy and Spain.

46.5.3.2 LACIDIPINE AND LERCANIDIPINE

Lacidipine and lercanidipine are third-generation dihydropyridine calcium antagonists that cause systemic vasodilatation by blocking calcium entry through L-type calcium channels in cell membranes; these agents also improve carotid atherosclerosis (Zanchetti *et al.*, 2004), small vessel disease (Frishman, 2002) and cerebral flow (Semplicini *et al.*, 2000) in hypertensive patients and offer some promise for the treatment of vascular dementia.

46.5.3.3 FASUDIL

Fasudil hydrochloride is a novel intracellular calcium antagonist, with Rho-kinase inhibitory activity on arterial walls affecting vessel remodelling (Pearce *et al.*, 2004). Kamei and colleagues (1996) reported the use of fasudil in the treatment of two patients with Binswanger's disease using ^{31}P -magnetic resonance spectroscopy and Xenon-computed tomography. Treatment with fasudil at 30 or 60 mg/day orally for 8 weeks controlled the fluctuating symptoms of Binswanger's disease in both patients. Mental tests and imaging also improved during the treatment.

46.5.4 Nootropic agents

The name nootropic (Greek *nous*, mind; *trophikos*, nourishing) describes a category of agents with neuroprotective capacity against anoxic or oxidative injuries. Piracetam, oxiracetam and citicoline will be reviewed here.

46.5.4.1 PIRACETAM

Piracetam (2-oxo-1-pyrrolidine acetamide), the first of the nootropic agents, is a cyclic derivative of γ -aminobutyric acid (GABA) which can cross the blood–brain barrier (Hitzenberger *et al.*, 1998) to concentrate selectively in the brain cortex (Vernon and Sorokin, 1991). At low doses, piracetam increases both oxygen and glucose utilization via ATP pathways and the

release of some neurotransmitters – in particular dopamine metabolites – whilst at higher dosages, it is associated with platelet anti-aggregation and rheological effects with antithrombotic properties (Moriau *et al.*, 1993). It enhances the microcirculation by promoting erythrocyte deformability and by reducing adherence to endothelial cells. However, studies of piracetam in acute stroke have been inconclusive, although improvement of aphasia in patients treated within 7 hours of stroke onset was seen (Hitzenberger *et al.*, 1998). Several animal studies showed effects of piracetam on memory and facilitation of retention over 24 hours. A Cochrane review (Flicker and Grimley Evans, 2001) concluded that the usefulness of piracetam in patients with AD and VaD in small clinical trials has been unclear, based mainly on subjective Global Impression of Change. A recent review of 19 trials in patients with several forms of dementia (Waegemans *et al.*, 2002) and a protective effect in patients undergoing coronary artery bypass surgery (Uebelhack *et al.*, 2003) appear to provide some support for a moderate effect of piracetam on cognitive impairment.

46.5.4.2 OXIRACETAM

Oxiracetam is a structural analogue of the nootropic agent piracetam. This compound has enhancing effects on vigilance and memory. In comparison with piracetam, oxiracetam exhibits greater improvement in memory (Itil *et al.*, 1986) and has been used extensively for the treatment of dementia, including AD, VaD, MID (Dysken *et al.*, 1989; Baumel *et al.*, 1989) and mixed forms. Green and colleagues (1992) failed to demonstrate a difference with placebo in AD patients. In contrast, Maina and co-workers (1989) studied 289 patients with MID in a double-blind placebo-controlled trial and after 12 weeks of treatment found that oxiracetam reduced behavioural symptoms.

46.5.4.3 CITICOLINE

Citicoline (Somazina), also known as CDP-choline or cytidine-5'-diphosphate choline, is a naturally occurring endogenous nucleoside that functions as an intermediate in three major metabolic pathways (Conant and Schauss, 2004):

- *Synthesis of phosphatidylcholine* (lecithin), one of the major cell membrane phospholipids with an important role in the formation of lipoproteins. Citicoline formation is the rate-limiting step in the synthesis of phosphatidylcholine.
- *Synthesis of acetylcholine*: citicoline by providing choline for this neurotransmitter could limit choline availability for membrane synthesis. This 'auto-cannibalism' of choline-containing membrane phospholipids as a source of acetylcholine has been postulated in AD (Ulus *et al.*, 1989).
- *Oxidation to betaine*, a methyl donor. The main components of citicoline, choline and cytidine, are readily absorbed in the gastrointestinal tract and cross the blood–brain barrier. As a dietary supplement, choline is grouped with the B vitamins.

In animal studies, citicoline is biologically active, enhancing repair of ischaemic neuronal injury and increasing levels of acetylcholine and dopamine (Secades and Frontera, 1995). In aged animals, citicoline increased dopamine release, improving learning and memory tasks (Cacabelos *et al.*, 1993). In a pooled analysis of clinical trials on acute ischaemic stroke, citicoline was shown to enhance the possibility of recovery (Davalos *et al.*, 2002). Citicoline has been used in a number of trials in patients with AD showing modest results in improvement of memory and behaviour (Cacabelos *et al.*, 1993). In a Cochrane review (Fioravanti and Yanagi, 2000) of four studies in VaD with a total of 217 patients (citicoline = 115, placebo = 102), evaluation with the Global Impression of Change showed a significant improvement in contrast with the placebo group. The effect size was very large (8.89 CI = 5.19–15.22) indicating a strong drug effect (Fioravanti and Yanagi, 2000). However, a more recent, placebo-controlled trial, on 30 patients showed no evidence of cognitive improvement (Cohen *et al.*, 2003).

46.5.5 Xanthine derivatives

The main xanthine derivatives used in the treatment of VaD are pentoxifylline or oxpentifylline (Trental), denbufylline – a phosphodiesterase 4 (PDE4) inhibitor, and propentofylline (PPF). Pentoxifylline, derived from theobromine, has haemorheological effects both on the microcirculation and on peripheral vascular disease (in particular for the treatment of intermittent claudication). Pentoxifylline has immunomodulatory properties, increasing the rate of neutrophil migration, suppressing monocyte production of tumour necrosis factor (TNF)- α , and inhibiting leukocyte stimulation by TNF- α and interleukin-1 (IL-1). These properties are strong contributors to its haemorheological effects (Samlaska and Winfield, 1994). PPF exhibits adenosine-mediated nootropic properties against post-anoxic neuronal cell damage, and glial-modulation effects with inhibition of microglial activation.

46.5.5.1 PENTOXIFYLLINE

Haemorheological changes are found in patients with AD and in some forms of VaD, such as Binswanger's disease, in comparison with age-matched controls (Solerte *et al.*, 2000). Abnormalities included hyperviscosity, increased sedimentation rate, hyperfibrinogenaemia and increased acute-phase reactants; these changes correlate with increased levels of TNF- α and interferon(IFN)- γ . Pentoxifylline (Trental) treatment lowers fibrinogen and TNF- α levels. Black and colleagues (1992) demonstrated beneficial effects of pentoxifylline in patients with MID. These preliminary findings were confirmed in the larger, multicentre European Pentoxifylline Multi-Infarct Dementia Study (1996) that demonstrated significant cognitive improvement in the MID form of VaD in comparison with placebo.

46.5.5.2 PROPENTOFYLLINE

Beneficial effects on learning and memory were observed in several European and Canadian double-blind, placebo-controlled, randomized, parallel group trials of PPF in AD and VaD (Kittner *et al.*, 1997; Mielke *et al.*, 1998; Kittner, 1999; Pischel, 1998). Most studies included patients with mild to moderate VaD according to NINDS-AIREN criteria (McKhann *et al.*, 1984). Significant symptomatic improvement and long-term efficacy in ADAS-cog and CIBIC-plus were noted up to 48 weeks of treatment compared with placebo. In addition, sustained treatment effects for at least 12 weeks after withdrawal suggested an effect on disease progression (Pischel, 1998; Rother *et al.*, 1998). Despite these positive results in controlled clinical trials in AD and VaD, the clinical development of PPF was halted in 2000.

46.5.5.3 DENBUFYLLINE

Denbufylline, a xanthine derivative and PDE4 inhibitor, has interesting effects such as vasodilatation of cerebral vessels (Willette *et al.*, 1997) and potent activation of the hypothalamo-pituitary–adrenal axis. PDE4 is one of the cyclic AMP (cAMP) specific phosphodiesterases whose tissue distribution is important in pathologies related to the central nervous and immune systems. In the experimental animal, denbufylline increases adrenocortico tropic hormone, circulating corticosterone, luteinizing hormone, corticotrophin releasing hormone, and cAMP content of the hypothalamic tissue, but is without effect on arginine vasopressin (Kumari *et al.*, 1997). It also stimulates inhibition of bone loss suggesting therapeutic potential for the treatment of osteoporosis (Miyamoto *et al.*, 1997). Treves and Korczyn (1999) studied a group of patients with AD, mixed dementia, and VaD treated with denbufylline. No significant differences were found in comparison with placebo for the treatment of AD or VaD, although patients who received denbufylline tended to improve in their cognitive scores.

46.5.6 Vasodilators

Yesavage and colleagues (1979) reviewed 102 studies from the literature on the use of vasodilating agents in senile dementias; the postulated effect of these agents was to counteract the ‘hardening of the arteries’. Recommendations for most of these agents were based in trials invalidated by the small number of participants, short open treatment periods, and variations in diagnostic criteria and clinical end points. Cochrane himself (1979) strongly criticized the poor quality of the evidence thus obtained.

The principal pharmacological agents with primary effect on smooth muscle resulting in vasodilatation include cyclospasmol (Cyclospasmol), papaverine (Pavabid), isoxsuprine (Vasodilan), cinnarizine (Stugeron), and nafronyl (Pralixene). No significant effects have been demonstrated with the use of vasodilating agents in VaD (Cook and James, 1981).

Nicotinic acid (niacin), used for many years for its vasodilating properties, has received renewed attention due to its effects in the treatment of primary hypercholesterolaemia and mixed dyslipidaemia. Nicotinic acid is the only drug that primarily lowers concentrations of non-esterified fatty acids and thereby lowers VLDL triglycerides. Nicotinic acid also seems to improve insulin resistance and to stimulate cholesterol mobilization from macrophages, offering an avenue for regression of the vascular lesions of atherosclerosis (Karpe and Frayn, 2004).

46.5.7 Ergot derivatives

The main ergot derivatives used for the treatment of VaD are nicergoline (Sermion) and codergocrine or ergoloid mesylates (Hydergine) – a mixture of the mesylated form of four dehydrogenated ergot peptide derivatives (in a 3:3:2:1 ratio), dihydroergocornine, dihydroergocristine, dihydro- α -ergocryptine, and dihydro- β -ergocryptine (Wadworth and Chrisp, 1992).

46.5.7.1 ERGOLOID MESYLATES

The metabolic effects of ergoloid mesylates (Hydergine) are incompletely understood; however, enhancement of noradrenergic, dopaminergic and serotonergic functions (Weil, 1988) and reduction of free radical formation (Favit *et al.*, 1995) have been proposed. Schneider and Olin (1994) reviewed 151 reports on the use of ergoloid mesylates (Hydergine) in senile dementia, but only 47 of these trials (31 per cent) met strict criteria for meta-analysis. The review by Schneider and Olin (1994) and a subsequent Cochrane report (Olin *et al.*, 2001) confirmed that patients with VaD appeared to benefit more from Hydergine than patients with AD in terms of cognition, clinical global ratings, and combined measures. However, compared with placebo, efficacy was very modest, at best, and there are at present no grounds to recommend its use.

46.5.7.2 NICERGOLINE

Nicergoline (Sermion) is an ergot derivative used for the treatment of cognitive, affective and behavioural disorders of the elderly. Although initially considered a vasoactive drug indicated for cerebrovascular disorders, nicergoline appears to have protective effects against degeneration of cholinergic neurones (Giardino *et al.*, 2002) and has been used for the treatment of various forms of dementia, including AD and VaD (Fioravanti and Flicker, 2001). The therapeutic effects of nicergoline were evident by 2 months of treatment and were maintained for 6 months. Cognitive assessment with the MMSE was performed in 261 patients. The difference between treatment and control groups on the MMSE favoured nicergoline; at 12 months the effect size was 2.86 (0.98, 4.74). Herrmann and colleagues (1997) conducted a randomized double-blind placebo-controlled trial involving 136 patients with MID. After 6 months of treatment, nicergoline was significantly better than placebo. Another placebo-controlled pilot study by Bes and colleagues (1999), recruited 72 elderly

hypertensive patients with VCI and evidence of leukoaraiosis, randomly assigned to either nicergoline ($n = 36$) or placebo ($n = 36$) for 24 months. Nicergoline (30 mg b.i.d. for 24 months) was well tolerated and attenuated the cognitive decline of elderly hypertensive patients with VCI.

46.5.8 Posatirelin

Posatirelin is a TRH analogue (*L*-6-ketopiperidine-2-carbonyl-*L*-leucyl-proline amide). In an experimental model of brain cholinergic deficit in the rat by lesion of the nucleus basalis magnocellularis, posatirelin treatment was shown to rescue cholinergic neurones of the nbM and their cholinergic projections to the cerebral cortex (Sabbatini *et al.*, 1998). Posatirelin has been used in patients with AD and VaD (Parnetti *et al.*, 1995, 1996). VaD patients treated with posatirelin showed a significant improvement in intellectual performance, orientation, motivation and memory as compared with controls. The drug was well tolerated.

46.5.9 Antithrombotic agents

Antiplatelet drugs have been shown to effectively prevent TIAs and ischaemic stroke (Easton, 2003). Aspirin provides a relative reduction of 19 per cent in the rate of major vascular events in patients with arterial disease in general, and 13 per cent in patients with ischaemic CVD (van Gijn and Algra, 2003). Other antiplatelet agents, such as sulfinpyrazone, ticlopidine, clopidogrel, dipyridamole and orally administered IIb/IIIa inhibitors have similar effects, although the combination of aspirin and dipyridamole may be more efficacious than aspirin alone. The Antithrombotic Trialists' Collaboration (Easton, 2003) assessed the effect of antiplatelet therapy in 135 000 patients. Antiplatelet therapy reduces the combined odds of stroke, myocardial infarction or vascular death by 22 per cent, and antiplatelet agents reduce the odds of a non-fatal stroke by 25 per cent in patients with or without a history of stroke. Likewise, among patients with non-valvular atrial fibrillation, anticoagulation (INR ≥ 2.0) reduces not only the frequency and severity, but also the mortality of ischaemic stroke (Hart, 2003; Hylek *et al.*, 2003). The few trials of antiplatelet agents conducted in patients with VaD will be mentioned below.

46.5.9.1 ASPIRIN

A population-based study by Sturmer and colleagues (1996) showed that aspirin (ASA) users have a slight protection against cognitive decline with an odds ratio ranging from 0.97 to 0.87. A single randomized trial used ASA (325 mg/day) in patients with mild MID type of VaD (Meyer *et al.*, 1989). Cognitive tests and CBF studies were performed at onset and 1 year later. Stabilization or mild improvement was seen in the active group compared with untreated controls. However, a recent Cochrane review (Williams *et al.* 2000) concluded that there is no evidence that aspirin is effective in treating patients with VaD.

46.5.9.2 TRIFLUSAL

Triflusal (Disgren) is an antiplatelet agent structurally related to the salicylates, but it is not derived from ASA. Triflusal and its active metabolite (3-hydroxy-4-trifluoro-methylbenzoic acid or HTB) produce specific inhibition of platelet arachidonic acid metabolism (McNeely and Goa, 1998). A single open-label trial of triflusal in 73 patients with VaD (López-Pousa *et al.*, 1997) showed, after 12 months of therapy, less decline in MMSE scores in the active group compared with the untreated subjects.

46.5.9.3 GINKGO BILOBA

Ginkgo, extract EGb 761 from the *Ginkgo biloba* tree (the maidenhair tree), has been widely used in several European countries and more recently in North America, for the treatment of 'chronic cerebral circulatory insufficiency' (Kleijnen and Knipschild, 1992; Gertz and Kiefer, 2004). *Ginkgo biloba* extracts are considered to have vasodilating and antioxidant properties, as well as haemorheological and nootropic effects, and to decrease platelet aggregability and blood viscosity, but the mechanism of action remains poorly understood (Zimmermann *et al.*, 2002; Gertz and Kiefer, 2004). Several trials have used ginkgo in patients with MID or with AD + CVD, with modest positive results (Le Bars *et al.*, 1997; Kanowski and Hoerr, 2003; van Dongen *et al.*, 2003). Using Cochrane data, Kurz and Van Baelen (2004) showed significant benefit versus placebo with ginkgo treatment only when all doses were pooled, although the effects appeared to be minimal. Ginkgo treatment in the elderly, has been associated with subarachnoid haemorrhage and other haemorrhagic complications such as subdural haematoma, intracranial and intraocular bleeding (Vale, 1998; Fong and Kinnear, 2003; Meisel *et al.*, 2003).

46.5.10 Choto-san

Choto-san (Gouteng-san) is a traditional Japanese (Kampo) herbal medicine with apparent neuroprotective effect against glutamate-induced neuronal death (Itoh *et al.*, 1999; Watanabe *et al.*, 2003). Choto-san was administered for 12 weeks to 10 patients with post-stroke VCI; P3 event-related brain potentials, MMSE, and verbal fluency tests significantly improved with treatment (Yamaguchi *et al.*, 2004). In a larger trial, Choto-san resulted in improvement of ADL, global rating, and subjective and psychiatric symptoms (Itoh *et al.*, 1999).

46.5.11 Jiannao yizhi

Zhang and colleagues (2002) evaluated the safety and efficiency of Jiannao yizhi, a Chinese herbal medicine, in the treatment of VaD. A multicentre, double-blind, randomized, placebo-controlled method was used to study 242 patients with mild to moderate VaD; 89 cases were randomized to the active group (Jiannao Yizhi Granules), 106 cases to the Western medicine group and 47 to the placebo group. MMSE

and Blessed Dementia Scale were used to evaluate the therapeutic effect after 60 days of therapy. Treatment with Jiannao Yizhi was superior to Western medicine and to placebo.

46.5.12 Vinpocetine

Vinpocetine is a synthetic ethyl ester of apovincamine, a vinca alkaloid obtained from the leaves of the lesser periwinkle (*Vinca minor*). For many years, vinpocetine has been used for the treatment of cognitive impairment but the mechanism of action remains unclear (Szatmari and Whitehouse, 2003). A recent Cochrane review of three short-term studies involving 583 patients with dementia (AD, VaD, mixed) treated with vinpocetine or placebo, concluded that patients treated with vinpocetine (30–60 mg/day) showed modest benefit compared with placebo (Szatmari and Whitehouse, 2003).

46.5.13 Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a weakly androgenic adrenal steroid and an intermediary in the biosynthesis of androgens and oestrogens. It is considered a neurohormone, since small quantities of DHEA are produced in the brain (Knopman and Henderson, 2003). DHEA or its sulphate ester metabolite (dehydroepiandrosterone sulphate, DHEAS) is the most abundant circulating steroid and declines in serum and CSF with aging. Bicikova and colleagues (2004) have suggested that variations in levels of these neurohormones could discriminate between AD and VaD. However, Kim *et al.* (2003) observed that DHEAS levels in the CSF were significantly decreased in both AD and VaD.

DHEA is classified as a dietary supplement; its effect on dementia could result from a direct action, or through testosterone, oestradiol, and other metabolites. However, there is no association between DHEAS levels and duration or severity of symptoms in AD. Wolkowitz and co-workers (2003) conducted a 6-month, randomized double-blind study of DHEA for AD. A modest improvement was seen with DHEA but increasing confusion, agitation and paranoid reactions were seen among DHEA-treated participants. A high dropout may have compromised the study. DHEA alone seems unlikely to be superior to currently available anticholinesterases for AD. A single open-label trial of DHEA in the MID type of VaD (Azuma *et al.*, 1999) used intravenous DHES (200 mg/day) for 4 weeks; the treatment markedly increased serum and CSF levels of DHEAS in seven MID patients; however, improvement of ADL and emotional disturbances was seen in only three patients.

46.5.14 Cerebrolysin

Cerebrolysin is a peptidergic drug produced from purified brain proteins, with postulated neurotrophic activity (Windisch *et al.*, 1998; Windisch, 2000) and probable neuroprotective effects (Rockenstein *et al.*, 2003). A small open-label trial in patients with AD and VaD (Rainer *et al.*, 1997)

showed minimal improvement in cognitive tests and clinical global impression.

46.5.15 Sulodexide

Sulodexide is a medium molecular weight glycosaminoglycan with effects on plasma viscosity by lowering plasma fibrinogen concentrations (Lunetta and Salantri, 1992). Sulodexide is effective and well tolerated in peripheral occlusive arterial disease with claudication (Shustov, 1997). In Italy, Parnetti and colleagues (1997) conducted a trial of sulodexide in patients that fulfilled NINDS-AIREN criteria for probable VaD; 46 patients were included in the active treatment group, compared with 40 in the pentoxifylline group. Larger reductions of plasma fibrinogen levels were seen with sulodexide, and both groups showed a slight reduction in activated factor VII levels. Dementia scores improved more in the sulodexide group.

46.5.16 Thrombin inhibitors

There is evidence indicating that hypercoagulable states could result in increased risk of dementia (Mari *et al.*, 1996). Bots and colleagues (1998) from the Dutch Vascular Factors in Dementia Study in Rotterdam, found that dementia, particularly post-stroke VaD, was associated with increased thrombin generation. In this population, increased levels of thrombin-antithrombin complex (TAT), cross-linked D-dimer and tissue-type plasminogen activator (tPA) activity were associated with increased risk of dementia. In addition, coagulation abnormalities have been described in patients with Binswanger's disease. Schneider and colleagues (1987) found increased fibrinogen levels and hyperviscosity in patients with Binswanger's disease. Iwamoto and co-workers (1995) demonstrated increased platelet activation in Binswanger's disease that was manifested by increased plasma β -thromboglobulin levels. Tomimoto and colleagues (1999, 2001) found coagulation activation leading to hypercoagulable state in Japanese patients with Binswanger's disease; levels of fibrinogen, TAT complex, prothrombin fragment 1 + 2, and D-dimer were found to be significantly increased, particularly in patients with recent aggravation of their deficits.

There are no controlled clinical trials of Binswanger's disease, but the above results point toward several potential therapeutic options (Román, 1999b). Iwamoto and co-workers (1995) reported that the use of ticlopidine hydrochloride in eight patients with Binswanger's disease resulted in lower levels of platelet activation, without major clinical change. There is a need for controlled trials of ticlopidine and other antiplatelet agents, such as aspirin, dipyridamole, and clopidogrel, alone or in combination, in Binswanger's disease.

Hyperfibrinogenaemia has deleterious effects on haemorheological conditions in the cerebral microcirculation that result in hyperviscosity and slowing of blood flow in deep border-zone territories in Binswanger's disease.

Therefore, the use of medications such as pentoxifylline (Trental), ancrod (Sherman, 2002) or bezafibrate (Tanne *et al.*, 2001) to lower fibrinogen levels could be indicated.

46.5.16.1 ANCROD

Ancrod, a defibrinating enzyme obtained from the venom of a Malayan pit viper (Sherman, 2002), was used by Ringelstein and colleagues (1988) in 10 patients with Binswanger's disease. Mean plasma levels of fibrinogen decreased from 3.26 g/L (SD 1.3) prior to treatment (normal 2.5–4.0 g/L), to 1.52 g/L (SD 0.53) after 1 month of treatment with subcutaneous ancrod. Treatment resulted in significant improvement of the timed retinal arteriovenous circulation (abnormally slow prior to treatment), and increase of CO₂-induced cerebral vasomotor response measured by transcranial Doppler. However, clinical condition and neuropsychological tests were unchanged, and there was no decrease in stroke recurrences during a 6-month observation period.

46.5.16.2 ARGATROBAN

As mentioned earlier, Walsh (1968, 1978) claimed significant improvement of dementia symptoms with a treatment based on warfarin anticoagulation. Currently, this treatment is reserved for patients with non-valvular atrial fibrillation (Hart, 2003), heart valve replacement, or with the anticardiolipin antibody syndrome. Direct thrombin inhibitors are equally effective; they inhibit fibrin-bound thrombin, produce a predictable anticoagulant response that is unaffected by platelet factor 4 and require no long-term monitoring and no dose adjustment (Weitz and Crowther, 2002; Donnan *et al.*, 2003). There are three parenteral direct thrombin inhibitors (hirudin, bivalirudin and argatroban), and one oral agent, ximelagatran (Francis *et al.*, 2003; Schulman *et al.*, 2003).

Argatroban, a selective competitive inhibitor of thrombin, was successfully used by Akiguchi and colleagues (1999) for the treatment of a Japanese patient with Binswanger's disease with antiphospholipid antibody syndrome, and a hypercoagulable state with abnormally high levels of TAT and fibrinogen. A long-term therapeutic regimen with argatroban (20 mg/day i.v. for 28 days), improved gait disturbances and mental dysfunction. Argatroban reduced TAT and improved levels of fibrinogen and other coagulation markers to normal limits. Kario and colleagues (1999) also reported similar positive effects with the use of argatroban in reducing silent ischaemic strokes in a patient with VaD.

46.5.16.3 HEPARIN-MEDIATED EXTRACORPOREAL LDL/FIBRINOGEN PRECIPITATION (HELP)

Since 1993, Walzl (1993, 2000) in Austria has developed an haemorheological treatment that he called HELP (Heparin-mediated Extracorporeal LDL/fibrinogen Precipitation) to reduce elevated fibrinogen levels and increased lipid fractions and to control thereby the high viscosity of plasma and whole blood, as well as to reduce the aggregability or sludging

of red blood cells. HELP was used in 141 patients with the MID type of VaD. Laboratory and clinical evaluations were performed before and after treatment. Each HELP treatment reduced whole blood and plasma viscosity and red cell transit time. Total cholesterol, low density lipoproteins and triglycerides were reduced significantly. Neurological improvement was documented by improved scores in MMSE, Mathew Scale and ADL.

46.5.17 Hyperbaric oxygen treatment

Vila and colleagues (1999), from Buenos Aires, reported on the use of hyperbaric oxygen treatment (HOT) in four patients with Binswanger's disease. Patients received daily sessions of HOT at 2.5 atmospheres absolute (ATA) for 45 minutes, for a total of 10 days. Controls received room air at 1.1 ATA. The procedure was well tolerated. After active treatment, noticeable improvements in gait, urinary and cognitive tests was observed in all subjects, with increase in independence. This improvement persisted for up to 5 months, after which the previous deficits reappeared but responded again to repeated HOT treatment. Despite the promise of the method, there has been no independent confirmation of the benefits of HOT in Binswanger's disease (Román, 1999c).

46.6 GENERAL MEDICAL MANAGEMENT OF THE PATIENT WITH VASCULAR DEMENTIA

Epidemiological studies have confirmed the increased risk of dementia associated with vascular risk factors, in particular hypertension (Launer *et al.*, 1995, 2000; Skoog *et al.*, 1996, 1998; Kilander *et al.*, 1998; Tzourio *et al.*, 1999). In a population-based study in France, Tzourio and colleagues (1999) found that in 4 years, untreated hypertensive persons (59–71 years of age) multiplied by four the risk of cognitive decline (OR 4.3, 95 per cent CI 2.1–8.8) compared with 1.9 (95 per cent CI 0.8–4.4) in those being treated.

Other important risk factors, include diabetes mellitus (Ott *et al.*, 1999; Stewart and Liolitsa, 1999), raised homocysteine (Seshadri *et al.*, 2002), and smoking (Ott *et al.*, 1998). These vascular risk factors increase the risk of both VaD and AD. Other than apolipoprotein (ApoE), genetic and racial factors are probably important. In Alabama, southern USA, Zamrini and colleagues (2004a) showed that Black Americans had higher rates of hypertension than White Americans, whereas the latter had a higher incidence of atrial fibrillation, coronary artery disease, and higher cholesterol. Therefore, primary and secondary prevention of stroke and CVD appears to be mandatory for the prevention of dementia (Lechner, 1998; Erkinjuntti and Gauthier, 2002; O'Brien *et al.*, 2003). There are clear guidelines for the use of anticoagulants (Hart, 2003) and antiplatelet medication in the prevention of stroke (Elkind, 2004).

46.6.1 Treatment of hypertension

Treatment of hypertension protects against cognitive decline even in the absence of stroke (Forette *et al.*, 1998, 2002; Clarke, 1999). No deleterious effects on cognition, mood and quality of life have been demonstrated with the treatment of hypertension in the elderly (Applegate *et al.*, 1994; Starr *et al.*, 1996; Prince *et al.*, 1996; Prince, 1997). On the contrary, Forette and collaborators (2002) confirmed that treatment of systolic hypertension with nitrendipine, a long-acting dihydropyridine calcium channel blocker, protects against dementia in older patients. Compared with placebo, long-term antihypertensive therapy reduced the risk of dementia by 55 per cent, from 7.4 to 3.3 cases per 1000 patient-years. After adjustment for sex, age, education and entry blood pressure, the relative hazard rate associated with the use of nitrendipine was 0.38 (95 per cent CI 0.23–0.64; $P < 0.001$). Treatment of 1000 patients for 5 years can prevent 20 cases of dementia (95 per cent CI 7–33) (Forette *et al.*, 1998, 2002). The most appropriate levels of blood pressure control remain undecided. The results of the ongoing SPS3 study should help solve this issue (Benavente, 2003).

Recently, the Study on Cognition and Prognosis in the Elderly (SCOPE) confirmed that treatment of mild to moderate hypertension in the elderly prevents stroke and dementia (Lithell *et al.*, 2003). SCOPE enrolled 4964 patients aged 70–89 years, with systolic blood pressure of 160–179 mmHg, and/or diastolic blood pressure of 90–99 mmHg, and a MMSE test score ≥ 24 ; patients were treated with candesartan, an angiotensin-receptor blocker, or with placebo, plus open-label active antihypertensive therapy added as needed. Blood pressure reduction was slightly better with candesartan therapy, compared with control therapy; this was associated with a modest, statistically non-significant, reduction in major cardiovascular events and with a marked reduction in non-fatal stroke. Cognitive function was well maintained in both treatment groups in the presence of substantial blood pressure reductions.

Finally, control of hypertension in patients with stroke (secondary prevention) is also helpful in preventing dementia. The PROGRESS trial (2001), a randomized clinical trial of perindopril, an angiotensin-converting enzyme (ACE) inhibitor, and a diuretic (indapamide) used in 6105 individuals with previous stroke or TIA, showed that after a follow up of 3.9 years, blood pressure was reduced, lowering the risks of stroke and other major vascular events. Dementia was also decreased, with a relative risk reduction of 12 per cent (Tzourio *et al.*, 2003). Cognitive decline occurred in 9.1 per cent of the actively treated group and 11.0 per cent of the placebo group (risk reduction, 19 per cent). In summary, active treatment resulted in reduced risks of dementia and of the cognitive decline associated with recurrent stroke (Tzourio *et al.*, 2003).

46.6.2 Treatment of hyperlipidaemia with statins

The most recent recommendations for the management of hyperlipidaemia suggest a reduction of low density lipoprotein

(LDL) cholesterol to below 100 mg/dL, and drug therapy for high-risk patients whose LDL ranges from 100 to 129 mg/dL (Grundy *et al.*, 2004). High-risk patients have coronary heart disease or disease of the blood vessels to the brain or extremities, or diabetes, or multiple (two or more) risk factors (e.g. smoking, hypertension) that give them >20 per cent chance of having a heart attack within 10 years. Very high-risk patients are those who have cardiovascular disease together with either multiple risk factors (especially diabetes), or severe and poorly controlled risk factors (e.g. continued smoking), or metabolic syndrome (a constellation of risk factors associated with obesity including high triglycerides and low high density lipoproteins – HDL). Patients hospitalized for acute coronary syndromes or stroke are also at very high risk (Grundy *et al.*, 2004).

There are indications suggesting that the use of statins (3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA] reductase inhibitors) can reduce the risk of dementia (Jick *et al.*, 2000; Rockwood *et al.*, 2002; Zamrini *et al.*, 2004b). In Boston, Jick and colleagues (2000) studied 284 patients with dementia and 1080 controls older than 50 years of age; the adjusted relative risk for those prescribed statins was 0.29 (95 per cent CI 0.13–0.63; $P = 0.002$) indicating a substantially lowered risk of developing dementia, independent of the presence or absence of untreated hyperlipidaemia. Furthermore, Zamrini and co-workers (2004b) conducted between 1997 and 2001 a study of veterans in Birmingham, Alabama, USA; patients with a new diagnosis of AD ($n = 309$) were compared with age-matched non-AD controls ($n = 3088$). In this group, statin users had a 39 per cent lower risk of AD relative to non-statin users (odds ratio 0.61, 95 per cent CI 0.42–0.87). These results indicate a possible antidementia effect of statins, perhaps related to the anti-inflammatory effects. However, the use of statins in non-demented, non-hyperlipidaemic patients cannot be recommended at this time (Miller and Chacko, 2004).

46.6.3 Control of diabetes

The abnormalities in carbohydrate, lipid and protein metabolism resulting from diabetes mellitus produce injury of blood vessels, nerves and other tissues. Diabetes increases up to 4-fold the relative risk for cardiovascular disease and CVD due to the microvascular (retinopathy, nephropathy, neuropathy, lacunes), and macrovascular (coronary heart disease, stroke, peripheral arterial disease) complications. Diabetes produces cognitive decline with doubling of the overall risk of dementia (Ott *et al.*, 1999; Stewart and Liolitsa, 1999).

Diabetes results in increased blood viscosity from hyperglycaemia, endothelial oxidative damage, loss of nitric oxide (NO)-mediated endothelial functions, and alterations of the blood–brain barrier (Mooradian *et al.*, 1997), as a result of excessive glycation as well as from glycoxidized LDLs. The end result is the impairment of perfusion through the cerebral and retinal microcirculation. In addition, stress-activated pathways such as the Jun-kinases play a major role in diabetic microangiopathy (Evans *et al.*, 2002). The most current

guidelines for treatment are the 2004 American Diabetes Association Clinical Practice Recommendations and those of the US Veterans Hospitals (Pogach *et al.*, 2004).

46.6.4 Cessation of smoking

Smokers double the risk of coronary artery disease, congestive heart failure, and peripheral vascular disease, and increase 1.5 times the risk of stroke and dementia (Ott *et al.*, 1998). Smoke, in addition to nicotine and carbon monoxide, contains a complex mixture of free radicals including quinone/hydroquinone, NO and nitrogen dioxide (NO₂) that cause morphological irregularities of the endothelium, formation of blebs, leakage of macromolecules and increased endothelial cell death (Pittilo, 2000). Smoke reduces prostacyclin release, enhances endothelium-derived vasodilatation, and decreases NO concentrations and cGMP production, increasing aggregation of platelets and leukocytes. Smoking worsens atheromatous plaque formation in carotid arteries, increases hypertension, blood coagulability, serum viscosity and fibrinogen. Smokers have worse cognitive performances than non-smokers including reduced psychomotor speed and reduced cognitive flexibility. This effect is observed in subjects as young as 45 years of age (Kalmijn *et al.*, 2002).

46.6.5 Diet

It is clear that dietary change with reduced sodium intake, is a crucial component of the treatment of arterial hypertension. The Dietary Approaches to Stop Hypertension (DASH) diet (Sacks *et al.*, 2001), is currently recommended by the US Department of Health and Human Services. This diet is rich in magnesium, potassium, calcium, protein and fibre and is low in saturated fat, cholesterol and total fat. There is emphasis in fruits, vegetables, and low fat dairy foods, whole grain products, fish, poultry and nuts. A recent clinical trial (McGuire *et al.*, 2004) randomized hypertensive patients to advice-only group; to a group treated with weight loss, increased physical activity and reduced sodium and alcohol intake; and to a third group that included the latter plus the DASH diet. At 6 months, compared with the advice-only group, the other groups had a decline of mean systolic blood pressure of 3.7 mmHg ($P < 0.001$) and 4.3 mmHg for the DASH diet group ($P < 0.001$) respectively. The study confirmed that hypertension control requires multiple lifestyle changes including an appropriate eating plan.

Epidemiological data suggested an association between dietary factors, in particular antioxidants, and cognition (Deschamps *et al.*, 2001). Similarities in the diets of patients with AD and VaD have been reported in Japan (Otsuka *et al.*, 2002), with higher energy intake from fats, in particular polyunsaturated fatty acids and decrease in antioxidant vitamins B, C and carotene. However, in the Honolulu-Asia Aging Study, mid-life intakes of antioxidants, such as beta-carotene, flavonoids, and vitamins E and C, did not modify the risk for

late life dementia, including AD and VaD (Laurin *et al.*, 2004). Likewise, no effect of fat intake in the development of dementia was found in the Rotterdam study (Engelhart *et al.*, 2002).

Wald and colleagues (2002) concluded, based on evidence from genetic and prospective studies, that the association between increased homocysteine and cardiovascular disease is causal. On this basis, lowering homocysteine concentrations by 3 $\mu\text{mol/L}$ from current levels (achievable by increasing folic acid intake) would reduce the risk of ischaemic heart disease (IHD) by 16 per cent (11–20 per cent), deep vein thrombosis by 25 per cent (8–38 per cent) and stroke by 24 per cent (15–33 per cent). However, meta-analysis of observational studies suggests that elevated homocysteine is at most a modest independent predictor of ischaemic heart disease and stroke risk in healthy populations (Homocysteine Studies Collaboration, 2002).

Moreover, folic acid/vitamin B₁₂ is not an effective treatment of dementia; a Cochrane review (Malouf *et al.*, 2003) concluded that in older patients with mild to moderate cognitive decline, supplementation with 750 $\mu\text{g/day}$ of folic acid, with or without B₁₂, had no beneficial effects on measures of cognition or mood, although folic acid plus vitamin B₁₂ effectively reduced serum homocysteine concentrations. Along the same lines, a trial on the use of vitamins to prevent recurrent stroke gave negative results (Toole *et al.*, 2004).

Nonetheless, a diet rich in antioxidant phytochemicals, such as those found in olive oil and red wine, appears to effectively inhibit endothelial adhesion molecule expression, explaining in part the protection from atherosclerosis afforded by Mediterranean diets (Carluccio *et al.*, 2003).

46.6.6 Chronic inflammation

Recent evidence indicates that markers of inflammation such as C-reactive protein (CRP) are important predictors of atherosclerotic disease, particularly in patients with diabetes (Rader, 2000). Chronic infections, including periodontal disease and persistent intracellular infection with *Chlamydia pneumoniae* have been associated with increased risk of vascular events (Kalayoglu *et al.*, 2002).

46.7 PUBLIC HEALTH ASPECTS OF VASCULAR DEMENTIA

Based on current population trends, the ageing of the population will lead to increasing incidence of stroke and heart disease in the near future. It is predicted that VaD will become the most common cause of senile dementia, both by itself and as a contributor to other degenerative dementias (Román, 2002e).

There is growing evidence that preventive measures to decrease the vascular burden on the brain may also decrease vascular dementia in the elderly. VaD and AD share with stroke a number of vascular risk factors, as demonstrated in

large epidemiological studies. The most important of the modifiable factors is hypertension, a treatable risk factor that explains at least half of the attributable risk of stroke. As mentioned above, three large controlled trials (Forette *et al.*, 1998, 2002; Lithell *et al.*, 2003; Tzourio *et al.*, 2003) have demonstrated that blood pressure lowering has a significant effect in decreasing the risk of dementia, including VaD and AD. Overall, these data suggest that interventions aiming at reducing the level of vascular risk factors might prevent dementia. The expected benefit of these interventions could be estimated from data provided by epidemiological studies; however, there is a dearth of large population-based controlled studies to demonstrate the efficacy of preventive interventions at public health level (Román, 2003b; Alperovitch *et al.*, 2004; Williams, 2004). Prevention appears to be the most promising avenue for decreasing the incidence of the two most common forms of senile dementia, AD and VaD.

Dementia with Lewy bodies: a clinical overview

IAN G McKEITH

47.1 Terminology, spectrum and epidemiology	603	47.4 Clinical investigation	611
47.2 Historical developments and diagnostic criteria for dementia with Lewy bodies	604	References	612
47.3 Differential diagnosis of dementia with Lewy bodies in clinical practice	609		

47.1 TERMINOLOGY, SPECTRUM AND EPIDEMIOLOGY

47.1.1 Dementia with Lewy bodies: what's in a name?

Dementia with Lewy bodies (DLB) is now the preferred term (McKeith *et al.*, 1996a) for a variety of clinical diagnoses including diffuse LB disease (DLBD) (Kosaka *et al.*, 1984; Dickson *et al.*, 1987; Lennox *et al.*, 1989), dementia associated with cortical Lewy bodies (DCLB) (Byrne *et al.*, 1991), the LB variant of Alzheimer's disease (LBVAD) (Hansen *et al.*, 1990; Förstl *et al.*, 1993), senile dementia of LB type (SDLT) (Perry *et al.*, 1989a, b; 1990) and LB dementia (LBD) (Gibb *et al.*, 1987). Initially thought to be uncommon, DLB is now thought to account for up to 20 per cent of all elderly cases of dementia reaching autopsy (Perry *et al.*, 1989a; Jellinger, 1996). This chapter reviews the evolution of clinical knowledge about the disorder. The term DLB is used throughout except when reference is made to specific reports in which authors have used alternative terminology. Pathology, neuropsychological changes and therapeutic aspects of DLB are considered in subsequent chapters.

47.1.2 The spectrum of Lewy body disease

Current thinking about Lewy body (LB) related disorders suggests that there is a spectrum of disease, the clinical presentation varying according to the site of LB formation and associated neuronal loss (Jackson *et al.*, 1995; Lowe *et al.*, 1996). Three broad patterns of disease can be identified:

- nigrostriatal involvement producing motor features of parkinsonism;

- cortical involvement producing cognitive impairment and neuropsychiatric symptoms;
- sympathetic nervous system involvement producing autonomic failure.

This may prove to be an oversimplified view since there are generally poor correlations between LB density and severity of clinical symptoms (Gómez-Tortosa *et al.*, 1999; Colosimo *et al.*, 2003). The majority of cases seen in clinical practice, particularly elderly patients, have a combination of these clinical features, reflecting multisite (diffuse) pathology. DLB is important in clinical practice because:

- it usually has a clinical presentation and course that differs from Alzheimer's disease (AD) and other non-AD dementias;
- the management of psychosis and behavioural disturbances, which are common in DLB, is complicated by sensitivity to neuroleptic medication;
- accumulating evidence (Chapter 50) suggests that DLB may be particularly amenable to treatment with cholinergic enhancers.

47.1.3 Epidemiology

Several studies in a range of settings have suggested that DLB accounts for just under 20 per cent of all cases of dementia referred for neuropathological autopsy (Perry *et al.*, 1989a, 1990; Jellinger, 1996). The male to female ratio in these autopsy series is 1.5:1, but it is unclear to what extent this represents increased male susceptibility to disease or reduced survival in men with DLB. A Finnish community study of people aged 85 and over found 5.0 per cent to meet Consensus Criteria for DLB (3.3 per cent probable, 1.7 per cent possible) representing 22 per cent of all demented cases (Rahkonen *et al.*, 2003),

higher than that in a London-based community sample of people aged 65 and over, in which 10.9 per cent of demented cases had DLB, which is consistent with estimates of LB prevalence in a dementia case register followed to autopsy (Holmes *et al.*, 1999). Twenty-six per cent of clinical referrals to an old age psychiatry service with dementia (Shergill *et al.*, 1994; Stevens *et al.*, 2002) and 24 per cent of demented day hospital attenders met clinical criteria for DLB (Ballard *et al.*, 1993).

Age at onset in reported series ranges from 50–83 years to 68–92 years at death (Papka *et al.*, 1998). Survival in DLB was initially reported as being significantly reduced compared with AD, but more recent series have not confirmed a general tendency to reduced survival or more rapid cognitive decline. It is possible that mean values could conceal disease heterogeneity, and survival times in DLB may be skewed to the left (McKeith, 1998) with very rapid progression in a few individuals (Armstrong *et al.*, 1991). Classical epidemiological studies to determine age and sex variation and potential risk factors for DLB have not yet been reported.

47.2 HISTORICAL DEVELOPMENTS AND DIAGNOSTIC CRITERIA FOR DEMENTIA WITH LEWY BODIES

47.2.1 Early case reports

When Friedrich Lewy first described the eosinophilic, neuronal inclusions that we now call Lewy bodies, in the brain stem of patients with paralysis agitans (Parkinson's disease – PD), he did not associate the inclusions with cognitive impairment and psychiatric disorder (Forster and Lewy, 1912). This was despite half of his sample being clinically demented and a quarter having mood disorders, hallucinations and paranoid delusions (Förstl and Levy, 1991). Although Woodard (1962) cites Hassler (1938) as reporting cortical Lewy bodies in association with dementia, the first case reports specifically describing patients with DLB did not appear until 1961 when Okazaki *et al.* (1961) published two cases, both elderly men, presenting with cognitive decline and subsequently developing severe dementia. Over the next 20 years, 34 similar cases were reported, all by Japanese workers. Kosaka *et al.* (1984) noted a 3:1 male predominance, with memory disturbance as the presenting feature in 67 per cent, psychotic states (*sic*) in 17 per cent and dizziness due to orthostatic hypotension in 17 per cent. Progressive dementia with muscular rigidity occurred eventually in 80 per cent although only 25 per cent of cases were diagnosed as parkinsonian. The first substantial listing of these Japanese cases in the Western literature was in 1987 by Gibb *et al.* (1987) who added four new UK cases.

47.2.2 Early diagnostic criteria

The following year, Burkhardt *et al.* (1988) listed 34 cases and carried out a simple meta-analysis. The most common

presentation was a 'neurobehavioural syndrome'; memory impairment and other cognitive deficits were typical, all but one patient eventually becoming demented. Psychotic features such as depression, hallucinations and paranoia were seen in 10 patients (29 per cent), two being psychotic for many years before developing other symptoms. Parkinsonian features, the most common of which was rigidity, were usually overshadowed by dementia; in only five cases (15 per cent) were no extrapyramidal features present. Duration of illness was very variable (1–20 years) with an end state of severe dementia, rigidity, akinetic mutism, quadriparesis in flexion and emaciation. The most common reported cause of death was aspiration pneumonia. Based upon these observations, Burkhardt *et al.* (1988) were the first to attempt a general description of the clinical syndrome associated with diffuse Lewy body disease, distinguishing it as separate from PD with dementia. They concluded that 'DLBD should be suspected in any elderly patient who presents with a rapidly progressive dementia, followed in short order by rigidity and other parkinsonian features. Myoclonus may be present.'

Crystal *et al.* (1990) in a paper entitled 'Antemortem diagnosis of diffuse Lewy body disease', criticized this approach on the grounds that 'extrapyramidal features occur in many patients with severe AD and since dementia occurs in many subjects with PD, the clinical criteria for the diagnosis of DLBD remain unclear'. The authors proposed alternative criteria of 'progressive dementia with gait disorder, psychiatric symptoms and a burst pattern on EEG at the time of moderate dementia'. No particular characteristics of the pattern of cognitive impairment were noted.

Although these early clinical definitions were important in drawing attention to the existence of DLB and describing some of its salient characteristics, neither could be regarded as satisfactory for clinical diagnostic purposes, since they lacked detail and were not operationalized in a way which would allow acceptable interrater reliability (Hansen and Galasko, 1992).

47.2.3 The Nottingham Group for the Study of Neurodegenerative Disorders

In 1989, Byrne *et al.* (1989) reviewed the situation, citing 51 pathologically confirmed cases and remarking upon the brevity of clinical details in most of these. Gibb *et al.* (1987) were among the first to describe fluctuating levels of consciousness and episodic confusion, now recognized as key features of DLB.

The Nottingham group reported the clinical characteristics of 15 new UK cases in considerable detail, the largest individual series published at that time (Byrne *et al.*, 1989). Seven were men, the mean age at onset was 72 years and the mean duration of illness, 5.5 years. Forty per cent presented with symptoms and signs of idiopathic PD, with cognitive impairment occurring 1–4 years later. A further 20 per cent had parkinsonism and mild cognitive impairment at presentation and the remaining 40 per cent showed motor features later in

their illnesses, gait disturbance and postural abnormalities being most common. These latter cases presented with neuropsychiatric features only, in various combinations of cognitive impairment, paranoid delusions and visual or auditory hallucinations; 14 of the 15 were demented before death, the exception presenting with classic PD and later becoming depressed, irritable and mildly forgetful with frequent falls. Fluctuating cognition with episodic confusion for which no adequate underlying cause could be found, was observed in 80 per cent of the Nottingham cases. Byrne *et al.* (1989) also drew attention to the frequent occurrence of depression (20 per cent) and psychosis (33 per cent). This led to the first formal proposal of operational criteria for dementia associated with cortical Lewy bodies (DCLB) (Byrne *et al.*, 1991) – see Box 47.1.

The presence of extrapyramidal features was mandatory although these could be mild and occur late in the course of the illness. Since at least 25 per cent of DLB cases reported in the whole literature (McKeith, 1997; Kosaka and Iseki, 1998; Papka *et al.*, 1998) never have motor parkinsonism, the sensitivity of

the Nottingham criteria was inevitably restricted by this requirement, which may have been influenced by the inclusion in their sample of five cases who had motor only PD diagnosed for at least 12 months before neuropsychiatric features developed. These cases would according to current criteria (McKeith *et al.* 1996a) be regarded as having PD + dementia and not a primary diagnosis of DLB (see section below on patients previously diagnosed with PD for further discussion of this).

47.2.4 The Newcastle criteria

At around the same time, Perry *et al.* identified 14 cases with the neuropathological features of 'senile dementia of Lewy body type' (SDLT) (Perry *et al.*, 1989a, b, 1990) accounting for 15 per cent of a series of dementia autopsies. These SDLT cases had been regarded as clinically atypical 'causing much diagnostic perplexity'. Acute onset, fluctuating course, more rapid deterioration, early and prominent hallucinatory and behavioural disturbances, and associated mild parkinsonian

Box 47.1 *Nottingham criteria for dementia associated with cortical Lewy bodies (Byrne et al., 1991, reproduced by kind permission of S. Karger AG, Basel)*

A, B, C and D should be present for a diagnosis to be made of *probable* dementia associated with cortical Lewy bodies

A *Either 1, 2 or 3*

1. Gradual onset of dementia syndrome (which fulfils DSM-III-R criteria) with prominent attentional deficits
or

The appearance early in the course of apparent acute confusional states for which no underlying toxic, metabolic, infective or other cause is identified
or

2. 'Classical' Parkinson's disease (defined as levodopa responsive parkinsonism) at onset with the later emergence of dementia syndrome (as described in 1)
or

3. The simultaneous occurrence at onset of dementia (as described in 1) and parkinsonism

B *Both 1 and 2 should be fulfilled*

1. The absence of any unequivocal history of stroke
2. No focal signs other than parkinsonism

C *Three of more of the following should be present*

1. Tremor
2. Rigidity
3. Postural change
4. Bradykinesia
5. Gait abnormality

These symptoms may be mild and may develop late in the course of the illness, and abnormal involuntary movements resulting from levodopa treatment are unusual in parkinsonism with cortical Lewy bodies

D *Other causes of dementia syndrome or parkinsonism have been excluded (eg boxer's encephalopathy, chronic phenothiazine poisoning), after thorough clinical and laboratory investigation*

A, B, C and D should be present to make a diagnosis of *possible* dementia associated with cortical Lewy bodies

A *Either 1 or 2*

1. Dementia (as described above) with acute onset and rapid course, sometimes associated with plateaux (periods where the symptoms do not progress) and frequently associated with psychiatric symptoms (depression or delusional states)
or

Dementia (as described above) with late presentation of parkinsonian symptoms which fulfil B

B *One or two of the following*

1. Tremor
2. Rigidity
3. Bradykinesia
4. Postural change
5. Gait abnormality

C *Both 1 and 2 should be fulfilled*

1. The absence of any unequivocal history of stroke
2. No focal signs other than parkinsonism

D *Other causes of dementia syndrome and parkinsonism have been excluded, after thorough clinical and laboratory investigation*

Table 47.1a *Mental state symptoms in Newcastle upon Tyne autopsy confirmed cases of senile dementia of Lewy body type (SDLT, n = 21) and dementia of Alzheimer type (DAT, n = 20). (From McKeith et al., 1992a – figures are percentages of patients)*

features were present. In 1992, McKeith and colleagues published further clinical details of two separate SDLT cohorts (21 and 20 cases respectively) and compared these with autopsy-confirmed AD (n = 57) cases (McKeith *et al.*, 1992a, b). SDLT patients were predominantly male (25:16) with mean survival reduced by about 50 per cent compared with AD. Tables 47.1a and 47.1b show clinical details of the first series of cases.

Depressive symptoms, unexplained falls, observed disturbances of consciousness and excessive sensitivity to side effects of neuroleptic medication were added to the list of clinical characteristics with potential to distinguish DLB pathology cases from AD.

Based upon these observations, an attempt was made to describe the typical course of illness (McKeith *et al.*, 1992a) and new clinical diagnostic criteria proposed with an emphasis upon cognitive dysfunction and neuropsychiatric features that could occur in the absence of extrapyramidal motor signs (Box 47.2).

The first stage is often recognized only in retrospect and may extend back 1–3 years prepresentation with occasional minor episodes of forgetfulness, sometimes described as lapses of concentration or 'switching off'. A brief period of delirium is sometimes noted for the first time, often associated with genuine physical illness and/or surgical procedures.

Box 47.2 Operational criteria for senile dementia of Lewy body type (SDLT)

- A** Fluctuating cognitive impairment affecting both memory and higher cortical functions (such as language, visuospatial ability, praxis or reasoning skills). The fluctuation is marked with the occurrence of both episodic confusion and lucid intervals, as in delirium, and is evident either on cognitive testing or by variable performance in daily living skills
- B** At least one of the following:
 1. Visual and/or auditory hallucinations which are usually accompanied by secondary paranoid delusions
 2. Mild spontaneous extrapyramidal features or neuroleptic sensitivity syndrome, i.e. exaggerated adverse responses to standard doses of neuroleptic medication
 3. Repeated unexplained falls and/or transient clouding or loss of consciousness
- C** Despite the fluctuating pattern, the clinical features persist over a long period of time (weeks or months) unlike delirium which rarely persists as long. The illness progresses, often rapidly, to an end stage of severe dementia
- D** Exclusion of any underlying physical illness adequate to account for the fluctuating cognitive state, by appropriate examination and investigation
- E** Exclusion of past history of confirmed stroke and/or evidence of cerebral ischaemic damage on physical examination or brain imaging

Disturbed sleep, nightmares and daytime drowsiness often persist after recovery.

Progression to the second stage frequently prompts psychiatric or medical referral. A more sustained cognitive impairment is established, albeit with marked fluctuations in severity. Recurrent confusional episodes are accompanied by vivid hallucinatory experiences, visual misidentification syndromes and topographical disorientation. Extensive medical screening is usually negative. Attentional deficits are apparent as apathy, and daytime somnolence and sleep behaviour disorder may be severe. Gait disorder and bradykinesia are often overlooked, particularly in elderly subjects. Frequent falls occur owing to either postural instability or syncope.

The third and final stage often begins with a sudden increase in behavioural disturbance leading to requests for sedation or hospital admission by perplexed and exhausted carers. The natural course from this point is variable and obscured by the high incidence of adverse reactions to neuroleptic medication. For patients not receiving, or tolerating, neuroleptics, a progressive decline into severe dementia with dysphasia and dyspraxia occurs over months or years, with death usually due to cardiac or pulmonary disease. During this

terminal phase patients show continuing behavioural disturbance including vocal and motor responses to hallucinatory phenomena. Lucid intervals with some retention of recent memory function and insight may still be apparent. Neurological disability is often profound with fixed flexion deformities of the neck and trunk and severe gait impairment.

Applied retrospectively to the original sample of autopsy-confirmed cases, these criteria identified 71 per cent of SDLT cases on initial presentation and 86 per cent between presentation and death (McKeith *et al.*, 1992a). Although some of the SDLT cases also met clinical criteria for AD, no AD cases met the proposed criteria for SDLT. Mega *et al.* (1996) reported a sensitivity of 50 per cent and a specificity of 71 per cent for the Newcastle criteria in a similar case note study.

Applied to another independent sample of DLB, AD and vascular dementia (VaD) patients, the Newcastle criteria yielded a 74 per cent sensitivity rate, averaged across four raters, and a specificity of 95 per cent. Interrater agreement was highest and diagnosis most accurate (90 per cent versus 55 per cent sensitivity) among more experienced clinicians. The most common errors among less experienced clinicians were failure to recognize cognitive fluctuations unique to DLB patients, and a tendency to overvalue comorbid disease as responsible for the clinical presentation (McKeith *et al.*, 1994a).

47.2.5 The Consensus criteria

By the early 1990s it was becoming apparent that DLB was a relatively common cause of dementia in old age and that the several research groups investigating it were adopting different terminologies for what were essentially the same patients. The Consortium on DLB therefore met in October 1995 to agree common clinical and pathological methods and nomenclature. The Consensus clinical criteria (McKeith *et al.*, 1996a) (Box 47.3) are largely based on the previous Newcastle scheme, but do differ in some important aspects.

The particular characteristics of the cognitive impairments of DLB are described in some detail as differing from the dementia syndrome of AD, in which memory deficits predominate. In DLB, attentional deficits and prominent visuospatial dysfunction are the main features (Sahgal *et al.*, 1992, 1995; Salmon and Galasko, 1996). Symptoms of persistent or prominent memory impairment are not always present early in the course of illness, although with disease progression they are likely to develop in most patients. DLB patients therefore perform better than AD patients on tests of verbal recall, but relatively worse on tests of copying and drawing (Gnanalingham *et al.*, 1997). With the progression of dementia, this selective pattern of cognitive deficits may be lost, making differential diagnosis based on neuropsychological examination difficult during the later stages. Probable DLB can be diagnosed if any two of the three key symptoms in Box 47.3 are present, namely fluctuation, visual hallucinations, or spontaneous motor features of parkinsonism and possible DLB if only one is present.

Box 47.3 *Consensus criteria for the clinical diagnosis of probable and possible dementia with Lewy bodies (DLB). Reproduced by kind permission of Lippincott, Williams & Wilkins. From McKeith IG, Galasko D, Kosaka K et al. (1996a) Consensus guidelines for the clinical and pathological diagnosis of dementia with Lewy bodies (DLB): report of the consortium on DLB international workshop. Neurology 47: 1113–1124*

- 1 The central feature required for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention and of fronto-subcortical skills and visuospatial ability may be especially prominent
- 2 Two of the following core features are essential for a diagnosis of *probable* DLB, one is essential for *possible* DLB:
 - a) Fluctuating cognition with pronounced variations in attention and alertness
 - b) Recurrent visual hallucinations which are typically well formed and detailed
 - c) Spontaneous motor features of parkinsonism
- 3 Features supportive of the diagnosis are:
 - a) Repeated falls
 - b) Syncope
 - c) Transient loss of consciousness
 - d) Neuroleptic sensitivity
 - e) Systematized delusions
 - f) Hallucinations in other modalities
- 4 A diagnosis of DLB is less likely in the presence of:
 - a) Stroke disease, evident as focal neurological signs or on brain imaging
 - b) Evidence on physical examination and investigation of any physical illness, or other brain disorder, sufficient to account for the clinical picture

Several retrospective and two prospective studies have examined the predictive accuracy of Consensus clinical criteria for probable DLB (Litvan *et al.*, 2003) (Table 47.2). These show that sensitivity of case detection is variable and although high in one prospective study (McKeith *et al.*, 2000) was unacceptably low in several others. In contrast, specificity is generally found to be high, suggesting that the clinical criteria for probable DLB are best used for confirmation of diagnosis (few false positives) whereas those for possible DLB may be of more value in screening but have a relatively high false negative rate. Improved methods of identifying the core feature 'fluctuation' have potential to increase diagnostic accuracy (Walker *et al.*, 2000a; Ferman *et al.*, 2004; Bradshaw *et al.*, 2004) as do biological markers such as FP-CIT SPECT neuroimaging (O'Brien *et al.*, 2004).

47.2.5.1 REPORT OF THE SECOND INTERNATIONAL WORKSHOP OF THE CONSORTIUM ON DLB

The Second International DLB Workshop met in July 1998 (McKeith *et al.*, 1999). The objectives were to review developments since publication of the Consensus guidelines and to determine whether these yet require to be modified. It was recommended that the clinical Consensus criteria should continue to be used in their current format although two additional features, supportive of a diagnosis of DLB, were identified.

47.2.5.2 RECENT DEVELOPMENTS

In an effort to further review and clarify current knowledge, concepts and methods for further enquiry, a specialist meeting was held in November 2002 by the International Psychogeriatric Association (IPA) with input from the European Movement Disorder Society (MDS). The product of this

international meeting was a systematic review of the current state of scientific knowledge about DLB that identified key issues requiring clarification and research necessary to advance knowledge in this area (McKeith *et al.*, 2004a). The Third Meeting of the International Consortium on DLB in September 2003 suggested revisions to the clinical and pathological diagnostic criteria and devised the first treatment algorithm. The Consortium also incorporated discussions about Parkinson's disease with dementia (PDD) in view of emerging clinical and pathological evidence that DLB and PDD share more similarities than was previously supposed (Emre, 2003). A report of this meeting will be published in 2005 and the new recommendations about assessment and diagnosis of DLB will be accompanied by guidelines for patient management (McKeith *et al.*, submitted for publication).

47.3 DIFFERENTIAL DIAGNOSIS OF DEMENTIA WITH LEWY BODIES IN CLINICAL PRACTICE

47.3.1 Clinical presentations of DLB

DLB patients may present to psychiatric services (cognitive impairment, psychosis or behavioural disturbance), internal medicine (acute confusional state or syncope) or neurology (movement disorder or disturbed consciousness). The details of clinical assessment and differential diagnoses will to a large extent be shaped by these symptom and specialty biases (McKeith *et al.*, 1995; Barber *et al.*, 2001). In all cases a detailed history from patient and reliable informants should document the time of onset of relevant key symptoms, the nature of their progression, and their effects on social, occupational and personal function.

47.3.1.1 COGNITIVE IMPAIRMENT

Although brief bedside tests of mental status may confirm the presence of cognitive impairment, more detailed psychometric examination is usually required to reveal a profile of deficits that helps to distinguish DLB from AD or other dementias. Prominent deficits on tests of executive function and problem solving, such as the Trail Making Test and verbal fluency for categories and letters, may be useful clinical discriminators (Salmon and Galasko, 1996), as may disproportional impairment on tests of visuospatial performance (Sahgal *et al.*, 1995; Gnanalingham *et al.*, 1997). Walker *et al.* (1996) tested DLB and AD patients with the CAMCOG battery, which is widely used in clinical practice. Although the mean, total CAMCOG scores were identical, significant differences were found in mean scores for the delayed recall subtest (DLB performing better) and the visuospatial praxis subtest (DLB performing worse). Disproportionately severe impairment on computer-based tasks of attentional function are characteristic of DLB (Ayre *et al.*, 1996) and wide test-retest variation in performance of such tasks (Walker *et al.*, 2000b) may ultimately provide a

reliable and widely applicable quantified measure well correlated with clinical expert estimates of fluctuating performance.

47.3.1.2 CORE FEATURES

A review of nine studies, which reported clinical details on 190 autopsy-confirmed DLB cases and compared them with 261 AD cases, provided a useful source of prevalence and incidence of the core features of DLB (Byrne *et al.*, 1989; McKeith *et al.*, 1992a, b; Förstl *et al.*, 1993; Galasko *et al.*, 1996; Klatka *et al.*, 1996; Hely *et al.*, 1996; Weiner *et al.*, 1996; Ala *et al.*, 1997; McKeith, 1998). The wide frequency ranges reported most likely reflect sampling biases and different methods of symptom ascertainment.

Fluctuation. Fluctuations in cognitive function, which may vary over minutes, hours or days, occur in 58 per cent of DLB cases at the time of presentation (range 8–85 per cent) and are observed at some point during the course of the illness in 75 per cent (45–90 per cent). Substantial changes in mental state and behaviour may be seen within the duration of a single interview or between consecutive examinations. Fluctuation includes, and indeed may be based on, pronounced variations in attention and alertness. Excessive daytime drowsiness with transient confusion on waking commonly occurs. Such episodes may last from a few seconds to several hours leading to misdiagnosis of transient ischaemic attack, with obvious implications for misdiagnosis of dementia subtype. These can be assessed by caregiver report, observer rating (Walker *et al.*, 2000a) or using computer-based measures of variation in attentional performance (Walker *et al.*, 2000b). Questions such as, 'Are there episodes when his/her thinking seems quite clear and then becomes muddled?' may be useful probes (Ballard *et al.*, 1993; Bradshaw *et al.*, 2004), although Ferman *et al.* (2004) found carers reports of fluctuation to be less reliable predictors of DLB diagnosis than more objective questions about daytime sleepiness, episodes of staring blankly or incoherent speech.

Visual hallucinations. Visual hallucinations are present in 33 per cent of DLB cases at the time of presentation (range 11–64 per cent) and occur at some point during the course of the illness in 46 per cent (13–80 per cent). Well-formed, detailed and animate figures are experienced, provoking emotional responses varying through fear, amusement or indifference, usually with some insight into the unreality of the episode once it is over. It is the persistence of visual hallucinations in DLB (McShane *et al.*, 1995) that helps distinguish them from the episodic perceptual disturbances that occur transiently in dementias of other aetiology or during a delirium provoked by an external cause (McKeith *et al.*, 1996a). It has been suggested that they arise from a combination of faulty perceptual processing of environmental stimuli, and less detailed recollection of experience, combined with intact image generation (Barnes *et al.*, 2003; Collerton *et al.*, in press). Visual hallucinations in DLB are associated with greater deficits in cortical acetylcholine (Perry *et al.*, 1991) and predict better response to cholinesterase inhibitors (McKeith *et al.*, 2004b).

Motor parkinsonism. Extrapyramidal signs (EPS) are reported in 25–50 per cent of DLB cases at diagnosis and the majority develop some EPS during the natural course. Up to 25 per cent of autopsy-confirmed cases may, however, have no record of EPS indicating that parkinsonism is not necessary for clinical diagnosis of DLB and indeed the principal cause for ‘missing’ DLB clinically in a prospective clinicopathological study was the absence of EPS (McKeith *et al.*, 2000). Initial suggestions that parkinsonism in DLB is mild have not been supported by studies finding equal severity with non-demented PD patients (Aarsland *et al.*, 2001) with similar annual progression rates in United Parkinson’s Disease Rating Scale (UPDRS) motor scores (Ballard *et al.*, 2000). The pattern of EPS in DLB shows an axial bias, e.g. greater postural instability and facial impassivity, with a tendency towards less tremor and consistent with greater ‘non-dopaminergic’ motor involvement (Burn *et al.*, 2003).

47.3.1.3 SUPPORTIVE FEATURES

Repeated falls, syncope, and transient losses of consciousness. Dementia of any aetiology is probably a risk factor for all three of these clinical features and it can be difficult clearly to distinguish between them. Repeated falls may be due to posture, gait and balance difficulties, particularly in patients with parkinsonism. Reported fall rates are 28 per cent at the time of presentation (range 10–38 per cent) and 37 per cent (22–50 per cent) at some point during the illness. Syncopal attacks in DLB with complete loss of consciousness and muscle tone may represent the extension of LB associated pathology to involve the brain stem and autonomic nervous system (as described in Section 47.1.2, p. 603). The associated phenomenon of transient episodes of unresponsiveness without loss of muscle tone may represent one extreme of fluctuating attention and cognition. Episodes of this type were recorded in 15 per cent of DLB cases at presentation and in 46 per cent during the whole course of illness (McKeith *et al.*, 1992a, b).

Neuroleptic sensitivity. The hypothesis made by the Newcastle group, of an abnormal sensitivity to adverse effects of neuroleptic medication was based upon two sets of independent observations. In the first (McKeith *et al.*, 1992a) 67 per cent (14/21) DLB patients received neuroleptics and 57 per cent (8/14) deteriorated rapidly after either receiving them for the first time, or following a dose increase. Mean survival time for these eight patients was reduced to 7.4 months (95 per cent CI 3.5–11.3) significantly less than for the six patients who had only mild to no adverse reaction, 28.5 months (12.9–44.1), and the seven never receiving neuroleptics, 17.8 months (–7.4–43.0). In the second study 54 per cent (7/16) neuroleptic treated DLB patients had neuroleptic sensitivity reactions and their mortality risk, estimated by survival analysis was increased by a factor of 2.7 (McKeith *et al.*, 1992b). Although this phenomenon had not previously been reported, literature review reveals that a small number of case reports of rapid deterioration following neuroleptic use were published from 1988 onwards (McKeith *et al.*, 1996b). A severe adverse

reaction to neuroleptic medication may be an important indicator of underlying LB disorder but is of more importance in management than in the diagnostic process, especially if neuroleptic prescribing is routinely and desirably avoided in patients suspected of having DLB (Committee on Safety of Medicines, 1994). Newer atypical antipsychotics used at low dose may be safer in this regard but sensitivity reactions have been documented with most and they should be used with great caution (McKeith *et al.*, 2004a).

Systematized delusions and hallucinations in other modalities. Delusions are common in DLB, in 56 per cent at the time of presentation and 65 per cent at some point during the illness (McKeith *et al.*, 1992a, b). They are usually based on recollections of hallucinations and perceptual disturbances and consequently often have a fixed, complex and bizarre content that contrasts with the mundane and often poorly formed persecutory ideas encountered in AD patients, which are based on forgetfulness and confabulation.

Auditory hallucinations occur in 19 per cent (13–30 per cent) at presentation and 19 per cent (13–45 per cent) at any point. Together with olfactory and tactile hallucinations, these may be important features in some DLB cases and can lead to initial diagnoses of late onset psychosis (Birkett *et al.*, 1992) and temporal lobe epilepsy (McKeith *et al.*, 1992a).

Sleep disorder. Rapid eye movement (REM) sleep behaviour disorder (SBD) is a parasomnia manifested by vivid and often frightening dreams associated with simple or complex motor behaviour during REM sleep. It is frequently associated with DLB, PD and multisystem atrophy (MSA) but rarely occurs in AD (Boeve *et al.*, 2001). REM sleep-wakefulness dissociations (SBD, daytime hypersomnolence, hallucinations, cataplexy), characteristic of narcolepsy may explain several features of DLB. Sleep disorders may contribute to fluctuations typical of DLB and their treatment may improve fluctuations and quality of life (Ferman *et al.*, 2001).

Depression. Depressive symptoms are reported in 33–50 per cent of DLB cases, a rate higher than in AD and similar to that in PD. In the first Newcastle clinical study (McKeith *et al.*, 1992a), depression was diagnosed at presentation in 38 per cent (AD = 16 per cent, $P < 0.05$, χ^2), and was the primary reason for referral in five of the eight patients in whom it was present. Klatka *et al.* (1996) found depression in 14/28 (50 per cent) DLB, 8/58 (14 per cent) AD and 15/26 (58 per cent) PD cases with autopsy diagnosis, and Papka *et al.* (1998) suggest that depression is sufficiently more common in DLB than AD to be a significant diagnostic predictor.

47.3.2 Differential diagnosis

There are four main categories of disorder that should be considered in the differential diagnosis of DLB. These are:

- other dementia syndromes
- other causes of delirium
- other neurological syndromes
- other psychiatric disorders.

47.3.2.1 OTHER DEMENTIA SYNDROMES

Sixty five per cent of autopsy-confirmed DLB cases meet the NINCDS-ADRDA clinical criteria for probable or possible AD (McKeith *et al.*, 1994b) and this is the most frequent clinical misdiagnosis of DLB patients who present with a primary dementia syndrome. Between 12 and 36 per cent of cases meeting NINCDS criteria for a clinical diagnosis of AD are unexpectedly found to have LB pathology at autopsy (Burns *et al.*, 1990; Hansen *et al.*, 1990). This suggests that DLB routinely should be excluded before the diagnosis of AD is made. Up to a third of DLB cases are additionally misclassified as VaD by the Hachinski Ischaemic Index by virtue of items such as fluctuating nature and course of illness. Pyramidal and focal neurological signs are, however, usually absent. When a false positive diagnosis of vascular dementia is made in a patient with DLB pathology, it is often associated at autopsy with concomitant microvascular abnormalities and a mixed pathology.

47.3.2.2 OTHER CAUSES OF DELIRIUM

In patients with intermittent delirium, appropriate examination and laboratory tests should be performed during the acute phase to maximize the chances of detecting infective, metabolic, inflammatory or other aetiological factors. Pharmacological causes are particularly common in elderly patients. Although the presence of any of these features makes a diagnosis of DLB less likely, comorbidity is not unusual in elderly patients and the diagnosis should not be excluded simply on this basis.

47.3.2.3 OTHER NEUROLOGICAL SYNDROMES

In patients with a prior diagnosis of PD, the onset of visual hallucinations and fluctuating cognitive impairment may be attributed to side effects of antiparkinsonian medications, and this must be tested by dose reduction or withdrawal (Harrison and McKeith, 1995; Goetz *et al.*, 1998). Other atypical parkinsonian syndromes associated with poor levodopa response, cognitive impairment and postural instability include progressive supranuclear palsy (Fearnley *et al.*, 1991), MSA and corticobasal degeneration. The development of myoclonus in patients with a rapidly progressive form of DLB may lead the clinician to suspect Creutzfeldt–Jakob disease. Syncopal episodes in DLB are often incorrectly attributed to transient ischaemic attacks, despite an absence of focal neurological signs. Recurrent disturbances in consciousness accompanied by complex visual hallucinations may suggest complex partial seizures (temporal lobe epilepsy) and vivid dreaming with violent movements during sleep may meet criteria for REM sleep behaviour disorder (Boeve *et al.*, 2001).

Patients with a previous diagnosis of Parkinson's disease. Patients who initially present with motor symptoms of PD, and who only develop the typical features of DLB after many years of severe motor disability, present some problems of classification. Antiparkinsonian medications are usually held

responsible for hallucinations and confusion in PD, but research findings do not fully support this clinical impression. Factors associated with the development of visual hallucinosis are: later age of onset of PD, total duration of illness and the presence of cognitive impairment. Hallucinators and non-hallucinators are distinguished neither by severity of motor disability nor dosage of antiparkinsonian medication. Patients with early onset of hallucinations are particularly likely to subsequently develop DLB (Goetz *et al.*, 1998). The DLB Consensus statement recommends that, if a syndrome meeting diagnostic criteria for DLB develops in a patient who has had motor PD for at least 12 months prior to the onset of neuropsychiatric features, a diagnosis of PD + DLB, should be made. This arbitrary 12-month rule is helpful in the diagnosis of individual cases and in selecting samples for clinical research studies, but is increasingly difficult to justify from a neurobiological point of view.

47.3.2.4 OTHER PSYCHIATRIC DISORDERS

If a patient spontaneously develops parkinsonian features or cognitive decline, or shows excessive sensitivity to neuroleptic medication, in the course of late onset delusional disorder, depressive psychosis or mania (Birkett *et al.*, 1992; Mullan *et al.*, 1996), DLB should be considered.

47.4 CLINICAL INVESTIGATION

Detailed psychometric testing (see Chapter 49) and expert neurological examination are likely to be informative and should be carried out whenever DLB is suspected (McKeith *et al.*, 1996a). No specific biomarkers for DLB have yet been identified but there have been sufficient studies to allow the conclusion that neuroimaging investigations can be helpful in supporting the clinical diagnosis.

47.4.1 Neuroimaging – structural and functional

Prominent atrophy of the medial temporal lobes on CT or MRI is indicative of AD rather than DLB (Barber *et al.*, 1999). Periventricular lesions and white matter hyperintensities are often present in (Barber *et al.*, 2000a) but, similar to measures of generalized atrophy and rates of progression of whole brain tissue loss (O'Brien *et al.*, 2001), are not helpful in differential diagnosis. Dopamine transporter loss in the caudate and putamen, a marker of nigrostriatal degeneration can be detected in DLB but not AD by dopaminergic SPECT. Abnormal scans in DLB were reported as more accurate in predicting neuropathological diagnosis than the application of clinical Consensus criteria (Walker *et al.*, 2002). A sensitivity of 88 per cent for detecting probable DLB with a specificity of 85 per cent for AD and 95 per cent for controls has

been reported (O'Brien *et al.*, 2004), a flatter rostrocaudal gradient of loss along the striatum indicating relatively greater loss in the caudate and lesser loss in the putamen compared with PD.

47.4.2 EEG

The electroencephalogram (EEG) is diffusely abnormal in over 90 per cent of DLB patients. Early slowing of the dominant rhythm, with 4–7 Hz transient activity over the temporal lobe area, is characteristic and correlates with a clinical history of loss of consciousness (Briell *et al.*, 1999). It is not possible reliably to differentiate DLB and AD subjects on the basis of the EEG, however (Barber *et al.*, 2000b). The diagnostic significance of bursts of bilateral frontal rhythmic delta activity, reported to be more common in DLB than AD, has yet to be established (Calzetti *et al.*, 2002).

47.4.3 Genotyping

No specific genetic markers for DLB have been identified and genetic testing cannot be recommended as part of the diagnostic process at present. DLB patients have an elevated apolipoprotein ε4 allele frequency (Benjamin *et al.*, 1994; Pickering-Brown *et al.*, 1994) similar to that reported in AD so a positive ε4 test does not provide additional information in the differential diagnosis of AD and DLB. Most DLB cases are sporadic, although there are a few reports of autosomal dominant Lewy body disease families.

Pathology of dementia with Lewy bodies

PAUL G INCE AND ELAINE K PERRY

48.1 Validation of consensus clinical diagnostic criteria	617	48.6 Molecular and anatomical pathology correlates of clinical features in dementia with Lewy bodies	624
48.2 Prevalence of dementia with Lewy bodies and α -synucleinopathy in ageing populations	617	48.7 Pathogenesis of dementia with Lewy bodies	625
48.3 Pathological phenotypes	617	48.8 Summary	626
48.4 Pathology of dementia with Lewy bodies	618	References	627
48.5 Neurotransmitters and neurochemistry in dementia with Lewy bodies	622		

The pathology of dementia with Lewy bodies (DLB) is that of a primary degenerative dementia with pathological features shared with both Alzheimer's (AD) and Parkinson's diseases (PD). There is a variable burden of Alzheimer-type pathology, together with Lewy bodies (LB) in both cortical and subcortical regions. Often the neocortical senile plaque formation is at densities equivalent to that found in AD, but neocortical neurofibrillary tangles are infrequent (Kosaka *et al.*, 1984; Dickson *et al.*, 1987; Hansen *et al.*, 1989, 1990; Perry *et al.*, 1990d). A group of DLB patients have only minimal plaque pathology, and a virtual absence of paired helical filament (PHF)-tau pathology including neurofibrillary tangles.

Controversies surrounding DLB and its relationship to AD remain unresolved and comparison of pathology data in the literature must be viewed from the perspective of the varied clinical provenance of case series from neurology and old age psychiatry. Problems also remain in defining the relationship between DLB and dementia occurring as part of PD. Lewy bodies are found as coincidental pathology in a wide range of conditions (Table 48.1) but are characteristically associated with idiopathic PD (Gibb and Lees, 1989; Lewy, 1912). Dementia is recognized to be a clinical component of PD (Mayeux *et al.*, 1990), especially in older patients. It is apparent that the range of clinical syndromes in which Lewy bodies form a characteristic part of the pathological substrate includes extrapyramidal movement disorders, cognitive impairment, autonomic dysfunction and gut motility disorders (Table 48.2). The concept of a spectrum of Lewy body disorders, among which PD is the most familiar (Yoshimura, 1983; Kosaka, 1993; Ince *et al.*, 1998), best accounts for this phenotypic diversity. The clinical manifestation of Lewy body

Dementia with Lewy bodies	++/+++	++/+++	+++	+/>++	+/>+++	??
Parkinson's disease	+/>++	++/+++	+++	+/>+++	+/>++	+/>++
Pure autonomic failure	0	0	0/>+	+/>++	++/+++	?
LB dysphagia	0	0	0/>+	0	?	+/>+++

0, no LB; +, mild LB formation/neuronal loss; ++, moderate LB and neuronal loss; +++, severe LB and neuronal loss; ?, not yet reported

pathology depends on the severity and anatomical distribution of Lewy body involvement in the central and peripheral nervous system (Kosaka *et al.*, 1989; Kosaka, 1993; Kosaka and Iseki, 1996).

A major advance in the understanding of pathogenetic relationships among these Lewy body disorders arose from the finding that familial PD is caused by a mutation of the gene encoding α -synuclein (α S) in a few families (Polymeropoulos, 1997) and subsequently that all sporadic Lewy body pathology has α S as the major underlying filamentous inclusion body protein (Spillantini *et al.*, 1997, 1998). These disorders are now classified as 'alpha-synucleinopathies'.

The pathogenesis of the different syndromes within this spectrum is not yet worked out. The biochemical basis for inclusion body formation related to α S is emerging in relation to the ubiquitin/proteasome system and aberrant phosphorylation of α S. The availability of α S immunocytochemistry has revealed extensive neuritic accumulation of fibrillated α S and a 'neuritic dystrophy hypothesis' of Lewy degeneration has been proposed (Duda, 2004). The balance of genetic and environmental factors that give rise to this disease process are unknown and may vary among individuals (De Palma *et al.*, 1998). Similarly, it is not known why individuals have different anatomical patterns of selective vulnerability to α S, although it seems that the population comprises major groups in terms of the disease phenotype that develop. Studies in this area currently focus heavily on genetic determinants, despite an earlier consensus that genetic influences in PD were of little significance.

Many pathological studies draw attention to the overlap, and common concurrence of the pathologies of PD and AD in the same patient (Forno *et al.*, 1978; Hakim and Mathieson, 1979; Boller *et al.*, 1980; Gaspar and Gray, 1984; Ditter and Mirra, 1987; Burkhardt *et al.*, 1988; Joachim *et al.*, 1988). The pathology of DLB therefore raises two areas of controversy, i.e.:

- What are the clinical, pathological and aetiological relationships among the 'alpha-synucleinopathies'?
- How does DLB relate to AD?

These issues have been reflected in the difficulty of classifying such patients, and the confusing nomenclature in the earlier literature (Box 48.1). Consensus guidelines on clinical diagnosis and pathological evaluation have been

Box 48.1 Nomenclature previously used to classify DLB cases

- Alzheimer's disease with incidental Lewy bodies
- Cortical Lewy body disease
- Diffuse Lewy body disease
- Lewy body dementia
- Lewy body variant of Alzheimer's disease
- Parkinson's disease plus Alzheimer's disease
- Parkinson's disease with dementia
- Senile dementia of the Lewy body type

adopted so that clinical work and research can be compared between centres (McKeith *et al.*, 1996). The outcome of this consensus, and subsequent revisions, is a compromise that leaves important issues unresolved. Two are of particular importance.

First, the term 'dementia with Lewy bodies' was adopted because it does not prejudge the significance of Lewy bodies as a pathological substrate for dementia. This approach creates the difficulty that any demented patient in whom a Lewy body can be demonstrated at autopsy could be regarded as a 'dementia with Lewy bodies'. What the clinical diagnostic guidelines for DLB seek to achieve is to define a particular neuropsychological syndrome in the elderly. Thus there is still a place in routine clinical practice for a more specific diagnostic label. The International DLB Consortium explicitly left open the possibility of using favoured terminology (Box 48.1) in routine clinical practice. Currently the most frequently used of these terms are 'diffuse Lewy body disease (DLBD)'; the 'Lewy body variant of Alzheimer's disease (LBVAD)' and 'senile dementia of Lewy body type (SDLT)'. For many practical purposes these terms are interchangeable.

Second, the Consensus pathological guidelines were designed only to allow uniform semiquantification of the pathological features. This allows any case with Lewy bodies to be put into one of three categories: 'neocortical', 'limbic (transitional)', and 'brain stem predominant'. There is no explicit assumption or requirement that patients must be in any of these categories to be classified as DLB. Evidence for the evolution of α S pathology along a definable anatomical hierarchy, beginning in medullary centres has been proposed (Braak *et al.*, 2003) analogous to that proposed in 'Braak staging' of AD (Braak and Braak, 1991). However, data

from a large sample of older brains undermines the absolute validity of this concept (Parkkinen *et al.*, 2003). While there is an expectation that dementia will be most frequent in cases in the neocortical or limbic categories, it is not necessary for them to be in a particular pathological category to be regarded as 'dementia with Lewy bodies', and a diagnosis of DLB should be made only on the basis of a clinical picture which fulfils the clinical diagnostic criteria. Finally, the diagnosis of DLB (or one of the more specific terms) does not preclude other diagnoses. Alzheimer-type pathology especially should be assessed, according to established diagnostic criteria for AD, e.g. CERAD (Mirra *et al.*, 1991, 1993), NIA-Reagan Institute (National Institute for Aging [NIA], 1997), or Braak stage (Braak and Braak, 1991) and an opinion given as to whether there is sufficient pathology to warrant that diagnosis.

48.1 VALIDATION OF CONSENSUS CLINICAL DIAGNOSTIC CRITERIA

Studies of the sensitivity and specificity of clinical diagnostic criteria for DLB show values similar to comparable studies of AD. Early studies were retrospective and the patients were diagnosed by using one of two protocols which preceded the DLB Consensus guidelines (Byrne *et al.*, 1989; McKeith *et al.*, 1992b). On average the sensitivity and specificity of the diagnostic criteria reported in these studies is around 80 per cent (McKeith *et al.*, 1994a, b; Mega *et al.*, 1996). Prospective evaluation of the performance of the Consensus Guidelines shows sensitivity of 83 per cent and specificity of 92 per cent compared with comparable values of 78 per cent and 87 per cent for a diagnosis of 'probable AD' (NINCDS-ARDRA criteria) in the same study (McKeith *et al.*, 2000a). There are a minority of patients reported in these series in which the pathological subtype is 'brain stem predominant', indicating that the clinical phenotype is not exclusively dependent on a pathologically demonstrable substrate (i.e. density of cortical Lewy bodies) based on quantifying Lewy bodies.

48.2 PREVALENCE OF DEMENTIA WITH LEWY BODIES AND α -SYNUCLEINOPATHY IN AGEING POPULATIONS

The true prevalence of α -synucleinopathy can only be established on the basis of pathology studies because none of the associated clinical phenotypes (e.g. PD, DLB) predict for the underlying pathologic substrate in better than four of five cases. Population-based data are limited. The UK Cognitive Function and Ageing cohort showed Lewy bodies in 11 per cent of 209 autopsies (Neuropathology Group MRC, 2001). This study is limited in that the sample is not truly representative of the population as a whole, being weighted to individuals with cognitive decline and to the more physically frail. The frequency

of Lewy bodies was no different between demented and non-demented people (12 per cent versus 10 per cent) and only a minority of demented individuals with Lewy bodies had clinical features suggestive of DLB. A recent Japanese study showed α -synucleinopathy in 19.5 per cent of a cohort of 1241 aged but only 4 per cent of the sample showed significant cortical α S pathology (Saito *et al.*, 2004). In the Hisayama study the prevalence of α -synucleinopathy at autopsy was 22.5 per cent of the sample, comprising 41 per cent of demented people. Only one other very large autopsy sample has been reported (Parkkinen *et al.*, 2001). In this Finnish sample the overall prevalence of Lewy body pathology was 14 per cent. Whether these differences between European and Asian populations reflect true differences in genetic factors and exposures, or different sampling strategies, remains to be confirmed.

48.3 PATHOLOGICAL PHENOTYPES

48.3.1 Spectrum of Lewy body disorders

The neuropathology of DLB is part of a spectrum in which α -synucleinopathy is regarded as a primary component of the disorder. These conditions can be interpreted in part on the basis of the anatomical distribution and severity of the degenerative process (see Table 48.2). The motor features of Lewy body disorders usually manifest as an extrapyramidal syndrome (e.g. PD with a 'paucity of movement'), but in some rare cases may be associated with dystonia (e.g. Meig's syndrome with an 'excess of movement'; Mark *et al.*, 1994) and such differences in clinical phenotype are not a specific consequence of Lewy body degeneration.

Rare cases of atypical dementia, with parkinsonism and cortical Lewy bodies, were first described by Okazaki *et al.* (1961) and the concept of a spectrum of Lewy body diseases was originally proposed by Kosaka and colleagues (Kosaka *et al.*, 1980; Kosaka and Iseki, 1996). The peripheral and central nervous system involvement by Lewy bodies in PD includes hypothalamic nuclei, nucleus basalis of Meynert, dorsal raphé, locus caeruleus, substantia nigra, dorsal vagus nucleus and intermediolateral nucleus (Den Hartog Jager and Bethlem, 1960). In addition, a 'neuritic' form of α S degeneration has been described, and is especially common in the dorsal vagus nucleus, sympathetic ganglia and myenteric autonomic ganglia. Kosaka and colleagues later demonstrated cases with extensive cortical and basal ganglia involvement (Kosaka, 1978; Kosaka and Mehraein, 1979). A spectrum of Lewy body diseases was proposed, categorized into three types (brain stem, transitional and diffuse), and this concept is now the basis for the categories defined by the Consensus Guidelines on the evaluation of DLB (McKeith *et al.*, 1996).

More recently, Kosaka proposed a 'cerebral' subtype of Lewy body disease in a patient with progressive dementia, no detectable parkinsonian features (Kosaka *et al.*, 1996) and widespread neocortical and limbic Lewy body involvement.

The pigmented brain stem nuclei only showed a few Lewy bodies with no neuronal loss, and the patient had no significant Alzheimer-type pathology. The significance of these observations relates especially to the evolution and spread of Lewy body pathology. In AD there is evidence that ‘tangle’ pathology follows a hierarchic evolution from medial temporal lobe regions to other ‘limbic’ areas and then to temporal, parietal, frontal and occipital neocortex (Arnold *et al.*, 1991; Braak and Braak, 1991). Within the spectrum of Lewy body diseases evidence for such hierarchic spread has been proposed (Braak *et al.*, 2003) but remains controversial (see above): cases present with brain stem Lewy bodies, clinically manifesting as PD, who do not dement and show few cortical Lewy bodies at autopsy. By contrast, DLB patients (including the ‘cerebral Lewy body disease’ patient described above) may get severe cortical involvement as an early feature with minimal brain stem disease. In addition, patients may develop predominant involvement of the peripheral nervous system, e.g. Lewy body dysphagia (Jackson *et al.*, 1995) and primary autonomic failure, with minimal central involvement. Isolated involvement of the amygdala is well documented (Parkkinen *et al.*, 2003).

The role of pathology in the evaluation of a case with an appropriate clinical history, is to address two questions:

- Is this disorder associated with α S/Lewy body pathology?
- What is the anatomical distribution of Lewy bodies and what is the regional severity of involvement?

In relation to the second question, the pathology section of the Consensus Guidelines for the evaluation of cortical Lewy bodies were offered as a means of standardizing assessment of Lewy body pathology in cortical regions (McKeith *et al.*, 1996). They were designed to be equally applicable to a survey of cortical Lewy body pathology in cases with or without dementia. With the advent of immunocytochemistry for α S this protocol needs to be re-assessed and reformulated taking account of neuritic changes.

48.3.2 Alzheimer and vascular pathologies

Both Alzheimer changes and cerebrovascular pathology are found in the brain of DLB patients at autopsy. The relationship between DLB and AD is not resolved. From studies of AD pathology in DLB there is an emerging consensus that cases can usually be assigned to one of two broad groups. In the first of these, and numerically the more numerous, there is sufficient AD pathology either to satisfy published pathological criteria for AD (Mirra *et al.*, 1991), or such that it is likely that AD pathology contributes significantly as a substrate for the neuropsychiatric phenotype. This ‘common form’ of DLB has been called ‘Lewy body variant of AD’ (Hansen *et al.*, 1989, 1990, 1997). The second group comprises cases in which the extent of AD pathology is within a spectrum from mild to negligible, and therefore is not a plausible substrate for cognitive impairment. This ‘pure form’ of DLB has been called ‘diffuse

Lewy body disease’ (Hansen, 1997). The SDLT cases (Perry *et al.*, 1990d) include both forms of DLB. A number of studies have recently reported on the clinical phenotype of DLB patients with and without significant AD pathology. They conclude that patients with more severe AD pathology are likely to resemble AD clinically (Merdes *et al.*, 2003; Ballard *et al.*, 2004). Other authors have suggested that ‘common form’ DLB patients may have more intense cortical Lewy body formation than ‘pure’ BLB and may show a more severe dementia than in pure AD or DLB (Serby *et al.*, 2003).

The Consensus clinical diagnostic criteria for DLB exclude cases where vascular disease is a demonstrable component of the clinical picture, either as infarcts on neuroimaging or as focal neurological deficits. Despite this it is the authors’ experience that, in common with AD cases, microvascular pathology is a frequent finding in DLB at autopsy (Ince *et al.*, 1998). Other studies have emphasized this aspect of CLB pathology (Londos *et al.*, 2002) so that exclusion of cases with vascular features may be of value in selecting the ‘pure’ disease for research studies but has no value in a routine clinical diagnostic setting. Thus the pathological diagnosis of DLB needs to be qualified by explicit confirmation of the extent of AD and vascular pathology.

48.4 PATHOLOGY OF DEMENTIA WITH LEWY BODIES

The pathological lesions encountered in DLB are listed in Box 48.2. None of these is exclusive to the disorder.

48.4.1 Lewy bodies – conventional and molecular pathology

Lewy bodies are encountered in both subcortical nuclei (e.g. substantia nigra as in PD) and also in cerebral cortical regions. In the pigmented brain stem nuclei Lewy bodies show a

Box 48.2 Pathological features associated with DLB

Essential for the diagnosis of DLB

- Lewy bodies

Associated with DLB but not essential

- Lewy neurites
- Alzheimer-type pathology
- Senile plaques
- Neurofibrillary tangles
- Regional neuronal loss, especially affecting substantia nigra, locus caeruleus, and nucleus basalis of Meynert
- Microvacuolation
- Synapse loss
- Neurochemical abnormalities/neurotransmitter deficits

classical morphology comprising an eosinophilic core and peripheral halo (Plate 17a). In the cortex they are much less distinct in conventional stains, appearing as diffusely granular, eosinophilic spheroids with no halo (Plate 17b). In routine practice most laboratories now use α S rather than ubiquitin immunocytochemistry (ICC) to demonstrate cortical Lewy bodies (Plate 17c), although haematoxylin and eosin (H&E) remains of value for brain stem lesions. It has been reported that ubiquitin ICC is more than twice as sensitive in the detection of cortical Lewy bodies compared with H&E (Lennox *et al.*, 1989), but others have shown either no difference between these methods or higher counts with H&E. Formal evaluation of α S ICC against other methods has not been published but experience suggests this method will detect rather more lesions, first because of variable ubiquitination of α S (Sampathu *et al.*, 2003) and second because the method reveals far more extensive pathology than ubiquitin ICC (Duda *et al.*, 2002). The only silver staining method that can reliably demonstrate cortical Lewy bodies is Campbell–Switzer (Braak *et al.*, 1995). The most important practical problem in the evaluation of cortical Lewy bodies is the distinction from small globular tangles in those cases with combined Alzheimer-type and Lewy body pathologies (Plate 17d). Since Lewy bodies are usually unstained by antibodies to PHF-tau it has been suggested that Lewy bodies should only be confirmed, in cases with cortical neurofibrillary tangles, if they are negative for a reliable anti-PHF tau antibody.

Since the discovery that a small minority of cases of familial autosomal dominant PD are associated with mutations in the gene encoding α S (Polymeropoulos *et al.*, 1997; Higuchi *et al.*, 1998; Vaughan *et al.*, 1998; Aarsland *et al.*, 2001) and that antibodies to α S are very consistent markers of Lewy bodies (Baba *et al.*, 1998; Spillantini *et al.*, 1997, 1998; Wakabayashi *et al.*, 1997b; Takeda *et al.*, 1998) (Plate 18a, b), this problem is largely historical. α S immunocytochemistry has therefore confirmed that:

- the different appearances of cortical and subcortical Lewy bodies are likely to be due to factors related to the cell types affected, not molecular pathogenesis;
- PD and DLB share a common molecular pathology suggesting close pathogenetic links.

48.4.2 Lewy bodies – anatomical pathology

In the substantia nigra, the frequency of Lewy bodies may be low in DLB, and there is often not a severe loss of neurones as compared with that in PD patients. DLB patients show substantia nigra neurone counts that are intermediate between PD and AD (Perry *et al.*, 1990d; Ince *et al.*, 1995), although individual cases vary and there may be substantia nigra neurone loss in the PD range associated with variable expression of parkinsonian symptoms. Another brain stem nucleus regularly affected in PD, the cholinergic pedunculopontine tegmental nucleus, may also be preferentially affected in DLB. Individual patients also vary in the involvement of serotonergic

raphé nucleus subdivisions, although no quantitative studies are published. The locus caeruleus is often severely affected by neuronal loss and Lewy bodies in both PD and DLB patients (Perry *et al.*, 1990d; Zweig *et al.*, 1993).

Between 75 and 95 per cent of PD cases have some degree of cortical Lewy body involvement whether or not the patient has dementia (Hughes *et al.*, 1993; Mattila *et al.*, 1998), with a tendency for dementia to be associated with neocortical Lewy bodies (Sugiyama *et al.*, 1994), although this is not an invariable correlate of cognitive decline (Colosimo *et al.*, 2003). Thus the difference between PD and DLB in terms of cortical Lewy body pathology is quantitative, not qualitative. In both DLB and PD the distribution of Lewy bodies in the cortex is most frequent in limbic areas. Quantitative studies have shown that cingulate cortex involvement is more marked in Brodmann area 23 compared with 24 (Perry *et al.*, 1990d). The amygdaloid complex, insula, entorhinal and transentorhinal cortices have also been shown to be sites of predilection for Lewy body formation (Kosaka *et al.*, 1984; Braak *et al.*, 1994; Iseki *et al.*, 1995; Rezaie *et al.*, 1996; Schmidt *et al.*, 1996). They were rarely described in the hippocampal formation prior to α S ICC but this region is now considered to fall within the spectrum of selective vulnerability (Harding *et al.*, 2002b). Neocortical involvement is usually most severe in the temporal lobe and follows the gradient: temporal > parietal = frontal > occipital (Kosaka *et al.*, 1984; Perry *et al.*, 1990d). The Consensus Guidelines do not include the occipital region where Lewy bodies are infrequent, even in the most severely involved cases of DLB, and where their presence does not contribute to a significant distinction between clinical phenotypes or pathological subgroups (Perry *et al.*, 1990d).

Cortical Lewy bodies are found in deeper cortical layers (especially cortical layers 4, 5 and 6) in all affected regions (Kosaka *et al.*, 1984), although the population of affected neurones has yet to be fully characterized. On morphological grounds they are small and medium-sized neurones (Kosaka *et al.*, 1984; Dickson *et al.*, 1987), which includes pyramidal neurones on the basis of expression of neurofilament (NF) medium and heavy subunits, and the absence of parvalbumin, a marker of GABAergic interneurones (Smith *et al.*, 1995; Wakabayashi *et al.*, 1995). The total number of SMI32 positive neurones was reported to be reduced by 70 per cent in DLB, suggesting that Lewy body formation is associated with severe neuronal dysfunction or death (Wakabayashi *et al.*, 1995). However, a recent study based on optical disector stereometry found the opposite (Shepherd *et al.*, 2002). There was also 40 per cent reduction in parvalbumin-immunoreactive neurones, suggesting that any selective vulnerability of pyramidal neurones is only relative. Cortical Lewy body frequency may be positively correlated with the intensity of dementia (Samuel *et al.*, 1996), although this finding remains controversial. Thus the extent to which Lewy bodies are themselves the substrate for dementia in DLB or PD is in doubt. Even in the most severely affected cases of DLB the frequency of cortical Lewy bodies (demonstrated by

H&E, ubiquitin ICC or α S ICC) is at least 10^{-3} times less than would be the case for neurofibrillary tangles in AD patients with a similar level of cognitive deficit (Perry *et al.*, 1990d). It is likely that the substrate of cognitive deficits in 'pure' DLB cases will eventually be explained on the basis of a complex interaction of pathological lesions (cortical and subcortical), diffuse molecular pathological changes, and neurochemical alterations in both cortical and subcortical neurotransmission. Recent work using α S ICC suggests that the more extensive pathological changes revealed by this method significantly contribute to the pathological substrate of DLB (Duda *et al.*, 2002).

48.4.3 Lewy neurites (Lewy-related neurites)

Ubiquitin-immunoreactive neuritic processes were first described in the CA2 sector of the hippocampus in DLB (Dickson *et al.*, 1991, 1994) and were proposed as a means of distinguishing hippocampal pathology in AD and cases of DLB where Alzheimer-type pathology can be significant (Plate 19a, b). Whilst this concept remains valid, further reports have shown that LB neurites are also a consistent feature of PD and do not predict dementia (de Vos *et al.*, 1995) simply by virtue of their presence. Neurites are immunoreactive for α S (Plate 19b, c), ubiquitin and (variably) neurofilament epitopes (especially phosphorylated epitopes). Immunoreactivity to Alz50 and Tau-2 have also been reported (Plate 19d), but not to neurofibrillary tangle-specific tau isoforms (Dickson *et al.*, 1994). Electron microscopy confirms a major component of α S filaments within these structures. They are also described in the amygdala (Braak *et al.*, 1994), basal forebrain, substantia nigra (Plate 19f), pedunculopontine nucleus, raphé nuclei, dorsal vagal nucleus and neocortex (Plate 19e) (Gai *et al.*, 1995; Pellise *et al.*, 1996). In all these sites neurites can be present in very high density but they are not co-localized with immunoreactivity to tyrosine hydroxylase, suggesting that they do not arise in distal projections of the substantia nigra. Lewy bodies and neurites coexist (Kim *et al.*, 1995) and in one study the intensity of CA2 neurites and cortical Lewy body formation were shown to be correlated (Pollanen *et al.*, 1993b).

The significance of Lewy neurites in DLB is uncertain both in terms of their pathogenesis and their role in neuronal dysfunction or clinical phenotype. Recent work using α S ICC in Lewy body disorders shows more extensive neuritic pathology than was previously appreciated with methods such as ubiquitin ICC (Baba *et al.*, 1998; Duda *et al.*, 2002). The appreciation that neuritic changes are frequently extensive and more prominent than Lewy bodies, and work in animal models of α -synucleinopathy (Giasson *et al.*, 2002) underpins the 'neuritic dystrophy hypothesis' of Lewy neurodegeneration (Duda, 2004).

48.4.4 Alzheimer-type pathology

Many cases of DLB have Alzheimer-type pathology which has led to concepts of the disorder being a variant of AD (Hansen

et al., 1990), or that the diseases represent phenotypic clustering along a continuous 'spectrum of neurodegeneration' (Perl *et al.*, 1998). However, there are pathological observations that support the distinction of DLB from AD:

- There are cases with no significant Alzheimer-type pathology (DLB 'pure form').
- Quantitative and qualitative analysis of the Alzheimer-type pathology shows differences between DLB and AD.
- The similarity is predominantly at the level of β -amyloid deposition, so that the neuronal inclusion pathology remains distinct.

Most cases of DLB have α S accumulation with low or minimal PHF-tau accumulation. The picture is reversed in AD where PHF-tau predominates and α S deposition is less prominent or absent.

The published series of autopsy cases which drew attention to DLB as a distinct dementing syndrome in the elderly included a minority of cases with virtually no Alzheimer-type pathology (Kosaka *et al.*, 1984; Dickson *et al.*, 1987; Perry *et al.*, 1990d), including cases with absence of senile plaques of any type. They were clinically indistinguishable from other DLB cases, and the burden of Alzheimer-type pathology was less than in many cognitively intact, age-matched individuals (Lippa *et al.*, 1994). These cases correspond to the category of 'pure diffuse Lewy body disease' described by Kosaka (1993) or the diffuse Lewy body disease of Hansen (1997) to distinguish them from those cases with Alzheimer-type pathology who comprise the 'common form of DLBD' of Kosaka (1993), or 'Lewy body variant of Alzheimer disease' of Hansen (1997).

Nevertheless, this relationship between AD and Lewy body diseases remains problematic. Various observations predating the emergence of DLB as a distinct entity are difficult to apply to the current debate because it is not clear to which disease categories the cases would now be assigned on clinical and pathological grounds. Such observations include:

- more frequent Alzheimer-type pathology in PD cases than in age-matched control (Forno *et al.*, 1978; Hakim and Mathieson, 1979; Boller *et al.*, 1980; Gibb, 1986; Hughes *et al.*, 1993);
- the frequency of Lewy bodies in familial AD (Ditter and Mirra, 1987; Joachim *et al.*, 1988; Lantos *et al.*, 1994; Halliday *et al.*, 1997).

Since these studies also predate a widespread awareness of the frequency of cortical Lewy bodies and neurites, and the use of sensitive methods to detect them, they are difficult to interpret in the context of more recent concepts. It is likely that DLB represents an undiagnosed group within many of the older reported cohorts, and account for much of the clinicopathological overlap described between AD and PD. Review of cases in the Newcastle centre prior to 1982 include a proportion of demented cases that correspond to the entity 'senile dementia of the Lewy body type'. This is certainly the case with respect to the category 'plaque-only AD', where re-examination of the original cohort from whom this

diagnostic category was formulated showed that most patients could be re-diagnosed as DLB (Hansen *et al.*, 1993).

In the neocortex, quantitative studies show that the burden of senile plaques is similar in many DLB cases and age-matched AD patients, even in cohorts among whom the DLB patients died more rapidly after onset of dementia (Plate 20a, b) (Hansen *et al.*, 1990; Perry *et al.*, 1990d). In image analysis studies of DLB and AD cohorts, matched for age and degree of dementia, the area occupied by β A4 immunoreactive deposits was reported to be equal, and there was no difference in the ratio of different morphological categories of plaque type (Gentleman *et al.*, 1992; McKenzie *et al.*, 1996). Qualitatively this reflects the burden of β A4 amyloidosis, and not the cytoskeletal pathology of AD. The major difference between the senile plaques of AD and those in DLB is the paucity of a neuritic component that is immunoreactive for PHF-tau (Plate 20c, d). This is not to say that DLB plaques of 'classical' appearance with neuritic involvement are not frequent, but rather that these neurites do not contain Alzheimer disease-related tau (Dickson *et al.*, 1989; Samuel *et al.*, 1997b). Reports indicate that these plaque neurites in DLB are reactive for α S (Takeda *et al.*, 1998). It is also reported that neuritic plaques in DLB have a higher expression of GAP-43 (Masliah *et al.*, 1993), interpreted as increased neuronal sprouting, compared with downregulation of GAP-43 expression in AD (de la Monte *et al.*, 1995). The extent to which clinical DLB cases have neocortical neurofibrillary tangles is very variable. In most cases tangles are infrequent and largely confined to the medial temporal lobe (Hansen *et al.*, 1990; Ince *et al.*, 1991). Some cases undoubtedly do have a burden of neocortical neurofibrillary tangles comparable with AD cases but they are a minority (Hansen *et al.*, 1990; Ince *et al.*, 1995), and recent work suggests this burden of tangle pathology is likely to be associated with clinical features more like AD (Merdes *et al.*, 2003; Ballard *et al.*, 2004). This distinction is one of the key features that discriminate AD from DLB. The possibility that AD-related PHF-tau changes occur in DLB without the formation of neurofibrillary tangles has been studied using ELISA of extracted cortical proteins and shows no evidence for a global alteration in tau isoforms towards insoluble PHF-related species (Harrington *et al.*, 1994; Strong *et al.*, 1995). It is now clear that the cortical dysfunction associated with DLB is not explicable on the basis of neurofibrillary pathology, and the more likely culprit is abnormal α S metabolism.

DLB cases have an excess of hippocampal Alzheimer-type pathology when compared with age-matched controls and with both demented and non-demented PD patients (Ince *et al.*, 1991; Harding *et al.*, 2002b). The burden of amyloidosis in the entorhinal cortex may be equal to AD in those DLB cases corresponding to the 'common form', but cases of 'pure form' DLB have much lower densities of senile plaques in this region (Armstrong *et al.*, 1997). Neurofibrillary tangles show intermediate densities with considerable intercase variation (Ince *et al.*, 1991). Morphological markers of the integrity of the perforant pathway also show intermediate changes in

DLB of lesser severity than in AD (Lippa *et al.*, 1997; Wakabayashi *et al.*, 1997a). Whilst these changes may contribute to neuropsychological features such as defective short-term memory, they do not account for much of the clinical picture of DLB.

The above discussion encapsulates the problem of defining the relationship between AD and DLB, and the confusion of nomenclature in the older literature. The issue centres around the criteria used to define AD. In the American literature these criteria have evolved from a scheme in which only the numerical burden of neocortical senile plaques was evaluated (Khachaturian, 1985), through the CERAD criteria (Mirra *et al.*, 1991, 1993) and its revisions, which rely on neuritic plaques, to the latest NIA-Reagan Institute guidelines, which include evaluation of both plaques and neocortical tangles (NIA and RI Working Group, 1997). Many authors would now also include a high score using the 'Braak stage' method as an additional part of the pathological diagnosis of AD (Braak and Braak, 1991). This represents a convergence towards the view that requires both neocortical plaques and tangles (Tomlinson *et al.*, 1970). Thus the extent to which DLB cases represent a variant of AD is entirely dependent on the diagnostic criteria used (Hansen and Samuel, 1997). If a plaque-based method is used, then many DLB patients can be interpreted to have AD, depending on the qualification of plaque molecular pathology. If a requirement for neocortical tangles, or PHF-tau plaque neurites, is adopted, then most DLB patients fall short of AD. If it is mistakenly assumed that cortical Lewy pathology, in the absence of consensus clinical features of DLB, is a basis for diagnosis then many AD patients would fall into the DLB spectrum.

48.4.5 Regional neuronal loss

A characteristic of the core clinical syndrome of DLB is the presence of parkinsonian signs which may be of a spectrum of severity ranging from fully developed PD to very subtle extrapyramidal features. In contrast to the cognitive features of DLB, the pathological and neurochemical substrate for this motor component is well characterized. DLB patients on average have substantia nigra degeneration intermediate between that seen in PD and normal control individuals of the same age (Perry *et al.*, 1990d; Agid, 1991). The degree of depigmentation of the substantia nigra is often only moderate, and microscopic evidence of neurone loss and incontinence of pigment is usually less than in PD. The mechanism of neuronal loss associated with Lewy body diseases is not known, although evidence supports the possibility of apoptosis (Tompkins *et al.*, 1997). The cellular pathology in the substantia nigra is identical in PD and DLB and includes both classical Lewy bodies and pale bodies, together with a variable background of neuritic changes best demonstrated by α S ICC. Pale bodies contain ubiquitin and α S, are regarded as a precursor lesion to Lewy bodies, and may be more numerous than Lewy bodies (Dale *et al.*, 1992). By contrast,

AD patients do not usually have significant nigral degeneration, although some cases have substantia nigra neurofibrillary tangles, and a small proportion may develop frank parkinsonism (Alvord *et al.*, 1974) sufficient to warrant a clinical diagnosis of PD arising on the basis of tangle pathology. Atypical AD patients may attract an erroneous clinical diagnosis of DLB due to the prominence of parkinsonian signs (Ince *et al.*, 1998). Erroneous diagnoses of DLB may also arise in the context of other atypical variants of tau-related neurodegenerative disorders including progressive supranuclear palsy and corticobasal degeneration (Chin and Goldman, 1996; Feany *et al.*, 1996).

Some cases of DLB have fully developed PD and in these cases the nigral cell loss will exceed the commonly cited threshold for the development of PD (<70 per cent of substantia nigra counts in age-matched controls). Occasional cases are encountered where there is marked substantia nigra neurone loss but no overt parkinsonism. In these cases it is postulated that additional pathology in the striatum produces a compensatory effect with no overall loss in the balance of neurotransmitter activity. The locus caeruleus is routinely more severely affected than the substantia nigra and is often totally depigmented to the naked eye. Lewy bodies are usually frequent in the surviving neurones. Some cases with additional significant Alzheimer-type pathology may show tangle formation in substantia nigra neurones in addition to Lewy bodies.

Other brain stem and mid-brain nuclei that project into the cerebrum contain Lewy bodies, including the serotonergic raphé subdivisions and the pedunculopontine nucleus. No quantitative studies have compared these nuclei in DLB, AD, PD and controls, but neuronal loss would be expected to occur. Neuronal loss in the cholinergic nucleus basalis of Meynert has been reported (Jellinger and Bancher, 1996). In PD, DLB and AD, the degree of cell loss is approximately 70 per cent of age-matched controls. In DLB cases with significant AD pathology this neuronal population may contain both Lewy bodies and neurofibrillary tangles.

48.4.6 Microvacuolation

Early reports of DLB emphasized the presence of cortical spongiform changes in the temporal cortex (Plate 21) (Hansen *et al.*, 1989). The appearance of this pathology was said to closely resemble prion disease, although the anatomical distribution was distinctive. The possible involvement of prion disease has been excluded on the basis of failed animal transmission experiments and lack of immunocytochemical staining for prion protein (Mancardi *et al.*, 1982; Smith *et al.*, 1987). There is no clear relationship between spongiosis and the distribution or severity of cortical Lewy body pathology in individual cases. However, affected areas have been shown to be related to the presence of 'ubiquitin-positive granular structures' (UPGS) (Iseki *et al.*, 1997). Spongiform degeneration is also encountered in otherwise typical cases of AD but there is a reduction in the frequency of UPGS (Iseki *et al.*,

1996). The frequency of α S reactive neurites in relation to spongiform changes has not been reported.

48.4.7 Synaptic loss

Reduced synaptic densities of up to 50 per cent have been reported in AD patients (Masliah *et al.*, 1991; Clinton *et al.*, 1994) and it is claimed that this abnormality is a major substrate for the reduced cognitive performance of Alzheimer patients compared with controls. Similar data have been reported for other diseases including vascular dementia (VaD) (Zhan *et al.*, 1994) and AIDS (Masliah *et al.*, 1991). Data relating to DLB are less easy to interpret. Reported synaptic loss in the neocortex and entorhinal cortex of DLB patients were equivalent to those of patients with AD (Masliah *et al.*, 1993; Wakabayashi *et al.*, 1994a). However, these patients were all from the 'common form' subgroup in whom there was significant concomitant Alzheimer-type pathology, especially in the entorhinal region. Thus the synaptic loss demonstrated may be due to Alzheimer-type and not Lewy body pathology. In a more recent study, a dot-blot assay for cortical synaptophysin was used to compare LBVAD patients with 'pure DLBD', and concluded that a significant synaptic loss of 20 per cent was present in LBVAD patients whereas the pure DLBD group showed only a non-significant decrease of 10 per cent (Samuel *et al.*, 1997a). A second study has confirmed this difference between the 'pure' and 'common' forms of DLB (Hansen *et al.*, 1998).

48.5 NEUROTRANSMITTERS AND NEUROCHEMISTRY IN DEMENTIA WITH LEWY BODIES

The neurochemical profile of the brain in DLB in comparison to AD and PD has been studied from three perspectives:

- correlation with the clinical features;
- correlation with the severity and distribution of pathological lesions;
- the identification of rational therapeutic targets.

Drugs currently used to treat psychotic features, depression, anxiety and cognitive impairment act on specific neurotransmitter systems (dopamine, 5-hydroxytryptamine (5HT), gamma-aminobutyric acid (GABA) and acetylcholine). In degenerative conditions such as AD, such therapies are considered to be symptomatic or palliative at best but evidence of neurotrophic consequences of neurotransmitter signalling, mediated at the level of alterations in gene transcription, indicate that chronic manipulation of neurotransmitter function can have either neurotoxic or neuroprotective effects. In DLB the major clinical features, particularly psychotic features, can occur in the absence of cortical Alzheimer-type pathology or synaptic loss and may be at least partly functional. The fluctuating course of the disease also supports this idea. Such observations raise the

possibility that neurotransmitter-targeted therapies may be of particular benefit in DLB compared with AD.

Neuronal loss occurs in specific subcortical nuclei in DLB as it does in AD and PD (see above). The systems that have received the most neurochemical attention in DLB, because of consistently observed abnormalities and likely clinical correlates, are the cholinergic (relating to cognitive and psychotic symptoms) and the dopaminergic (relating to parkinsonism). The role of noradrenergic or 5HT systems in depression or delusions, as has been suggested in AD, has not yet been explored in DLB, nor the significance of neuropeptide changes, e.g. somatostatin or corticotropin-releasing factor (CRF) which are evident in DLB (Dickson *et al.*, 1987; Leake *et al.*, 1990).

48.5.1 Cholinergic systems

Cortical cholinergic abnormalities and degeneration of basal forebrain nuclei are considered to contribute to cognitive impairments including memory loss in AD. In PD, cortical cholinergic activities and nucleus basalis neurone counts are lower in demented compared with non-demented individuals. In DLB, neocortical choline acetyltransferase (ChAT) is lower than in AD and similar to that in demented PD (Dickson *et al.*, 1987; Langlais *et al.*, 1993; Perry *et al.*, 1994). In comparison with AD the cortical loss of ChAT is a relatively 'early' and severe phenomenon in DLB (Tiraboschi *et al.*, 2002). Cognitive impairment is generally less severe in DLB than AD, and the clinical correlate of this neocortical cholinergic deficit may not be cognitive but neuropsychiatric, specifically visual hallucinations. Cholinergic activity is lower in hallucinating compared with non-hallucinating DLB cases whereas 5HT activity is relatively preserved (Perry *et al.*, 1990a). This observation may be linked to the tendency of antimuscarinic agents such as atropine and hyoscine (scopolamine) to induce visual hallucinations of a type similar to those experienced by patients with DLB (Perry and Perry, 1995). Such drugs interact with muscarinic M1, M3 and M4 receptor subtypes, which predominate in the cortex, thalamus and striatum.

Loss of striatal ChAT in DLB (Langlais *et al.*, 1993), which reflects pathology of intrinsic local circuit neurones, may account for the reduced severity of extrapyramidal clinical symptoms in some DLB patients who have equivalent loss of dopaminergic substantia nigra neurones as PD patients (Perry *et al.*, 1998). The reticular nucleus receives joint innervation from basal forebrain and brain stem pedunclopontine cholinergic nuclei. Disturbances in its function may lead to disruption of sensory processing and affect attentional or perceptive processes, possibly contributing to visual hallucinations.

In DLB, the muscarinic M1 subtype is elevated in the cortex, as it is in PD (Perry *et al.*, 1990c), reflecting upregulation of postsynaptic receptors in response to cholinergic denervation. Together with a normal extent of receptor coupling via G proteins, this suggests that cholinergic neurones are intact in DLB (Perry *et al.*, 1998). By contrast, there is no upregulation of the M1 subtype in AD, at least in advanced

cases, and receptor uncoupling is widely reported. These differences reflect the more 'destructive' cortical pathology, including neurofibrillary tangle formation, in AD. In contrast striatal M1 receptor density is lower in DLB, and parallels low D2 receptor density, which may relate to the relatively mild movement disorder (Piggott *et al.*, 2003).

The nicotinic receptor, which binds nicotine with high affinity (considered to consist primarily of $\alpha 4\beta 2$ subunits), is equally reduced in the cortex in DLB compared with AD and PD (Perry *et al.*, 1990c). In the substantia nigra, where nicotine binding is concentrated in the pars compacta in association with the pigmented dopaminergic neurones, receptor binding is as depleted in DLB as in PD, despite the greater loss of neurones in PD (Perry and Perry, 1995). This suggests that loss or down-regulation of the receptor may precede neurodegeneration. However, expression of various receptor subunits ($\alpha 2$, $\alpha 7$, $\beta 2$, $\beta 3$ nAChR) is unchanged in DLB suggesting a problem at the level of receptor assembly (Martin-Ruiz *et al.*, 2002). Nicotinic agonists upregulate the receptor and possible protective effects of nicotine may involve reversal of age- or disease-related loss of the receptor. Another nicotinic receptor subtype, comprising $\alpha 7$ subunits, binds α -bungarotoxin and is not affected in the cortex in DLB or AD. In the thalamus this receptor is concentrated in the reticular nucleus and is reduced in both disorders (Perry *et al.*, 1998), although a clinical correlate of this additional thalamic cholinergic abnormality is not established.

The therapeutic implications of the cholinergic neurochemical pathology so far identified in DLB can be summarized as follows:

- Since cortical cholinergic abnormalities exist in most cases in the absence of typical Alzheimer pathology (especially tangles), and muscarinic receptors are functionally intact, cholinergic replacement therapy (anticholinesterases, muscarinic or nicotinic agonists) is likely to be more effective than in AD.
- Since the cortical cholinergic deficits in DLB relate more to psychiatric than cognitive symptoms, therapy may be more effective in alleviating the former.

There is already some support for the second of these propositions. In AD patients the anticholinesterase tacrine has been reported to be more effective in alleviating psychotic features such as hallucinations and delusions than in improving cognition (Cummings, 1997). In a small series of patients with PD and dementia, hallucinations have been reported to be reduced or abolished in all cases treated with tacrine (Hutchinson and Fazzini, 1996). Paradoxically, given that extrapyramidal movement disorder is relieved by muscarinic antagonists, parkinsonian features were not exacerbated but actually alleviated. One explanation of this effect of tacrine may be that elevating acetylcholine in the striatum leads to nicotinic as well as muscarinic stimulation, resulting in greater release of nigral dopamine. Stimulation of nicotinic receptors as a therapeutic strategy in DLB may be of particular relevance because both mental and motor symptoms

should be relieved. The possibility that nicotinic stimulation may also be neuroprotective has been raised by epidemiological studies of smoking in PD and AD (Court and Perry, 1994). Recent interest in the correlation between butyrylcholinesterase activity in DLB and cognitive decline suggests that inhibitors of this enzyme might also have therapeutic potential (Perry *et al.*, 2003).

48.5.2 Dopaminergic systems

The loss of pigmented substantia nigra neurones and clinical evidence of parkinsonian symptoms in DLB indicate disruption of the dopaminergic input to the striatum. Reduced dopamine or the metabolite (homovanillic acid):dopamine ratio have been reported in autopsy tissue in DLB (Perry *et al.*, 1990b; Langlais *et al.*, 1993). Whilst a correlation between nigral neurone loss and striatal dopamine loss has been reported (Perry *et al.*, 1993), interpretation is complicated by selection of patients (e.g. via neurology or old age psychiatry, with less emphasis on extrapyramidal symptoms in the latter), and by treatment with neuroleptic drugs (which block D2 receptors and also reduce dopamine metabolism).

The dopamine transporter molecule is affected in both PD and DLB. Single photon emission computed tomography (SPECT) imaging shows that the striatal/cerebellar ratio is significantly lower in DLB compared with AD (2.1 versus 5.5) (Donnemiller *et al.*, 1997). Loss of mazindol binding, which also marks the transporter, also distinguishes DLB from AD (Perry *et al.*, 1990b). Compared with the striatum, there is much less dopamine in the cortex and, in autopsy tissue, no marked changes have been observed in those cortical areas that have been examined (Perry *et al.*, 1993). Although L-dopa may induce hallucinations in PD, no dopaminergic parameters distinguish between patients with and without hallucinations.

The status of dopaminergic receptors in DLB is less clear. Autopsy findings suggest no alteration in D1, D2 or D3 subtypes in unmedicated patients (Perry *et al.*, 1990b; Piggott *et al.*, 1999). The absence of any D2 upregulation, such as occurs in the course of PD in response to diminishing dopaminergic input, is surprising and suggests that basal ganglia pathology may be distinct between the two diseases. There is also clinical evidence to support this possibility. In a retrospective survey of cases, rest tremor and response to L-dopa were significantly less prevalent and myoclonus significantly more prevalent in DLB compared with PD (Louis *et al.*, 1997) and DLB patients are unusually sensitive to typical neuroleptic D2 antagonists (McKeith *et al.*, 1992a). This neuroleptic sensitivity may be related to a dysregulation in D2 receptors: receptor numbers were upregulated in patients tolerant of the drugs but not in the drug-sensitive group (Piggott *et al.*, 1994). *In vivo* SPECT or PET imaging shows a reduced caudate:putamen ratio in DLB compared with AD and has diagnostic value (Walker *et al.*, 1997; O'Brien *et al.*, 2004; Gilman *et al.*, 2004).

The limited neurochemical studies so far conducted in DLB show some features similar to those in PD (cortical cholinergic and striatal dopaminergic deficits), and others to those in AD (striatal cholinergic deficits). D2-receptor dysregulation and changes in cortical 5HT and turnover levels may differ in DLB compared with both AD or PD (Perry *et al.*, 1993). The Consensus Guidelines for clinical diagnosis of DLB (McKeith *et al.*, 1996) raise the possibility that DLB patients will be distinguished by their therapeutic response to cholinergic and dopaminergic therapies. Initial clinical evidence from trials supports this hypothesis (McKeith *et al.*, 2000b).

48.6 MOLECULAR AND ANATOMICAL PATHOLOGY CORRELATES OF CLINICAL FEATURES IN DEMENTIA WITH LEWY BODIES

48.6.1 Structural brain imaging

Data on regional atrophy in DLB when compared with related disorders, including AD and PD with no cognitive decline, and with elderly controls have largely come from *in vivo* brain imaging using voxel-based morphometry to analyse structural MRI studies. In DLB there is grey matter volume loss in frontal, temporal and insular cortices compared with controls (Burton *et al.*, 2002). However, the medial temporal lobe (including hippocampus and amygdala) are relatively preserved in comparison with AD patients but there is also increased thalamic atrophy in AD. The caudate nucleus is atrophic in AD, commensurate with overall global brain volume loss (Almeida *et al.*, 2003). Caudate volume is also reported to be reduced in DLB (Barber *et al.*, 2002) but not in PD (Almeida *et al.*, 2003).

48.6.2 Cognitive decline in DLB

Neurochemical pathology (see Section 48.4.5, pp. 621–622) already establishes a number of neurotransmitter-related changes that correlate with cognition in DLB. Establishing the possible role of molecular pathological changes as a basis for the substrate of cognitive decline in DLB is complicated by the frequent co-existence of significant ATP (i.e. in 'common form' DLB). The possibility that α -synucleinopathy and ATP may interact synergistically on cognition is raised by the finding of more severe cognitive disability in 'common form' DLB compared with AD or 'pure' DLB (Serby *et al.*, 2003). Whether the anatomical distribution of α -synucleinopathy, and the quantitative expression of pathology, influence cognitive decline is not fully resolved. Many authors have interpreted the consensus guidelines for documenting Lewy body pathology (McKeith *et al.*, 1996) as diagnostic guidelines, implying that dementia is associated with at least 'limbic' pathological stage. However, it is quite clear that patients with only 'brain stem' LB pathology can have the full clinical expression of DLB (McKeith *et al.*, 2000a). In general there is a strong body of evidence that increased

neocortical Lewy body pathology is associated with cognitive decline in DLB and PD (Samuel *et al.*, 1996; Hurtig *et al.*, 2000; Maffila *et al.*, 2000; Kovari *et al.*, 2003).

48.6.3 Visual hallucinations

The obvious candidate regions studied as correlates of visual hallucinations in DLB are the components of the visual pathways and related higher processing brain areas. Neurochemical studies have indicated that cortical cholinergic activity is lower in patients with hallucinations whilst serotonergic neurotransmission is relatively preserved (Perry *et al.*, 1990a). No studies have reported on the relative burden of pathology in serotonergic projection pathways or in the raphé nuclei in DLB in relation to this observation. It has long been appreciated that the occipital neocortex is relatively spared from α -synucleinopathy in terms of Lewy body formation (Perry *et al.*, 1990d) but occipital hypometabolism has been consistently demonstrated in DLB compared with AD (Imamura *et al.*, 2001; Lobotesis *et al.*, 2001). In one study visual hallucination was more frequent in DLB patients with a lower Braak score (Merdes *et al.*, 2003). It is also suggested that an increased burden of medial temporal lobe (parahippocampus, amygdala) Lewy body pathology is an important correlate of visual hallucination (Harding *et al.*, 2002a). Finally it has been proposed that an intrinsic α -synucleinopathy of the retina may characterize hallucinations in DLB (Maurage *et al.*, 2003).

48.6.4 Parkinsonism

The pathological and neurochemical basis of mild parkinsonian features of DLB are probably the most satisfactorily characterized aspect of DLB pathology. The presence of nigral dopamine neurone loss with reduced presynaptic dopamine transporter activity in the striatum now form the basis for a clinical diagnostic strategy (Walker *et al.*, 1997; Gilman *et al.*, 2004; O'Brien *et al.*, 2004) to distinguish DLB from other dementia syndromes. Rather less well resolved is the whole debate about the relationship between DLB and PD, especially in those cases of PD who go on to develop dementia. This topic is beyond the scope of the present chapter and has not been resolved through pathological studies to date. The opportunity to extend studies of α -synucleinopathy from quantification of Lewy bodies to include the neuritic component of the disorder, which can be abundant within the basal ganglia, may well illuminate this question in the future (Duda *et al.*, 2002).

49.6.5 Fluctuation in conscious level

The neuroanatomical structures that are key to regulation of consciousness are not well characterized so that clear candidate brain regions have not been established for the changes found in DLB. One potential candidate brain region is the thalamic intralaminar nuclei (Henderson *et al.*, 2000), which have been shown to be affected in PD.

48.6.6 Supportive features of DLB

Pathological correlates for some of the supportive features of DLB are beginning to emerge or have been hypothesized:

- *Repeated falls.* Orthostatic hypotension is a very frequent correlate of PD and is thought to reflect α -synucleinopathy affecting central (dorsal vagus, medullary reticular formation) and peripheral (autonomic, cardiac) nervous tissues involved in cardiovascular regulation. It is likely that similar changes occur in DLB and contribute to the increased risk of falls in this disorder compared with AD (Imamura *et al.*, 2000; Kaufmann *et al.*, 2001; Londos *et al.*, 2002).
- *REM sleep disorder.* REM-sleep behaviour disorder (RBD) is now regarded as a supportive feature of the diagnosis of DLB following revision of the Consensus diagnostic criteria (McKeith *et al.*, 2004). There is now an impressive body of evidence indicating that RBD is frequently a correlate of α -synucleinopathy and is associated with DLB (Turner *et al.*, 2000; Ferman *et al.*, 2002; Boeve *et al.*, 2003).

48.7 PATHOGENESIS OF DEMENTIA WITH LEWY BODIES

48.7.1 Molecular pathology of Lewy bodies

The biogenesis of Lewy bodies remains incompletely understood. There is a group of disorders in which the formation of α S inclusion bodies is a characteristic, invariable, and apparently primary component of the pathogenetic cascade (Table 48.2, p. 616). In addition, there is a large group of conditions in which Lewy bodies, as defined by modern immunocytochemical concepts, are sometimes associated (Table 48.1, p. 615). The development of animal models of α S aggregation is rapidly increasing understanding of the pathogenesis of α -synucleinopathy (Giasson *et al.*, 2002).

48.7.2 α -Synuclein

The finding that point mutations of the gene encoding α S are associated with the development of autosomal dominant familial PD has had a major impact on studies of the pathology and pathogenesis of Lewy body disorders (Polymeropoulos *et al.*, 1997). It is now apparent that all the major features of the cellular pathology of Lewy body disorders (Lewy bodies, pale bodies, neurites) are intensely immunoreactive for this protein (Spillantini *et al.*, 1997, 1998; Takeda *et al.*, 1998).

The function of the synuclein family is not yet defined. α S is concentrated within synaptic fractions of brain extracts but is not a component of the synaptic vesicle mechanism. A proportion of α S is transported via the rapid vesicle-moving component of axonal transport (Jensen *et al.*, 1998). This vesicle-binding property is abolished by one of the mutations

found in familial PD patients. α S is homologous with the β -, γ -synucleins and Persyn, as a family of small, soluble, heat-stable and abundant brain proteins (Buchman *et al.*, 1998; Clayton and George, 1998). α S exists as two alternatively spliced isoforms in man and three in rat (Maroteaux and Scheller, 1991; Hashimoto *et al.*, 1997). The avian homologue of α S is synelfin, which is implicated in synaptic remodelling during song learning (George *et al.*, 1995). Persyn is particularly interesting because it has been shown to promote the disassembly of neurofilament heavy chain subunits when overexpressed in neural cells (Buchman *et al.*, 1998). The possibility is therefore raised that abnormal neurofilament metabolism in Lewy body degeneration results from an abnormal interaction with α S.

An alternative hypothesis has been proposed on the basis of the tendency of α S to self-aggregate. Experiments *in vitro* with human recombinant α S show that certain conditions (e.g. low pH, high temperature) favour the development of thioflavin-S-positive aggregates, which resemble amyloid fibrils (Hashimoto *et al.*, 1998). This is pertinent for two reasons:

- α S was first recognized to be relevant to neurodegeneration when it was unexpectedly isolated from plaque amyloid in AD (Iwai *et al.*, 1995a, b).
- Filamentous proteins can be isolated from Lewy body cases (including both PD and DLB) using a method for isolating paired helical filaments from AD brain. The extracted filaments are either straight or twisted and appear to be composed of regularly orientated α S molecules (Spillantini *et al.*, 1998).

These data therefore suggest that self-aggregation of α S may be a primary mechanism for Lewy body formation. Subsequent enzymatic modifications are reported including phosphorylation (Fujiwara *et al.*, 2002) and proteolytic truncation (Tofaris *et al.*, 2003). It has been argued that ubiquitination of α S in PD and DLB is predominantly by mono-, di- or tri-ubiquitin chains and may represent a proteasome-independent and disease-specific sequence of biochemical changes (Tofaris *et al.*, 2003). Other work suggests that ubiquitination of α S (see below) is not required for inclusion body formation (Sampathu *et al.*, 2003).

48.7.3 Neurofilaments

By analogy with other conditions (e.g. hepatic Mallory body formation), the Lewy body was originally regarded as an intermediate filament inclusion, a view which was supported by immunoelectron microscopic studies, which indicated that the core filamentous component contains neurofilaments (Pollanen *et al.*, 1993a). Since the formation of another intermediate filament inclusion, the Mallory body, can be studied in murine models of hepatocellular toxicity (Denk *et al.*, 1976), this approach has been used to gain insight into Lewy body formation (Pollanen *et al.*, 1994). There is no evidence for an underlying alteration in neurofilament expression in

Lewy body formation (Bergeron *et al.*, 1996), although the mechanism may involve primary damage to neurofilaments. However, the primary pathogenetic insult may be directed at intracellular targets that are crucial to the regulation and maintenance of neurofilament assembly, transport or disassembly. The currently favoured candidate is α S (see Section 48.4.4, pp. 620–621). In this alternative model, the subsequent phosphorylation and truncation of aggregated neurofilaments occurs as a secondary process (Lowe *et al.*, 1996).

Candidate enzymes involved in the phosphorylation of neurofilaments incorporated into Lewy bodies have been sought. Cyclin-dependent kinase 5 has been proposed as a likely candidate on the basis of immunolocalization, in both cortical and subcortical Lewy bodies (Brion and Couck, 1995), together with its regulatory subunit p35^{nck5a} (Nakamura *et al.*, 1997). Such studies do not overcome the problem of whether phosphorylation of neurofilaments precedes or follows Lewy body formation.

48.7.4 Ubiquitin

Much interest has focused on the role of the ubiquitin pathway in Lewy body formation and the concept has developed of Lewy bodies as a cellular protective mechanism (Lowe *et al.*, 1996). Cortical Lewy bodies purified from DLB brains react predominantly to an antibody recognizing polyubiquitin chains rather than free ubiquitin or monoubiquitinated forms (Iwatsubo *et al.*, 1996). The possibility was raised that incomplete activation of ubiquitin-mediated proteolytic pathways may contribute to the pathogenesis of Lewy body degeneration. The dynamic nature of Lewy body formation in comparison to some other inclusion bodies in neurodegenerative diseases has been suggested (Lowe *et al.*, 1990, 1992; Iwatsubo *et al.*, 1996). Differences in the expression of both ubiquitin and the 26S proteasome in Lewy bodies compared with neurofibrillary tangles have been described (Ii *et al.*, 1997).

48.7.5 Other proteins

A large diversity of other peptide constituents have been detected in Lewy bodies by immunocytochemical methods (Table 48.3), but the significance of many of these should be interpreted with caution because of their normal widespread cytosolic distribution.

48.6 SUMMARY

The relationship between DLB, PD and AD is complex and incompletely understood. Within the spectrum of Lewy body disorders there is a neuropsychiatric syndrome, with associated parkinsonism, in the elderly, which is sufficiently distinct in terms of its clinical, pathological and neurochemical profile to warrant recognition as a distinct condition. syndrome can be reliably diagnosed by the Consensus Guidelines and has particular therapeutic and other management implications compared with PD or AD. The pathology and neurochemistry of the disorder should be considered from two perspectives:

- α -Synucleinopathy is central to DLB and PD but with a different anatomical distribution of the major burden of lesions.
- The Alzheimer-type pathology, which frequently, but not invariably, complicates the pathological picture, may change the clinical and neurochemical features so that they more closely resemble AD. Genetic studies indicate that DLB cases tend to share many risk factors for AD.

Most elderly demented patients whose clinical course fulfils the Consensus diagnostic criteria for DLB and who have

Lewy body pathology will be compatible with a diagnosis of DLB. Others may more comfortably be interpreted as 'AD with incidental Lewy bodies' or 'dementia in PD'. Clarification of the relationship between patients within these and other diagnostic categories is emerging based on pathological, genetic and neurochemical data in order to understand pathogenesis.

Neuropsychological changes in dementia with Lewy bodies

DAVID P SALMON AND JOANNE M HAMILTON

49.1 Clinical manifestations of dementia with Lewy bodies	635	49.4 Contributions of Lewy body pathology to cognitive dysfunction in dementia with Lewy bodies	641
49.2 Neuropsychological features of dementia with Lewy bodies	636	49.5 Conclusions	643
49.3 Cognitive deficits in patients with clinically diagnosed dementia with Lewy bodies	640	References	643

Dementia with Lewy bodies (DLB; [McKeith *et al.*, 1996b]) refers to a clinicopathologic condition in which the brains of patients who exhibited insidious and progressive cognitive decline during life are found to have a diffuse distribution of Lewy bodies and cell loss in subcortical structures and in widespread regions of the neocortex (Kosaka *et al.*, 1984; Gibb *et al.*, 1985; Dickson *et al.*, 1987; Gibb *et al.*, 1989; Lennox *et al.*, 1989; Hansen *et al.*, 1990; Kosaka, 1990; Perry *et al.*, 1990). The subcortical pathology that occurs in DLB is similar to that of Parkinson's disease (PD), but the number of Lewy bodies and the degree of cell loss in the substantia nigra and in other pigmented brain stem nuclei (e.g. locus caeruleus and dorsal vagal nucleus) is usually intermediate between that of patients with PD and age-matched normal individuals (for reviews, see Perry *et al.*, 1990; Hansen and Galasko, 1992; Ince *et al.*, 1998). The cortical Lewy body pathology of DLB occurs primarily in the cingulate, insula, amygdaloid complex, entorhinal cortex, and transentorhinal cortex, and in the neocortex (usually in deeper layers such as 4, 5, and 6) of the temporal, parietal, and frontal lobes (Double *et al.*, 1996; Kosaka and Iseki, 1996; Ince *et al.*, 1998; Gómez-Tortosa *et al.*, 1999; Gómez-Tortosa *et al.*, 2000; Harding *et al.*, 2002). Some Lewy body pathology also occurs in the occipital cortex (Kosaka and Iseki, 1996; Pellise *et al.*, 1996; Rezaie *et al.*, 1996; Gómez-Tortosa *et al.*, 1999; Harding *et al.*, 2002), but white matter spongiform change with coexisting gliosis appears to be the most prominent feature of occipital lobe pathology associated with DLB (Higuchi *et al.*, 2000). This occipital pathology is accompanied by hypometabolism and decreased blood flow in primary visual and visual association cortex that is evident with positron emission tomography

(PET) or single photon emission computed tomography (SPECT) scanning (Albin, *et al.*, 1996; Ishii *et al.*, 1998; Imamura *et al.*, 1999; Higuchi *et al.*, 2000; Imamura *et al.*, 2001; Lobotesis *et al.*, 2001; Minoshima *et al.*, 2001).

The majority of patients with DLB have concomitant Alzheimer's disease (AD) pathology (i.e. neuritic plaques, neurofibrillary tangles) that is sufficient to meet standard criteria for AD (e.g. Khachaturian, 1985; Mirra *et al.*, 1993). This AD pathology occurs in the same general distribution throughout the brain as in patients with 'pure' AD (Armstrong *et al.*, 1998; Gómez-Tortosa *et al.*, 2000), although the severity of AD pathology is usually less than in pure AD (Samuel *et al.*, 1996; Brown *et al.*, 1998; Gearing *et al.*, 1999; Heyman *et al.*, 1999). Neuropathological (Lippa *et al.*, 1994, 1998) and neuroimaging studies (Hashimoto *et al.*, 1998; Barber *et al.*, 2000, 2001) also indicate that medial temporal lobe structures, and the hippocampus in particular, are somewhat less atrophic in DLB patients than in patients with AD. Patients with DLB have abnormal ubiquitinated neurites in the CA 2/3 region of the hippocampus that are not present in AD (Dickson *et al.*, 1991, 1994; Lippa *et al.*, 1994).

A number of neurochemical abnormalities have been identified in patients with DLB (for review, see Ince *et al.*, 1998). As in PD, one of the primary neurochemical changes is a disruption of dopaminergic input to the striatum due to the loss of pigmented substantia nigra neurones (Perry *et al.*, 1990). This loss may be as severe as that in PD (Langlais *et al.*, 1993) and most likely mediates the extrapyramidal motor dysfunction that usually accompanies DLB (see below). Cortical dopamine, in contrast, has been reported to not markedly decrease in DLB (Perry *et al.*, 1993). DLB is also

characterized by a widespread depletion of striatal and neocortical choline acetyltransferase (ChAT) that is greater than that observed in pure AD (Reid *et al.*, 2000; Tiraboschi *et al.*, 2000, 2002). Loss of ChAT activity occurs in the striatum due to pathology of intrinsic local circuit neurones and, as suggested by Perry *et al.* (1990) and Langlais *et al.* (1993), this loss may attenuate the manifestation of the severe motor dysfunction that usually occurs with the loss of striatal dopamine in PD. The severe loss of neocortical ChAT activity in DLB is thought to contribute to the cognitive and neuropsychiatric features (e.g. visual hallucinations) of the disorder (Aarsland *et al.*, 2001; Perry *et al.*, 2003). There is also some evidence that the grey matter level of a particular cholinesterase involved in the breakdown of acetylcholine, butyryl-cholinesterase, is correlated with rate of cognitive decline in patients with DLB (Perry *et al.*, 2003).

49.1 CLINICAL MANIFESTATIONS OF DEMENTIA WITH LEWY BODIES

The initial clinical manifestation of DLB is usually the insidious onset of cognitive decline with no other prominent neurological abnormalities (Hansen *et al.*, 1990; McKeith *et al.*, 1996b). Memory impairment is often the earliest feature of DLB but, with time, cognitive deficits become widespread and patients inexorably progress to severe dementia. These aspects of DLB are similar to the dementia syndrome associated with AD, and patients with DLB are often clinically diagnosed as having probable or possible AD during life (e.g. Hansen *et al.*, 1990; Merdes *et al.*, 2003). Because of the extensive pathological, clinical, and genetic overlap that DLB often shares with AD (Galasko *et al.*, 1994; Hansen *et al.*, 1994; Katzman, *et al.*, 1995; Olichney *et al.*, 1996), Hansen and colleagues (1990) distinguish between what they refer to as the Lewy body variant (LBVAD) of AD and diffuse Lewy body disease (DLBD) without concomitant AD.

Despite the general similarities in the two disorders, numerous retrospective studies that have compared the clinical features present in autopsy-confirmed DLB and AD patients have identified a number of distinguishing characteristics (Hansen *et al.*, 1990; McKeith *et al.*, 1992; Beck, 1995; McShane *et al.*, 1995; Galasko *et al.*, 1996; Hely *et al.*, 1996; Weiner *et al.*, 1996; Ala *et al.*, 1997; Graham *et al.*, 1997; for reviews, see Perry *et al.*, 1996; Cercy and Bylsma, 1997). These studies have demonstrated that patients with DLB are more likely than those with pure AD to manifest extrapyramidal motor features (e.g. bradykinesia, rigidity, masked facies; but without a resting tremor) at some point during the course of the disease (Hansen *et al.*, 1990; McKeith *et al.*, 1992; Galasko *et al.*, 1996). In addition, it is estimated that 40–45 per cent of patients with DLB experience well-formed visual hallucinations (Galasko *et al.*, 1996; McKeith *et al.*, 1996b; Verghese *et al.*, 1999; Harding *et al.*, 2002; Merdes *et al.*, 2003) in comparison to approximately 25 per cent of patients with pure AD

(Ballard *et al.*, 1999) or PD (Aarsland and Karlsen, 1999; Fenelon *et al.*, 2000). Patients with DLB are more likely than those with AD to exhibit fluctuations in cognition and consciousness and to have unexplained falls (McKeith *et al.*, 1992; Ballard *et al.*, 2001).

Patients with DLB may develop urinary incontinence earlier in the course of the disease than do AD patients (Del-Ser *et al.*, 1996); they appear to be quite susceptible to REM sleep disorder (Turner *et al.*, 1997; Boeve *et al.*, 1998; Ferman *et al.*, 2002); they respond poorly to neuroleptic treatment for their psychotic symptoms (for review, see McKeith *et al.*, 1996a), and they may show a better clinical response than AD patients to acetylcholinesterase (AChE) inhibitor treatment of their cognitive deficits (Levy *et al.*, 1994). Patients with DLB have also been shown to decline more rapidly than patients with AD (Olichney *et al.*, 1998; McKeith *et al.*, 2000), although some investigators have found similar rates of progression and survival in DLB and AD (Heyman *et al.*, 1999; Stern *et al.*, 2001).

There is some evidence that the clinical manifestation of DLB is directly related to the distribution and severity of Lewy body pathology. In a study of 46 patients with autopsy-confirmed DLB (25 with LBVAD, 10 with DLBD, and 11 with PD or PD + AD), Haroutunian and colleagues (2000) found a significant correlation ($r = 0.34$) between the total number of Lewy bodies in the entire brain and scores achieved 6 months before death on the Clinical Dementia Rating (CDR) scale. When the analysis was limited to neocortical Lewy bodies only, the relationship with CDR scores was even stronger ($r = 0.52$). This relationship remained significant after the severity of AD pathology was accounted for by means of partial correlation analysis ($r = 0.32$), indicating that the extent of Lewy body pathology in DLB contributes to level of dementia severity independent of AD pathology. In another study, Gómez-Tortosa and colleagues (1999) compared clinical features in 13 patients with autopsy-confirmed DLBD and 12 patients with autopsy-confirmed LBVAD in order to determine if Lewy body pathology alone could produce the typical clinical presentation associated with DLB. The results of the study showed no differences in initial clinical symptoms, including age at onset, age at death, or disease duration. In addition, comparison of pathological changes showed no difference in the distribution of Lewy bodies within the brains of the two groups, and there were no significant differences in regional Lewy body counts for patients with and without initial parkinsonism, hallucinations, recurrent falls, fluctuations, or delusions. Although the relationship between Lewy body pathology and clinical symptoms is complex, these results indicate that this pathology makes a distinct contribution to the clinical manifestation of DLB.

Many of the clinical features of DLB that are described above have been incorporated into the primary clinical criteria for the disorder that were adopted by the International Consortium on DLB (McKeith *et al.*, 1996b). These criteria include, in addition to dementia, spontaneous motor features of parkinsonism, recurrent and well-formed visual hallucinations, and fluctuating cognition with pronounced variations

in attention or alertness. Probable DLB is diagnosed if two of these three features are present; possible DLB if only one is present. An examination of the performance of these consensus guidelines against autopsy verification of DLB demonstrated 83 per cent sensitivity and 91 per cent specificity (McKeith *et al.*, 2000). This was comparable to the 87 per cent sensitivity and 83 per cent specificity for AD (using NINCDS-ADRDA criteria) that was obtained in the same study. Despite these reports of relatively high sensitivity and specificity for the DLB clinical criteria, other studies have reported less success in using these criteria to distinguish between DLB and AD during life (e.g. Lopez *et al.*, 2000; Hohl *et al.*, 2002; Merdes *et al.*, 2003). Furthermore, at least two studies have shown that some autopsy-confirmed DLB patients displayed none of the core features of the disorder, other than dementia, during life (Stern *et al.*, 2001; Merdes *et al.*, 2003). The results of these studies indicate that additional ways to clinically identify patients with DLB are needed. As reviewed in the ensuing sections, neuropsychological studies of the disease indicate that DLB may be associated with a distinct pattern of cognitive changes that might aid in differentiating DLB from AD.

49.2 NEUROPSYCHOLOGICAL FEATURES OF DEMENTIA WITH LEWY BODIES

The specific neuropsychological deficits associated with DLB have been largely identified through the retrospective examination of prospectively collected data from patients in whom the disease was neuropathologically confirmed. Early studies of cognitive changes in DLB clearly demonstrated that the disorder is characterized by global cognitive dysfunction and a pattern of deficits that is very similar to the one associated with AD, including memory impairment, dysphasia, constructional dyspraxia, executive dysfunction and attention deficits (Gibb *et al.*, 1985; Byrne *et al.*, 1989). Several studies have directly compared the nature and severity of the neuropsychological deficits associated with the relatively early stages of DLB and pure AD. Förstl and colleagues (1993), for example, found similar degrees of language, praxis, and memory impairment on the cognitive portion of the Cambridge Mental Disorders of the Elderly Examination (CAMCOG) in eight autopsy-confirmed DLB patients and eight patients with AD. In another study, McKeith and colleagues (1992) found that 21 patients with autopsy-verified DLB performed significantly better than 37 patients with pure AD on the standardized Mental Test Score of Blessed. The superior performance of the DLB patients was most evident on the recall component of the test, and occurred despite similar degrees of impairment on measures of temporal and parietal lobe function.

A more detailed comparison of the neuropsychological deficits associated with DLB and AD was carried out by Hansen and colleagues (1990) who retrospectively examined the cognitive performance of nine patients with autopsy-proven

DLB (all with LBVAD) and nine patients with pure AD. As part of a prospective study of cognitive deficits associated with dementia, all patients had been evaluated with a comprehensive neuropsychological test battery that included measures of memory, language, executive functions, attention and visuospatial abilities. The DLB and AD patients included in the study were matched one-to-one on the basis of age, education, overall level of global dementia as assessed by the Information-Memory-Concentration test of Blessed, and the interval between cognitive testing and death. The results of this study showed that the DLB and AD patients were equally impaired (relative to elderly normal control subjects) on tests of episodic memory, confrontation naming (e.g. Boston Naming Test), and arithmetic (Wechsler Adult Intelligence Scale – Revised [WAIS-R] Arithmetic subtest), but the patients with DLB performed significantly worse than those with AD on a test of attention (WAIS-R Digit Span subtest) and on tests of visuospatial and constructional ability (Wechsler Intelligence Scale for Children – Revised [WISC-R] Block Design subtest and Copy-a-Cross test). In addition, the DLB and AD patients produced different patterns of impairment on tests of verbal fluency: the DLB group scored significantly lower than the AD group on the phonemically based letter fluency task (i.e. generating words that begin with a particular letter) but the two groups performed similarly on the semantically based category fluency task (i.e. producing words that belong to a particular category such as ‘animals’).

Subsequent studies have generally replicated these findings in much larger cohorts of autopsy-confirmed DLB and AD patients (Yeatman *et al.*, 1994; Gnanalingham *et al.*, 1996; Wagner *et al.*, 1996; Connor *et al.*, 1998; Galasko *et al.*, 1998; Hamilton *et al.*, 2004). Hamilton and colleagues (2004), for example, found that 24 patients with autopsy-confirmed DLB (all with LBVAD) performed significantly worse than 24 patients with autopsy-confirmed AD on several tests of visuospatial ability (e.g. the WISC-R Block Design Test, copying figures from the Visual Reproduction Test) but significantly better than the AD patients on verbal tests of episodic memory (see Figure 49.1). These differences in the cognitive changes associated with the two disorders occurred despite similar levels of impairment on a test of language production (Boston Naming Test) and equivalent levels of overall dementia as measured by the Mini-Mental State Examination (MMSE). The apparent double dissociation between the severity of visuospatial and episodic memory deficits in the two groups suggests that the distinct patterns of performance cannot be easily attributed to differences in dementia severity or difficulty of the various cognitive tasks, but instead reflects a true difference in the brain-behaviour relationships underlying DLB and AD.

In a related study of 66 patients with autopsy-verified DLB and 132 patients with autopsy-verified AD, Salmon *et al.* (2002) found that a derived measure of the difference between memory test and visuoconstructive test standardized scores revealed the same dissociation observed by Hamilton and colleagues (2004). Patients with DLB were significantly

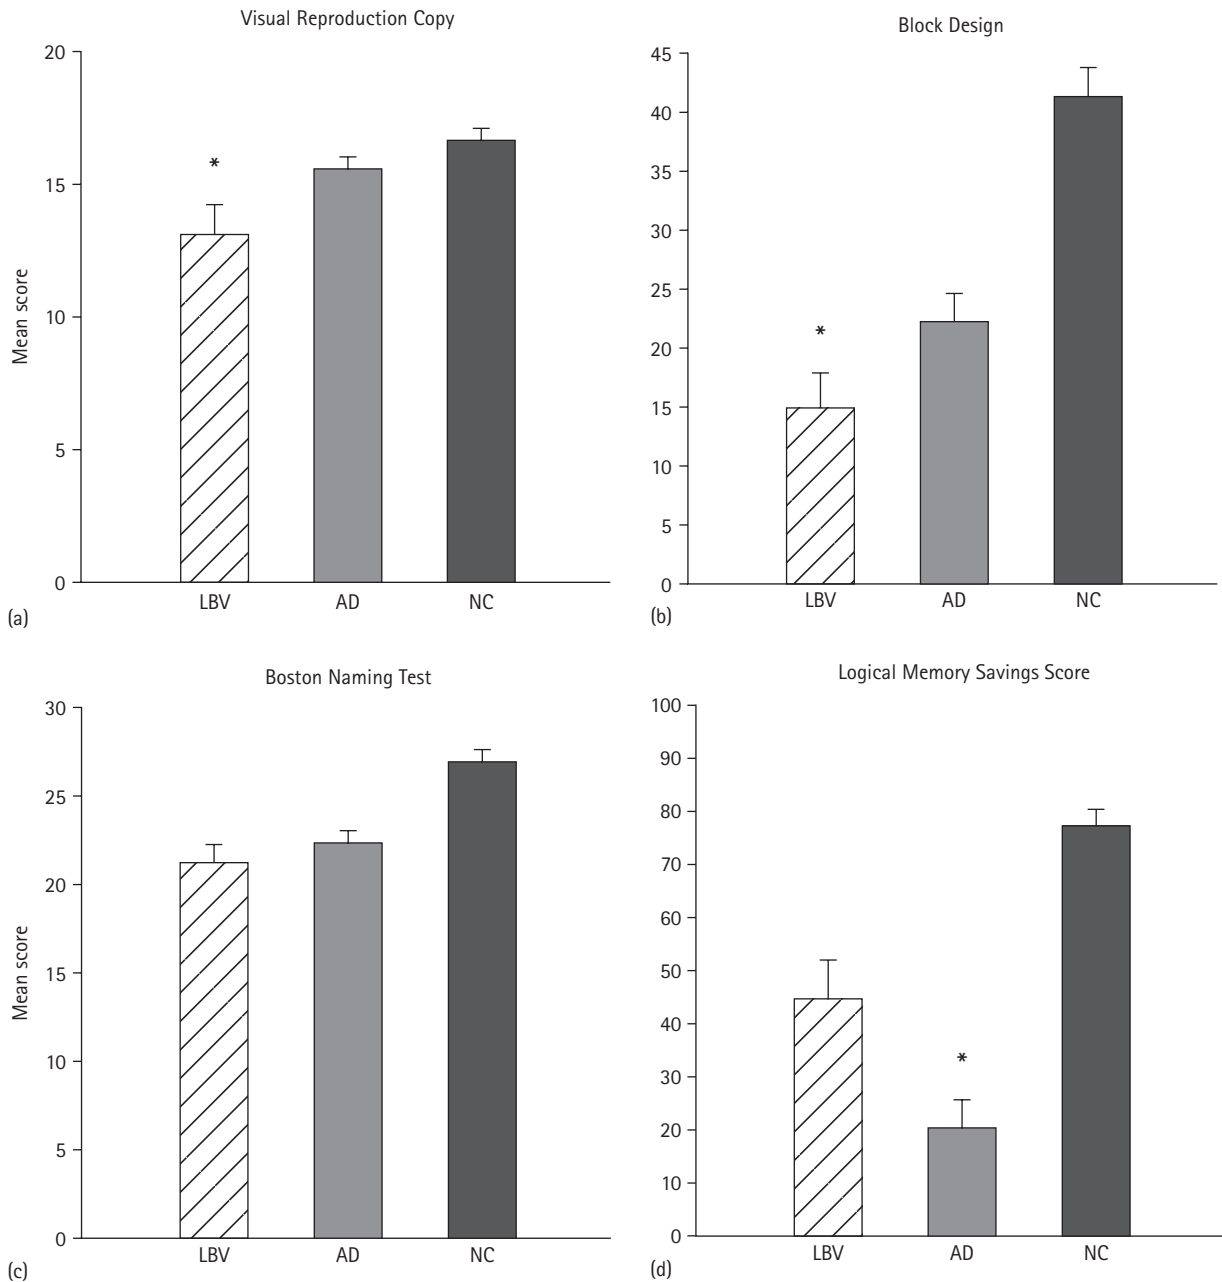

Figure 49.1(a–d) The average scores achieved by normal control (NC) subjects ($n = 24$), patients with Alzheimer's disease (AD; $n = 24$), and patients with dementia with Lewy bodies (DLB; all with the Lewy body variant of AD; $n = 24$) on several neuropsychological tests. Despite equivalent deficits on a test of confrontation naming (Boston Naming Test), the DLB patients were disproportionately impaired compared to the AD patients on tests of visuospatial ability (Visual Reproduction Copy and Block Design). (The opposite pattern was observed on a test of verbal memory [Logical Memory Savings Score]). (Adapted from Hamilton *et al.*, 2004.)

more impaired (relative to normal control subjects) on tests of visuoconstructive ability (i.e. WISC-R Block Design Test) than on tests of memory (i.e. Dementia Rating Scale [DRS] Memory Subtest), whereas the opposite pattern was true for patients with AD. These dissociable patterns of performance were apparent in both mild and moderate stages of dementia. Furthermore, there is some indication that distinct patterns of cognitive decline occur in patients with DLB and patients with AD. In a 1-year longitudinal study of 20 patients

with autopsy-confirmed DLB (all with LBVAD) and 20 patients with autopsy-confirmed AD, Salmon and colleagues (1998) found that the two groups exhibited similar rates of decline on measures of confrontation naming (Boston Naming Test), general semantic knowledge (Number Information Test), and episodic memory (DRS Memory subtest), but the DLB patients declined more rapidly than those with AD on measures of verbal fluency (also see Ballard *et al.*, 1996) and visuospatial abilities (WISC-R Block Design Test).

The possible clinical utility of distinct cognitive profiles in patients with DLB and AD was examined in a study by Galasko and colleagues (1998). These investigators compared the neuropsychological test performances of 50 patients with autopsy-verified DLB (all with LBVAD) and 95 patients with autopsy-verified AD. As in the previous studies by this group of investigators (Hansen *et al.*, 1990; Hamilton *et al.*, 2004), the DLB patients performed significantly worse than the AD patients on tests of visuospatial ability, verbal fluency, and abstract reasoning, and exhibited greater psychomotor slowing than the AD patients. In contrast, the groups did not differ on tests of global cognitive functioning (i.e. the MMSE) or on specific tests of confrontation naming, general semantic knowledge, attention, or episodic memory (it should be noted that this study did not examine performance on the rigorous episodic memory tests used by Hamilton *et al.* [2004]).

Based upon these results, Galasko and colleagues (1998) developed a logistic regression model designed to differentiate between DLB and AD patients on the basis of their performances on tests of verbal fluency (Phonemic Fluency Test), visuospatial ability (WISC-R Block Design Test, Clock Drawing Test), psychomotor speed and attention (Part A of the Trail Making Test), and general semantic knowledge (Number Information Test). The resulting model was highly significant and correctly classified approximately 60 per cent of DLB patients and 88 per cent of AD patients, for an overall successful classification rate of 77 per cent.

The distinct patterns of neuropsychological deficits exhibited by DLB and AD patients on large batteries of rigorous cognitive tests are robust enough to be detected on relatively brief, standardized tests of mental status (Connor *et al.*, 1998; Ala *et al.*, 2002; Aarsland *et al.*, 2003). For example, when Connor and colleagues (1998) compared the Mattis DRS subscale scores of 23 autopsy-verified DLB (all with LBVAD) and 23 pure AD patients, they found that patients with DLB performed significantly worse than those with AD on the Initiation/Perseveration subscale, which is heavily weighted towards verbal fluency and other executive functions. In contrast, the AD patients performed significantly worse than those with DLB on the Memory subscale of the test (see Figure 49.2). When Connor *et al.* (1998) limited their analyses to mildly demented patients, the DLB patients also performed significantly worse than the AD patients on the Construction subtest. This pattern of results was recently replicated in a larger sample of 60 autopsy-verified patients with DLB whose performance was compared with 29 clinically diagnosed patients with AD (Aarsland *et al.*, 2003). Despite comparable dementia severity at the time of testing, Aarsland and colleagues (2003) found that the DLB patients had higher Memory subscale scores than patients with AD, but lower scores on the Initiation/Perseveration and Construction subscales. Interestingly, the subscale score profiles of patients with DLB were identical to those of patients who initially presented with idiopathic PD and developed concomitant dementia.

Figure 49.2 The average percentage of the maximum possible score on each subtest of the Mattis Dementia Rating Scale achieved by patients with neuropathologically confirmed Alzheimer's disease (AD; solid bars) or dementia with Lewy bodies (DLB; striped bars). Patients with DLB scored significantly lower than patients with AD on the Initiation/Perseveration and Construction subtests but significantly higher on the Memory subtest. ATTN, Attention; IN/PER, Initiation/Perseveration; CONST, Construction; CONCP, Conceptualization; MEM, Memory. (Adapted from Connor *et al.*, 1998.)

Reports of less impaired memory performance in patients with DLB than in patients with AD were recently confirmed by the results of a study that compared the two groups on rigorous tests of episodic memory (Hamilton *et al.*, 2004). Hamilton and colleagues (2004) compared the performances of 24 patients with autopsy-confirmed DLB (all with LBVAD) and 24 patients with autopsy-confirmed AD on the California Verbal Learning Test (CVLT) and the Logical Memory Test from the Wechsler Memory Scale – Revised. Although the DLB and AD patients were equally demented as shown by equivalent scores on the Mattis DRS, they exhibited distinct patterns of performance on various components of the episodic memory measures (see Figure 49.3). The two groups were equally impaired in their ability to learn new verbal information on these tests, but the DLB patients exhibited better retention and recognition memory than patients with pure AD. These results suggest that the episodic memory deficit associated with DLB is generally less severe than that of AD, substantiating previous studies that used less rigorous memory tests with smaller samples of autopsy-confirmed patients (Salmon *et al.*, 1996; Connor *et al.*, 1998; Heyman *et al.*, 1999) or that used clinically diagnosed patient groups (Ballard *et al.*, 1996; Graham *et al.*, 1997; Walker *et al.*, 1997; Shimomura *et al.*, 1998; Calderon *et al.*, 2001).

The differences exhibited by DLB and AD patients on the retention and recognition measures of the verbal memory tests suggest that specific memory processes may be differentially impaired in the two disorders. Consistent with previous studies (Delis *et al.*, 1991; Tröster *et al.*, 1993), the patients with AD exhibited a severe learning deficit, rapid forgetting

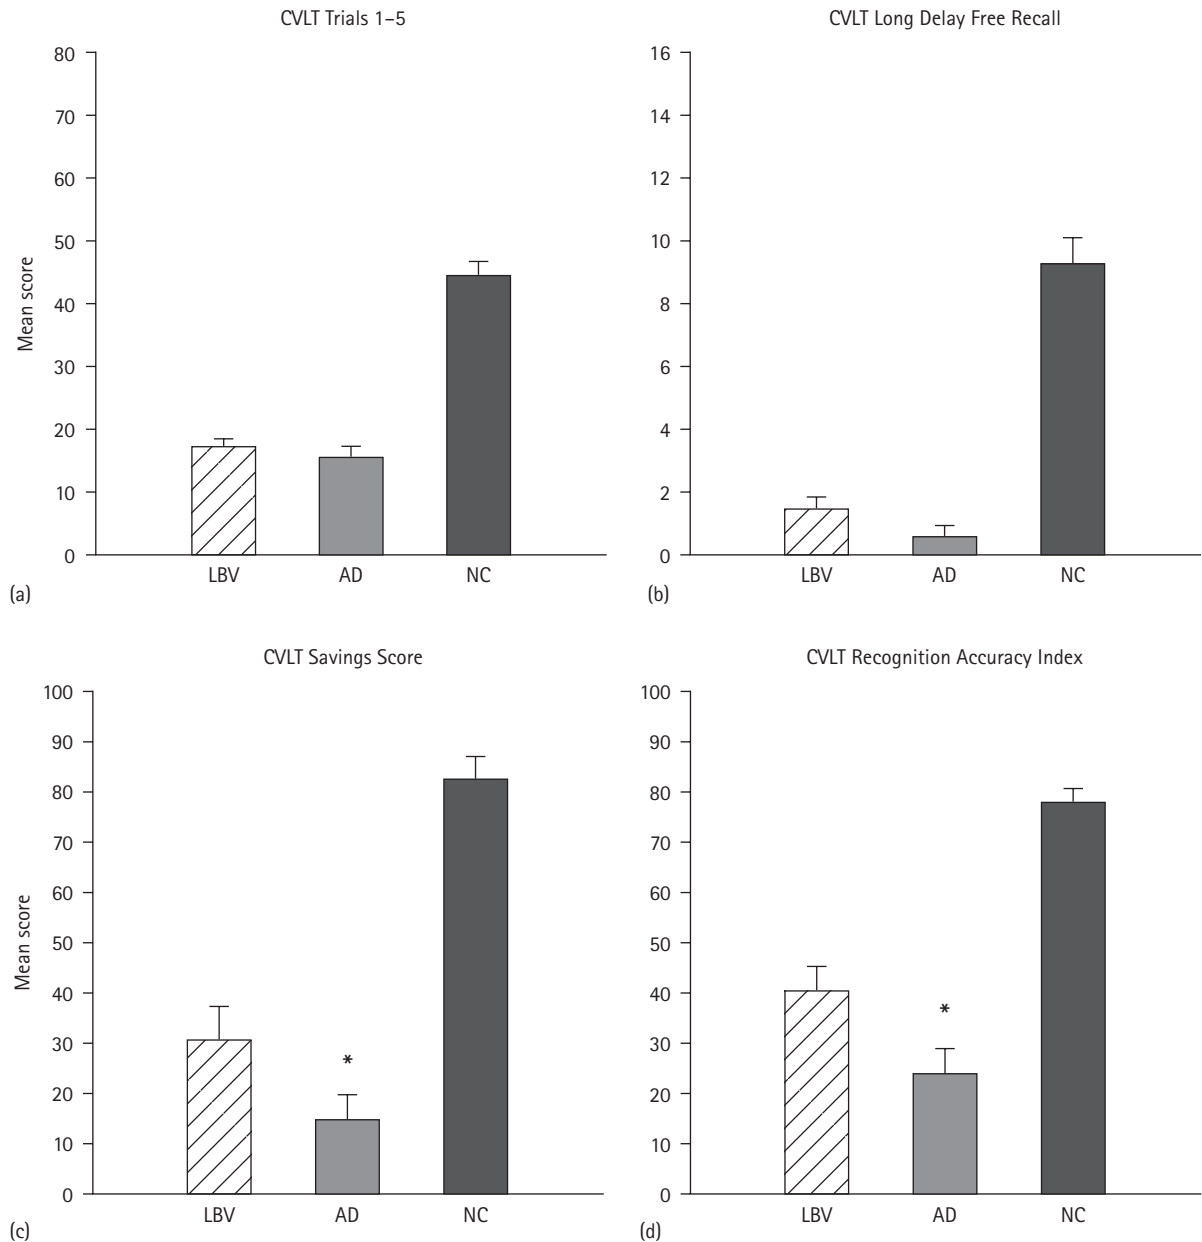

Figure 49.3(a-d) The average scores achieved by normal control (NC) subjects ($n = 24$), patients with Alzheimer's disease (AD; $n = 24$), and patients with dementia with Lewy bodies (DLB; all with the Lewy body variant of AD; $n = 24$) on various learning and memory measures from the California Verbal Learning Test (CVLT). Despite equivalent deficits in free recall, the DLB patients were less impaired than the AD patients on measures of retention (memory savings score) and recognition memory (recognition accuracy index). (Adapted from Hamilton et al., 2004.)

of information over a delay interval (indicated by low Savings scores), and severely impaired recognition memory. This pattern of deficits suggests a primary impairment of encoding and storage in which information is unavailable even when retrieval support is provided by the recognition memory format (Delis *et al.*, 1991). Despite similarly severe impairment in the learning and delayed recall conditions when free recall was required, the patients with DLB had better savings over the delay interval than patients with AD, and performed better on the recognition memory component of the

CVLT. These differences in performance suggest that a deficit in retrieval plays a greater role in the memory impairment of patients with DLB than in that of patients with AD. While the pattern of deficits does not rule out the possibility that poor encoding contributes to memory impairment in the two disorders, it is clear that DLB patients have better retention than patients with AD when retrieval demands are reduced through the use of the recognition format.

The observed differences in the severity of impairment of specific memory processes in DLB and AD are consistent with

the particular pathological changes that occur in the two disorders. As mentioned previously, a number of studies using neuropathologic (Lippa *et al.*, 1994, 1998) or magnetic resonance imaging (Hashimoto *et al.*, 1998; Barber *et al.*, 2000, 2001) procedures have shown that the medial temporal lobe structures important for memory (e.g. hippocampus, entorhinal cortex, parahippocampal gyrus) are more severely affected in AD than in DLB. The extensive damage to these structures that occurs in AD is thought to mediate the severe amnesia that characterizes the disorder (Hyman *et al.*, 1990). In contrast, damage to subcortical structures that are affected in Parkinson's disease and other disorders of the basal ganglia (e.g. Huntington's disease) is greater in DLB than in AD. Damage to these structures has been implicated in a memory disorder characterized by a general deficit in the ability to initiate and carry out the systematic retrieval of successfully stored information (Martone *et al.*, 1984; Butters *et al.*, 1985, 1986; Moss *et al.*, 1986; Delis *et al.*, 1991). Thus, the less severe retention deficit and the greater impact of deficient retrieval processes in DLB than in AD is consistent with the combination of moderate medial temporal lobe damage and frontostriatal dysfunction that occurs in the disease.

49.3 COGNITIVE DEFICITS IN PATIENTS WITH CLINICALLY DIAGNOSED DEMENTIA WITH LEWY BODIES

With the development of standardized criteria for the clinical diagnosis of probable DLB (e.g. McKeith *et al.*, 1996), a number of investigators have compared the cognitive deficits exhibited by clinically diagnosed DLB and AD patients who are relatively mildly demented. While these studies may be somewhat less reliable than studies of autopsy-verified patients because of the difficulty in clinically distinguishing between DLB and AD, they are informative and their results are generally consistent with those from autopsy series. In one such study, Shimomura and colleagues (1998) compared the performances of 26 patients with probable DLB and 52 patients with probable AD on items from the MMSE, the Alzheimer's Disease Assessment Scale (ADAS), the WAIS-R subtests, and the Raven Colored Progressive Matrices test. These investigators found that patients with probable DLB scored significantly worse than those with probable AD on the Raven Colored Progressive Matrices test and on the Picture Arrangement, Block Design, Object Assembly, and Digit Symbol Substitution subtests of the WAIS-R. In contrast, the patients with probable AD performed significantly better than those with probable DLB on measures of orientation and word recall. Consistent with the results from a study of autopsy-verified DLB and AD patients (Salmon *et al.*, 2002), a discriminant function analysis showed that the two groups could be most effectively differentiated by their scores on a word recall measure and the WAIS-R Block Design subtest. A similar discrepancy in the pattern of visuospatial and memory

deficits exhibited by patients with probable DLB and probable AD was reported by Walker and colleagues (1997).

A series of studies was carried out to compare the cognitive deficits exhibited by clinically diagnosed DLB and AD patients using a microcomputer-based testing paradigm (the CANTAB) that allowed a detailed assessment of memory, attention, and executive functions such as attentional set shifting, conditional pattern discrimination learning, and strategic thinking. In the first of these studies, Galloway and colleagues (1992) found that seven patients with probable DLB and 10 patients with probable AD were equally impaired on a recognition memory test, but DLB patients required significantly more trials than patients with AD to reach a learning criterion on a conditional pattern-location, paired-associates learning task. In a second study in this series, Sahgal and colleagues (1992a) showed that, while the same AD and DLB subjects from the Galloway *et al.* study were impaired on simultaneous and delayed matching to sample tasks, patients with probable DLB performed worse than those with probable AD only in the delayed condition. Sahgal and colleagues also showed in a third study (Sahgal *et al.*, 1992b) that these same DLB and AD patients were equally impaired on a complex set-shifting task that required both intradimensional (i.e. from one set of lines to another) and extradimensional (i.e. from lines to colours) shifts of attention, but only the patients with DLB were impaired (relative to normal control subjects) on a visual search task that assessed the ability to focus attention. In a final study in this series, Sahgal and colleagues (1995) compared the performance of DLB and AD patients on a spatial working memory task that assessed both spatial memory and the ability to use an efficient search strategy. In this task, subjects were required to search through a number of boxes presented on a computer screen in order to locate a hidden 'token'. They were not to re-examine an empty box before finding the token on the current trial (i.e. a within-search error), nor were they to search a box in which the token had been found on a previous trial (i.e. a between-search error). The results showed that patients with probable DLB made more within-search and between-search errors than those with probable AD, but the groups did not differ in the search strategies they used to complete the task.

Consistent with the disproportionately impaired visual attention and visuospatial working memory deficits exhibited by patients with DLB in the studies by Sahgal and colleagues, Calderon and colleagues (2001) found that 10 patients with probable DLB performed significantly worse than nine patients with probable AD on tests of fragmented letter identification, discrimination of 'real' objects from non-objects, and segregation of overlapping figures. These particularly severe deficits in visuospatial and visuoperceptual abilities were apparent even though the DLB patients performed significantly better than the patients with AD on a verbal memory test and at the same level on tests of semantic memory (also see Lambon Ralph *et al.*, 2001). Similar results were obtained by Mori and colleagues (2000) who found that

24 patients with probable DLB performed significantly worse than 48 equally demented patients with probable AD on tests of visual attention, size and form discrimination, and visual figure-ground segregation. Mori and colleagues noted that DLB patients with visual hallucinations were more impaired than those without hallucinations on the figure-ground segregation test. Simard *et al.* (2003) reported a similar finding in which patients with probable DLB with visual hallucinations performed worse than those without hallucinations on the Benton Judgement of Line Orientation task.

Several studies have reported that patients with DLB perform worse than those with AD on simple visuospatial tests such as the Clock Drawing Test, and suggest that such tasks might be useful for clinically differentiating between the two disorders (Gnanalingham *et al.*, 1996, 1997). While this possibility has some support, the utility of simple visuoconstructive tests for this purpose remains in question (Swanick *et al.*, 1996; Cahn-Weiner *et al.*, 2003).

Consistent with the results of studies that have compared groups of patients with clinically diagnosed probable DLB and probable AD, a number of studies have shown that AD patients with extrapyramidal motor signs (EPS; e.g. bradykinesia, rigidity, tremor) which may be indicative of DLB are more severely impaired on tests of visuospatial/visuoconstructive ability (e.g. Block Design, Figure Copying) and executive functions (e.g. Wisconsin Card Sorting Test, Trail Making Test, Verbal Fluency) than those without EPS, even though the groups exhibit comparable deficits on tests of long-term memory, naming, and verbal comprehension (Girling and Berrios, 1990; Richards *et al.*, 1993; Merello *et al.*, 1994). Furthermore, a 1-year longitudinal study showed that AD patients with EPS declined more rapidly than those without EPS on tests of reasoning and abstraction, visuospatial abilities, praxis, verbal fluency, and language processing (Soininen *et al.*, 1992). These differences in rate of decline occurred despite the two groups being equivalently impaired on all of these tests at their initial evaluation. This pattern of cognitive decline is consistent with the disproportionate decline in verbal fluency and visuospatial abilities displayed by autopsy-confirmed patients with DLB in the study by Salmon and colleagues (1998).

It is interesting to note that the cognitive abilities that appear to be disproportionately impaired in DLB are the same abilities that are mildly impaired in non-demented patients with PD. A number of studies have shown that compared with age-matched normal control subjects PD patients exhibit psychomotor slowing (Brown and Marsden, 1991) and have mild deficits in visuospatial abilities (Stern *et al.*, 1993; Jacobs *et al.*, 1995), verbal fluency (Jacobs *et al.*, 1995), and other executive functions that are necessary to perform tasks such as the Wisconsin Card Sorting Test (Lees and Smith, 1983; Brown and Marsden, 1988), the interference condition of the Stroop Test (Brown and Marsden, 1991), dual-processing tasks (Brown and Marsden, 1991; Dalrymple-Alford *et al.*, 1994), and tasks that require rapid shifts of attention (Filoteo *et al.*, 1997).

49.4 CONTRIBUTIONS OF LEWY BODY PATHOLOGY TO COGNITIVE DYSFUNCTION IN DEMENTIA WITH LEWY BODIES

While the studies described above suggest that the Lewy body pathology present in DLB contributes importantly to the severity and nature of the dementia associated with the disease, the presence of concomitant AD pathology in most DLB patients makes it difficult to determine the unique role this pathology plays in the disorder's clinical and neuropsychological manifestation. Fortunately, a number of clinicopathologic studies address this important question. Samuel and colleagues (1996), for example, compared quantitative measures of pathology and dementia severity in 14 patients with autopsy-verified DLB (all with LBVAD) and 12 patients with autopsy-verified pure AD. Despite being matched for disease duration and having similar scores on mental status tests when last evaluated prior to death, the DLB patients had fewer neurofibrillary tangles and total plaques than the AD patients, and were in a lower Braak stage (a rating system based upon severity of neurofibrillary tangle pathology in the medial temporal lobe and neocortex). Furthermore, the number of neurofibrillary tangles was correlated with level of dementia in the AD patients but not in the DLB patients, whereas the number of Lewy bodies was correlated with level of dementia in the DLB patients. These findings suggest that the additional Lewy body pathology in the DLB patients contributed to their dementia severity above and beyond the contribution of any AD pathology.

In a second study of 17 patients with autopsy-verified DLB (12 LBVAD, 5 DLBD), Samuel and colleagues (1997) found that the number of neocortical Lewy bodies, the number of neocortical neuritic plaques, Braak stage, and the severity of ChAT activity loss all correlated significantly with dementia severity as measured by the MMSE and the Information-Memory-Concentration Test of Blessed. In contrast to previous findings from patients with AD (e.g. Terry *et al.*, 1991), the severity of dementia in these DLB patients was not correlated with the number of neocortical neurofibrillary tangles or neocortical synaptic density. A strong relationship between ChAT activity and cognitive decline in patients with DLB was not supported by a subsequent study (Sabbagh *et al.*, 1999) of 41 patients with autopsy-verified DLB (all with LBVAD). In this study, Sabbagh and colleagues (1999) found only a weak correlation between ChAT activity and scores on the MMSE, and no significant relationship between ChAT activity and scores on the Information-Memory-Concentration Test of Blessed. The DLB patients in the study by Sabbagh and colleagues (1999) were more severely impaired than those studied by Samuel and colleagues (1997), but the strength of the correlations did not change appreciably when the most severely impaired patients were excluded from the analyses.

Further evidence for the role of Lewy body pathology in the dementia associated with DLB was provided by a study

that retrospectively examined the neuropsychological test performance of five patients with DLBD (Salmon, *et al.*, 1996). All five of these patients initially presented with insidious cognitive decline that progressed to severe dementia. Sometime after the onset of cognitive decline, all of the patients developed mild extrapyramidal motor dysfunction, three developed visual, auditory or tactile hallucinations, and two developed delusions. All were clinically diagnosed with probable or possible AD or one of its variants (i.e. LBVAD, mixed AD and vascular dementia) at their initial evaluation. At autopsy, subcortical and diffusely distributed cortical Lewy bodies were observed in the brains of all five patients. AD pathology was absent in two of the cases and at a level comparable to that found in normal elderly individuals in the other three cases.

Despite only borderline to mild impairment on the MMSE (mean = 23.2; range = 22–26), detailed neuropsychological testing revealed deficits in memory, attention, language, executive functions, and visuospatial abilities in all five patients with DLBD. A comparison with five equally demented patients with autopsy-verified AD showed similar levels of impairment on tests of executive functions, language, and attention, but disproportionately severe deficits in the DLBD patients on tests of psychomotor speed (parts A and B of the Trail Making Test) and visuospatial/visuoconstructive ability (WISC-R Block Design Test, Clock Drawing Test). Indeed, four of the five DLBD patients were at floor performance on the WISC-R Block Design subtest and the fifth was severely impaired. A similarly severe deficit was evident in the performance of DLBD patients on the copy condition of the Clock Drawing test (see Figure 49.4).

All five of the DLBD patients scored two to three standard deviations below normal performance on key measures of the California Verbal Learning Tests (CVLT), but their performance differed somewhat from that typically observed in patients with AD. Mildly demented AD patients usually exhibit severe impairment on CVLT measures of immediate learning and recall, very poor retention over delay intervals (i.e. an average long delay savings score of 17 per cent), an increased propensity to produce intrusion errors in the cued recall condition, and very poor recognition discrimination (Delis *et al.*, 1991). In contrast to this typical AD pattern, four of the five DLBD patients did not show exceptionally poor retention and recognition discrimination, and three of the five did not show a strong propensity to produce intrusion errors. When the scores of the DLBD patients were subjected to discriminant function equations that have been previously shown to effectively distinguish between patients with cortical (e.g. AD) and subcortical (e.g. Huntington's disease) dementia using these key CVLT measures, four of the five DLBD patients were classified as 'subcortical' and one as 'cortical'.

The deficits exhibited by patients with DLBD in the study by Salmon and colleagues (1996) indicate that subcortical and diffusely distributed neocortical Lewy body pathology, in the absence of AD pathology, can produce a global dementia syndrome characterized by deficits in memory, attention,

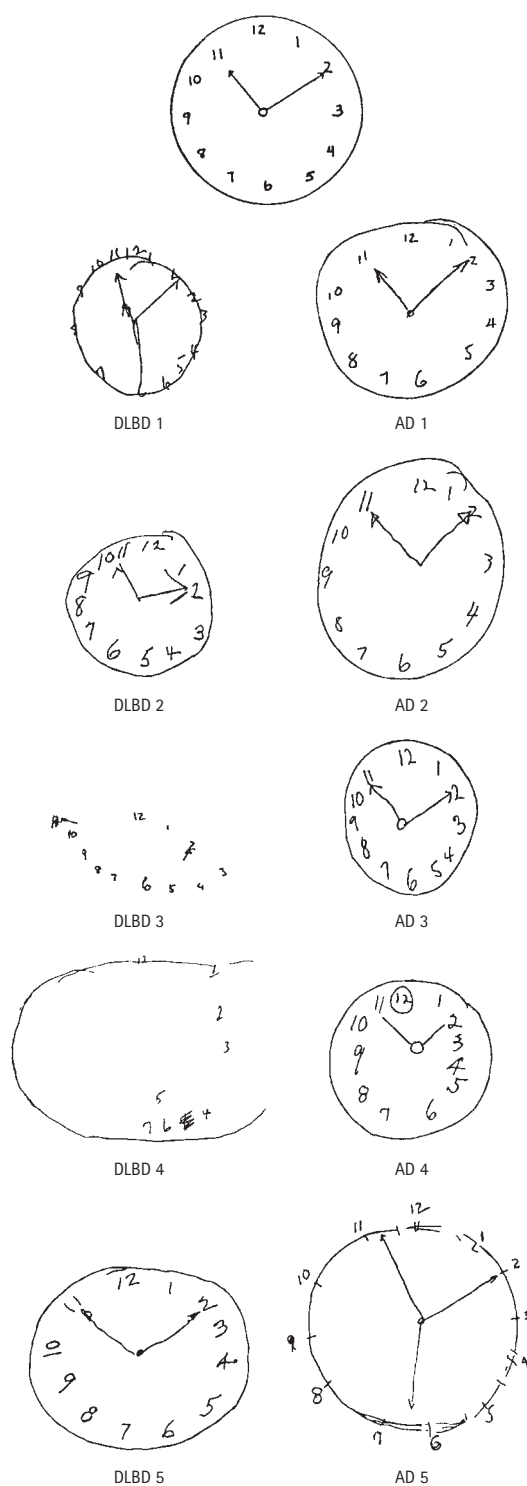

Figure 49.4 Copies of clocks drawn by patients with diffuse Lewy body disease (DLBD) and Alzheimer's disease (AD) in the copy condition of the Clock Drawing Test. The clock on top illustrates the model that patients were asked to draw. Although each DLBD (cases 1–5) patient was matched in terms of overall severity of dementia to each AD (cases 1–5) patient, the patients with DLBD produced significantly worse copies than the patients with AD. (Reprinted by kind permission of Raven's Press from Salmon and Bondi, 1999 in Terry *et al.*, *Alzheimer's Disease 2E.*)

language, and executive functions, and strikingly severe deficiencies in visuospatial/visuoconstructive abilities and psychomotor speed. This pattern of neuropsychological deficits is consistent with the cortical and subcortical brain damage that occurs in the disease. DLBD results in neuropathological abnormalities in the neocortex of the temporal, frontal and parietal lobe, and these changes may be responsible for such cortical features of the dementia as impaired language, executive dysfunction, and impaired visuospatial abilities. Neuropathological changes in the substantia nigra of patients with DLBD, and the corresponding depletion of dopaminergic input to the striatum (Perry *et al.*, 1990), most likely contribute to the cognitive deficits typical of subcortical dysfunction, such as impaired learning, decreased attention, impaired visuoconstructive abilities, and psychomotor slowing (for review, see Cummings, 1990). The nature of the memory deficit associated with DLBD appears to reflect ineffective retrieval similar to that observed in other patients with striatal dysfunction (Butters *et al.*, 1986). Although ubiquitin-immunoreactive dystrophic neurites are often present in the CA2–3 region of the hippocampus in patients with DLBD (Dickson *et al.*, 1991, 1994), the hippocampus and related structures (e.g. entorhinal cortex, parahippocampal gyrus) that are thought to underlie memory storage are generally less damaged than in AD (Lippa *et al.*, 1994). This disparity leads to overall milder memory impairment in patients with DLBD than in those with AD.

49.5 CONCLUSIONS

A growing body of evidence indicates that DLB is a distinct clinicopathologic entity that can be differentiated from pure AD on the basis of specific clinical features. Neuropsychological studies indicate that distinct features of the cognitive decline associated with DLB might aid in this differentiation. Although both DLB and AD result in global cognitive impairment and often engender comparable impairments in new learning and language abilities, patients with DLB appear to have significantly greater deficits than patients with AD in visuospatial abilities, some executive functions, verbal fluency, some aspects of attention, and psychomotor speed. The nature of the memory deficits associated with DLB and AD may also differ, with DLB patients exhibiting milder deficits in retention and recognition memory than patients with AD.

The pattern of neuropsychological deficits exhibited by patients with DLB suggests that they are often as severely impaired as patients with AD in those cognitive abilities usually affected by AD pathology (e.g. episodic memory, language), but more impaired in those abilities thought to be additionally affected by subcortical (and possibly neocortical) Lewy body pathology (e.g. verbal fluency, psychomotor speed, visuospatial/constructional ability; Alexander *et al.*, 1986). This suggests that both AD and Lewy body pathology contribute importantly to the cognitive manifestations of

DLB. However, the specific neuropsychological processes and neuropathological factors that underlie the cognitive changes of DLB remain largely unknown. It is not known, for example, whether the disproportionately severe visuospatial and visuoconstructive deficits associated with DLB are due to:

- a primary visuo-perceptual deficit that might arise from Lewy body pathology in the occipital cortex;
- an impaired ability to mentally manipulate information in space that might arise from concomitant AD and Lewy body pathology in parietal lobe cortex;
- an inability to plan constructions due to the interruption of frontostriatal circuits by pathology in the substantia nigra or frontal lobe cortex; or
- some combination of these or other factors.

Similar questions remain regarding the source of the severe deficits in attention, executive functions, verbal fluency, and psychomotor speed exhibited by patients with DLB. These questions can only be answered through additional systematic clinicopathologic studies of these patients.

The treatment of dementia with Lewy bodies

E JANE BYRNE

50.1 Primary prevention	648	50.4 Other putative treatments	652
50.2 Treatment of established dementia with Lewy bodies	649	50.5 Conclusion	652
50.3 Treatment of sleep disorders	652	References	653

The treatment of dementia with Lewy bodies (DLB) presents the clinician with several challenges. The aetiology and nosology of the condition are unknown and some of the most persistent and troublesome symptoms may be made worse by 'conventional' therapies. Some treatments are empirical and there are a few controlled studies.

50.1 PRIMARY PREVENTION

In a condition whose nosological status is certain, it may seem premature to discuss therapies or strategies that may prevent or delay the onset of the condition. Whilst the pathological features of DLB are increasingly well described, the controversy lies in the interpretation of the histological features. Do they indicate a variety of Alzheimer's disease (AD), a variety of Parkinson's disease (PD), a separate distinct entity, the coexistence of the two, or a spectrum disorder? Some authors suggest that DLB is more similar to PD, especially in cases with dementia (Byrne, 1995). The recent proposal for the reclassification of neurodegenerative disorders into synucleinopathies or tauopathies may help clarify the nosological status of DLB. As described in Chapter 48, the pathology of DLB consists of Lewy bodies in brain stem and cortex together with varying degrees of Alzheimer-type histological change (Duda, 2004; Iseki, 2004). Clinically about 20 per cent of cases begin with a motor syndrome indistinguishable from idiopathic PD, 40 per cent with parkinsonism and dementia and 20 per cent with dementia alone (Lennox, 1992). The clinical presentation is influenced by the degree of concomitant AD histological change (Merdes *et al.*, 2003).

So-called pure DLB cases (without significant Alzheimer histological change) are more likely to be young (under 70

years), male and with prominent early parkinsonian features (Kosaka, 1990; Hely *et al.*, 1996; Byrne, 2003). A small number of familial cases have been described (Tsuang *et al.*, 2004). The parasomnia rapid eye movement sleep behaviour disorder (RBD) is common in DLB and often precedes the development of the full syndrome by many years (Byrne, 1996, 2003; Boeve *et al.*, 2003). Putative strategies to prevent motor or cognitive progression might be effective in such cases.

Exposure to pesticides has been postulated as a risk factor for the development of PD (Liou *et al.*, 1997, Herishanu *et al.*, 1998). Hubble *et al.* (1998) have reported a possible gene-toxin interaction as a putative risk factor for PD with dementia. They found that subjects who had exposure to pesticides and at least one copy of the CYP2D629B + allele had an 83 per cent predicted probability of the development of dementia in association with PD.

Apoptotic-like changes have been described in nigral cells in PD and DLB and in neurones containing LB in DLB (Tompkins *et al.*, 1997; Katsuse *et al.*, 2003). One mechanism whereby this may occur is through the actions of nitric oxide (NO) (Snyder, 1996). Nitric oxide is formed from arginine by NO synthase (NOs), which has three forms, each with different genetic derivation glutamate neurones from synapses with neuronal NOs (nNOs) neurones. Glutamate in excess causes a release of NO, which leads to cell death (Dawson *et al.*, 1996). NO metabolites were found to be increased in the cerebrospinal fluid in 22 DLB patients compared with 13 normal controls in one study (Molina *et al.*, 2002), and Xu *et al.* (2000) reported that the CCTTT polymorphism in the NOS2A gene was associated with DLB. The exon 22 inducible nitric oxide synthase (iNOs) genotype is protective against PD (Hague *et al.*, 2004) and the expression of this gene was shown to be decreased in one study by the novel antioxidant EseroS-GS (Wei *et al.*, 2003).

NOs inhibitors have been shown to prevent this NO-mediated cell death in MPTP treated baboons (Hantraye *et al.*, 1996). As NO has also been implicated as a cause of cell damage in AD (Molina *et al.*, 1998), the use of NOs inhibitors in DLB has some theoretical justification. This rationale might also suggest the potential of excitatory amino acid antagonists as putative treatments in DLB (Sandhu *et al.*, 2003). The aggregation of misfolded α -synuclein is postulated to be cytotoxic in PD and in DLB. One recent study reported that the molecular chaperone Hsp70 reduced the amount of misfolded, aggregated α -synuclein *in vivo*, in transgenic mice (Klucken *et al.*, 2004). Other neuroprotective or preventative strategies that might be applicable to DLB include antioxidants, anti-inflammatory drugs and oestrogen (Cummings, 1995; Beal, 2003; Di Matteo and Esposito, 2003; Fernandez-Espejo, 2004). The antioxidant vitamin E has been assessed as a therapeutic agent in both PD and AD. In PD the results are equivocal with both positive (de Rijk *et al.*, 1997) and negative results (Parkinson Study Group, 1993) reported. Negative results may have been due to too low a dose (Fariss and Zhang, 2003; Mandel *et al.*, 2003). In AD, recent research suggests that vitamin E in combination with vitamin C as dietary supplements may prevent the disease (Zandi *et al.*, 2004) and that vitamin E supplementation, only if given early in the course of the illness (at least in an animal model), may be beneficial (Sung *et al.*, 2004). In AD there is some, though limited, evidence that vitamin E slows the progression in established disease (Knopman, 1998). The free radical scavenger coenzyme Q10 (an antioxidant) reduces apoptosis, possibly independent of its antioxidant action (Papucci *et al.*, 2003). In a randomized controlled trial of coenzyme Q10 (at dosages of 300, 600 or 1200 mg/day) in 80 people with early PD, less disability developed in the treatment group compared with the placebo group, with the greatest effect in those receiving the highest dosage (Shults *et al.*, 2002).

There is also evidence from epidemiological studies that prior oestrogen use may delay the onset of AD (Henderson, 1997; Honjo *et al.*, 2003; Smith and Levin-Allerhand, 2003). In ovariectomized rats oestrogen administered concurrently with MPTP reduces the DA release induced by MPP+ (Disshan and Dluzen, 1997). DLB certainly has a male preponderance and, in particular, pure DLB cases are predominantly male (Hely *et al.*, 1996). Oestrogen may be protective against PD as well as AD.

50.2 TREATMENT OF ESTABLISHED DEMENTIA WITH LEWY BODIES

There have been a number of reviews of the treatment of DLB (Byrne, 2002; Burn and McKeith, 2003; Fernandez *et al.*, 2003; Mosimann and McKeith, 2003; Wild *et al.*, 2003). Transmitter-related therapy and the treatment of prominent symptoms in DLB will now be reviewed.

50.2.1 Transmitter replacement therapy

50.2.1.1 ACETYLCHOLINESTERASE INHIBITORS

In DLB there is a severe cholineacetyltransferase (ChAT) deficiency, even more profound than that seen in AD (Dickson *et al.*, 1987; Perry *et al.*, 1990; Tiraboschi *et al.*, 2000). The Newcastle group were the first to suggest the use of acetylcholinesterase inhibitors (AChEIs) for the treatment of DLB. Evidence from the early placebo controlled trials of tacrine supported this suggestion when the first three responders in a London trial to reach autopsy were found to have cortical Lewy bodies (CLB) (Levy *et al.*, 1994). Others have found that response to tacrine was not limited to those AD cases with CLB (Wilcock and Scott, 1994). Lebert *et al.* (1998) studied the effects of tacrine (120 mg/day) in clinically diagnosed AD and DLB cases, using the McKhann *et al.* (1984) and the McKeith *et al.* (1996) criteria respectively. They found that whilst the ratio of AD and DLB cases did not differ between responders and non-responders, the pattern of response was different between the two groups. In the DLB group cognitive performance improved significantly on tests of attention (digit span and verbal initiation), while the AD group improved significantly on tests of conceptualization. In this study tacrine was apparently not associated with adverse effects on the mental state of DLB patients. However, in a smaller study of tacrine, and at a lower dose (80 mg/day), Querforth *et al.* (2000) found no clinical benefit in six DLB subjects. There is also a case report of possible adverse effects of tacrine in clinically diagnosed DLB (Witjeratne *et al.*, 1995).

Second generation AChEIs are beginning to be used in DLB. A recent Cochrane review of cholinesterase inhibitors (ChEIs) for DLB found only one randomized controlled trial (RCT) (McKeith *et al.*, 2000). The reviewers concluded that neuropsychiatric symptoms may be improved but that the evidence is modest (Wild *et al.*, 2003). In this single RCT of DLB (McKeith *et al.*, 2000), 120 patients were entered into the study and randomized to placebo or to rivastigmine (up to 12 mg/day by individual titration to maximum tolerated dose) for 20 weeks. Significant differences in neuropsychiatric symptoms (as measured by the Neuropsychiatric Inventory 4 and 10 item subscales (NPI-4 and NPI-10)) were found in favour of rivastigmine over placebo at 20 weeks in the analysis of observed cases (OC), but smaller differences were seen with intention to treat (ITT) and last observation carried forward (LOCF) analysis. In an open-label follow up of the treated subjects in this trial, improvement in NPI scores were maintained up to 24 weeks, and at 96 weeks these scores were not significantly worse than at baseline (Grace *et al.*, 2001).

Table 50.1 summarizes the other case series and open-label trials of ChEIs in DLB. All studies show benefit of treatment, most especially in neuropsychiatric symptoms. Only one study (Shea *et al.*, 1998) reports worsening of extrapyramidal symptoms during treatment. Two of these studies reported the effects of cholinesterase inhibitors on sleep disorder in DLB. Catt and Kauffer (1998) found beneficial effects on

Table 50.1 Summary of open label studies of cholinesterase inhibitors in dementia with Lewy bodies

Study	n	Duration (weeks)	Drug	Results	Adverse effects
Catt and Kaufer, 1998	2	NR	Donepezil	Improved; somnolence and psychosis	None
Shea <i>et al.</i> , 1998	9	12	Donepezil	Improved; cognition* and visual hallucinations	Worse EPS
Lancetot <i>et al.</i> , 2000	7	8	Donepezil	Improved; cognition* and BPSD	NR

Edwards <i>et al.</i> , 2004	25	24	Galantamine	Improved; BPSD	GI

*Mini-Mental state score

**Extended Mini-Mental state score

BPSD, behavioural and psychological symptoms of dementia; GI, gastrointestinal symptoms; NR, not reported; EPS, extrapyramidal symptoms

hypersomnolence and psychotic features in two clinically diagnosed cases treated with donepezil (dose not stated for either case). These beneficial effects persisted in both cases at 6 months follow up. MacLean *et al.* (2001) reported that seven out of the eight cases at baseline had sleep disruption (some of which clinically resembled RBD), six of these seven cases improved with rivastigmine and their neuropsychiatric symptoms (NPI scores) also improved. One recent study (Onofrj *et al.*, 2003) found beneficial effects of donepezil on fluctuating cognition in dementia. Similar beneficial effects on neuropsychiatric symptoms are reported in a number of case series of PD with dementia (PDD) treated with ChEIs (Reading *et al.*, 2001; Aarsland *et al.*, 2002; Bullock and Cameron, 2002; Giladi *et al.*, 2003; Leroi *et al.*, 2004).

As with many drug therapies trial doses often have to be modified when used in clinical practice. Some DLB cases clinically diagnosed who are unable (because of adverse effects, predominantly severe nausea and vomiting) to tolerate full dose rivastigmine 6–12 mg/day in divided doses have benefited from low dose therapy (1.5 mg b.i.d.). This dose level has successfully stopped troublesome visual hallucinations and improved attention in one case in South Manchester who was unresponsive to any other empirical treatment. In clinical practice slow titration of the ChEIs enhances tolerability. A diagnosis of either DLB or PDD were predictive of response to ChEIs in a study of routine clinical practice (Pakrasi *et al.*, 2003) and Minett *et al.* (2003) showed the benefit of donepezil in both DLB and PDD. Of importance was their observation that sudden withdrawal of the drug was usually detrimental.

Other putative therapeutic agents aimed at enhancing cholinergic function in DLB are muscarinic agonists (Harrison and McKeith, 1995) and nicotinic agonists (Perry and Perry, 1996). Xanomeline, an MI muscarinic receptor agonist, has been the subject of a controlled trial in AD. Whilst significant improvements in both cognitive function and behavioural abnormalities were found, in oral form the drug is poorly tolerated (Bodick *et al.*, 1997). Trials of transdermal administration of xanomeline are currently under way.

Loss of nicotinic receptors has been described in both AD and PD (Newhouse *et al.*, 1997). Two trials of transdermal administration of nicotine in AD found no improvement in cognitive function, though both were of short duration

(up to 4 weeks) (Wilson *et al.*, 1995; Snaedal *et al.*, 1996). Sahakian *et al.* (1989) reported improvement of attention in AD patients treated with nicotine and nicotinic agonists improve motor function and arousal in PD (Fagerstrom *et al.*, 1994). Sagar *et al.* (1996) suggested that nicotinic agonists may be an alternative to L-dopa for the treatment of DLB.

50.2.1.2 DOPAMINERGIC THERAPIES

Although dopamine levels are reduced in post-mortem studies in DLB (Perry *et al.*, 1990) and CSF homovanillic acid levels are reduced in autopsy-confirmed cases of DLB (Weiner *et al.*, 1996), there has been little systematic enquiry into the effects of L-dopa therapy in DLB. Some early studies found little or no L-dopa response in those who were treated (Hansen *et al.*, 1990; Perry *et al.*, 1990; Mark *et al.*, 1992).

Other early studies reported a variable response (Byrne *et al.*, 1989; Gibb *et al.*, 1989; Kosaka 1990). In eight autopsy diagnosed cases of DLB reported by Louis *et al.* (1995) four had been treated with L-dopa during life and all responded. In nine pure DLB cases described by Hely *et al.* (1996) six had received L-dopa. In four cases there was response and in two cases little or no response. In post-mortem diagnosed cases of DLB (Lippa *et al.*, 1994), three of six with prominent motor symptoms had responded to L-dopa or bztropine with no apparent worsening of mental state. Of 10 clinically diagnosed cases of DLB (Geroldi *et al.*, 1997), eight received L-dopa (or other antiparkinsonian therapy). Six showed a moderate to good response with no or only mild adverse effects. In clinically diagnosed cases of DLB reported by Gnanalingham *et al.* (1997), 12 of 15 received L-dopa and all responded to treatment. The case of DLB reported by Kato *et al.* (2002) showed improvement in motor and psychotic symptoms when treated with both L-dopa (300–750 mg/day) and risperidone (1 mg/day).

One small open trial of L-dopa in DLB has been reported (Williams *et al.*, 1993). Five cases who fulfilled clinical criteria for DLB (Byrne *et al.*, 1991) were longitudinally assessed in terms of motor function, cognitive function and activities of daily living (ADL), during an open trial of L-dopa and selegiline. The dose of L-dopa (with carbidopa) was commenced at a low level and slowly titrated upwards to reach

best response (defined as a 2-week plateau in motor response). Three cases showed considerable improvement in motor function and two cases modest improvement. In no case was there an adverse effect on mental state.

Acute confusional states (delirium) and other adverse effects are not uncommon with L-dopa therapy. This may (together with the perception that parkinsonian symptoms are atypical or mild and not so responsive to treatment) lead to a lack of enthusiasm for using these drugs in DLB. In my clinical experience, and as Williams *et al.* (1993) have shown, some cases with DLB may benefit from L-dopa therapy. A pragmatic strategy is to start with low doses and titrate upwards having made a careful record of the mental state (non-cognitive and cognitive features) and the range of fluctuation in symptoms both before and during treatment. Only then can one assess whether the treatment is beneficial or harmful. This pragmatic approach has been advocated by others (McKeith *et al.*, 1995a; Mosimann and McKeith, 2003). Another strategy to treat motor symptoms in DLB has been beneficial in one reported case (Moutoussis and Orrell, 1996). This case fulfilled International Consensus Criteria (McKeith *et al.*, 1996) for DLB. Severe rigidity was 'markedly improved' by using baclofen 15 mg t.i.d., a γ -aminobutyric acid (GABA) mimetic. However, baclofen was found to be ineffective in treating a severe case of neuroleptic sensitivity in DLB (McKeith *et al.*, 1992).

50.2.1.3 OTHER TREATMENTS FOR NEUROPSYCHIATRIC SYMPTOMS

Psychiatric symptoms especially visual hallucinations are common and troublesome in DLB. The Newcastle group were the first to draw attention to the phenomenon of neuroleptic sensitivity in DLB (McKeith *et al.*, 1992). They noted a high rate of adverse responses (over 50 per cent of which were severe) in 16 of 20 autopsy-confirmed DLB cases. In contrast, only one of 21 AD cases showed a severe adverse reaction. The nature of the adverse response comprised worsening motor function, aggravation or precipitation of cognitive dysfunction or non-cognitive features and drowsiness, together with some features suggestive of neuroleptic malignant syndrome (NMS) with fever, generalized rigidity and raised serum creatinine kinase. In some cases the neuroleptic sensitivity response was life-threatening. Survival analysis of the seven cases with severe reactions showed increased mortality compared with those with no or mild neuroleptic sensitivity.

The most recent report from the same group (Ballard *et al.*, 1998) is of 80 longitudinally assessed autopsy-confirmed cases (40 AD, 40 DLB, matched for age and sex). Severe neuroleptic sensitivity only occurred in DLB and was seen in 29 per cent cases, in all instances occurring within 2 weeks of a new neuroleptic prescription or a dose change. In this series 47 per cent of the neuroleptics were the newer, atypical compounds compared with 16 per cent in the 1992 series (McKeith *et al.*, 1992). Although neuroleptic sensitivity is not an inevitable consequence of neuroleptic medication in DLB, it is certainly

common and commonly severe. Gnanalingham *et al.* (1997) found comparable rates of neuroleptic sensitivity, 33 per cent, in their clinical series though none was severe. This may have been related to the low doses of neuroleptics used. Of concern is the fact that no features have yet been identified that will distinguish those cases of DLB likely to develop neuroleptic sensitivity. Ballard *et al.* (1998) found no predictive value of age, sex, severity or clinical profile. Furthermore, of the six cases with severe reactions, four were on novel or atypical neuroleptics and all were on low doses. Two of these six cases died within 2 weeks of the prescription. The mechanism by which traditional antipsychotics induce neuroleptic sensitivity is not completely understood, Piggot *et al.* (1994) suggest it is due to a failure to up-regulate D₂ receptors. It is possible that other mechanisms may be involved with the atypical antipsychotics.

Adverse effects of neuroleptics are not confined to DLB. McShane *et al.* (1997), in a prospective clinical study of 71 people with dementia initially living at home who were followed to necropsy, found that the mean decline in cognitive score was twice as great in the 16 patients treated with neuroleptics compared with those who were not medicated. Forty-two of these subjects have undergone necropsy. Cortical Lewy body pathology did not make an independent contribution to more rapid decline. Those observations have been confirmed by Holmes *et al.* (1997) who studied 135 AD cases of whom 23 subjects took neuroleptics and 112 did not. Those who did had a significantly greater rate of cognitive decline than those who did not. They also found that apolipoprotein E ϵ 4 allele carriers were most sensitive to the effects of neuroleptics.

Atypical neuroleptics have been reported as effective in treating psychotic symptoms in DLB. Risperidone has been used in DLB with benefit (remission of psychotic features) (Lee *et al.*, 1994; Allen *et al.*, 1995; Shiwach and Woods 1998; Kato *et al.*, 2002) However, adverse reactions including neuroleptic sensitivity are increasingly reported (McKeith *et al.*, 1995b; Ballard *et al.*, 1998; Morikawa and Kishimoto 2002). Although the case reported by Shiwach and Woods (1998) benefited from risperidone it was in an unusual way – this patient had severe withdrawal bruxism following cessation of traditional antipsychotic medication, which was reversed by risperidone. In some cases clozapine may be beneficial in treating psychotic symptoms in DLB (Ableksov and Tordahl, 1993; Chacko *et al.*, 1993) but others report worsening of cognition and behaviour with clozapine treatment in DLB (Burke *et al.*, 1998).

Olanzapine and quetiapine show similarly variable results in the treatment of DLB. In the case series reported by Walker *et al.* (1999), three of the eight cases were unable to tolerate even the lowest dose (2.5 mg/day); three showed minimal benefit and only two showed improvement in neuropsychiatric symptoms. In contrast, Cummings *et al.* (2002) found that olanzapine, 5–10 mg/day improved psychotic symptoms in DLB without worsening parkinsonism. Adverse effects (somnolence or orthostatic hypotension, worsening of parkinsonian

symptoms) were reported in around 30 per cent of patients with DLB treated with quetiapine in two recent small case series (Fernandez *et al.*, 2002; Takahashi *et al.*, 2003). In both of these studies, those subjects who could tolerate the drug showed benefit in their troublesome psychotic symptoms.

Other empirical treatments of psychotic symptoms in DLB include chlormethiazole and carbamazepine. The use of chlormethiazole was suggested because of its effectiveness in delirium tremens and because some patients with DLB have delirious-like episodes. In addition there is some evidence that chlormethiazole has neuroprotective effects (Cross *et al.*, 1991; Baldwin *et al.*, 1993; Vaishnav and Lutsep, 2002). In clinical practice it may reduce or obviate visual hallucinations and is helpful in sleep disorders in DLB (McKeith *et al.*, 1992; Byrne, 1995, 1997). Carbamazepine, an antiepileptic drug with antidepressant actions, has also been used empirically to treat psychotic features in DLB. Lebert *et al.* (1996) found great benefit in two cases of DLB treated with 100–400 mg/day. Both chlormethiazole and carbamazepine are GABAergic agents. GABA has been suggested as an important transmitter in delirium (Ross *et al.*, 1991), and GABA has an important function in motor control.

50.3 TREATMENT OF SLEEP DISORDERS

Disturbance of sleep is common in dementia but have only recently been especially associated with DLB (Byrne, 1996; Grace *et al.*, 2000; MacLean *et al.*, 2001). Some case reports (Schenck *et al.*, 1997; Turner *et al.*, 1997) linked DLB with rapid eye movement (REM) sleep behaviour disorder (RBD). RBD is a 'parasomnia defined by intermittent loss of electromyographic atonia during REM sleep with emergence of complex and vigorous behaviours' (ICSD 1997; Schenck *et al.*, 1997). Behaviours include kicking, punching and leaping from the bed. Boeve *et al.* (1998) found 37 patients with dementia and RBD confirmed by polysomnography; 34 per cent were male and 54 per cent had signs of parkinsonism; 92 per cent (32 cases) met criteria (McKeith *et al.*, 1996) for DLB. Three patients underwent necropsy and all had limbic Lewy bodies with or without cortical Lewy bodies. More recent studies have suggested a specific relationship between RBD and the synucleinopathies (Olson *et al.*, 2000; Boeve *et al.*, 2001; MacLean *et al.*, 2001) and, except in multisystem atrophy (MSA) the greater preponderance of male subjects (Olson *et al.*, 2000); RBD may precede the onset of the full clinical syndrome of a synucleinopathy by many years (Boeve *et al.*, 2001).

RBD can be successfully treated with clonazepam or desimipramine (Schenck *et al.*, 1987; Massironi *et al.*, 2003b). Potential problems with clonazepam (at a dose of 0.5 mg) are day-time sedation and loss of efficacy over time. In a study by Schenck *et al.* (1987), five patients did not experience these effects. Clonazepam is not always successful in treating RBD in established DLB (MacLean *et al.*, 2001). Boeve *et al.* (2003b) report the use of melatonin (3–12 mg) in 14 people with

RBD (including seven with a diagnosis of DLB). Eight of the 14 showed persistent benefit beyond 12 months of melatonin therapy. There is one case report of the successful treatment of RBD in DLB with L-dopa (Yamauchi *et al.*, 2003). Hypersomnolence, which improved on donepezil, has also been reported in DLB (Catt and Kaufer, 1998). There is one case report of improvement in 'sundowning' (increased restlessness and agitation in dementia in the evening) in DLB with treatment with donepezil (Skjerve and Nygaard, 2000).

50.4 OTHER PUTATIVE TREATMENTS

A number of other putative treatments for DLB have been suggested. Ondansetron, a selective 5HT₃ antagonist, has been suggested as a treatment for DLB because of the relative serotonergic overactivity in the condition (Perry *et al.*, 1993; Sagar *et al.*, 1996). In PD, ondansetron at a dose of 12–24 mg daily reduced psychotic symptoms in the majority of 16 patients with severe disease in an open trial (Zoldan *et al.*, 1993). Benzodiazepines have been reported as of use in the management of anxiety and restlessness in DLB (Lennox, 1992; McKeith *et al.*, 1996). Neurotrophins, because of their neuroprotective effect, have been postulated as a therapy for AD and other neurodegenerative disorders. However, little is known about the role of neurotrophic factors in DLB (Wilcock, 1996).

50.5 CONCLUSION

The severity, persistence and adverse effects of the neuropsychiatric symptoms of DLB and their distressing consequences for both the person with dementia and for their carers, are familiar to all practising clinicians. The Committee on Safety of Medicines (CSM) recommendations (Committee on Safety of Medicines, 1994, and as noted by Ballard *et al.*, 1998) to use caution in prescribing neuroleptic medication in dementia is warranted given the accumulating evidence cited above. However, it is unfortunate that, at least in the UK, a risk aversion culture can dictate clinical practice at the expense of the very real and severe suffering of people with DLB. The recent prohibition of the prescription of risperidone and olanzapine for the treatment of behavioural and psychological symptoms in dementia because of increased stroke risk issued by the CSM in 2004, in the absence of an adequate risk/benefit calculation or of suggested alternative treatments, leaves clinicians to face the challenge of treating DLB deprived of an important part of their therapeutic armamentarium.

Whilst many of the treatments described in this chapter are empirical, some show great promise at least in producing symptomatic relief. Greater understanding of the neuropathological mechanisms underlying DLB will lead to treatments targeted at basic processes. Until that time the treatment of DLB presents great challenges to the physician in which art as much as science still plays a part.

Cognitive impairment and dementia in Parkinson's disease

DAG AARSLAND AND CARMEN JANVIN

51.1 Mild cognitive impairment in Parkinson's disease	657	51.4 Conclusions	661
51.2 Dementia	658	References	661
51.3 Treatment	660		

Parkinson's disease (PD) is a common neurodegenerative disorder affecting about 1.5 per cent of people aged 65 or older (de Rijk *et al.*, 1997). PD is defined pathologically as cell loss in the pigmented dopaminergic cells of substantia nigra, pars compacta and synuclein pathology (Lewy neurites and Lewy bodies) in the surviving cells. In addition, cholinergic fore-brain nuclei and other brain stem nuclei including the serotonergic raphe nuclei and the noradrenergic locus caeruleus, are usually affected. The topographical progression subsequently involves the anteromedial temporal mesocortex, including the transentorhinal region, and reaches into adjoining high-order sensory association areas and important limbic structures such as amygdalae and hippocampus (Braak *et al.*, 2003; Jellinger, 2003a). In addition, amyloid plaques and even neurofibrillary tangles, are found in most cases at autopsy (Mattila *et al.*, 1999; Jellinger, 2002). The cardinal clinical features of PD are resting tremor, bradykinesia, rigidity and postural abnormalities. However, owing to the wide distribution of neurodegeneration, it is not surprising that a wide range of non-motor symptoms occur as well, including neuropsychiatric symptoms and autonomic dysfunction.

The treatment of PD involves dopamine replacement therapy with L-dopa, and several dopamine agonists including the selective dopamine D3 receptor agonists ropinirole and pramipexole. In addition, the monoamine oxidase inhibitor selegiline with a potential neuroprotective effect may slow disease progression. The use of anticholinergic agents has declined drastically owing to concerns relating to their risk of cognitive impairment and delirium, particularly in the elderly. Deep cerebral stimulation with implantation of electrodes can be very helpful for selected patients. A wide range of behavioural side effects can occur during drug and surgical treatments.

During the last decade a considerable literature has shown that cognitive impairment is common even in early PD, and that as the disease progresses, a substantial proportion develop dementia (Emre, 2003). In addition, other neuropsychiatric symptoms, such as visual hallucinations, depression and apathy, are also common (Aarsland *et al.*, 1999). It is thus increasingly recognized that PD is a neuropsychiatric disorder and not merely a movement disorder. Independent of the motor symptoms of PD, dementia and other neuropsychiatric symptoms affect quality of life, contribute to caregiver distress and increased risk of nursing home placement, and is associated with more psychiatric symptoms such as depression and hallucinations, higher mortality and functional disability, and higher risk for drug toxicity. This chapter will discuss the epidemiology, pathophysiologic mechanism, clinical presentation and management of cognitive impairment and dementia in patients with PD.

51.1 MILD COGNITIVE IMPAIRMENT IN PARKINSON'S DISEASE

Cognitive impairment is present even at the earliest stages of PD. The prevalence of subjects with parkinsonism and mild cognitive impairment in the community is about 10 per cent (Waite *et al.*, 2001), and cognitive impairment may be present even in young patients (Wermuth *et al.*, 1996). In a series of 91 PD patients with a mean duration of PD of <2 years, impairment on a range of neuropsychological tests was found in 16 per cent of patients (Reid *et al.*, 1996). Similarly, in a study of 10 high-functioning PD patients, identified on the basis of exceptional

professional distinction who continued to function successfully in leadership positions, significant impairments on tests of episodic memory and visuospatial function were reported (Mohr *et al.*, 1990). In one of the few community-based studies, more than 50 per cent of the non-demented PD subjects had some form of cognitive impairment (Janvin *et al.*, 2003).

The cognitive profile in early PD varies. Executive impairment, including working memory and attention-shift, is the earliest cognitive manifestation in PD, but visuospatial functions, and even memory, may be impaired in some patients as well (Dubois and Pillon, 1997). In a study of 42 PD patients with mild cognitive impairment, 20 per cent exhibited predominantly memory deficits, 30 per cent a dominant executive impairment, whereas 50 per cent had a more global cognitive impairment (Janvin *et al.*, 2003). With advancing PD, there is an increase in severity and broadening of cognitive impairment (Owen *et al.*, 1992). Whereas mildly impaired subjects have reduced storage of new information and visuospatial impairment, reduced storage of old material was evident only in those with a more marked impairment (Huber *et al.*, 1990). Although variations occur, the cognitive impairment in early PD is of a fronto-subcortical type, with the superimposition of deficits typically associated with cortical dementia evolving later in course (Reid *et al.*, 1996; Aarsland *et al.*, 2003c).

51.1.1 Mechanisms underlying mild cognitive impairment in PD

The heterogeneous cognitive deficits in PD may reflect differing forms of neuropathological involvement. Executive impairment is related to the dopaminergic deficits, caused by either disruption of nigrostriatal circuitry with altered outflow of the caudate nuclei to frontal cortex via thalamus (Rinne *et al.*, 2000; Lewis *et al.*, 2003) or diminished dopamine activity in the frontal projections consequent to degeneration of mesocortical projections (Mattay *et al.*, 2002). This hypothesis is supported by the worsening of executive functioning, but not memory, after withdrawal of L-dopa (Lange *et al.*, 1995). Although the exact contribution of non-dopaminergic lesions to the cognitive impairments in PD is not known, there is some evidence linking the cortical noradrenergic system to extradimensional shift performance, whereas visual memory may be dependent on acetylcholine rather than DA (Robbins *et al.*, 2003).

The more global cognitive impairment in later disease stages suggests that cortical regions are becoming involved as well. In a study using single photon emission computed tomography, non-demented, but cognitively impaired PD patients with decrements in multiple spheres of cognition, had diminished temporal perfusion relative to controls. A differential pattern of relationships between cortical perfusion and cognitive functions was observed, with temporal and parietal perfusion showing relationships to global cognitive impairment, while dorsolateral frontal perfusion was related to executive impairment (Jagust *et al.*, 1992). A positron emission tomography study revealed that non-demented PD patients had

widespread cortical glucose hypometabolism, involving mainly frontal, but also left temporal and parietal regions, compared with more a more marked and global reduction, including severe bilateral temporoparietal defects, in PD patients with dementia (Peppard *et al.*, 1992).

Thus, in early PD, heterogeneous cognitive impairments exist, ranging from executive dysfunction caused by degeneration of dopaminergic fronto-subcortical circuitry to a memory dominant impairment possibly related to cholinergic deficits. At least in some patients, the selective cognitive impairment progresses to a more global impairment secondary to involvement of medial temporal and parietal cortices. The aetiology of the cortical involvement is not yet clear, and Alzheimer-like changes, synuclein degeneration and cerebrovascular pathology may contribute.

51.1.2 Course of mild cognitive impairment in PD

Few prospective studies of mild cognitive impairment in PD exist. Overall, the annual decline on the Mini-Mental State Examination (MMSE) in PD is 1 point, but with wide interindividual variations (Aarsland *et al.*, 2004). Mild executive and memory impairments are predictors of subsequent dementia in PD, independent of age and stage of PD (Levy *et al.*, 2002a). In non-PD populations with mild cognitive impairment (MCI), the annual progression to dementia is about 15 per cent (Petersen *et al.*, 2001). In PD, this question has not been subject to systematic research yet. We reassessed 38 PD patients with MCI (six with amnesic, 17 with single non-memory, and 15 with multiple domains MCI) after 4 years, and found that 62 per cent had developed dementia, which is consistent with the conversion rate to dementia in non-PD MCI patients. The proportion that progressed to dementia did not differ between the three different MCI groups, but was higher than among cognitively intact patients (20 per cent) ($P < 0.05$) (unpublished results).

51.2 DEMENTIA

51.2.1 Epidemiology

51.2.1.1 CROSS-SECTIONAL STUDIES

In addition to the mild cognitive impairment discussed above, dementia develops in a considerable proportion of patients with a diagnosis of PD. Wide variation in prevalence estimates of dementia in PD have been reported, based on differences in selection and number of patients studied, diagnostic criteria for PD, assessment of cognition and diagnostic criteria for dementia. Studies using community-based samples of more than 100 patients, standardized cognitive assessment and DSM-III-R criteria for dementia have yielded prevalences ranging from 23 to 41 per cent (Levy and Marder, 2003).

Since dementia is associated with increased mortality in PD (Levy *et al.*, 2002c); prevalence studies underestimate true frequency of dementia in PD, and longitudinal studies are thus required to accurately describe the frequency of dementia in PD.

51.2.1.2 LONGITUDINAL STUDIES

Few studies of the incidence of dementia in PD populations exist. Estimates vary from 42.6 (Hughes *et al.*, 2000) to 112.5 (Marder *et al.*, 1995) per 1000 patient years. In the two community-based studies, the incidence was 95.3 (Aarsland *et al.*, 2001) and 112.5 (Marder *et al.*, 1995), indicating that about 10 per cent of PD patients develop dementia per year. The risk for developing dementia in PD is nearly six times higher than in non-PD subjects (Aarsland *et al.*, 2001). Although little is known regarding the life-time risk of developing dementia in patients with a diagnosis of PD, the available evidence suggests that the risk is high. Only one study to date has prospectively followed *de novo* PD patients to assess the frequency of dementia. After 5 years a cumulative prevalence of dementia of 36 per cent could be estimated from the data presented (Reid *et al.*, 1996). We performed an 8-year prospective study of a community-based sample of 224 PD patients with a mean duration of disease of 9 years at baseline: 122 subjects received a diagnosis of dementia at baseline or at subsequent evaluations. After controlling for attrition due to death, the 8-year cumulative prevalence of dementia was calculated to be 78 per cent (Aarsland *et al.*, 2003a). Thus, it is clear that a substantial proportion of patients with PD develop dementia, which is usually diagnosed for the first time >10 years after the diagnosis of PD (Hughes *et al.*, 2000; Aarsland *et al.*, 2003a).

51.2.1.3 RISK FACTORS FOR DEMENTIA

Several factors have been reported to be associated with dementia in PD, including male sex, low education, depression, hallucinations, age, age at onset, mild cognitive impairment, family history of dementia and genetic factors (Emre, 2003). However, prospective studies that use multivariate statistical approach indicate that age, advanced parkinsonism and mild cognitive impairment are predictors of dementia in PD (Hughes *et al.*, 2000; Levy *et al.*, 2002b; Aarsland *et al.*, 2003a). With regard to parkinsonian symptoms, rigidity and symptoms mediated mainly by non-dopaminergic systems, such as speech, gait and postural disorders, are particularly related to subsequent development of dementia, whereas patients with a tremor-dominant pattern have a lower risk (Levy *et al.*, 2000). Although some studies suggest that patients with late onset of PD have a higher risk of dementia, the evidence suggests that it is age, and not age at onset, that is associated with incident dementia in PD (Hughes *et al.*, 2000; Levy *et al.*, 2002b; Aarsland *et al.*, 2003a). The relationship with age and severity of parkinsonism seems to be related to their combined effect rather than separate effects (Levy *et al.*, 2002b).

51.2.1.4 GENETICS AND DEMENTIA IN PD

Although PD was long thought of as a non-genetic disorder, over the past few years, several genes for the disorder have been cloned, including α -synuclein and parkin, both involved in the ubiquitin-dependent protein degradation pathway (Gwinn-Hardy, 2002). The relationship of these genes to dementia is not clear, but there are mutation carriers who have both PD and PD with dementia. (Muentert *et al.*, 1998). Several studies have explored the effect of apolipoprotein (ApoE) polymorphism, a risk factor for AD, on the risk for PD and dementia, with conflicting results. Increased risk of PD and, in particular, PD with dementia, in carriers of the ApoE ϵ 2 allele has been reported (Harhangi *et al.*, 2000). An association between ApoE ϵ 4 allele and Alzheimer pathology in PD patients has also been reported (Mattila *et al.*, 2000). Most studies have failed to find an association between ApoE polymorphism and dementia in PD, however.

51.2.2 Diagnosis of dementia in PD

The motor symptoms of PD, such as masked facies, bradykinesia, slow speech and apathy can make the diagnosis of cognitive impairment and dementia difficult, and both over- and underdiagnosis may occur (Litvan *et al.*, 1998). Cognitive rating scales should be used, taking into account the disabilities from motor symptoms. Screening tests such as the MMSE (Folstein *et al.*, 1975) may be employed, although instruments including executive dysfunction, such as the Dementia Rating Scale (Mattis, 1976) and the Cambridge Cognitive Examination (CAMCOG), the cognitive section of CAMDEX (Roth *et al.*, 1986), are more sensitive to the cognitive disorders in PD. Particular care should be taken to distinguish between dementia and confusional states from drug toxicity. There are no generally accepted clinical criteria for the dementia in PD. In research, the use of the dementia criteria of DSM-IV (American Psychiatric Association, 1994) is generally recommended, but it can be difficult to decide whether cognitive impairment adds to the social and occupational impairment caused by the motor symptoms of the disease. In addition to a careful history emphasizing the onset, course, profile and chronology of motor, cognitive and psychiatric symptoms, neuropsychological assessment is useful in the diagnosis of mildly affected cases.

Although subcortical clinical features, such as executive and visuospatial impairment, are typical in mildly impaired cases, some patients with more advanced PD exhibit more cortical features (see above). The cognitive profile is quite similar to the profile observed in DLB, and differs from the profile observed in patients with AD (less memory but more executive impairment) and a pure subcortical dementia such as progressive supranuclear palsy (more memory but less executive impairment) (Aarsland *et al.*, 2003c). A diagnosis of PDD should be made in patients who are diagnosed as PD and develop dementia >1 year later. If dementia develops before or within 1 year after the diagnosis of PD, a diagnosis of DLB

should be made. However, this time-window is rather arbitrary. DLB and PDD overlap both clinically and neuropathologically, and there is debate whether they represent distinct diseases or rather two syndromes on a spectrum of Lewy body diseases.

51.2.2.1 IMAGING

Few studies have explored the dementia of PD using structural imaging techniques. Annual brain volume loss in non-demented PD patients correlated with cognitive decline (Hu *et al.*, 2001). Reduced hippocampal volumes in PD patients have been shown, and in PDD patients, hippocampal volumes were even smaller than in AD patients (Laakso *et al.*, 1996). Preliminary results from studies using modern techniques such as voxel-based morphometry, show volume loss in the temporal and frontal cortices, as well as hippocampus, in PDD compared with non-demented PD patients (Beyer *et al.*, 2003), and frontal and temporal cortical loss in PDD compared with normal controls, indistinguishable from changes in DLB patients (Burton *et al.*, 2003).

As discussed above, functional imaging studies have shown decreases in glucose metabolism of frontal, temporal and parietal cortices in patients with PDD (Peppard *et al.*, 1992; Jagust *et al.*, 1992; Vander Borghet *et al.*, 1997). In addition, and contrary to AD, occipital hyperfusion has been reported (Vander Borghet *et al.*, 1997), even in non-demented subjects (Abe *et al.*, 2003), similar to findings in DLB. Although both structural and functional imaging techniques may assist in the diagnostic work-up of patients with parkinsonism and cognitive impairment, until longitudinal imaging studies with clinicopathological correlation are available, the final diagnosis must be based on the history and clinical examination including routine blood tests.

51.2.3 Mechanisms

The aetiology of dementia in PD is not yet clear. The heterogeneous cognitive profile of dementia in PD, with features of both subcortical and cortical dementia, is consistent with the various neuropathological and neurochemical involvements in PD. Cortical LBs are associated with dementia in PD (Hurtig *et al.*, 2000), although LBs may occur in the cortex of non-demented PD patients (Colosimo *et al.*, 2003). There is also evidence that Alzheimer-like changes contribute to dementia in PD (Jellinger, 2002). In elderly patients, vascular changes may contribute as well (Jellinger, 2003b), although the contribution of vascular factors to dementia in PD is not known. In a recent longitudinal study, an association of dementia with smoking, but not with hypertension or diabetes mellitus, nor with stroke or atrial fibrillation was found (Levy *et al.*, 2002a).

As discussed above, neurochemical changes involving dopamine, noradrenaline and acetylcholine, may influence cognition in PD. In particular, much interest has focused on the relationship between cholinergic deficits and dementia in PDD. Selective loss of cells in the cholinergic nucleus basalis of Meynert and cortical cholinergic losses of similar degrees

as in AD have been reported, and these changes are more pronounced in PD patients with dementia compared with non-demented patients (Whitehouse *et al.*, 1983; Perry *et al.*, 1993; Kuhl *et al.*, 1996; Tiraboschi *et al.*, 2000).

51.3 TREATMENT

No pharmacological agents have been approved for treatment of dementia in PD. There are several pharmacological agents available to treat the various motor and psychiatric manifestations of PD, all of which have the potential to improve one symptom domain at the expense of exacerbating another. The only evidence-based treatment for neuropsychiatric symptoms in PD is the use of clozapine for hallucinations (Goetz, 2002). Non-specific measures such as reviewing and removing drugs that may cause worsening of cognition, such as anticholinergic agents, and treating comorbid conditions, are thus of importance. Informing the patient and family about the risk of progressive worsening of cognitive functioning in addition to motor symptoms are also important.

L-dopa treatment may improve some and impair other cognitive functions (see above), but has probably no effect on dementia. Other drugs frequently prescribed for PD patients may potentially improve cognition. In a placebo-controlled trial, neither selegiline nor vitamin E had a significant effect on cognitive functioning in non-demented PD patients (Kiebertz *et al.*, 1994). An observational study suggested that postmenopausal oestrogen use was protective for the development of dementia within the setting of PD (Marder *et al.*, 1998), but controlled studies supporting this promising result have not been performed.

The cholinergic loss in PDD, an increase of muscarinic receptor binding (Perry *et al.*, 1993) and less neurodegenerative changes in neocortex compared with AD, indicate that cholinergic drugs may be particularly useful in PDD. This hypothesis received support from an early study showing remarkable improvements of cognition, hallucinations and even parkinsonism, during treatment with tacrine (Hutchinson and Fazzini, 1996). Subsequent uncontrolled case series have shown improved cognition in PDD during treatment with the more recently developed cholinesterase inhibitors, i.e. rivastigmine (Reading *et al.*, 2001) and galantamine (Aarsland *et al.*, 2003c), although the improvements were less dramatic than those reported with tacrine. These promising results were supported in one placebo-controlled cross-over trial with donepezil (Aarsland *et al.*, 2002). Since there are clinical, neuropathological and neurochemical similarities between DLB and PDD, the improvement on rivastigmine in a large randomized trial with in DLB patients (McKeith *et al.*, 2000) also supports the usefulness of cholinesterase inhibitors for PDD. Worsening of motor symptoms does occur in some patients, although most patients tolerate the drug well without increasing parkinsonism. A recent large-scale placebo-controlled trial provided strong evidence that the

cholinesterase inhibitor rivastigmine can improve cognition, activities of daily living and neuropsychiatric symptoms in patients with PDD (Emre *et al.*, 2004).

The currently available cholinergic drugs differ in their pharmacodynamic profiles. It is currently not known whether these differences, such as the additional effect on butyryl cholinesterase of rivastigmine and the modulating effect on nicotinic receptors of galantamine, have therapeutic relevance in the treatment of PDD. However, there is evidence that temporal cortex butyrylcholine esterase is associated with cognitive decline in DLB (Perry *et al.*, 2003); nicotine appears to have a beneficial effect on arousal, attention, and processing speed, and may even improve motor symptoms in PD (Rusted *et al.*, 2000), suggesting that these drugs may differ in their clinical effects in PDD. However, clinical trials are necessary to corroborate these hypotheses.

51.4 CONCLUSIONS

Cognitive impairment and dementia are very common in patients with PD, with important clinical consequences for patients and their caregivers. Clinicians need to focus on these and other neuropsychiatric symptoms in addition to the motor symptoms in order to provide optimal care for these patients. The underlying aetiology and the clinical presentation of cognitive impairment in PD are highly variable, and the nosological classification of PDD and its relationship to other dementias, in particular DLB, is not yet clarified. The complex clinical presentation in these frail and elderly individuals poses considerable challenges for the clinical management. Emerging evidence indicates that cholinesterase inhibitors are useful for patients with PDD.

Frontotemporal dementia (FTD) is a focal degenerative disorder of the frontal and anterior temporal lobes, characterized by profound alteration in personality and social conduct and impaired frontal executive functions. The disorder is the most common of a spectrum of clinical syndromes that are associated with frontotemporal lobar degeneration and share a common non-Alzheimer pathology. Other related syndromes include progressive non-fluent aphasia and semantic dementia (Chapter 55). The distinct clinical syndromes reflect the distribution of pathological change within the anterior cerebral hemispheres. FTD involves bilateral and typically symmetrical atrophy of the prefrontal and anterior temporal lobes and the basal ganglia, whereas progressive aphasia involves the perisylvian regions of the left hemisphere and semantic dementia the anterior temporal neocortices.

52.1 HISTORICAL BACKGROUND

The earliest description of a progressive behavioural disorder associated with bilateral frontal lobe atrophy was by Pick (1906). The frontal lobe emphasis was noted in several subsequent reports of focal cerebral atrophy to which Pick's name was ascribed (Schneider, 1927; Lowenberg, 1935; Ferrano and Jervis, 1936; Neumann, 1949). Despite these early studies, by the second half of the twentieth century clinical reports of focal cerebral atrophy had dramatically diminished, reflecting the prevailing wisdom of dementia as a generalized and undifferentiated impairment of mental function.

Attention was revived by longitudinal clinical studies of patients in Lund, Sweden (Gustafson and Risberg, 1974; Gustafson *et al.*, 1977; Gustafson, 1987, 1993) and Manchester, England (Neary *et al.*, 1986, 1987, 1988; Snowden *et al.*, 1996), who showed progressive alteration in personal and interpersonal behaviour in association with atrophy of the frontal and anterior temporal lobes. The histological changes were not uniform. In some brains microvacuolation was the prominent feature, whereas in others there was severe gliosis, sometimes with Pick cells and bodies (Brun, 1987, 1993; Mann and South, 1993; Mann *et al.*, 1993). In some brains motor neurone disease-type pathological changes were present. The findings led to the publication of a consensus statement outlining the clinical and pathological characteristics (Lund and Manchester groups, 1994). The term frontotemporal dementia was introduced as a clinical descriptor of the behavioural syndrome, to avoid the pathological implications of the term Pick's disease and implicit assumptions of the aetiological equivalence of underlying histologies.

Reports of FTD have proliferated (e.g. Filley *et al.*, 1994; Frisoni *et al.*, 1995; Jagust *et al.*, 1989; Knopman *et al.*, 1990; Knopman, 1993; Miller *et al.*, 1991, 1993; Starkstein *et al.*, 1994; Stevens *et al.*, 1998) and more detailed consensus diagnostic criteria have been produced (Neary *et al.*, 1998) (Box 52.1). Moreover, in recognition of the need to draw the attention of non-specialists such as general practitioners to the existence of FTD, guidelines have been produced to aid its identification (McKhann *et al.*, 2001).

Box 52.1 *Clinical diagnostic features of FTD***I Core diagnostic features**

- Insidious onset and gradual progression
- Early decline in social interpersonal conduct
- Early impairment in regulation of personal conduct
- Early emotional blunting
- Early loss of insight

II Supportive diagnostic features**A. Behavioural disorder**

- Decline in personal hygiene and grooming
- Mental rigidity and inflexibility
- Distractibility and impersistence
- Hyperorality and dietary changes
- Perseverative and stereotyped behaviour
- Utilization behaviour

B. Speech and language

- Altered speech output
 - Spontaneity and economy of speech
 - Press of speech
- Stereotypy of speech
- Echolalia
 - Perseveration
 - Mutism

C. Physical signs

- Primitive reflexes
- Incontinence
- Akinesia, rigidity and tremor
- Low and labile blood pressure

D. Investigations

- Neuropsychology: significant impairment on frontal lobe tests in the absence of severe amnesia, aphasia or perceptuospatial disorder
- Electroencephalography: normal on conventional EEG despite clinically evident dementia
- Brain imaging (structural and/or functional): predominant frontal and/or anterior temporal abnormality

Adapted from Neary *et al.* (frontotemporal lobar degeneration. A consensus on clinical diagnostic criteria. *Neurology* [1998] 51: 1546–1554)

Box 52.2 *Demographic features in FTD*

- Usual onset 45–65 years
- Earliest recorded onset 21 years
- Equal sex incidence
- Mean illness duration 8 years, range 2–20 years
- Family history in up to 50%
- No known geographical or environmental influences

in a first-degree relative is identified in about half of patients indicating a higher familial incidence than in Alzheimer's disease. The pattern of inheritance in some families with FTD clearly indicates the action of an autosomal dominant gene, whereas in other familial cases the mode of inheritance is less clearly defined. No environmental determinants have been identified. Patients come from all social classes and a wide range of occupational backgrounds and from different parts of the world. It has been estimated by some that FTD accounts for approximately a quarter of cases of early-onset degenerative dementia (Brun, 1987; Neary *et al.*, 1988), although other studies (Ratnavalli *et al.*, 2002) suggest the proportion may be even higher. The estimated prevalence in the Netherlands has been reported to be 3.6 per 100 000 (Rosso *et al.*, 2003) at age 50–59, increasing to 9.4 per 100 000 at age 60–69 and reducing to 3.8 per 100 000 at 70–79 years. A higher prevalence of 15 per 100 000 aged 45–64 years has been reported in the Cambridge area of the United Kingdom (Ratnavalli *et al.*, 2002). Differences in prevalence estimates may in part reflect natural geographical variation arising from the cluster effects that are common in highly familial disorders.

52.3 BEHAVIOUR AND AFFECT**52.3.1 Personal and social**

The overriding presenting feature is of breakdown in the patient's personal and interpersonal conduct. Patients neglect personal responsibilities, leading to mismanagement of domestic and financial affairs and impaired occupational performance. Medical referral may occur following demotion or dismissal from work. Patients show a decline in their manners, social graces and decorum. Some patients are purposelessly overactive and may show frank social disinhibition, talking to strangers, or laughing or singing inappropriately. They may make social *faux-pas* or breaches of etiquette, such as drinking from the wine bottle in a restaurant. They may pace restlessly and wander. Other patients are apathetic and avolitional. In all cases there is a notable lack of insight into the mental changes.

Consistent with their general lack of concern patients may neglect personal hygiene and need to be encouraged, if not forced, to wash and change their clothes. Patients cease to show interest in their personal appearance. The tendency to put on

52.2 DEMOGRAPHIC FEATURES

Onset of symptoms is most commonly in the middle years of life (Box 52.2). However, there is a wide range. FTD can occur both in the elderly and in youth, the youngest recorded onset being 21 years (Lowenberg *et al.*, 1939; Snowden *et al.*, 2004). There is an equal incidence for men and women. The length of illness is variable. Very short duration is typically associated with the additional presence of motor neurone disease (MND) (see Section 52.9, p. 674). A family history of dementia

the same clothes each day is one sign of patients' increasing inflexibility. Patients may adopt a fixed daily routine. They may be intransigent, having difficulty seeing another's point of view.

Behavioural disinhibition is commonly associated with overt distractibility and lack of attention to tasks. Both disinhibited and apathetic patients may show economy of effort and lack of persistence, so often abandon tasks unfinished.

52.3.2 Eating and oral behaviours

Changes in eating and drinking patterns are common, and may be an early symptom. Patients often become gluttonous, eating indiscriminately, cramming food and stealing food from the plates of others. Relatives may have to ration food to prevent obesity. Patients often develop a preference for sweet foods, which they may seek out and hoard. Excessive and indiscriminate eating may be superseded later in the disease by selective food fads, usually involving the favoured sweet foods. Hyperorality (Kluver–Bucy syndrome), involving the mouthing of inedible objects, is observed in some patients, although typically only in the late stages of disease. In some patients excessive eating or drinking appears attributable to gluttony, whereas in others it appears to be part of more general stimulus-boundedness and environmental dependency. Repetitive eating and drinking may constitute one aspect of utilization phenomena (Lhermitte, 1983), the tendency to use objects within reach, regardless of contextual inappropriateness (e.g. continued drinking from an empty cup; putting on another person's glasses on top of one's own).

52.3.3 Sleeping and sexual behaviour

Increased somnolence may occur, particularly in apathetic patients. Altered sexual behaviour is common. Usually this constitutes a loss of libido, particularly in apathetic, inert patients. Less commonly patients show some sexual disinhibition, making inappropriate sexual advances. This may reasonably be construed as secondary to the patients' behavioural disinhibition and lack of awareness of social mores. A smaller minority of patients do, however, exhibit a preoccupation with sex. Such patients may make increased sexual demands on their partner or acquire an interest in mild sexual perversions.

52.3.4 Repetitive behaviours, compulsions and rituals

Repetitive, stereotyped behaviours are common in FTD. They take different forms. They may comprise simple motor mannerisms, such as hand rubbing, foot tapping or grunting. Conversely they may constitute complex behavioural routines. Patients may clock-watch, carrying out a particular activity at precisely the same time each day. They may pace and wander a fixed route. They may produce verbal stereotypies, comprising a favoured word or phrase or a complete

anecdote or repertoire, repeated verbatim on each occasion. They may repeatedly sing the same ditty, dance the same steps, produce the same puns, or clap a favoured rhythm.

Hygiene and dress and toileting may themselves be the source of stereotyped behaviours: the patient may carry out a set sequence of activities at precisely the same time each day. Occasionally patients adopt superstitious rituals such as not walking on the gaps between paving stones. Although many repetitive behaviours have a compulsive quality, they are not associated with the feelings of anxiety and relief from anxiety that are characteristic of obsessional–compulsive disorder. However, if rituals are interrupted or prevented by others, then irritability or aggression may be provoked.

One striking form of repetitive behaviour, present in a minority of patients, is that of forced-utilization. Objects that are within the patient's reach elicit the motor actions appropriate to those objects, even though the action may be contextually inappropriate: an empty cup elicits a drinking action; a comb results in the patient combing his or her hair. If the object remains in view the action may be repeated over and over again.

52.3.5 Affect

The onset of FTD is insidious and may sometimes be heralded by affective changes that include depression, anxiety and excessive sentimentality, as well as hypochondriasis and somatic preoccupation (Lund and Manchester groups, 1994). In some cases discrete episodes of mood disturbance, which can be treated effectively, may occur several months or even years before the emergence of gross behavioural change. Commonly, however, subtle mood disturbances are the precursor to the major alterations in personality and social conduct and profound blunting of affect that characterize the disease.

A salient feature of FTD is emotional unconcern. Affect is typically bland, shallow and indifferent. Patients show no frustration or distress at their own altered social and occupational circumstances. They demonstrate a lack of feelings of empathy, sympathy or compassion towards others and are described as selfish and self-centred. Indeed, relatives may be alerted to the fact that something is wrong by the patient's lack of demonstration of grief on the death of a close relative or callous response to a tragic incident. Patients no longer exhibit social emotions of shame or embarrassment, and may show a lack of personal modesty. Disinhibited patients may display a fatuous jocularity.

Loss of appropriate emotional responses may include a failure to respond to painful stimuli. Patients may respond with indifference to scalds and burns. However, sometimes the converse is seen: patients respond in an exaggerated, melodramatic way to neutral tactile stimuli, such as light touch. Paradoxically the two may co-occur in the same patient. The patient tolerates the pain of a needle without comment, yet withdraws in apparent agony as a person brushes past.

52.4 PHYSICAL FINDINGS

52.4.1 General physical examination

Patients typically are physically well. However, low and labile blood pressure may be noted. Incontinence is often an early feature.

52.4.2 Neurological signs

Typical patients remain remarkably free from neurological signs, even in the presence of gross behavioural and cognitive change. Signs generally are limited to the emergence of primitive reflexes, such as grasping, pouting, sucking and extensor plantar responses. Clinical signs of striatal disorder only become evident, in some cases, after many years, when akinesia, rigidity and tremor appear. The extrapyramidal signs reflect breakdowns in nigrostriatal dopaminergic function (Rinne *et al.*, 2002). Myoclonus is not seen. Corticospinal weakness is not evident. Muscular wasting only occurs in a subgroup of patients who develop motor neurone disease. Ataxia does not occur.

52.5 INVESTIGATIONS

52.5.1 Electroencephalography (EEG)

Routine EEG typically remains normal even in the context of severe dementia, a feature that helps to distinguish FTD from Alzheimer's disease, in which there is slowing of wave forms.

52.5.2 Structural and functional brain imaging

Computed tomography (CT) reveals non-specific cerebral atrophy in the majority. Sometimes, however, pronounced widening of the interhemispheric and sylvian fissures suggests a frontotemporal distribution of atrophy. Emphasis of pathology in the frontal lobes is more reliably demonstrated on magnetic resonance imaging (MRI).

Single photon emission tomography (SPET) reveals reduced tracer activity in the frontal and temporal lobes (Plate 22). Abnormalities are typically bilateral, but may be symmetrical or asymmetrical. *Positron emission tomography (PET)* studies indicate ventromedial frontal cortex as the critical affected area (Salmon *et al.*, 2003). The pattern of anterior hemisphere dysfunction contrasts with the prototypical pattern of posterior hemisphere dysfunction seen in Alzheimer's disease (Talbot *et al.*, 1998). Functional MRI has shown loss of frontal activation even in early FTD cases in whom structural MRI imaging is normal (Rombouts *et al.*, 2003).

In comparing the patterns of regional cerebral atrophy in FTD, Alzheimer's disease and vascular dementia, severe

frontal atrophy (unilateral or bilateral) and/or asymmetrical atrophy on MRI is highly characteristic of FTD. By contrast milder or severe reductions in regional cerebral blood flow on SPET in the parietal lobes exclude FTD and is highly suggestive of Alzheimer's disease (Varma *et al.*, 2002; Varrone *et al.*, 2002).

52.6 NEUROPSYCHOLOGY

52.6.1 Historical reports

Features of personality and behavioural change are prominent, and outweigh specific cognitive symptoms. Nevertheless, some cognitive change may be reported. Relatives may comment on alterations in the patient's language, which may include a reduction in speech output, stereotyped usage of words or phrases, or preoccupation with certain themes. They may note a tendency to echo the speech of others. They may describe memory disturbances, although often feel that this is variable in the patient's favour (the patient remembers what they want to remember), suggesting absent-mindedness and faulty attention rather than a primary amnesia. Symptoms of visuospatial disorientation are, however, notably absent. Relatives may remark with surprise that the patient wanders several miles from the home, yet find their way back.

52.6.2 Quality of neuropsychological test performance

Some patients are markedly distractible and restless and a minority may wander and attempt to leave the room during a testing session, and compliance may be lost. Economy of mental effort and cursory, superficial responses characterize test performance in apathetic, inert patients. The lack of concerted application to tasks is an important feature, because it effectively impairs performance across a wide range of tests that are purportedly designed to evaluate a spectrum of psychological functions. Test scores taken at face value could lead to spurious interpretations of the nature of the patient's psychological deficit.

Other 'frontal' features that compromise test performance include perseveration and concreteness of thought. Response perseverations may occur on both verbal and motor tasks. They are a dominant characteristic of performance on traditional 'frontal-lobe' tests. However, they also may represent a major source of errors in naming tests, writing and drawing. In motor tasks, perseverations may occur at both an elementary (repetition of a single movement) and higher-order (repetition of a complete programme of actions) level. Concreteness of thought can compromise interpretation of verbal instructions, pictures and stories. Patients may fail to abstract an underlying narrative or draw inferences that go beyond the elements physically present.

52.6.3 Language

Speech output characteristically is reduced. Patients do not initiate conversation, and responses to questions are brief and unelaborated, with minimal application of mental effort. As noted above concreteness of thought is common, and is elicited most readily by the use of metaphors and proverbs. There may be increased reliance on irrelevant, stereotyped remarks, which contrast with the prevailing taciturnity. These may constitute favoured words or phrases, or sometimes an entire well rehearsed repertoire. Echolalia and verbal perseverations are common. Despite the economy of speech, utterances are fluent and effortless, without pronunciation difficulties. However, hypophonia and loss of prosody may become evident. Mutism invariably ensues in the final stages of the disease. The apparent lack of generative language or 'adynamia', which dominates the clinical picture, bears resemblance to the 'dynamic aphasia' described by Luria and Tsvetkova (1968).

The profound attenuation of conversational discourse stands in contrast to the relative preservation of overlearned, 'automatic' aspects of language. Patients may repeat phrases, recite series such as the months of the year, complete nursery rhymes and join in songs at a time when spontaneous utterances are virtually absent.

There is typically little evidence of comprehension failure at a single word level. However, patients may have difficulty grasping complex syntax or following sequential commands. Performance on tests of comprehension is typically governed by the mental demands of the task.

Naming to confrontation is relatively well preserved, although may be compromised by response perseverations. Open-ended verbal fluency tasks, involving generation of words from a semantic category or beginning with a specified letter are usually disproportionately impaired compared with object naming.

Reading aloud is relatively preserved and free from linguistic errors. Indeed, patients may develop a habit of reading aloud road signs and advertising hoardings, even when their spontaneous conversation is minimal. In a test setting, virtually mute patients may read aloud test material accurately, much to the surprise of their relatives. Errors in reading typically arise secondary to patients' poor attention rather than to primary linguistic deficits. Reading for comprehension characteristically mirrors comprehension of spoken language. In reading a complete narrative, such as a fable-like short story, patients typically show poor abstractive and synthetic powers.

Written output usually is reduced and patients tend to write single words or brief phrases, rather than complete sentences. Spelling may be surprisingly accurate, although is sometimes erratic, reflecting lack of checking. Markedly perseverative responses characterize the writing of a proportion of patients.

The ability to communicate non-verbally by symbolic gesture, conveying actions such as waving, saluting or beckoning, may be preserved, at least initially. However, just as speech output decreases so too do the patient's body movements,

and in late stage disease it may be impossible to elicit any gestures, either to command or by demonstration. Buccofacial movements typically fail to convey a range of facial expression: an inane or fatuous expression predominates.

52.6.4 Visual perception and spatial skills

Patients typically have no difficulty in the perceptual recognition of objects, do not make perceptual errors on naming tests involving pictorial material, and for the most part use objects appropriately. Moreover there is no convincing evidence of 'parietal'-type deficits, even with advanced disease. Clinical observation suggests that patients have no difficulty localizing objects, can manipulate and orientate clothing correctly, and negotiate their environment, without becoming lost. Even when patients become formally untestable and are mute, they may fixate and reach for objects without difficulty, and may show behaviours as part of a stereotypic repertoire, which demonstrate preserved spatial localization skills, such as repeated folding of a handkerchief or aligning of papers. It is noteworthy, however, that impairment often may be elicited on formal neuropsychological tests of perceptuospatial function as a secondary consequence of patients' poor mental application, failure to check responses, lack of concern for accuracy as well as their poor organizational and strategic skills. The notable preservation of spatial function in FTD patients contrasts with the severe impairment of spatial skills common in Alzheimer's disease.

52.6.5 Memory

Patients typically perform poorly on formal tests of memory, both recall and recognition. However, patients are not evidently clinically amnesic: they are typically orientated for time and place and can provide accurate information about current autobiographical events. Moreover, test performance can be improved under certain conditions. First, recall performance is enhanced by the use of specific, directed questions rather than broad open-ended questions. Second, memory performance benefits from cues and from the provision of multiple-choice alternative responses. These features suggest that patients have available to them information that they do not or are unable to generate spontaneously, and reinforce the notion that the patient's inefficient memorizing is not attributable to a primary failure of retention. This 'frontal' type of memory impairment contrasts with the classical amnesia typical of Alzheimer's disease. Memory performance in FTD patients may be compromised by failures of sustained and selective attention.

52.6.6 Motor skills

Patients have normal manual dexterity, and can manipulate objects, use feeding implements and carry out complex actions

such as lighting a cigarette until relatively late in the disease. Some patients exhibit 'utilization behaviour', in which objects placed within reach of the patient elicits the motor actions appropriate to those objects even though those behaviours are contextually inappropriate. Despite the general preservation of motor skills, some abnormalities do occur on motor tasks, performance being compromised particularly by perseveration and motor imperistence.

With progression of disease it may become increasingly difficult to elicit motor responses in inert, apathetic patients. However, actions may be more easily evoked by imitation than through verbal command, and a minority of patients exhibit frank echopraxia, copying actions of the examiner without being requested to do so.

52.6.7 Frontal executive functions

Patients show impairments in a range of executive skills, including abstraction, planning, organizational and strategic functioning, sustained, selective and switching of attention. 'Frontal lobe' tests that are sensitive to such changes include the Wisconsin card sorting test, Weigl's test, Stroop test, Trail Making test, verbal fluency, design fluency, Haylings and Brixton test and the Test of Everyday Attention. Details of test administration can be found in Lezak (2002).

52.6.8 Social cognition

There is accumulating evidence that FTD patients have impaired ability to infer the mental states of others, a capacity that has come to be known as 'theory of mind' (Lough *et al.*, 2001; Gregory *et al.*, 2002; Snowden *et al.*, 2003). These social inferential skills may be impaired even in patients who perform relatively well on standard executive tasks (Lough *et al.*, 2001), a factor likely to contribute to patients' severe breakdown in social, interpersonal conduct.

52.6.9 Performance on standard tests of intelligence

Some patients who present with disinhibition and overactivity may initially perform normally on standard test batteries, such as the Wechsler Adult Intelligence Scale, highlighting a dissociation between the profound alteration in personality and behaviour and breakdown in social competence, and relative preservation of cognitive skills. Often, however, performance is impaired, and becomes so in all individuals with progression of disease. A pattern of test scores may be evident, which points to a predominant frontal lobe dysfunction: disproportionate impairment for the Comprehension, Similarities and Picture Arrangement subtests. A verbal performance discrepancy, occurring in a minority of patients, will tend to favour performance items. However, commonly, performance is impoverished across all subtests, with no clear pattern

Box 52.3 Cognitive characteristics of FTD

Language

- Economy of mental effort and output
- Perseveration, echolalia, stereotypy
- Concreteness
- Late mutism

Perceptuospatial function

- Preserved; errors on constructional tasks arise secondary to organizational deficits

Memory

- Variable, idiosyncratic day to day memory
- Preserved orientation in time and place
- Poor information retrieval
- Recall enhanced by cues and directed probes

Motor skills

- Poor temporal sequencing
- Perseveration

Abstraction and planning

- Concrete responses
- Poor set shifting
- Organizational and sequencing failure
- Perseveration

of deficits emerging across tasks. This profile, which appears to arise as a consequence of patients' lack of effortful application to tasks and cursory mode of responding, may misleadingly give rise to the interpretation of a 'generalized' dementia.

The principal cognitive characteristics are summarized in Box 52.3.

52.7 BEHAVIOURAL SUBTYPES

FTD patients are not entirely homogeneous. All share the major features of gross change in personality and social conduct and exhibit a picture suggestive of 'frontal lobe' disorder on neuropsychological testing; the behavioural disorder outweighs both primary cognitive and physical deficits. Nevertheless, the precise characteristics of the disorder are not uniform. Three broad prototypical behavioural patterns have been identified (Box 52.4).

52.7.1 Disinhibited type

Some patients present with features reminiscent of hypomania. They are overactive, restless, inattentive and distractible, rushing unproductively from one activity to another, with

Box 52.4 *Clinical sub-types of FTD***Disinhibited**

- Restless, overactive, disinhibited
- Fatuous, jocular, unconcerned
- Profound social breakdown
- Behavioural disorder more prominent than cognitive disorder

Apathetic

- Inert, asponaneous, avolitional
- Bland, apathetic, unconcerned
- Mentally rigid and perseverative
- Severely impaired on frontal-lobe cognitive tests

Stereotypic

- Stereotypic, ritualistic, compulsive
- Bland, unconcerned
- Mentally rigid
- Behavioural disorder salient feature

marked lack of application and persistence. Their demeanour is fatuous, inappropriately jocular, disinhibited and socially inappropriate. Patients may perform surprisingly well on cognitive tasks at least in the early stages of disease. In such patients functional imaging with SPET typically reveals relatively circumscribed tracer deficits involving the orbitofrontal and anterior temporal lobes.

52.7.2 Apathetic type

Some patients exhibit a pattern of behaviour that is at opposite poles to that described above. They present with an apathetic, amotivational, pseudodepressed state. Their behaviour is characterized by loss of volition and inertia, so that, if left to their own devices, they would spend their day in bed or sitting unoccupied. All behaviours are economical, with minimal expenditure of mental effort. Response latencies to questions are often excessively prolonged, although once initiated, rate of execution of verbal or motor responses is unremarkable. With disease progression the patient becomes increasingly unresponsive, so that virtually no verbal or motor behaviour can be elicited. It is in these patients that perseverative behaviour, both verbal and motor, is the most pronounced, and that marked loss of speech prosody is liable to occur. These patients are particularly impaired on formal tests of executive function. In these patients there is typically widespread anterior hemisphere abnormalities on SPET, with involvement of dorsolateral convexity regions.

52.7.3 Stereotypic type

In some patients the dominant presenting characteristic is of repetitive, ritualistic and idiosyncratic behaviours. Patients

adhere to a rigid routine and become agitated if their daily schedule is altered. They adopt personal rituals, which have a compulsive quality, although lack the accompanying feelings of anxiety and release from anxiety characteristic of obsessive-compulsive states. Such patients exhibit extrapyramidal signs at a relatively early stage of the illness. In patients with marked stereotypic behaviour, SPET imaging typically reveals the frontal and temporal lobes to be functionally disordered in a widespread fashion.

Behavioural differences reflect differences in distribution of pathology within frontotemporal structures. The apathetic type reflects the presence of dorsolateral-frontal atrophy, whereas the disinhibited type corresponds to orbitobasal frontal degeneration. The stereotypic type is strongly related to severe striatal disease with lesser involvement of frontal or temporal neocortex. In all subtypes the temporal poles are affected. To some extent behavioural differences reflect stage of disease: patients who are initially disinhibited and have relatively circumscribed atrophy of the orbital frontal lobes and temporal poles may become increasingly apathetic with disease progression and pathological spread into dorsal frontal regions. However, there are also significant clinical differences in the earliest stages of disease: some patients present initially with disinhibition and others with apathy, indicating that phenotypic differences exist that are not mere artefacts of disease severity.

52.8 FRONTOTEMPORAL DEMENTIA AND MOTOR NEURONE DISEASE

An association between dementia and motor neurone disease (MND) (amyotrophic lateral sclerosis) is well known and the pathology has been extensively described, especially in Japan (Mitsuyama and Takamiya, 1979; Morita *et al.*, 1987). The form of dementia is identical to that of FTD (Neary *et al.*, 1990).

Patients present with a rapidly progressive dementia of the frontal lobe type and subsequently develop motor neurone disease of the amyotrophic type. Personality change with disordered personal and social conduct and stereotyped behaviours are prominent. Reduced verbal output in superseded rapidly by mutism. Profound abnormalities are evident on tests of frontal lobe function. Visuospatial abilities are notably preserved.

Neurological examination reveals widespread muscular fasciculations in the tongue, limbs and trunk in addition to the finding of primitive reflexes and hyperreflexia. With disease progression muscular wasting increases and bulbar palsy emerges, with dysarthria and ineffective coughing. Patients do not develop a spastic increase in tone of the limbs. Death due to bulbar palsy occurs within 3 years.

The EEG is normal and remains so on serial investigation. Electrophysiological studies of neuromuscular function reveal normal nerve conduction studies, multifocal muscular fasciculations, reduced muscular firing rates and giant motor units,

compatible with widespread muscular denervation due to anterior horn cell death.

52.9 NEUROPATHOLOGY

The principal atrophy in FTD involves the frontal and anterior temporal neocortices, the amygdala and basal ganglia (Brun, 1987, 1993; Mann and South, 1993; Mann *et al.*, 1993). Within the neocortex the histological changes principally involve layers II and III, the origin of corticocortical associational neurones, sparing layer V, the major source of cortico-subcortical neurones. Three distinct histological changes are associated with the cortical atrophy (Lund and Manchester groups, 1994):

- microvacuolation or spongiosis (FLD-type);
- gliosis with or without swollen neurones and inclusion bodies (Pick-type);
- degeneration of bulbar cranial nerve nuclei and anterior horn cells (MND-type).

The distribution of the first two histologies are identical and either may underlie the clinical syndrome of FTD in both familial and non-familial cases. In FTD and MND the cerebral histology is usually of the first type (microvacuolation), and the degree of cerebral atrophy is milder, presumably due to the short duration of illness associated with death from MND.

A more detailed description of the neuropathological changes seen in FTD is given in Chapter 54.

52.10 NEUROCHEMISTRY

The neurochemical changes in autopsied cases of FTD have been compared with those of Alzheimer's disease (Procter *et al.*, 1999). In FTD there is no cholinergic deficit. Serotonin receptors are lost from frontal and temporal cortex in FTD whereas they are lost from temporal and parietal cortex in Alzheimer's disease. In FTD there is no loss of kainate receptors but loss of AMPA receptors from both temporal and frontal lobes. Loss of AMPA receptors differentiated FTD with Pick-type histology from FTD with FLD-type histology, suggesting selective loss of subpopulations of cortical pyramidal neurones.

52.11 MOLECULAR GENETICS

In familial forms of FTD the mode of inheritance is autosomal dominant and in some families missense and splice-site mutations have been identified in the tau sequencing gene on chromosome 17 (Hutton *et al.*, 1998; Poorkaj *et al.*, 1998; Janssen *et al.*, 2002; Pickering-Brown *et al.*, 2002). Linkage to

chromosome 3 has been reported in an extended Danish family (Brown *et al.*, 1995; Gydesen *et al.*, 2002) and to chromosome 9 in patients with FTD/MND (Hosler *et al.*, 2000). See Chapter 54 for a detailed description of the genetics and molecular pathology of FTD.

52.12 TREATMENT AND MANAGEMENT

The severe behavioural disorder of FTD places great a burden on carers. The early onset of the disorder entails breakdown in families where children may still be relatively young. The altered personality leads the patient to be regarded as a stranger and alien within the home and therefore social and psychiatric intervention with daycare provision and facilities for respite and relatively early potential hospitalization are even more desirable than in Alzheimer's disease. Unfortunately the youth and overactivity of many patients makes their placement in homes and hospitals largely dedicated to the elderly both inappropriate and distressing to carers. Facilities for the care of patients with presenile dementia are urgently required.

Tranquilizers may be effective in reducing overactive disinhibited behaviour and serotonin reuptake inhibitors (Swartz *et al.*, 1997; Moretti *et al.*, 2003) can sometimes diminish the repetitive behaviours that can dominate the patient's activities and place severe stress on carers.

Within the setting of a hospital environment the repetitive behaviours can sometimes be turned to the advantage of the group by harnessing the stereotypic activity to socially useful ends.

52.13 DIFFERENTIAL DIAGNOSIS

Features that distinguish FTD from Alzheimer's disease are summarized in Table 52.1. However, in the very early stages patients with both FTD and Alzheimer's disease may show few neurological symptoms or signs. Moreover, disinhibited FTD patients may perform relatively well on standard neuropsychological tests, including 'frontal lobe' tests (Gregory *et al.*, 1999), so that neuropsychological assessment is not invariably informative. Neuroimaging techniques are not available in all centres. Differential diagnosis is therefore crucially dependent on the evaluation of the patient's behaviour and affect, hence the emphasis on behavioural features in current diagnostic criteria. Informant-based behavioural interviews can elicit information that is highly discriminating (Bozeat *et al.*, 2000; Bathgate *et al.*, 2001; Ikeda *et al.*, 2002). In a comparative study of FTD and Alzheimer's disease (Bozeat *et al.*, 2000) behavioural stereotypies, altered eating habits and loss of social awareness best discriminated the two groups. Similarly, in a comparative study of FTD, Alzheimer's disease and vascular dementia (Bathgate *et al.*, 2001), the best discriminators included changes in eating habits, especially

Table 52.1 Comparison of clinical features in FTD and AD

Clinical features	FTD	AD
Demographics	Typically early onset	Typically late onset
History	Early personality change Social breakdown	Memory loss Spatial disorientation
Affect	Altered eating habits	Aphasia
Neurology	Blunted, fatuous Early primitive reflexes	Concerned, anxious Akinesia and rigidity, myoclonus
Language	Adynamic speech, mutism	Aphasia
Visuospatial skills	Preserved	Impaired
Memory	'Frontal-type' amnesia	'Limbic-type' amnesia
EEG	Normal	Abnormal, slow
SPECT	Anterior cerebral abnormality	Posterior cerebral abnormality

overeating and the presence of repetitive, stereotyped behaviours. Particularly discriminating also was the reduced capacity of FTD patients to demonstrate both primary and social emotions (e.g. sadness, fear, sympathy, embarrassment), and the loss of emotional insight (i.e. a lack of distress or concern when confronted by deficits). Informant-based interviews have been found to have discriminatory value even when carried out retrospectively several years after the patient's death (Barber *et al.*, 1995).

52.14 CONCLUSION

Frontotemporal dementia, arising from progressive degeneration of the frontal and temporal lobes, is a relatively common form of early-onset dementia. It is characterized by profound alteration in personality and social conduct, and by cognitive defects in attention, abstraction planning, judgement, organization and strategic functioning. In contrast, instrumental tools of cognition, particularly spatial navigational skills, are relatively preserved. The neuropsychological disorder, indicative of anterior hemisphere dysfunction, is the converse of that seen in Alzheimer's disease, in which profound breakdown in the tools of cognition: memory, language and perceptuospatial abilities, occur in the context of remarkably well preserved social skills. The paucity of neurological signs in FTD and in particular the absence of myoclonus, the normal EEG and the selective anterior hemisphere abnormalities seen on functional brain imaging also help to separate FTD from the relatively more common dementia of Alzheimer's disease. FTD is not clinically uniform. Distinct behavioural patterns mirror differences in the topographical distribution of pathological change within frontal and temporal structures, but are not determined by the precise histopathological features that are of frontotemporal lobar degeneration, Pick or MND-type. Molecular genetic advances already have distinguished mutations responsible for FTD in

some familial cases and are likely in the future to clarify nosological issues relating the status of the different histologies underlying FTD and its relationship to other clinical syndromes that share those same histopathologies. Genetic advancement also holds the prospect of future treatment for this devastating form of dementia.

53.4 Corticobasal degeneration, progressive supranuclear palsy and frontotemporal dementia	683	53.8 Conclusions	685
		References	685

Considerable advances continue to be made in our understanding of the group of neurodegenerative diseases that present with focal cognitive deficits arising from circumscribed pathology of the frontal and/or temporal lobes, most commonly referred to collectively as Pick's disease (PiD) or frontotemporal dementia (FTD). However, the literature on these conditions is filled with a confusing plethora of terms, which can make these developments difficult to follow for the non-expert in the field. Central to the problem is a lack of clarity as to the intended level of description (clinical syndrome versus clinicopathological entity versus specific histological diagnosis) and a lack of concordance between these levels. For example, while some labels denote a clinical syndrome without specific histological implications (e.g. progressive aphasia, semantic dementia, or dementia of frontal type), others denote specific neuropathological entities (e.g. PiD, or familial tauopathy), hybrid clinicopathological entities (e.g. FTD), or even specific genetic disorders (e.g. FTD with parkinsonism linked to chromosome 17). Recent differences in opinion over terminology are well illustrated by the titles of the following books, all published in the last decade: *Pick's Disease and Pick Complex* (Kertesz and Munoz, 1998), *Frontotemporal Dementia* (Pasquier *et al.*, 1996) and *Fronto-Temporal Lobar Degeneration: Fronto-Temporal Dementia, Progressive Aphasia, Semantic Dementia* (Snowden *et al.*, 1996). This lack of clarity is acknowledged, and efforts to rationalize terminology and

achieve clinicopathological and nosological consensus have been made (Brun *et al.*, 1994; Neary *et al.*, 1998; McKhann *et al.*, 2001). Even at a recent meeting of experts, agreement over terms was far from universal (Kertesz *et al.*, 2003b).

The aims of this chapter are to review the evolution of the terms used to describe this spectrum of disorders; to highlight recent advances; and examine areas of continuing controversy. Whilst our own bias within the Cambridge group is to prefer the term Pick's disease for this group of disorders – which is more readily understood by carers and parallels our use of the label Alzheimer's disease (AD) – the current tide of opinion is to use frontotemporal dementia as an umbrella term for the overall clinical syndrome.

53.1 WHAT DID PICK ACTUALLY DESCRIBE?

In 1892, Arnold Pick, working in Prague, reported a 71-year-old man with progressive mental deterioration and unusually severe aphasia who at post mortem had marked atrophy of the cortical gyri of the left temporal lobe (Pick, 1892; Girling and Berrios, 1994). Pick wanted to draw attention to the fact that local accentuation of progressive brain atrophy may lead to symptoms of local disturbance (in this instance aphasia). He also made specific and, as we will see below, highly

perceptive predictions regarding the role of the mid-temporal region of the left hemisphere in the representation of word meaning. In subsequent papers, he described four further patients with left temporal atrophy (Pick, 1904; Girling and Berrios, 1997) or frontotemporal atrophy (Pick, 1901; Girling and Markova, 1995), again stressing their progressive language disturbance. It was only in his 1906 publication that Pick turned his attention to bilateral frontal atrophy with resultant behavioural disturbance. Spatt (2003) has reviewed Pick's approach to cognitive disorders and his concept of dementia.

Several points should be emphasized:

- Pick's primary interest in these patients was their language disorder, particularly the clinicoanatomical correlates of aphasia.
- He did not claim to have discovered a new disease, merely novel phenomena arising from asymmetric degeneration.
- He did not describe distinct neuropathological changes in his patients with focal atrophy.
- Both the major syndromes now included under the rubric of FTD (dementia of frontal type and semantic dementia) were clearly reported by Pick.

In view of these monumental contributions, it is sad that Pick has been relegated to a minor place in the modern terminology of FTD.

The histological abnormalities associated with PiD were, in fact, described a few years later by Alzheimer (1911) who recognized changes distinct from those found in the form of cerebral degeneration later associated with his name. Alzheimer recognized both argyrophilic intracytoplasmic inclusions (Pick bodies), and diffusely staining ballooned neurones (Pick cells) in association with focal lobar atrophy. It is interesting to note that a comprehensive review of 20 patients from the literature with aphasia owing to focal lobar atrophy written soon after Alzheimer's description (Mingazzini, 1914) did not use the label Pick's disease, which was introduced by Gans some 8 years later (Gans, 1922). The term was then taken up by Onari and Spatz (1926), but Carl Schneider (1927, 1929) is probably most responsible for its popularization.

Unfortunately, however, Schneider concentrated on the frontal lobe component of the syndrome and thus began the neglect of the temporal lobe syndromes. He distinguished three clinical phases, the first characterized by impaired judgement and behaviour, the second by local symptoms, and the third by generalized dementia. Many papers describing PiD then appeared in the 1930s and 1940s (Ferrano and Jervis, 1936; Lowenberg and Arbor, 1936; Nichols and Weigner, 1938; Lowenberg *et al.*, 1939; Neumann, 1949), which again mainly focused on the frontal lobe aspects of the disorder.

After World War II, interest in PiD faded, together with a general waning of interest in the cognitive aspects of neurology in the English-speaking world. The focus of interest in English-language publications became the neuropathology, and latterly the genetics, of PiD. This resulted in a gradual

change in the criteria for PiD, which evolved to include the necessity for specific pathological changes (i.e. focal atrophy with Pick cells and or Pick bodies). Indeed, many authors went as far as to claim that AD and PiD were clinically indistinguishable in life (Katzman, 1986; Kamo *et al.*, 1987). In continental Europe, however, there remained a strong interest in the clinical phenomena of the dementias; PiD remained an *in vivo* diagnosis based on a combination of clinical features suggestive of frontal and/or temporal lobe dysfunction and focal lobar atrophy (Mansvelt, 1954; Tissot *et al.*, 1975). This controversy continues and has contributed to the adoption of the many labels to describe patients with the clinical syndrome of progressive frontal or temporal lobe degeneration (Baldwin and Förstl, 1993).

53.2 REDISCOVERING PICK'S DISEASE: FROM DEMENTIA OF THE FRONTAL TYPE AND PROGRESSIVE APHASIA TO FRONTOTEMPORAL DEMENTIA

53.2.1 Dementia of frontal type

A renaissance of interest in the focal dementias occurred in the 1980s. Workers from Lund (Gustafson, 1987; Brun, 1987) reported on a large series of patients with dementia and found that of 158 patients studied prospectively, who came to post mortem, 26 had evidence of frontal lobe degeneration. Since only a small proportion had Pick cells and Pick bodies – the remainder had very similar findings but without specific inclusions (i.e. focal lobar atrophy with severe neuronal loss and spongiosis) – the Lund group preferred to adopt the term 'frontal degeneration of non-Alzheimer type'. At approximately the same time, Neary and co-workers (1986) in Manchester began a series of important clinicopathological studies of patients with presenile dementia. They, likewise, found a high proportion of cases with a progressive frontal lobe syndrome that had neither specific changes of AD (plaques and tangles) nor specific Pick pathology. They introduced the term 'dementia of frontal type'. Over the next few years other groups described very similar cases under the labels 'frontal lobe degeneration' (Miller *et al.*, 1991) and 'dementia lacking distinct histological features' (Knopman *et al.*, 1990). Our own preferred term for this group of patients is frontal variant FTD (FvFTD).

In the advanced stages of the disease, patients with this disorder present no diagnostic difficulty. They have the triad of:

- a profound change in personality and behaviour;
- neuropsychological impairments indicative of selective or disproportionate frontal pathology; and
- appropriate changes on structural and/or functional brain imaging.

Diagnosing early cases is by no means as easy and one of the challenges is to develop better methods of early, accurate

detection (Gregory *et al.*, 1999). Since patients are typically unaware of the insidious changes noted by others, we rely upon carer-based assessments. One undoubted advance in the area has, therefore, been the development of standardized carer interviews such as the Neuropsychiatric Inventory (Cummings *et al.*, 1994), which appears to differentiate patients with FTD and AD (Levy *et al.*, 1996). In an attempt to develop a local instrument capable of early diagnosis, we identified 15 key symptoms that occurred very commonly in a group of 12 patients with FvFTD (Gregory and Hodges, 1993, 1996). Kertesz and his group have developed a tool specifically aimed at frontal behaviours, the Frontal Behaviour Inventory, which appears to discriminate patients with FTD from those with AD or depression (Kertesz *et al.*, 1997, 2000, 2003a). Recent work has focused on specific behaviours that can discriminate patients with FvFTD and semantic dementia from patients with AD, such as changes in appetite, food preferences and eating habits (Ikeda *et al.*, 2002), or the presence of stereotypies (Nyatsanza *et al.*, 2003).

Many patients with FvFTD present to psychiatrists and acquire a label of functional psychiatric disorder (including simple schizophrenia, depression and obsessive-compulsive disorder) because despite gross behavioural changes other aspects of cognition are typically preserved (Ames *et al.*, 1994; Tonkonogy *et al.*, 1994; Gregory and Hodges, 1996; Miller *et al.*, 1997). This is understandable in terms of the site of pathology in FvFTD, the orbital and mesial frontal lobes, which are critically involved in social judgement, motivation, risk assessment and the pathophysiology of obsessive-compulsive behaviour (Cummings, 1999). By contrast, dorsolateral frontal regions, which have been the focus of classic neuropsychological studies, are spared in the early stages of the disease. The development of quantifiable tasks sensitive to orbital and mesial frontal function has begun with paradigms involving probability and gambling (Rogers *et al.*, 1998; Rahman *et al.*, 1999), emotion processing (Keane *et al.*, 2002), and 'theory of mind' (ToM) tasks (Gregory *et al.*, 2002), but much work remains to be done in this area.

53.2.2 Progressive aphasia and semantic dementia

The other strand of the story concerns the rediscovery of the syndrome of progressive aphasia in association with focal left perisylvian or temporal lobe atrophy. In 1982, Mesulam reported six patients with a long history of insidiously worsening aphasia in the absence of signs of more generalized cognitive failure. One of these patients underwent a brain biopsy, which revealed non-specific histology without specific markers of either AD or PiD. Following Mesulam's seminal paper, approximately 100 patients with progressive aphasia were reported over the next 15 years (for reviews see: Mesulam and Weintraub, 1992; Hodges and Patterson, 1996; Snowden *et al.*, 1996; Garrard and Hodges, 1999). From this literature it is clear that, although the language impairment

in patients with progressive aphasia is heterogeneous, there are two identifiable and distinct aphasia syndromes: progressive non-fluent aphasia and progressive fluent aphasia. In the latter syndrome, speech remains fluent and well articulated but becomes progressively devoid of content words. The language and other non-verbal cognitive deficits observed in these patients reflect a breakdown in semantic memory that has led many authors to apply the label of 'semantic dementia' (Snowden *et al.*, 1989; Hodges *et al.*, 1992; Hodges *et al.*, 1994; Saffran and Schwartz, 1994; Hodges and Patterson, 1996).

Although the term 'semantic dementia' is recent, the syndrome has, as discussed above, been recognized under different labels for many years. Pick (1892, 1904) and a number of other early authors (Rosenfeld, 1909; Mingazzini, 1914; Stertz, 1926; Schneider, 1927) recognized that the chief clinical manifestations of temporal lobe atrophy were 'amnesic aphasia' or 'transcortical sensory aphasia', together attributed to atrophy of the middle and inferior temporal gyri leaving Wernicke's area intact. These language impairments were typically associated with a type of dementia variously described as a reduction in categorical or abstract thinking, psychic blindness or sensory or 'associative agnosia' (Malamud and Boyd, 1940; Robertson *et al.*, 1958). These features – amnesic aphasia and associative agnosia – can now be united by the concept of 'semantic memory loss'.

Warrington (1975) was the first clearly to delineate the syndrome of semantic memory impairment in three patients. Drawing on the work of Tulving (1972, 1983), Warrington recognized that the progressive anomia in her patients was not simply a linguistic deficit, but reflected a fundamental loss of semantic memory (or knowledge) about the items, which thereby affected naming, word comprehension, and object recognition. Semantic memory is the term applied to the component of long-term memory that contains the permanent representation of our knowledge about things in the world and their interrelationship, facts and concepts as well as words and their meaning (Hodges *et al.*, 1992, 1998; Garrard *et al.*, 1997; Hodges and Patterson, 1997). Cases of semantic dementia have also been recognized for many years in Japan as cases of 'gogi (word meaning) aphasia' (Imura *et al.*, 1971; Sasanuma and Mondì, 1975; Morita *et al.*, 1987; Tanabe, 1992; Tanabe *et al.*, 1992).

Our original paper reported five cases with progressive loss of semantic memory and focal temporal atrophy (Hodges *et al.*, 1992). All five presented with a fluent aphasia and all the characteristics of semantic memory loss: empty speech with word finding difficulty and occasional semantic paraphasias (mother for father), a severe reduction in the generation of exemplars on category fluency tests (in which subjects are asked to produce as many examples as possible from defined semantic categories, such as animals or musical instruments, within 1 minute), impaired single word comprehension on picture-pointing tests, a loss of fine-grained attribution knowledge about a range of items with preservation of broad superordinate information on verbal and pictorial tests of knowledge. By contrast, other aspects of language competency

(phonology and syntax) were strikingly preserved. In contrast to AD, the patients also had good day-to-day (episodic) memory, although we have more recently shown that this sparing of autobiographical memory applies to fairly recent memories only (Graham and Hodges, 1997; Hodges and Graham, 1998). They also showed no impairment on tests of immediate (working) memory, visually based problem solving or visuo-perceptual abilities. Four of the five patients showed severe and circumscribed temporal lobe atrophy on computed tomography (CT) or magnetic resonance imaging (MRI) scanning. Since 1992, we have studied many further such patients and have confirmed the association with focal atrophy of the temporal lobe – involving the temporal pole and inferolateral neocortex (particularly the perirhinal cortex and fusiform gyrus), with relative sparing of the hippocampal formation. In many cases the atrophy is strikingly asymmetric but always involves the left side (Hodges *et al.*, 1998; Mummery *et al.*, 1999; Garrard and Hodges, 1999; Galton *et al.*, 2001).

This lateralization raises the issue of what are the cognitive and/or behavioural signatures of isolated right temporal atrophy. In 1994, we reported a patient, VH, with progressive prosopagnosia followed by a specific loss of knowledge about people (Evans *et al.*, 1995). VH was unable to identify from face or name even very famous people, yet had intact general semantic and autobiographical memory (Kitchener and Hodges, 1999). In a more recent study, Thompson *et al.* (2004) reported a dissociation of person-specific from general semantic knowledge in two patients with contrasting patterns of temporal atrophy. Subject MA, with predominantly left temporal atrophy, showed impairment of general semantics with relative preservation of knowledge about people, while subject JP, with predominantly right temporal atrophy, showed the opposite pattern of impairments with severely impaired person-specific knowledge in the context of relatively preserved knowledge about objects and animals. The group led by Miller have also drawn attention to the bizarre behaviours (including irritability, impulsiveness, alterations in dress, limited and fixed ideas and decreased facial expression) exhibited by patients with predominantly right temporal lobe atrophy (Edwards Lee *et al.*, 1997; Miller *et al.*, 1997). A recent review of 47 patients with semantic dementia identified distinct behavioural and cognitive profiles associated with the left and right temporal variants of the disease (Thompson *et al.*, 2003). Social awkwardness, job loss, lack of insight and difficulty with person identification were all more likely to be associated with major right temporal atrophy; while word-finding difficulties and reduced comprehension were all more likely to be associated with predominantly left-sided atrophy.

There are a number of compelling reasons to consider semantic dementia as part of the same disease spectrum as FvFTD. The first is pathological: in early clinicopathological studies of cases fulfilling criteria for semantic dementia, all had either classic PiD (i.e. Pick bodies and/or Pick cells) or non-specific spongiform change of the type found in the majority of cases with the frontal form of lobar atrophy (Wechsler, 1977;

Wechsler *et al.*, 1982; Holland *et al.*, 1985; Poeck and Luzzatti, 1988; Graff-Radford *et al.*, 1990; Snowden *et al.*, 1992; Scholten *et al.*, 1995; Harasty *et al.*, 1996; Hodges *et al.*, 1998; Schwarz *et al.*, 1998). More recently, a broader spread of pathology has been described, including FTD of the motor neurone disease (MND) type with tau-negative but ubiquitin-positive inclusions (Rossor *et al.*, 2000; Hodges *et al.*, 2004). Second is the evolution of the pattern of cognitive and behavioural changes over time: although semantic dementia patients present with progressive anomia and other linguistic deficits, on follow up the features that characterize the frontal form of FTD emerge (Hodges and Patterson, 1996; Edwards Lee *et al.*, 1997). Indeed, semantic dementia and FvFTD may share many behavioural features on presentation (Bozeat *et al.*, 2000). Third is the fact that modern neuroimaging techniques demonstrate subtle involvement of the orbitofrontal cortex in the majority of cases presenting with prominent temporal atrophy and semantic dementia (Mummery *et al.*, 2000; Rosen *et al.*, 2002a).

The status of patients with the non-fluent form of progressive aphasia within the spectrum of FTD is less certain. Clinically, such cases are clearly separable from cases of semantic dementia. Speech is faltering and distorted with frequent phonological substitutions and grammatical errors. Other non-language-based aspects of cognition remain well preserved, as do activities of daily living. Changes in behaviour and personality of the type that typify dementia of frontal type, and are seen in the later stages of semantic dementia, are rare, but after a number of years, global cognitive decline occurs (Green *et al.*, 1990; Hodges and Patterson, 1996). In Cambridge, some patients with progressive non-fluent aphasia have had classic Alzheimer pathology at post mortem, albeit with an atypical distribution; that is to say, marked involvement of perisylvian language areas but sparing of medial temporal structures (Greene *et al.*, 1996; Croot *et al.*, 1997; Galton *et al.*, 2000). Review of the published literature reveals that approximately equal numbers of cases with non-fluent aphasia have AD pathology whilst the remainder have Pick-like pathology but almost invariably without Pick bodies or Pick cells (Weintraub *et al.*, 1990; Mesulam and Weintraub, 1992). Recent functional neuroimaging studies have implicated the anterior insula as the key abnormal region (Nestor *et al.*, 2003).

53.2.3 Frontotemporal dementia and frontotemporal lobar degeneration

The final terms to be considered are those of FTD and frontotemporal lobar degeneration (FTLD). In 1994, the Lund and Manchester groups introduced the term FTD and suggested tentative criteria for the diagnosis (Brun *et al.*, 1994). The term FTD was subsequently replaced by FTLD, and consensus clinical diagnostic criteria were published (Neary *et al.*, 1998). The adoption of the terms FTD or FTLD has the advantage of avoiding specific pathological implications; it also brings to attention the fact that patients with the same disease may present with different clinical syndromes and

that with time both types of deficit are likely to emerge. Three main clinical syndromes are recognized: FTD, progressive non-fluent aphasia and semantic dementia and associative agnosia (Neary *et al.*, 1998; see Figure 53.1). However, disadvantages of the term FTLD are the blurring of levels of description and the amalgamation of distinct clinical syndromes. In particular, confusion may occur between FTD (now referring only to the frontal or behavioural variant of the disorder) and FTLD (the new term for the overall spectrum of presentations). Figure 53.2 presents the preferred Cambridge nomenclature.

It remains to be established which of the long list of phenomena listed as 'criteria' actually separate FTD and AD, although a study by Miller *et al.* (1997), using SPECT as the gold standard, suggested that loss of personal awareness (self-care), disordered eating, perseverative behaviour and reduction in speech most clearly differentiate FTD from AD. We have also looked at a wide range of neurobehavioural symptoms in a large group of patients with FTD (FvFTD and semantic dementia) and AD and identified four distinct clusters of symptoms by factor analysis:

- stereotypic and eating behaviours;
- executive function and self care;
- mood changes; and
- loss of social awareness (Bozeat *et al.*, 2000).

Figure 53.1 Clinical classification of FTD according to the Lund–Manchester criteria. FTD, frontotemporal dementia; FTLD, frontotemporal lobar degeneration; PNFA, progressive non-fluent aphasia; SD, semantic dementia.

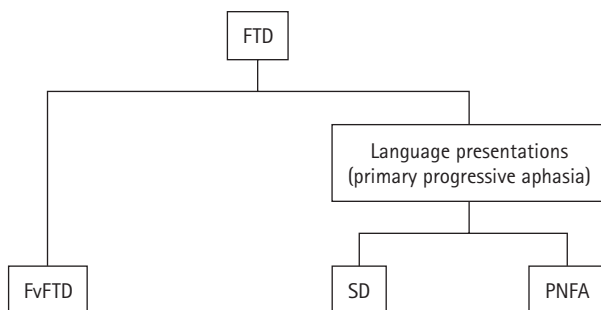

Figure 53.2 Clinical classification of FTD according to the Cambridge group. FTD, frontotemporal dementia; FvFTD, frontal or behavioural variant of FTD; PNFA, progressive non-fluent aphasia; SD, semantic dementia.

In this study, stereotypic and eating behaviours together with loss of social awareness reliably differentiated FTD from AD. At the level of individual symptoms, patients with semantic dementia showed increased rates of mental rigidity and depression compared with patients with FvFTD, while conversely, the latter group showed more disinhibition.

53.3 FAMILIAL CHROMOSOME 17-LINKED FRONTOTEMPORAL DEMENTIA AND THE DISCOVERY OF UNIQUE TAU PATHOLOGY

The term FTD increased in usage with the discovery of a specific gene mutation in familial cases. Linkage had been established in a number of families in which FTD was inherited as an autosomal dominant trait to chromosome 17q21–22, a region which contains the gene for the microtubule-associated protein tau (Wilhelmsen, 1997).

The story of the chromosome 17 linkage is extraordinary in a number of ways. Families around the world with what has become known as FTD with parkinsonism linked to chromosome 17 (Spillantini *et al.*, 1998a) had originally been reported under a range of headings including: disinhibition-dementia-parkinsonism–amyotrophy complex (DDPAC) (Wilhelmsen *et al.*, 1994); rapidly progressive autosomal dominant parkinsonism and dementia with pallidopontoni-gral degeneration (Wszolek *et al.*, 1992); familial progressive subclinical gliosis (Petersen *et al.*, 1995); hereditary dysphasic dementia (Morris *et al.*, 1984); hereditary FTD (Heutink *et al.*, 1997); multiple system tauopathy with presenile dementia (Spillantini *et al.*, 1997); familial presenile dementia with psychosis (Sumi *et al.*, 1992) and Pick's disease (Schenk, 1951). In 1996, a meeting of representatives from all of the groups identifying linkage to chromosome 17 was held in Ann Arbor, Michigan, USA (Foster *et al.*, 1997). Comparison of clinical and pathological data revealed a great deal of similarity between the families who all shared the characteristics of predominately frontotemporal distribution of pathology with marked behavioural changes. Extrapyramidal dysfunction was present in most. In some families psychotic symptoms were a major feature and a number had amyotrophy. It was recognized at that time that some of the families shared the common pathology with microtubule-associated protein tau-positive inclusions. Progress in the field was then rapid. It was soon discovered that most, if not all, families had tau inclusions with a distinctive morphological pattern leading to the coining of the term 'familial tauopathy' and the suggestion that the disease might reflect a mutation in the tau gene known to be located in the 17q21–22 region (Spillantini *et al.*, 1998a). Within 2 years of the Ann Arbor meeting, the first mutations were identified (Dumanchin *et al.*, 1998; Hutton *et al.*, 1998; Poorkaj *et al.*, 1998; Spillantini *et al.*, 1998b). Subsequent progress has been rapid: more than 25 different tau mutations have now been reported in

association with familial FTD, differing according to their positions in the tau gene, their effects on tau mRNA and protein, and the type of tau pathology they cause (Ingram and Spillantini, 2002).

Not all cases of familial FTD are caused by tau mutations. In one large Danish family with autosomal dominant FTD, linkage has been established to chromosome 3 (Brown *et al.*, 1995; Brown, 1998) and, in some families with FTD-motor neurone disease, linkage has been established to chromosome 9. In a series of 22 cases of familial FTD, 11 (50 per cent) had tau mutations (Morris *et al.*, 2001). For 17 of the 22 families pathology was available, and three main pathological diagnoses were made: FTD with neuronal and glial tau deposition; FTD with ubiquitin inclusions; and FTD with neuronal loss and spongiosis but without intracellular inclusions. In this study, the families with neuronal and glial tau deposition all had a tau mutation, whereas no mutations were found in the other two pathological groups. A lack of tau deposition does not necessarily exclude an abnormality of tau processing: it has been suggested that a post-transcriptional deficit of brain tau may be the causative pathological process in cases FTD lacking distinctive histopathology (Zhukareva *et al.*, 2001, 2003).

53.4 CORTICOBASAL DEGENERATION, PROGRESSIVE SUPRANUCLEAR PALSY AND FRONTOTEMPORAL DEMENTIA

In 1967 Rebeiz, Kolodny and Richardson described three patients with a neurodegenerative illness affecting both cortex and basal ganglia (Rebeiz *et al.*, 1968). Each patient presented with a progressive asymmetrical akinetic-rigid syndrome and apraxia; on the basis of neuropathology findings Rebeiz *et al.* called the disorder 'corticodentatonigral degeneration with neuronal achromasia', later renamed to corticobasal degeneration (CBD). Initially CBD was conceptualized as a distinct clinicopathological entity, but in the early 1990s it was recognized that considerable clinical and pathological heterogeneity existed within the disorder. Clinically, cases of pathologically proven CBD were described presenting with the clinical syndromes of frontotemporal dementia (Mathuranath *et al.*, 2000) or progressive aphasia (Lippa *et al.*, 1991). Conversely, it was recognized that other pathologies might underlie the clinical syndrome of CBD; in a review of 32 consecutive cases of clinically diagnosed CBD (Boeve *et al.*, 1999), the underlying pathological diagnosis was CBD in 18; AD in three; PiD in two; progressive supranuclear palsy in six, and dementia lacking specific histology in two. A distinction has been drawn by some authors between the corticobasal syndrome (the constellation of clinical features characteristically associated with CBD) and corticobasal degeneration (the histopathological disorder itself). In our experience, there is considerable overlap between the clinical syndrome of CBD and progressive non-fluent aphasia (PNFA): many patients with PNFA develop apraxia and

parkinsonian features and conversely many CBD patients have subtle language production deficits that worsen as the disease progresses (Graham *et al.*, 2003).

The related disorder progressive supranuclear palsy (PSP), originally described by Steele, Richardson and Olszewski in 1964 is classically characterized by progressive axial rigidity, bradykinesia, vertical gaze palsy and dysarthria. Pathologically, tau-positive neurofibrillary tangles and threads are found in the substantia nigra, the subthalamic nucleus and the dentate nucleus. It is increasingly recognized that pathological PSP may present with the clinical features of CBD, or even progressive aphasia or a frontal lobe syndrome. Conversely, the PSP phenotype may result from tau gene mutations (Morris *et al.*, 2003; Soliveri *et al.*, 2003). Both CBD and PSP share an identified genetic risk factor, the H1 haplotype of the tau gene, and the tau deposits in both these diseases consist of the four-repeat isoforms of tau.

In their original case report, Rebeiz *et al.* (1968) recognized the similarity of the neuropathology in CBD to that seen in PiD. The Work Group on Frontotemporal Dementia and Pick's Disease (McKhann *et al.*, 2001) now includes both CBD and PSP among the pathological causes of the FTD syndromes.

53.5 FRONTOTEMPORAL DEMENTIA WITH MOTOR NEURONE DISEASE

Although MND has traditionally been regarded as a disorder which spares higher cognitive abilities, it has become clear since early reports from Japan (Mitsuyama and Takamiya, 1979) that the rate of dementia in MND is significantly greater than expected. Indeed, up to 10 per cent of patients with MND might show features of dementia and/or aphasia if such features are systematically elicited (Rakowicz and Hodges, 1998). Neuroimaging in MND with cognitive impairment demonstrates widespread frontal and temporal atrophy. Conversely, a significant minority of patients with FTD develop features of MND (Neary *et al.*, 1990; Caselli *et al.*, 1993; Rakowicz and Hodges, 1998; Bak and Hodges, 1999; Strong *et al.*, 2003). Most such patients present with cognitive symptoms, either FvFTD or progressive aphasia, which then progresses rapidly, followed by the emergence of bulbar features and mild limb amyotrophy. Such cases have a characteristic pattern of histological change with ubiquitin-positive, tau-negative, inclusions in cortical regions and the dentate gyrus. One interesting observation is that such patients almost invariably have disproportionately greater impairment of verb rather than noun processing, which affects both production and comprehension (Bak *et al.*, 2001).

From a practical perspective, this variant of FTD should be suspected in any cases with rapidly progressive disease or the emergence of bulbar symptoms. The overlap in clinical presentation between FTD and related disorders is illustrated schematically in Figure 53.3.

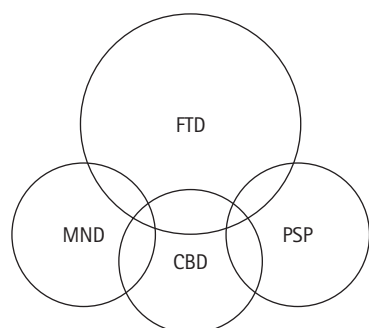

Figure 53.3 *Overlap in clinical presentation of FTD and related disorders. CBD, corticobasal degeneration; FTD, frontotemporal dementia; MND, motor neurone disease; PSP, progressive supranuclear palsy.*

53.6 CORRELATION BETWEEN CLINICAL SYNDROMES AND NEUROPATHOLOGY

The definitive diagnosis of FTD depends upon neuropathological examination. Unlike other dementia syndromes, notably AD, FTD encompasses considerable pathological heterogeneity. To summarize the preceding, three broad subdivisions have been recognized depending on the profile of immunohistochemical staining and the pattern of intracellular inclusions (Jackson and Lowe, 1996; Dickson, 1998; McKhann *et al.*, 2001; Hodges *et al.*, 2003). First, patients with tau-positive pathology, which in turn comprise a number of subvariants including those with classic argyrophilic, tau-positive, intraneuronal Pick bodies; those with tau gene mutations (FTDP-17) and diffuse tau-positive neuronal and astrocytic immunoreactivity; those characterized by tau-positive astrocytic plaques and ballooned achromatic neurones (CBD); and those with tau-positive argyrophilic grain disease (AGD). Second, cases with tau-negative, ubiquitin-positive inclusions in the dentate gyrus and brain stem motor nuclei (FTD with motor neurone disease or FTD-MND). Third, dementia lacking distinctive histology (DLDH).

The question as to whether distinct pathological subtypes map onto distinct clinical syndromes is of great interest. However, few clinicopathological series have been reported (Rosen *et al.*, 2002b; Rascovsky *et al.*, 2002). Munoz and

Ludwin (1984) studied, in detail, six patients whom they classified as either 'classical PiD' (i.e. marked focal neocortical atrophy with numerous Pick bodies) or 'atypical PiD' (i.e. those with predominant caudate atrophy and scarce inclusions). The ultrastructural changes in the two groups differed, and there was also a suggestion of a younger age of onset in the subcortical cases. A similar classification was proposed by Neumann in 1949. In the studies by Brun (Brun, 1987; Brun *et al.*, 1994), patients with frontal lobe atrophy and with Pick bodies were compared with those without specific histological changes. There were no demographic, clinical or neuropsychological differences, although the latter group had much less prominent cortical atrophy and involvement of the frontal convexity rather than the basal surface.

As discussed above, the majority of familial cases linked to chromosome 17 have lacked Pick bodies despite having abundant tau-positive inclusions, suggesting that classic Pick's disease cases are rarely familial.

A multicentre European initiative has pooled clinical and pathological data on 50 cases with classic PiD (i.e. with Pick bodies) and has proposed criteria that stress the marked asymmetry of atrophy found in many cases and the lack of family history. These criteria are currently being tested prospectively (Rossor, 1998). In a recent large series of 61 patients from Cambridge and Sydney (Hodges *et al.*, 2004), FvFTD was associated with a range of underlying pathologies. By contrast, motor neurone disease predicted ubiquitinated inclusions; parkinsonism and apraxia predicted corticobasal pathology; in progressive non-fluent aphasia there was a preponderance of tau-positive pathology while semantic dementia was generally associated with ubiquitin-positive (MND-type) inclusions. An attempted, and preliminary synthesis of the available clinicopathological data is illustrated in Figure 53.4.

53.7 HOW COMMON IS FRONTOTEMPORAL DEMENTIA?

Historically, it has long been recognized that FTD is less common than AD. Until recently, however, most estimates of the prevalence of FTD were based on reports from specialist units where FTD tended to be over-represented as a diagnosis. This

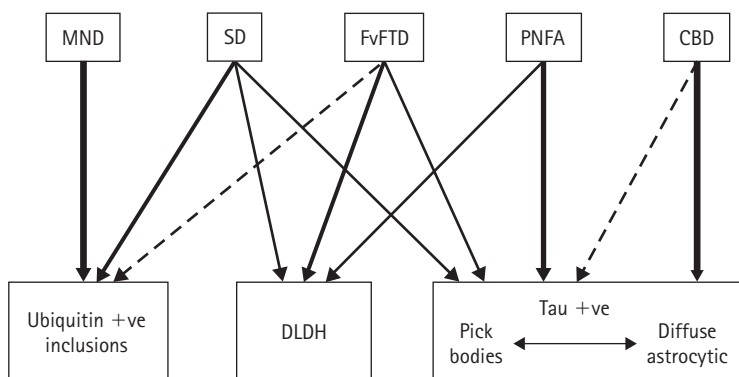

Figure 53.4 *Relationship between clinical syndrome and underlying pathology for FTD and related disorders. MND, motor neurone disease; SD, semantic dementia; fvFTD, frontal or behavioural variant of FTD; PNFA, progressive non-fluent aphasia; CBD, corticobasal degeneration; DLDH, dementia lacking distinctive histology. Thickness of arrow lines denotes the relative strengths of relationships between clinical syndromes and pathology.*

has changed with the publication of a number of community-based studies that give a clearer picture of the true prevalence of FTD.

Ratnavalli *et al.* (2002) conducted a prevalence survey aiming to ascertain all cases of early-onset dementia (age of onset less than 65 years) in a UK region with a total population of 326 000. The overall prevalence for early-onset dementia was 81 per 100 000 for patients aged 45–64 years, with equivalent prevalences of AD and FTD at 15 per 100 000. Of 185 cases seen by the study group, 23 (12 per cent) fulfilled the Lund–Manchester criteria for FTD, suggesting that, although FTD is by no means rare, it still represents only a minority of cases of dementia in the under-65s. (For comparison, AD was diagnosed in 34 per cent, vascular dementia in 18 per cent, alcohol-related dementia in 10 per cent and dementia with Lewy bodies in 7 per cent.)

Similar figures were obtained by Harvey *et al.* (2003), who surveyed three London boroughs with a total population of 567 500 people and calculated an overall prevalence for early onset-dementia of 98 per 100 000 for patients aged 45–64 years.

The prevalence of FTD in the over-65s is largely unknown. In a recent prospective investigation of 451 85-year-olds in Sweden, 86 (19 per cent) fulfilled the criteria for a frontal lobe syndrome and 14 (3 per cent) fulfilled the Lund–Manchester criteria for fvFTD (Gislason *et al.*, 2003).

53.8 CONCLUSIONS

It is clear that this is a rapidly evolving field but that further detailed clinicopathological studies are required to address the many outstanding questions. Kertesz (2003) suggests that the disorders of PiD, FTD, primary progressive aphasia, CBD, PSP and FTD-MND should be regarded as part of a clinically and biologically cohesive spectrum and subsumed by the umbrella term ‘Pick’s complex’. However, we continue to prefer the use of separate clinical syndromic labels, which avoid specific pathological connotations.

54.3 Tau biochemistry in frontotemporal lobar dementia	696	References	698

Frontotemporal lobar degeneration (FTLD) refers to a clinically and pathologically heterogeneous group of early onset, non-Alzheimer forms of dementia. Although relatively rare when compared with Alzheimer's disease (AD) over all ages, FTLD is actually the second most common cause of dementia within the presenium, there being one case of FTLD for every four of AD with disease onset before 65 years of age (Snowden *et al.*, 1996). Historically, many of the various forms of FTLD were originally described under the rubric of 'Pick's disease' and its variants, though within the past 10–15 years there has been a great resurgence of interest in the disorder, largely because of the longitudinal clinical and pathological studies carried out in Lund and Manchester during the late 1980s and early 1990s from which the spectrum of disease has come to be recognized (see Snowden *et al.*, 1996), and with that consensus diagnostic criteria for the various clinical forms of FTLD have emerged (Neary *et al.*, 1998).

The prototypical, and most common, clinical syndrome within FTLD is frontotemporal dementia (FTD). This manifests as behavioural and personality changes involving disinhibition, stereotypy, antisocial acts and language disorders, and leads to apathy, mutism and late neurological (frontal release or extrapyramidal) signs. However, the breadth of illnesses can extend far wider and involve cases where a parkinsonian-type movement disorder or a progressive apraxia (PAX), with relatively mild dementia, is the major disabling feature, or others in which a language disorder of a fluent or non-fluent aphasia, known as semantic dementia (SD) or progressive aphasia (PA), respectively, predominate. Moreover, cases of FTD may be complicated both clinically, but more usually pathologically, by changes associated with motor neurone disease (MND), and in these instances the disorder

has been termed frontotemporal dementia with MND (FTD-MND), or recognizing the presence of MND-type pathology in the absence of MND clinical phenotype, motor neurone disease inclusion dementia (MNDID). The clinical and neuropsychological features of these disorders are described by David Neary in Chapter 52.

As described in this present chapter, molecular genetics has now begun to rationalize classification of FTLD, though major nosological uncertainties remain. Clinical diversity remains an obstacle and the pathological heterogeneity within this group of disorders remains largely unexplained. Here, the genetics and molecular pathology of FTLD associated with mutations in tau and other possible mutations on chromosome 17 and elsewhere, as well as that in other cases of FTLD, where no such chromosomal associations are present or at least known, is reviewed. It is recognized that FTLD is unlikely to have a single unifying cause to clinical symptomatology and underlying pathological change.

54.1 THE GENETICS OF FRONTOTEMPORAL LOBAR DEGENERATION

A previous family history of a similar disorder occurs in about half of patients with FTLD (Snowden *et al.*, 1996). It was this degree of inheritability that triggered much of the current upsurge in interest among research scientists into the biology of FTLD, by leading to the crucial identification that certain inherited forms of FTLD were genetically linked to a locus on chromosome 17 (this form of the disorder then became known as 'frontotemporal dementia with parkinsonism

linked to chromosome 17' [FTDP-17] and was associated with mutations in the tau gene, tau [Hutton *et al.*, 1998; Poorkaj *et al.*, 1998; Spillantini *et al.*, 1998]). Since then there has been an explosion of data concerning the genetics and biochemistry of FTLD.

Although the occurrence of tau mutations within FTLD is relatively rare – prevalence rates vary from about 6 to 18 per cent (Houlden *et al.*, 1999a; Poorkaj *et al.*, 2001; Rosso *et al.*, 2003) – their identification has been of paramount importance, providing crucial insight through the ability to 'model' the disorder in cell systems and animals. This has greatly increased our knowledge not only of the pathogenesis of FTLD, but also how the production and function of tau protein is normally regulated. Moreover, the characterizing neuropathological feature of FTLD due to tau mutations is the presence of insoluble aggregates of tau protein in the absence of deposits of amyloid β protein (A β). This proves that tau pathology can lead to neurodegenerative disease in its own right and has focused attention once again upon the key role that neurofibrillary degeneration may play in AD.

54.1.1 Genetics of FTLD associated with tau mutations

54.1.1.1 THE STRUCTURE OF TAU AND THE FUNCTION OF TAU PROTEINS

Tau has 15 coding regions (exons), and transcripts of this gene are alternatively spliced to produce different isoforms within the brain and peripheral nervous system. In the central nervous system, the precise tau isoform expression pattern is under developmental regulatory control. In fetal brain only a single isoform containing exons 1, 4, 5, 7, 9 and 11–13 is expressed. However, in adult brain five additional isoforms are produced by the alternative inclusions of exons 2, 3 and 10, these ranging from 352 to 441 amino acids in length and differing according to the (alternatively spliced) inclusion of three or four (when exon 10 is included) imperfect repeat domains of 31 or 32 amino acids within the carboxy terminal region of the molecule, and also according to the absence or presence of one or two, 29 or 58 amino acid inserts (encoded by exons 2 and 3, respectively) in the amino terminal region. The conditional inclusion of exon 10 therefore generates three tau isoforms each with four microtubule binding domains compared with tau isoforms without exon 10 that have only three microtubule binding domains (known as 4-repeat tau, 4R, and 3-repeat tau, 3R, respectively). The six tau isoforms are designated 3R0N, 3R1N, 3R2N, 4R0N, 4R1N, 4R2N, respectively according to inclusion or otherwise of exons 2, 3 and 10. The carboxy-terminal domains, along with some adjoining sections of the molecule, act as the microtubule-binding region; the function of those sequences encoded by exons 2 and 3 remains unknown.

Splicing of exon 10 is regulated in a complex hierarchical way involving a variety of *cis*-acting sequences within exon 10, and within the intron to exon 11, which collectively modulate

the function of a putative stem loop structure to determine the degree to which splicing of exon 10 is permitted (Hutton *et al.*, 1998; D'Souza and Schellenberg, 2002). In this way a strict stoichiometric balance between 3R and 4R tau isoforms is maintained, since it is both the presence and proportion of 3R and 4R tau isoforms that is critical to the proper functioning of tau. Slightly more than half the tau molecules normally produced are 3R forms.

Tau protein is localized in neuronal axons and is involved in the regulation of microtubule assembly/disassembly and the axonal transport of proteins and organelles. All six isoforms play a precise role in this maintenance of microtubular structure and if one or more of the various isoforms fails to function, or if there is a stoichiometric imbalance in the different variants, microtubule formation will become more difficult or the stability of microtubules formed will become compromised. Any excess of unused tau (of any isoform composition) can be bundled into indigestible residues that choke the cell. Hence, a neuropathological aggregation of tau within the somatodendritic compartment of the neurone occurs in several neurodegenerative diseases, including FTLD, but also in AD and certain parkinsonian disorders such as progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD). The formation and accumulation of these insoluble tau aggregates within neurones (and sometimes glial cells) is widely believed to be critical to the neurodegenerative cascade that leads to nerve cell dysfunction and death in these disorders, possibly involving a toxic action of the filaments formed from the tau aggregates.

54.1.1.2 TAU MUTATIONS IN FTLD

To date, about 30 tau mutations in around 70 families with an FTLD phenotype have now been identified. Many of the tau mutations exist as missense, deletion or silent mutations within coding regions of exon 1 (R5H, R5L), exon 9 (K257T, I260V, L266V, G272V), exon 11 (L315R, S320F), exon 12 (Q336R, V337M, E342V, K369I) and exon 13 (G389R, R406W) (Hutton *et al.*, 1998; Poorkaj *et al.*, 1998, 2001; Rizzu *et al.*, 1999; Murrell *et al.*, 1999; Pickering-Brown *et al.*, 2000a, b; Rizzini *et al.*, 2000; Lippa *et al.*, 2000; Neumann *et al.*, 2001; Hayashi *et al.*, 2002; Saito *et al.*, 2002; Rosso *et al.*, 2002, 2003; Grover *et al.*, 2003; Hogg *et al.*, 2003; Kobayashi *et al.*, 2003b; van Herpen *et al.*, 2003). These tau mutations are located outside exon 10 and therefore affect all six tau isoforms. They generate mutated tau molecules that, *in vitro*, (variably) lose their ability to interact with α and β tubulin molecules in the promotion of microtubule assembly and axonal transport (Hasegawa *et al.*, 1998; Hong *et al.*, 1998). Some of the mutations also increase, but again variably, the propensity of the mutated tau to self-aggregate into the fibrils (Hasegawa *et al.*, 1998; Goedert *et al.*, 1999a; Nacharaju *et al.*, 1999) that form the characterizing pathological structures within the brain. Nonetheless, even those mutations that cause only a modest effect on microtubule binding or promote only mild or slow tau aggregation may over many years course of illness build sufficiently to cause FTLD.

Other tau mutations (N279K, Δ K280, L284L, Δ N296, N296H, N296N, P301L, P301S, S305S and S305N – the last two also being known as –1 and –2 splice site mutations) occur within the alternatively spliced exon 10, or lie close to the splice donor site of the intron that follows exon 10 within a regulatory region of tau that determines the alternative splicing inclusion of exon 10 during gene transcription (these being known as +3, +11, +12, +13, +14 and +16 splice site mutations) (Clark *et al.*, 1998; Dumanchin *et al.*, 1998; Hong *et al.*, 1998; Hutton *et al.*, 1998; Poorkaj *et al.*, 1998; Spillantini *et al.*, 1998, 2000; Delisle *et al.*, 1999; D'Souza *et al.*, 1999; Goedert *et al.*, 1999b; Hasegawa *et al.*, 1999; Iijima *et al.*, 1999; Mirra *et al.*, 1999; Morris *et al.*, 1999; Nasreddine *et al.*, 1999; Rizzu *et al.*, 1999; Sperfeld *et al.*, 1999; Yasuda *et al.*, 1999, 2000a, b; Stanford *et al.*, 2000, 2003; Tolnay *et al.*, 2000; Iseki *et al.*, 2001; Miyamoto *et al.*, 2001; Pastor *et al.*, 2001; Kowalska *et al.*, 2002; Pickering-Brown *et al.*, 2002; Kobayashi *et al.*, 2003a; Werber *et al.*, 2003). These mutations affect only that part of the tau protein sequence encoded by exon 10, and so affect only 4R tau isoforms.

The S305S (–1), S305N (–2), +3, +11, +12, +13, +14 and +16 splice mutations lie close to or within the predicted regulatory stem loop structure of a splice acceptor domain. These mutations may destabilize this stem loop, and disrupt its function, interfering with the binding of U1snRNP splice regulatory elements. Their effect is to increase the use of this particular splicing mechanism, thereby increasing the proportion of tau mRNA transcripts containing exon 10, and the amount of 4-repeat tau protein, such that the ratio between 4R and 3R tau isoforms becomes increased 2–3-fold (Hutton *et al.*, 1998; Spillantini *et al.*, 1998). With exception of S305N mutation, which changes the consensus sequence for 4-repeat tau isoforms, none of these regulatory mutations alter the primary amino acid structure of the tau proteins transcribed and therefore do not *per se* impair microtubule binding (Hong *et al.*, 1998; Hasegawa *et al.*, 1999).

The N279K mutation also increases the splicing of transcripts containing exon 10 by strengthening an exon-splicing-enhancing element in the 5' region of exon 10, but likewise does not impair microtubule binding (D'Souza *et al.*, 1999; Hasegawa *et al.*, 1999). The L284L silent mutation likewise strengthens exon 10 splicing by destroying the function of a splice-silencing element, and as a consequence no tau transcripts without exon 10 (i.e. 3R tau isoforms) are produced (D'Souza *et al.*, 1999). Conversely, the Δ K280 mutation destroys the function of the splice-enhancing region and results in the abolition of transcripts containing exon 10, i.e. only 3R tau isoforms are produced (D'Souza *et al.*, 1999). Interestingly, this mutation also affects microtubule binding and may therefore possess a dual pathogenicity.

The coding P301L and P301S mutations do not affect the splicing of exon 10 (Hutton *et al.*, 1998; D'Souza *et al.*, 1999) but induce conformational changes in tau molecules containing exon 10 alone that interfere with microtubule function, and lead to the specific aggregation of the mutant 4-repeat tau into fibrils (Miyasaka *et al.*, 2001). Mutational events at

codon 296 (N296H, N296N, Δ N296) (Spillantini *et al.*, 2000; Stanford *et al.*, 2000; Iseki *et al.*, 2001; Pastor *et al.*, 2001) also lead to impaired ability of mutated (4-repeat) tau to interact with microtubules and promote fibrillogenesis (Spillantini *et al.*, 2000; Grover *et al.*, 2002; Yoshida *et al.*, 2002), though both N296H and N296N mutations increase splicing of exon 10 (Spillantini *et al.*, 2000; Grover *et al.*, 2002; Yoshida *et al.*, 2002), perhaps by disrupting the exon-splicing-silencing sequence (Spillantini *et al.*, 2000) or creating an exon-splicing-enhancing sequence (Grover *et al.*, 2002). The Δ N296 mutation has been reported to lead to an increase (Yoshida *et al.*, 2002) or no change (Grover *et al.*, 2002) in exon 10 splicing.

There are also *cis*-acting intron splicing silencer (ISS) and intron splicing modulator (ISM) sequences extending downstream from the 5' splice site, encompassing nucleotides +11 to +18, and nucleotides +19 to +26 following the stem loop structure (D'Souza and Schellenberg, 2002). These act in conjunction with the splice-enhancing and splice-silencing sequences within exon 10 to collectively regulate exon 10 splicing. Damage to these ISS and ISM sequences should mimic the action of +12, +13, +14 and +16 point mutations (D'Souza and Schellenberg, 2002). Indeed, two Australian families with FTD have recently been described (Stanford *et al.*, 2003) with mutations at positions +19 and +29 in the 5' splice donor region of exon 10 which have been claimed to destroy the function of the ISM sequence, leading to the abolition of exon 10 splicing and thereby reducing splicing of exon 10, decreasing the proportion of 4R tau isoforms (Stanford *et al.*, 2003), analogous to Δ K280 mutation (D'Souza *et al.*, 1999). However, the +29 change has also been reported in controls (D'Souza *et al.*, 1999; Poorkaj *et al.*, 2001; Stanford *et al.*, 2003; Hutton, personal communication) and may be a rare (coincidental) polymorphism. The +19 variant has not been reported in controls and may be pathogenic.

54.1.1.3 FOUNDER EFFECTS OF TAU MUTATIONS

Other than the above mutational events associated with FTL, tau is 'naturally' subject to multiple polymorphic changes in exons 1, 2, 3, 7, 9 and 11 (Baker *et al.*, 1999). These natural variations are usually in complete linkage disequilibrium, being co-inherited as two common haplotypes H1 and H2; H1 has a frequency of 78.4 per cent in the normal Caucasian population. The P301L tau mutation is the most common FTL mutation to date, being present worldwide in many families with French or Dutch ancestry (Hutton *et al.*, 1998; Houlden *et al.*, 1999a; Rizzu *et al.*, 1999; Rosso *et al.*, 2003; Sobrido *et al.*, 2003). Because many of these families share the less common H2 haplotype on the disease gene, it is likely that they might share a common founder. However, Japanese families with P301L tau mutation share the extended H1 haplotype, implying separate founders. The presence of other varying tau polymorphisms under H1 haplotype unique to the Japanese population within P301L subjects suggests multiple founders. The P301S mutation has been reported in German (Sperfeld *et al.*, 1999), Jewish-Algerian (Werber *et al.*,

2003) and Japanese (Yasuda *et al.*, 2000a) patients, but these are unlikely to be all related to a common founder. Hence, P301L and P301S tau mutations have probably arisen separately on multiple occasions, this particular codon being especially susceptible to mutagenesis.

The N279K mutation has been described in American (Clark *et al.*, 1998; Tsuboi *et al.*, 2002), French (Delisle *et al.*, 1998) and Japanese (Yasuda *et al.*, 1999) families but it is unlikely that any of these kindreds are related (Tsuboi *et al.*, 2002) with this particular mutation also having arisen independently on at least three occasions.

Haplotype analysis (Pickering-Brown *et al.*, 2004a) has shown a likely common founder for British, North American and Australian families with +16 splice site mutation. Indeed, even today, many of the British families with this mutation live in, or have originated from, North Wales, a rural and relatively remote region of United Kingdom. It is therefore quite likely that the founder with this mutation lived in this part of United Kingdom with 'spread' of the mutation into industrialized regions of the country during the Industrial Revolution.

54.1.2 Other genetic changes in FTLD

54.1.2.1 OTHER AUTOSOMAL DOMINANT MUTATIONS

Tau mutations only account for about 10–20 per cent cases of FTLD (Houlden *et al.*, 1999a; Rizzu *et al.*, 1999; Poorkaj *et al.*, 2001; Rosso *et al.*, 2003), but the frequency of these remains around 40 per cent when only cases with previous family history of similar disease consistent with autosomal dominance are considered (Rizzu *et al.*, 1999). Hence, other genetic loci may be associated with FTLD.

Indeed, there are at least five well described, definitely chromosome 17-linked, families in which no mutational event within tau has as yet been determined (Basun *et al.*, 1997; Froelich *et al.*, 1997; Lendon *et al.*, 1998; Rosso *et al.*, 2001; Rademakers *et al.*, 2002; Froelich Fabre *et al.*, 2003). Interestingly, in these families no insoluble aggregates of tau are seen either biochemically or histopathologically though ubiquitin positive inclusions may be variably present in some family members of at least three of these families (Rosso *et al.*, 2001; Rademakers *et al.*, 2002; Froelich Fabre *et al.*, 2003). Although intensive candidate gene investigations within the chromosome 17-linked region, including tau, has been performed in at least two of these families (Rademakers *et al.*, 2002; Froelich Fabre *et al.*, 2003), no disease-associated mutations have yet been detected. It remains possible therefore that in these particular families changes within promoter or regulatory elements within tau may be causal. Indeed, there may be (many) other 'tau-negative' FTLD families, with or without ubiquitin pathology, that share this presently unknown change on chromosome 17.

Alternatively, there may be genetic loci associated with autosomal dominant FTLD on chromosomes other than 17. In this latter respect linkage to chromosome 9 in several families clinically sharing an FTD and MND phenotype (also

known as frontotemporal dementia with ubiquitin inclusions) has been claimed (Hosler *et al.*, 2000) but not confirmed (Ostojic *et al.*, 2003). In one family with pathologically typical FTD and MND no definite linkage to chromosome 9q21–22 (or to chromosomes 17 or 3) was detected (Savioz *et al.*, 2003). Similarly, no linkage to chromosome 17 was found in another family with FTD and MND pathological phenotype (Kertesz *et al.*, 2000), but it is not known whether this family is linked to chromosome 9 or not.

Linkage to chromosome 3p11–12 has been reported in a Danish family showing FTD with frontotemporal atrophy, neuronal loss and gliosis, with a few tau immunoreactive neurofibrillary tangles in the absence of senile (amyloid) plaques (Gydesen *et al.*, 2002; Yancopoulou *et al.*, 2003). The significance of this particular family to the pathogenesis of FTD in general remains unknown, and it is possible that this family might represent a genetic change private to this geographically isolated kindred. Similarly, in a large Calabrian family with FTD phenotype, linkage studies excluded the above loci on chromosomes 3 and 9 but gave indeterminate data for chromosome 17 (Curcio *et al.*, 2002). Complicating matters is the finding of linkage to a different region of chromosome 9 in four families with hereditary inclusion body myopathy, Paget disease and frontotemporal dementia (Kovach *et al.*, 2001), but in these the brain pathology description is limited and does not appear to conform to FTLD.

Given the shortage of families of this kind for linkage and the lack of obvious candidate genes, this represents a difficult, but evolving, area of research that will be important in furthering our understanding of FTLD, providing insight into the pathogenetic mechanism underpinning the pathology in those cases where aggregation and accumulation of insoluble tau proteins are not the cardinal features.

54.1.2.2 TAU HAPLOTYPES AS GENETIC RISK FACTORS FOR FTLD

Possession of the H1 tau haplotype been associated with other neurodegenerative disorders characterized by tau pathology such as PSP and CBD. However, it is not clear whether this haplotype is acting simply as a marker for a more relevant change in a nearby gene or defining pathogenic changes in tau with which this is in linkage disequilibrium. While the H1 tau haplotype and the H1H1 tau genotype may be overall increased in patients with clinically diagnosed FTD (Verpillat *et al.*, 2002, but see Sobrido *et al.*, 2003), other studies suggest this increase may be accentuated in patients with apolipoprotein E (ApoE) ϵ 4 allele (Short *et al.*, 2002) or microvacuolar-type, rather than Pick-type, histology (Hughes *et al.*, 2003). An increase in the frequency of H2H2 tau genotype in cases with Pick-histology has been claimed (Russ *et al.*, 2001), but not confirmed (Morris *et al.*, 2002; Hughes *et al.*, 2003). Similarly, an increase in H2 tau haplotype frequency in SD, but not in PA or FTD, has been reported (Short *et al.*, 2002) but not confirmed (Hughes *et al.*, 2003). It is likely that differences in patient cohort size and ethnicity, and the use of

clinically diagnosed, as opposed to autopsy verified, cases of FTLD with possible mixing of clinical and pathological subtypes have all contributed to the present lack of clear vision as to the role of tau haplotypes in FTLD. Further studies on carefully chosen clinical and pathological subgroups are therefore needed to define the association between tau haplotypes and FTLD.

While the tau H1H1 genotype may play a role in promoting, or at least predisposing towards the tau pathology of PSP and CBD in the form of NFT predominantly composed of 4R tau, the possible increase in H1H1 tau genotype in FTD from microvacuolar-histology is interesting, since in this particular pathological form of FTLD no insoluble tau species are present. This suggests therefore that, in this instance, the H1 haplotype is operating via a different mechanism, or that it is merely serving as a marker for an (as yet) unidentified susceptibility locus that is either present on the tau H1 haplotype itself, or on a nearby gene.

54.1.2.3 APOLIPOPROTEIN E (ApoE) ϵ 4 ALLELE AS A RISK FACTOR

Although it is well known that the ApoE ϵ 4 allele is a risk factor for late onset sporadic and familial AD, the consensus seems to indicate that possession of this does not overall increase the risk of FTLD (Pickering-Brown *et al.*, 2000b; Short *et al.*, 2002; Verpillat *et al.*, 2002). Nonetheless, within FTLD it is possible that ApoE ϵ 4 allele frequency is raised in certain clinical subgroups. Short *et al.* (2002) reported ApoE ϵ 4 allele frequency to be increased in patients with SD, compared with those with FTD and PA, though Pickering-Brown *et al.* (2000b) found this to be normal in FTD and SD, but tended to be increased in PA. Interactions between the tau haplotypes and ApoE ϵ 4 allele have been variously claimed (Ingelson *et al.*, 2001; Short *et al.*, 2002) but not always confirmed (Hughes *et al.*, 2003). Further studies are needed to validate any such putative interactions.

In contrast to AD, possession of ApoE ϵ 4 allele does not affect age at onset of disease (or duration of illness) in either sporadic FTLD (Pickering-Brown *et al.*, 2000b; Short *et al.*, 2002) or FTDP-17 (Houlden *et al.*, 1999b; Pickering-Brown *et al.*, 2002; Tsuboi *et al.*, 2003). Hence it seems unlikely that ApoE ϵ 4 allele acts either as a risk factor or disease modifier in FTLD generally or FTDP-17 specifically, but it remains possible that this may play a part in other clinical subtypes such as SD or PA.

Results from small series of FTLD patients have suggested ApoE ϵ 2 allele might act as a risk factor (Lehmann *et al.*, 2000; Verpillat *et al.*, 2002), but again this remains to be substantiated (Pickering-Brown *et al.*, 2000b).

54.2 THE PATHOLOGY OF FRONTOTEMPORAL LOBAR DEGENERATION

Within FTLD, there are wide variations in the gross pathological appearance of the brain and in the underlying

histological changes. To a large extent, the gross anatomical changes can be correlated with the clinical phenotype, though at tissue level variations in histological appearance do not necessarily correlate with, nor predict, the clinical or genetic phenotype.

54.2.1 The gross pathology of FTD

There is nothing distinctive to distinguish the pattern of brain atrophy in cases of FTD with tau mutations from those of FTD without such mutations. Indeed, despite the large range of mutations, and the differing underlying pathogenetic mechanisms and histopathological changes associated with coding or splice site mutations, the gross pathological changes within the brain in patients with FTD with tau mutations are also remarkably consistent. Furthermore, is it not possible to distinguish cases of 'sporadic' FTD owing to microvacuolar-type histology from those with Pick-type histology, either on the basis of brain weight or pattern of cerebral atrophy (Mann and South, 1993; Schofield *et al.*, 2003). Hence, on external inspection alone, it cannot be predicted whether tau mutation will be present, nor whether Pick- or microvacuolar-type histology will occur.

Most patients with FTLD have a brain weight ranging within 1000–1250 g, though instances where this falls (well) below 1000 g are not uncommon (Lantos *et al.*, 2002). Weight loss is due to atrophy involving mostly the frontal, anterior parietal, cingulate, insular and temporal regions of the cerebral cortex, sometimes so severe as to produce 'knife-edge' atrophy (Plates 23 and 24). Usually the frontal and temporal lobes are equivalently affected, though the temporal lobes can be more affected in FTDP-17 cases when Pick-type pathology is involved (Rizzini *et al.*, 2000; Neumann *et al.*, 2001; Rosso *et al.*, 2002; Pickering-Brown *et al.*, 2004b). The pattern of cerebral atrophy generally appears symmetrical, or sometimes displays a slightly greater involvement of the left cerebral hemisphere. Even in extreme cases, motor, sensorimotor and posterior cerebral cortical regions, and the cerebellum and brain stem, are largely unaffected. Conspicuously, the superior temporal gyrus is often spared (Plate 24). The distinction between grey and white matter in atrophic areas is usually well maintained, although in severe cases there can be a great loss of axons and myelin, and the white matter becomes brownish in colour and soft and 'rubbery' in texture. The hippocampus and amygdala are frequently atrophic, as is the caudate nucleus, though the putamen, globus pallidus and thalamus are less affected. The corpus callosum is usually thinned, particularly anteriorly. The lateral ventricles are much enlarged though the temporal horns are little changed, except in severe cases. In most instances the substantia nigra, and sometimes also the locus caeruleus, are noticeably underpigmented. The cerebellum usually appears normal. This typical pattern of brain atrophy is illustrated diagrammatically in Plate 25.

Nonetheless, when the disorder is terminated early, or in FTD cases where disinhibition remains the principal clinical

symptom, even terminally, a preferential atrophy of the inferior frontal and anterior temporal gyri is seen (Snowden *et al.*, 1996). When stereotypic behaviours dominate in FTD, a marked striatal atrophy, particularly of the caudate nucleus, is present with lesser neocortical involvement, which in turn can be focused either on frontal or temporal lobes or involve both (Snowden *et al.*, 1996).

Cases of FTD and MND share a similar topography of brain atrophy to those with FTD alone though the severity of the atrophy is often less (Mann and South, 1993), possibly reflecting the shorter disease duration common among such cases. In most instances brain weight is reduced only little, to around 1250 g. Typically, the substantia nigra is underpigmented (Snowden *et al.*, 1996).

Cases of FTLN with a progressive language disorder of either a fluent aphasia (SD) or a non-fluent aphasia (PPA) may show preferential, bilateral atrophy of the temporal lobes or a grossly asymmetrical left hemispheric involvement, respectively (Snowden *et al.*, 1996). In PAX there is preferential involvement of the motor and premotor cortices.

These differing clinical syndromes reflect the topographical distribution of the brain pathology rather than the underlying histological nature.

54.2.2 The histopathology of FTLN

Histopathological changes underlying FTLN can vary widely and several patterns of histological change have been identified. In some instances the histological changes are tightly associated with a particular clinical form of FTLN, and indeed may be taken as the specific diagnostic features of that condition (e.g. some forms of FTLN with tau mutations and cases of MNDID), whereas in other instances the underlying histological changes cross over into more than one of the clinical phenotypes. These histological profiles are:

- tau mutation (FTDP-17)-type
- Pick-type
- microvacuolar type (DLDH-type)
- ubiquitin-type (MNDID-type).

54.2.2.1 HISTOLOGY OF FTD WITH *TAU* MUTATIONS

By conventional neurohistology, many cases of FTD owing to tau mutations show a microvacuolar type of histology with spongiosis of the outer cortical laminae (Lantos *et al.*, 2002; Pickering-Brown *et al.*, 2002), from shrinkage and severe loss of pyramidal nerve cell bodies and their processes (dendrites) from cortical layers II and III. Astrocytosis is usually mild and largely subpial. Loss of nerve cells from deeper laminae is less pronounced with many neurones being shrunken. Occasional swollen, chromatolytic (ballooned) neurones are seen, especially in layers V and VI. Conversely, other cases display a more severe and widespread neuronal loss with florid transcortical astrocytosis. Intraneuronal inclusion bodies can be seen and ballooned neurones are widely present.

However, it is by immunohistochemistry using antibodies to phosphorylated forms of tau protein that FTD in patients with tau mutations can be best distinguished both from other forms of FTLN and from each other according to the particular tau mutation they bear. Although all cases show a deposition of insoluble, aggregated tau proteins within neurones and (sometimes) glial cells of the cerebral cortex and other brain regions, there are nevertheless distinctive features to the tau pathology that fall into two histological patterns according to mutation type:

- FTDP-17 cases with microvacuolar histological changes are generally associated with mutations in and around the exon 10 splice site (i.e. S305S, S305N, +3, +11, +12, +13, +14 and +16 splice site mutations) and in these neurofibrillary tangle (NFT)-like structures within large and smaller pyramidal cells of cortical layers III and V (Plate 26a), and prominently within glial cells in the deep white matter, globus pallidus and internal capsule (Plate 26b) are seen (Lantos *et al.*, 2002; Pickering-Brown *et al.*, 2002). Typically, these NFT-like structures are 'classically' stained with phospho-dependent antibodies (e.g. AT8) against residues Ser202/Thr205 but not antibodies (e.g. 12E8) against Ser262 (Pickering-Brown *et al.*, 2002). Neurones within subcortical structures, such as corpus striatum, medial thalamus, nucleus basalis of Meynert, dorsal raphe, pontine and dentate nuclei, locus caeruleus and substantia nigra, can also be affected by neurofibrillary degeneration, but less severely so, and are similarly immunoreactive (for tau) as cortical neurones (Lantos *et al.*, 2002; Pickering-Brown *et al.*, 2002). However, in one patient with S305N mutation, Pick-type bodies not NFT were present within neurones (Kobayashi *et al.*, 2003b). Cases with P301L mutation show more neuronal than glial tau pathology (Mirra *et al.*, 1999) and N296H mutation more glial than neuronal pathology (Iseki *et al.*, 2001).
- Conversely, most cases associated with missense mutations in exons 9, 11, 12 and 13 show florid astrocytosis with swollen nerve cells (Plate 26c) and neuronal inclusions (Plates 26d and 26e). Here, the insoluble tau aggregates appear as rounded structures, reminiscent of Pick bodies (Plates 26d and 26e) (Pickering-Brown *et al.*, 2000; Rizzini *et al.*, 2000; Neumann *et al.*, 2001; Rosso *et al.*, 2002) as in some sporadic forms of FTLN (Plate 26f). These are mainly present within large and small pyramidal neurones, often scattered widely throughout affected cortical regions without laminar predilection. Pick bodies are also numerous within the pyramidal cells and the granule cells of the dentate gyrus of the hippocampus (Plate 26e). Again, these structures are strongly immunoreactive with AT8 but weakly, if at all, with 12E8. The swollen cells are particularly immunoreactive to AT270 (Plate 24) as well as AT8 antibody. Similar Pick body-like structures are also widely seen

throughout subcortical areas, particularly the corpus striatum. Tau-positive tufted astrocytes reminiscent of those seen in PSP, neuropil threads and coiled bodies are also sometimes widely seen within the cerebral cortex in some cases (Hogg *et al.*, 2003; Kobayashi *et al.*, 2003a).

Nevertheless, other mutations in exons 12 and 13 (V337M and R406W) are associated with NFT, similar both in appearance and in pattern of tau immunostaining (i.e. both AT8 and 12E8 immunoreactive) to those in AD, within nerve cells, but not glial cells, of the cerebral cortex (Van Swieten *et al.*, 1999; Saito *et al.*, 2002). Conversely, the exon 1 mutation, R5H displays a tau neurofibrillary pathology principally affecting oligodendroglial cells and, to a lesser extent, astrocytes (Hayashi *et al.*, 2002), but here the tangles are AT8, but not 12E8, immunoreactive.

Why certain tau mutations produce a (wholly) neuronal pathology (as in V337M and R406W mutations) and others both neuronal and glial pathology (as in splice site mutations) is not clear. It may reflect differing patterns of cellular expression of tau with neurones expressing all six isoforms whereas glial cells express only, or predominantly, 4R tau, and so are only involved when the mutation affects exon 10 splicing or function.

54.2.2.2 PICK-TYPE HISTOLOGY

About 25 per cent cases with FTLT not associated with tau mutations display Pick-type of histology similar to that seen in cases of FTD with tau mutations, where pyramidal cell loss in the cerebral cortex and hippocampus is accompanied by a florid transcortical astrocytosis (Mann *et al.*, 1993; Schofield *et al.*, 2003) and intraneuronal inclusions (Pick bodies) and swollen (Pick) cells (Taniguchi *et al.*, 2004). However, in contrast to cases of FTD with tau mutations, the Pick bodies in sporadic FTLT are distributed in laminar fashion, mostly in cortical layers II and VI (Taniguchi *et al.*, 2004). Nonetheless, the Pick bodies in these (presumed) sporadic cases of FTLT display the same tau immunohistochemical features as those in cases of FTD with tau mutations (Taniguchi *et al.*, 2004).

54.2.2.3 MICROVACUOLAR-TYPE HISTOLOGY

This is perhaps the most common histology present in FTLT, occurring in about 75 per cent of FTLT patients, including some of those cases of FTD with tau mutations (see above) as well as clinical cases of FTD, SD or PA (Taniguchi *et al.*, 2004). In these, a microvacuolar type of histology in outer cortical laminae, mainly in layer II and upper layer III, is present. Cases of FTLT with this form of histology have also in the past been known as having dementia lacking distinctive histological features (DLDD), recognizing the lack of 'specific' pathologies like plaques, tangles, Pick or Lewy bodies in this histopathological appearance. However, it is now accepted that this pattern of change is so characteristic and consistent between cases as to make it of diagnostic relevance. The

severity of tissue damage matches closely the topographic distribution of the atrophy. Astroglial reaction is less severe, usually being confined to subpial regions or occurring at the border between grey and white matter (Mann *et al.*, 1993; Schofield *et al.*, 2003). Loss of myelin and axons is often inconspicuous, except in severely atrophic areas, and white matter astrogliosis is mild. Microglial cell reaction is confined to white matter (Schofield *et al.*, 2003).

The hippocampus is usually quite normal, although sometimes a severe loss of nerve cells from area CA1 occurs in the absence of neurofibrillary degeneration. On occasions some NFTs are present among the stellate cells of layer II of the entorhinal cortex. Despite the widespread atrophy frequently seen within the basal ganglia and amygdala, no specific histopathological changes are evident microscopically in such regions except for a variable degree of astrocytosis. In some instances, particularly in cases where stereotypic behaviours are prominent, this can be more severe and obvious neuronal loss will also have taken place. Some cases show pronounced cell loss from the substantia nigra, with residual pigment free within the neuropil or in macrophages, and grumose bodies occur when neuronal cell loss is heavy. The locus caeruleus can be affected, though is usually spared, sometimes even when nigral involvement is severe. Occasionally, scattered ubiquitinated inclusions of the type more frequently seen in FTD and MND, are present within granule cells of the dentate gyrus (Tolnay and Probst, 1995; Taniguchi *et al.*, 2004) (see below).

54.2.2.4 UBIQUITIN-TYPE (MNDID) HISTOLOGY

In many, and perhaps up to two-thirds of, patients with FTLT with microvacuolar-type histology (Taniguchi *et al.*, 2004), and indeed in some with SD (Rossor *et al.*, 2000) and PPA (Caselli *et al.*, 1993), the pathological (and sometimes clinical) features of MND have also been recorded. Here, along with the microvacuolation and mild subpial astrocytosis, ubiquitin-, but not tau-, immunoreactive intraneuronal inclusions are characteristically seen in pyramidal cells of layer II of the frontal and temporal cortex, less commonly in layers III and V. This histology has been termed MND-type (Jackson *et al.*, 1996), and such cases referred variously as ones of FTD-MND as here, MNDID, inclusions, tau and synuclein negative, ubiquitinated (ITSNU) or frontotemporal dementia with ubiquitin-positive, tau-negative inclusions.

Similar ubiquitinated inclusions are (characteristically) present in granule cells of the dentate gyrus of the hippocampus (Jackson *et al.*, 1996; Woulfe *et al.*, 2001), less commonly so in the amygdala (Anderson *et al.*, 1995). Interestingly, some cases also show ubiquitinated inclusions within the nuclei of cortical pyramidal neurones, dentate gyrus granule cells and striatal neurones (Woulfe *et al.*, 2001). The substantia nigra is nearly always damaged, often severely so showing subtotal nerve cell loss but without inclusions (Jackson *et al.*, 1996; Snowden *et al.*, 1996). A profound astrocytosis is seen and grumose bodies are frequent.

Like classic MND, the characteristic skein or rounded ubiquitin inclusions within the motor neurones of the anterior horns of the spinal cord and brain stem cranial nerve nuclei can be seen in FTD-MND, and the pattern of nerve cell loss is similar though usually milder than that of classic MND.

54.2.2.5 OTHER PATHOLOGICAL CHANGES

Senile (neuritic) plaques are generally not seen in cases of FTLN with, or without, tau mutations. However, diffuse deposits of A β may sometimes occur mostly within the otherwise undamaged posterior cerebral cortex. Numerically, these are not usually beyond that which might be expected for age, and are commonly associated with possession of ApoE ϵ 4 allele (Mann *et al.*, 2001; Lantos *et al.*, 2002; Pickering-Brown *et al.*, 2002).

54.2.3 Clinicopathological correlations

It is important to recognize that any one of these four histological profiles can occur in patients with FTLN, and generally it is not immediately predictable from the clinical symptomatology which pattern will underlie the clinical changes. Similarly, an underlying microvacuolar- (Snowden *et al.*, 1996) or Pick-type (Graff-Radford *et al.*, 1990) histopathology can occur in cases of SD and PA, though most commonly this is microvacuolar-type. The fundamental pathological process behind these latter disorders is likely to be the same as in FTD, the differing topography of change dictating the clinical symptoms present. FTD-MND in conjunction with a Pick-type histology appears to be much less common (Sam *et al.*, 1991). However, all cases of PAX to date appear to have Pick-type histology (Snowden *et al.*, 1996) and this condition may therefore represent a parietal lobe manifestation of a pathological process that more usually afflicts frontal and temporal lobes. Although patients with progressive anomia and progressive proposagnosia have been described clinically (Snowden and Neary, 2003) pathological analysis remains incomplete, though one patient with progressive anomia showed underlying pathology of microvacuolar-type with ubiquitin inclusions in frontal cortex and hippocampus (Mann, unpublished data).

54.3 TAU BIOCHEMISTRY IN FRONTOTEMPORAL LOBAR DEMENTIA

54.3.1 Tau biochemistry in FTD with tau mutations

By Western blotting, the insoluble tau aggregates that accumulate in the brain as Pick-like bodies in neurones, and sometimes within glial cells and neuropil threads, in cases with missense mutations in exons 9 (K257T, L266V, G272V), 11 (S309N, L315P), 12 (G336R, G342V) and 13 (K369I, G389R)

are composed of variable mixtures of 3R and 4R tau species, sometimes with a preponderance of 4R species (Murrell *et al.*, 1999; Lippa *et al.*, 2000; Neumann *et al.*, 2001; Pickering-Brown *et al.*, 2001; Kobayashi *et al.*, 2003a), but on other occasions more 3R is present (Rizzini *et al.*, 2000; Hogg *et al.*, 2003). The reasons for these differences in tau isoform composition remain unclear but may relate to the particular conformational properties to the tau molecules that each mutation imposes.

On the other hand, mutations in and around the stem loop structure at the exon 10 splice site (N279K, L284L, P301L, P301S and S305N plus +3, +11, +12, +13, +14 and +16 form insoluble tau aggregates) contain mostly 4R tau (Pickering-Brown *et al.*, 2002), as do R5H and R5L mutations (Poorkaj *et al.*, 2001; Hayashi *et al.*, 2002).

In V337M and R406W, the insoluble tau aggregates are composed of an equal mixture of 3R and 4R tau (Hong *et al.*, 1998; Hutton *et al.*, 1998; Poorkaj *et al.*, 1998; Rizzu *et al.*, 1999; Van Swieten *et al.*, 1999), similar to the paired helical filaments of AD.

54.3.2 Tau biochemistry in FTLN not associated with tau mutations

As in cases of FTD with tau mutations and Pick bodies, cases of sporadic FTLN with Pick histology show variable patterns of tau isoform by both western blotting and immunohistochemistry. In many instances, western blotting shows the insoluble tau is composed mostly, or even exclusively, of 3R tau isoforms (Delacourte *et al.*, 1998), although on other occasions substantial quantities of 4R tau are present (Arai *et al.*, 2001; Ikeda *et al.*, 2002; Zhukareva *et al.*, 2002; Taniguchi *et al.*, 1994). As in some cases of FTD with tau mutations with Pick bodies (Hogg *et al.*, 2003; Pickering-Brown *et al.*, 2004b) the Pick bodies in such sporadic FTLN cases are in fact immunoreactive only with 3R, and not 4R, tau-specific antibodies (even though both 3R and 4R tau isoforms are detectable on western blotting (Arai *et al.*, 2001; Ikeda *et al.*, 2002), because of the presence of 4R tau isoforms in glial cells and neuropil threads, which show up on western blot. However, other immunohistochemical studies on cases showing 4R tau isoforms by western blot have revealed the Pick bodies also to contain 4R tau (Zhukareva *et al.*, 2002). Hence, as in FTD with tau mutations, the precise tau isoform composition of Pick bodies in sporadic FTLN can vary greatly; why this biochemical heterogeneity of tau should occur remains unclear.

Cases of FTD, FTD and MND, SD and PPA not due to mutations in tau, but showing microvacuolar histology, display either no, or only trace amounts of, insoluble tau on western blot (Zhukareva *et al.*, 2001, 2003; Taniguchi *et al.*, 2004). When present, this tau is comprised of all six tau isoforms, consistent with the presence of rare (age-related) NFTs seen on immunohistochemistry (Taniguchi *et al.*, 2004). However, there is considerable loss of soluble tau proteins

(Zhukareva *et al.*, 2000, 2003; Adamec *et al.*, 2001; Taniguchi *et al.*, 2004), both in microvacuolar- and Pick-type histological cases. Because this loss of soluble tau is paralleled by loss of other soluble neuronal perikaryal markers, and because similar losses of soluble tau are seen in severe cases of AD, Huntington's disease and FTD with tau mutations (Taniguchi *et al.*, 2004), it is more likely that this loss of soluble tau in FTLD reflects a broad neurodegeneration that carries tau proteins in its wake along with many other cellular proteins.

54.4 DIAGNOSTIC CONSIDERATIONS

54.4.1 How far does the FTLD phenotype extend?

A chromosome 3-linked family with FTD (Gydesen *et al.*, 2002) shows similar 'non-specific' features of FTLD, like neuronal loss and gliosis, sometimes with (a few) neurofibrillary changes in the absence of neuritic plaques (Yancopoulou *et al.*, 2003). Indeed, most recently, Josephs *et al.* (2003) reported four cases of FTD with microvacuolar histology and ubiquitin inclusions, the latter also, and atypically so for FTD/FTD and MND, being reactive with antibodies against heavy and light chain neurofilament proteins, which they termed neurofilament inclusion body disease; a similar case was also reported by Bigio *et al.* (2003). Whether these potentially related conditions should be included under FTLD is, for the present, uncertain – future molecular genetic analyses may define their nosological position.

Moreover, it can be asked whether the tauopathy of FTLD can, or even should, be extended to include other non-Alzheimer forms of dementia such as PSP and CBD. The increased frequency of the tau H1 haplotype may be a genetic pointer to such inclusion. Moreover, the tangles of PSP and CBD appear as flat ribbons of 4R tau (Sergeant *et al.*, 1999), and affect both nerve cells and glial cells. Such changes are strongly reminiscent of those FTD cases associated with (splicing) changes in exon 10 of tau (Pickering-Brown *et al.*, 2002), thereby further strengthening the case for including such disorders under FTLD.

54.4.2 Diagnostic relevance of *tau* mutations

Currently, there are no clear cut family history, clinical, radiological or gross histopathological distinctions that can distinguish cases of FTD owing to tau mutations from those without such (or other) mutations, nor is it possible to predict which cases of FTD might be associated with Pick bodies and which with a microvacuolar type change. Only direct tau gene analysis can determine which cases of FTLD are due to such mutations. Yet, as we have already seen, these account for less than 10 per cent of all cases of FTD. Clearly cases of FTD with tau mutations account for a minority of FTLD, and the expectation of detecting such cases by genetic analysis

is low. This is not only of practical histopathological diagnostic relevance, but also has implications for genetic testing, not only in actual patients with FTLD, but also in (unaffected) relatives who may be at risk and concerned about predictive testing. For a successful and meaningful genetic testing service that will be of benefit to patients and relatives in terms of the knowledge or reassurance it may provide and the potential for appropriate (future) therapeutic or clinical management, it is necessary to know the full extent of the association of the tau gene with disease phenotype, and questions relating to the degree of penetrance of mutations be fully answerable. As regards the former, it is likely that the full range of mutations within coding and associated splicing regions in tau will soon become known as research into the biology of FTLD continues apace. However, there may still be many cases of FTLD where causative changes in tau are less clear cut, affecting, for example, promoter or other regulatory elements leading to (variably) increased risk of disease. As with ApoE ϵ 4 allele in AD, the diagnostic or predictive value of such risk factors may be limited. Second, there are issues of incomplete or delayed penetrance, even within presently known tau mutations associated with FTD (Murrell *et al.*, 1999; Pickering-Brown *et al.*, 2000a, 2002; van Herpen *et al.*, 2003). There may well also be several other causative genes for FTLD, each carrying its own particular load of questions relating to association and penetrance. All of these issues (presently) reduce the utility of clinical testing for FTLD by genetics. Nonetheless, there is current, albeit low, interest in genetic testing for early onset familial dementia, including FTD (Steinbart *et al.*, 2001). Whether this demand will increase with future knowledge regarding the genetics of FTLD is uncertain. Even in genetically 'well-understood' disorders such as Huntington's disease where genetic testing within a genetic counselling service has been widely available now for many years, and clear-cut advice can be given to the benefit of patients and relatives, take-up rates of genetic testing are still relatively low.

54.4.3 Ubiquitinopathy or tauopathy?

In the absence of any laboratory test based on the levels of pathological (i.e. phosphorylated) tau in blood, serum or cerebrospinal fluid that can unequivocally distinguish cases of FTLD from healthy controls, or from cases with other tauopathies such as AD, neuropathology remains the 'gold standard' for diagnosis. Nonetheless, here too there are pathological heterogeneity and nosological uncertainties that cloud diagnostic precision. Evaluations of autopsy-based series (Rosso *et al.*, 2003; Taniguchi *et al.*, 2004) show that cases with tau-based pathology (tauopathy) within FTLD only account for up to about 45 per cent cases. Of those with tau-positive inclusions, about half will have Pick bodies, but not be associated with a mutation in tau, with the remainder being associated with tau mutations displaying either a Pick-type histology or a NFT-type histology depending upon the

mutation in question. Of the 55 per cent or more cases with non-tau (microvacuolar) histology, as many as half to two-thirds of these will have also ubiquitin-positive inclusions, seemingly making this the most common pathological form underlying FTLD.

However, the diagnostic relevance of these ubiquitin inclusions is not clear, nor is it certain that they are indexing the same cellular change in all instances. Apart from their widespread presence within frontal and hippocampal neurones in cases which have now become classed as FTD and MND (MNDID, ITSNU or frontotemporal dementia with ubiquitin inclusions), they are also present in these same brain regions (but less severely so) in cases of FTD without MND (see above), as well as in cases of MND alone (Kawashima *et al.*, 2001; Mackenzie and Feldman, 2003). This suggests patients with FTD, but not MND, and MND alone, may represent polar points on an evolving pathological continuum, which eventually leads from either direction into the 'merging' pathology of FTD and MND. A cognitive change (perhaps eventually evolving into dementia) within classic MND may go thus unrecognized in many instances. Indeed frontal and temporal lobe deficits by SPECT in many cognitively normal patients with MND suggest the presence of preclinical changes in the frontal lobes, possibly commensurate with the (early) presence of ubiquitin inclusions.

54.5 OUTSTANDING ISSUES

Within the putative entity of FTLD, a spectrum of clinical and pathological phenotypes can be entered, all of which share, to a greater or lesser extent, a non-Alzheimer-type of histological profile characterized by cerebral cortical neuronal loss, gliosis and microvacuolar change, with or without intraneuronal tau or ubiquitin inclusions, along with subcortical glial and neuronal tau pathology and a (severe) degeneration of the substantia nigra. Such overlaps argue strongly for aetiopathogenetic interrelationships. Nonetheless, it remains to be established how much of the FTLD spectrum relates to a 'tau pathology' of some kind or other. For example, are cases of sporadic FTLD where no tau inclusions are present related to deleterious imbalances in regulatory elements of tau gene, which detrimentally disturb the normal levels, or stoichiometric composition, of tau proteins? Furthermore, how do disorders like MND-FTD, PA and SD, where ubiquitin inclusions are commonplace, relate genetically and biochemically to FTLD with tau inclusions? To date, no mutations in tau have been identified in patients with these particular disease phenotypes. What is the significance of the ubiquitin inclusions in FTD (SD/PA) + MND, and what is the key protein present within such inclusions that is being 'tagged' by the ubiquitin? Answers here will be critical to our understanding of the causative mechanism behind this form of FTLD, and will help to pin-point responsible genetic changes,

and clarify nosology with respect to cases of FTLD associated with tau inclusions.

The challenge to define and classify these non-Alzheimer forms of dementia, some of which manifest as FTLD, others as differing neuropsychological syndromes, remains to be completed. To date at least three major clinical syndromes, FTD, SD and PA, each combined or not with MND, can be included under FTLD, as well as less common disorders such as PAX, progressive anomia and progressive prosopagnosia. Maybe PSP and CBD should also be included under FTLD? Pathologically, there is also great heterogeneity underpinning each of these clinical syndromes, with microvacuolar-type or Pick-type histologies being present, the former often being associated with ubiquitin inclusions but on other occasions not or minimally so. Some cases of FTD with microvacuolar changes are associated with mutations in tau, which translate into distinctive tau pathology, but these are relatively rare within FTLD and may represent a minority cause of inherited FTLD. To what extent do other risk factors in tau, or other genes, contribute to 'sporadic' FTLD? The huge advances gained in the past 5 years through molecular genetics and biochemistry will no doubt continue to be built upon, and it will not be long before the many of the present mysteries surrounding the causes and mechanics of FTLD that confound attempts at nosology are ultimately yielded up and a proper and rational means of chemically and genetically defining these disorders becomes closer.

Semantic dementia is a distinctive clinical syndrome that arises from circumscribed degeneration of the temporal lobes. It is one of a number of distinct syndromes, which include frontotemporal dementia and primary progressive non-fluent aphasia, encompassed within the pathological rubric of frontotemporal lobar degeneration. The disorder is characterized by a progressive loss of semantic (conceptual) knowledge about the world. This includes loss of the ability to understand the meaning of words, to recognize faces, and to understand the significance of objects, non-verbal sounds, tastes and smells. Despite the wide-ranging nature of this loss of 'meaning', the disorder is remarkably circumscribed in the sense that non-semantic aspects of cognitive functioning remain well preserved. Patients have normal sensory perception: the problem lies in ascribing meaning (connotative associations) to stimuli that are perceived normally. Moreover, day-to-day memory is well preserved. As a consequence patients are able to retain a high degree of functional independence well into the course of disease. It is the dramatic, yet selective nature of the semantic disorder, together with characteristic accompanying behavioural changes, that distinguishes this non-Alzheimer focal temporal lobe degeneration clinically from Alzheimer's disease. Although relatively rare, recognition of the disorder is important because of its distinct implications for management and treatment. Moreover, in recent years it has attracted considerable academic interest because of its potential to shed light on the organization of semantic memory and its neural basis.

55.1 HISTORICAL BACKGROUND

The term semantic dementia is relatively new. It was introduced (Snowden *et al.*, 1989) to encapsulate the multimodal loss of semantic knowledge that occurs in the face of relatively preserved non-semantic cognitive skills and has since been widely adopted (e.g. Hodges *et al.*, 1992a; Breedin *et al.*, 1994; Graham *et al.*, 1997; Lauro-Grotto *et al.*, 1997). Clinical criteria have been published to aid its identification (Neary *et al.*, 1998) and are summarized in Box 55.1.

Clinical cases of semantic dementia undoubtedly existed prior to the introduction of contemporary classifications. There are seminal reports in the literature of patients with circumscribed impairments of semantic memory occurring in association with a unspecified degenerative brain disease who would now be recognized as having semantic dementia (Warrington, 1975; Schwartz *et al.*, 1979, 1980). Moreover, some patients, described as having a fluent form of primary progressive aphasia (Basso *et al.*, 1988; Poeck and Luzzatti, 1988; Tyrrell *et al.*, 1990a; Snowden *et al.*, 1992), in fact have a disorder of semantics that extends beyond the domain of language and would fulfil criteria for semantic dementia. Similarly, patients with progressive prosopagnosia (Tyrrell *et al.*, 1990b; Evans *et al.*, 1995) may be examples of semantic dementia presenting in the visual domain. In the classical neurological and psychiatric literature there are reports of patients with lexical-semantic impairment occurring in association with

Box 55.1 *Clinical diagnostic features of semantic dementia.***I Core diagnostic features****A. Insidious onset and gradual progression****B. Language disorder characterized by:**

- i) progressive, fluent, empty spontaneous speech
- ii) loss of word meaning, manifest by impaired naming and comprehension
- iii) semantic paraphasias

*and/or***C. Perceptual disorder characterised by:**

- i) prosopagnosia: impaired recognition of identity of familiar faces

and/or

- ii) associative agnosia: impaired recognition of object identity

D. Preserved perceptual matching and drawing reproduction**E. Preserved single word repetition****F. Preserved ability to read aloud and write to dictation orthographically regular words****II Supportive diagnostic features****A. Speech and language**

- i) pressure of speech
- ii) idiosyncratic word usage
- iii) absence of phonemic paraphasias
- iv) surface dyslexia and dysgraphia
- v) preserved calculation

B. Behaviour

- i) loss of sympathy and empathy
- ii) narrowed preoccupations
- iii) parsimony

C. Physical signs

- i) absent or late primitive reflexes
- ii) akinesia, rigidity and tremor

D. Neuropsychological testing

- i) profound semantic loss, manifest in failure of word comprehension and naming and/or face and object recognition
- ii) preserved phonology and syntax, elementary perceptual processing, spatial skills and day-to-day memorizing

E. Electrophysiology

- normal

F. Brain Imaging (structural and/or functional)

- predominant anterior temporal abnormality (symmetric or asymmetric)

Reproduced with kind permission from Lippincott, Williams & Wilkins from Neary *et al.* (Frontotemporal lobar degeneration. A consensus on clinical diagnostic criteria. *Neurology* [1998] 51: 1546–1554)

focal temporal lobe atrophy (Pick, 1892; Rosenfeld, 1909), whose clinical description appears prototypical of semantic dementia (Snowden, 2001). The neurological term ‘transcortical sensory aphasia’ has historically been applied to the form of language disorder.

Aside from such cases it is likely that there are many patients with semantic dementia who, in the past, were not recognized as clinically distinct and were subsumed under the broad rubric of degenerative dementia or were wrongly classified as Alzheimer’s disease. Alzheimer’s disease continues to be the main misdiagnosis.

55.2 DEMOGRAPHIC FEATURES

Semantic dementia most commonly presents between the ages of 50 and 65 and affects both men and women. The time course of the illness is variable, the median illness duration being approximately 8 years, ranging from about 3 to 15 years. Most cases appear to occur sporadically. A history of dementia in a first-degree relative is documented in approximately 25 per cent of cases, although it is difficult to determine, in view of the retrospective nature of family history data, whether the form of dementia in affected relatives is similar. Nevertheless, the established clinical and pathological link between semantic dementia and the highly familial frontotemporal dementia (see below) suggests that genetic factors are likely to play an important role. There are no known geographical or socioeconomic factors that affect incidence. Accurate incidence and prevalence data are not currently available. However, the disorder would appear to be relatively rare. In an analysis of patient referrals to a specialist dementia clinic in a neurological department in Manchester, patients with prototypical, ‘pure’ semantic dementia accounted for approximately 10 per cent of cases of focal cortical degeneration (frontotemporal lobe degeneration), which in turn accounted for 20–25 per cent of cases of primary degenerative dementia presenting in the presenium.

55.3 PRESENTING COMPLAINTS

Patients’ own complaints, often supported by reports from relatives, are often that they ‘can’t remember things’. However, careful history-taking will reveal that the problem is not one of memory loss in the traditional sense. Patients are able to remember day-to-day events, keep track of time, remember appointments, find their way around without becoming lost, and retain a degree of functional independence that would be incompatible with a classical amnesia. The problem lies in the realm of semantic memory: in remembering what words mean, who people are and what objects are for. The presenting symptoms are most often in the verbal domain, manifest by patients’ difficulty in the understanding and use of words. Semantic errors occur in speech (for example, a rabbit is referred to as a ‘cat’) and patients may express perplexity and

lack of understanding of words previously known to them. However, in some patients the earliest symptoms are in the visual realm, manifest particularly by a difficulty recognizing faces. Relatives may also report a failure of object recognition: patients may, for example, no longer recognize fruits and vegetables in the supermarket. Medical referral may sometimes be precipitated by behavioural alterations. Patients are typically physically well, without neurological symptoms.

55.4 COGNITIVE CHARACTERISTICS

55.4.1 Language

Patients speak fluently and effortlessly, with normal articulation and grammar and without phonological (sound-based) errors, giving the superficial impression of normal output. Indeed, patients are often garrulous (Box 55.2). Nevertheless, there is typically a reduction in content words, and patients' reliance on broad generic terms, stereotyped usage of words and phrases and in particular the presence of within-category

errors such as 'sock' for glove may provide the clue to the underlying semantic impairment.

The semantic impairment, which may be scarcely apparent at clinical interview, becomes strikingly evident on formal testing of naming and word comprehension. Patients commonly exhibit difficulty naming even common objects and derive no benefit from first-letter cues. They may also show difficulty selecting the correct name when given semantically related alternatives, reflecting the fact that the naming problem is not simply one of word retrieval but represents a central breakdown of knowledge of the word itself. Word comprehension is affected. Expressions of lack of understanding of previously familiar words (e.g. 'Tiger, tiger, what's a tiger? I don't know what that is') commonly occur and are a revealing demonstration of the loss of word meaning. There is a tendency for vocabulary relating to patients' daily life to be better preserved than non-personally relevant vocabulary (Snowden *et al.*, 1994, 1995). Word comprehension and naming tests should therefore not be restricted to the common objects and body parts typically used in bedside testing, but should include names of animals, foods and objects, such as 'sheep', 'plum', 'violin' which are unlikely to relate directly to the patient's daily routine. Loss of knowledge about a word's meaning may not be absolute. The patient may, for example, know that a lemon is a food rather than an animal, but not know how it differs from an apple or banana. Assessment of word understanding should therefore probe knowledge of attributes as well as broad category knowledge.

Language comprehension problems arise principally at the single word level. Comprehension of syntactic rules of language is typically relatively well preserved. Thus, a patient may respond with ease to the question 'If the tiger is killed by the lion which animal is dead?', while failing the apparently simpler question 'Is a tiger bigger than a mouse?'. The former depends on understanding of grammatical relationships, whereas the latter on understanding of the lexical terms tiger and mouse.

Patients' ability to repeat what is said, to read aloud and write to dictation is relatively well preserved, although not entirely normal by virtue of the semantic deficit. Inevitably it is more difficult to repeat a meaningless sentence than one that carries meaning. In reading, patients read phonetically rather than for meaning, and produce regular pronunciations of words with irregular spelling-to-sound correspondences, consistent with surface dyslexia (Patterson *et al.*, 1985). Thus, 'glove' may be pronounced to rhyme with 'rove' and 'stove'; 'pint' to rhyme with 'mint'. Similar regularization errors occur also in writing: the word 'caught' written as 'cort'.

With progression of disease, speech content is increasingly empty and stereotyped in nature. Favoured terms may be adopted and used in a generic sense (e.g. 'twisting' to refer to all actions; 'plate' to refer to all objects). There is a gradual contraction in the themes of conversation, which centre exclusively on autobiographically relevant topics. At no time is speech non-fluent or effortful in production: conversational repertoire simply becomes progressively reduced until only a few verbal stereotypies remain.

Box 55.2 Characteristics of language disorder in semantic dementia

Spontaneous speech

- Fluent, effortless, often garrulous
- Empty content, reduced nominal terms
- Semantic paraphasias
- Substitution of generic terms
- Verbal stereotypies
- Preserved use of syntax
- Preserved phonology
- Normal articulation and prosody

Comprehension

- Impaired word understanding
- Good understanding of syntax

Repetition

- Relatively preserved

Naming

- Profound anomia
- Semantic errors present (e.g. 'dog' for elephant)
- No benefit from phonemic cues

Reading

- Fluent reading aloud
- Accurate reading of regular words
- Regularization of irregular words (surface dyslexia)
- Impaired comprehension of written material

Writing

- Fluent, effortless execution
- Regularization of irregular words (e.g. 'cort' for caught) (surface dysgraphia)

55.4.2 Face recognition

Problems in recognizing familiar faces occur early in the course of disease. Difficulties are most profound for impersonal faces, such as those of current and past celebrities, and least marked for family and friends with whom the patient maintains daily contact. The problem in face recognition lies at a semantic level: in assigning an identity to faces. That patients are able to perceive and discriminate faces adequately is demonstrated by their ability to carry out matching tasks of unfamiliar faces.

55.4.3 Object recognition

Object recognition difficulties represent one component of the insidious breakdown in semantics. Such difficulties may not be evident early in the course, but emerge with disease progression. Recognition failure, like that for words, is not all or none. Patients may, for example, be able to sort objects into those which are edible and those non-edible, but be unable to distinguish foods that are normally cooked (e.g. potatoes) and those normally eaten uncooked (e.g. lettuce). Patients may recognize a picture of a camel as depicting an animal, but have no idea how it differs from a dog. Moreover, they may recognize and use entirely appropriately their own belongings while failing to recognize other examples of those same objects or pictures of those objects (Snowden *et al.*, 1994; Bozeat *et al.*, 2002). This latter feature helps to explain the clinical observation that the degree of functional independence maintained by patients in daily life belies the magnitude of their underlying semantic disorder: patients are able to function reasonably well within the narrow confines of their familiar environment and repertoire of daily activities at a time when abstract semantic knowledge is profoundly impaired. With progression of disease even highly familiar objects may no longer be recognized.

Non-semantic aspects of object perception are well preserved. Patients can copy drawings normally, sometimes to a strikingly proficient level (Snowden *et al.*, 1996a). They also have no difficulty carrying out perceptual matching tasks, which are not dependent upon recognition of object meaning.

55.4.4 Numeracy

Understanding of number concepts and the ability to carry out arithmetical procedures are often remarkably well preserved (Cappelletti *et al.*, 2001, 2002; Crutch and Warrington, 2002). Patients are able to count money and reckon change despite major difficulties in word comprehension and naming. Perhaps because of this preserved ability patients often enjoy number puzzles and television quiz shows involving manipulation of numbers. Eventually, however, arithmetical skills too become compromised by patients' semantic

disorder: patients may cease to recognize coins and no longer understand the meaning of spoken and written numerals.

55.4.5 Spatial skills

Spatial and navigational skills are generally excellent. Patients are able to find their way without becoming lost and may use spatial cues to compensate for object recognition difficulties (for example, by recalling the spatial location of food items on a supermarket shelf). On neuropsychological testing, patients perform well on traditional spatial tests such as line orientation (Benton *et al.*, 1978), dot counting, position discrimination, and cube estimation (Warrington and James, 1991).

The preservation of spatial skills is an important feature in distinguishing semantic dementia from Alzheimer's disease. It is worth recognizing, however, that performance on putative spatial tasks may be compromised secondarily by failures of perceptual recognition or verbal skills. A patient who, for example, fails to 'locate' their comb or toothbrush, may do so because of impaired recognition of object identity and not because of a problem in spatial localization *per se*. A patient who, in late stage disease, fails a simple dot counting task may have difficulty recalling the names of numbers.

Evidence that spatial skills are indeed well preserved throughout the course of disease is suggested by qualitative characteristics of patients' behaviour. Patients with semantic dementia even in advanced disease negotiate their environment skilfully, have no difficulty orientating themselves with respect to furniture when sitting or lying down, recall the location of their chair or bed on a hospital ward, localize and manipulate with ease objects in the environment and spatially align objects perfectly.

55.4.6 Memory

A feature that is striking on clinical grounds and that helps to distinguish semantic dementia from other forms of dementia is the apparent preservation of patients' current autobiographical memory. Patients remember appointments and personally relevant events and keep track of time. They negotiate the environment without becoming lost. If they move home, they have no difficulty learning their new surroundings. In contrast, they show a gross breakdown in impersonal, factual (semantic) knowledge about the world, including knowledge about public figures and important world events. The preservation of autobiographical memory is not easily captured by standard memory tests, which typically involve lists of words, faces or line drawings that may have little meaning for the patient. Moreover, routine bedside questions, designed to probe orientation, such as 'What town are we in?' demand naming skills and thus may be compromised in semantic dementia. Bedside testing needs to include questions regarding the patient's own daily life, and formal neuropsychological testing should include recognition memory tests using

perceptually distinct pictures. Also worthy of note is that semantic dementia patients commonly answer time orientation questions better than those relating to place orientation, reflecting the fact that number-related vocabulary is better preserved than the names of places.

55.4.7 Praxis

Motor actions are carried out adeptly, dextrously and effortlessly. Activities with high motor executive demands, such as painting, sewing or playing golf, may continue to be pursued with a high level of proficiency, a feature that is both clinically dramatic and important in distinguishing semantic dementia from Alzheimer's disease. Practical skills are inevitably compromised to some extent by patients' semantic loss: for example, a difficulty in cooking arises because of patients' inability to recognize ingredients or understand the words of a recipe.

55.4.8 Touch, taste, smell and hearing

Primary sensory abilities are well preserved, so patients have no difficulty detecting the presence of tactile, gustatory, olfactory and auditory stimuli and discriminating whether two stimuli are the same or different. However, the disorder of meaning may extend to all sensory modalities. Patients may have difficulty recognizing the identity of textures, tastes, smells, and non-verbal sounds such as the ringing of a telephone or doorbell, despite perceiving those stimuli normally.

55.5 BEHAVIOURAL CHANGES

Although the semantic deficits are the defining characteristic of the disorder, there are also accompanying behavioural changes. Some are included as supporting features in clinical diagnostic criteria (Box 55.1, p. 703). Others are summarized in Box 55.3. Recognition of behavioural changes is important because their highly characteristic nature is valuable in differential diagnosis. Moreover, behavioural changes may represent the most problematic aspect of the condition from the

Box 55.3 *Behavioural changes in semantic dementia*

- Self-centredness (narrowed world view)
- Inflexibility and intransigence
- Hyperreactivity to sensory stimuli
- Loss of awareness of danger
- Food fads
- Preference for sweet foods
- Preference for routine, clockwatching
- Stereotypies, rituals and compulsions

management point of view and the greatest source of burden to carers.

Patients are commonly described as self-centred and lacking in their former sympathy and empathy for others. They may be inflexible and intransigent and have difficulty seeing others' point of view. They may appear mean and lacking in their former generosity. Their behavioural repertoire becomes narrowed and they frequently become preoccupied with one or two activities, which they pursue relentlessly to the exclusion of all else. Moreover, they may become mentally preoccupied by one or two themes, which they repeat incessantly to the increasing exasperation of family members.

Patients may show hypersensitivity to sensory stimuli and overact to light touch or to ostensibly innocuous environmental sounds such as bird-song. Patients may be oblivious to danger, a feature that is probably linked to their loss of conceptual understanding of the world. Patients commonly show narrowed food preferences and usually favour sweet foods.

Perhaps the most striking change, however, is the presence of behaviours that have a compulsive quality. Patients commonly adopt a fixed routine and have a preference for order. They will clock-watch, carrying out specific activities at precisely the same time each day. They may align objects, straighten out folds in the curtains and plump up the cushions as soon as a person rises from an armchair. They may develop meaningless rituals, such as avoiding standing on a particular carpet tile, or playing the same few notes on the piano each time they enter the room where the piano is located. Nevertheless, the affective responses of anxiety and release from anxiety that are associated with obsessional-compulsive disorder are typically absent.

55.5.1 Insight

Patients are aware of and may become preoccupied by their difficulties. However, they frequently provide trivial explanations for them, such as being 'out of practice with talking' by virtue of being alone all day, and they demonstrate little real distress or concern. A possible reason is that they have no internal 'model' of their former conceptual knowledge for comparison and thus have no mechanism by which to appreciate the magnitude of what they have lost.

55.6 NEUROLOGICAL SIGNS

Patients are generally physically well and free from neurological signs until late in the disease. Extrapyrarnidal signs of akinesia and rigidity, and frontal release phenomena may emerge in advanced disease. Neurological signs of motor neurone disease may emerge in a small minority of patients. Myoclonus does not occur.

55.7 INVESTIGATIONS

55.7.1 Electroencephalography

This is usually normal, with minor slowing of wave forms occurring only in late stage disease.

55.7.2 Structural brain imaging

Magnetic resonance imaging reveals cerebral atrophy, particularly marked in the anterior temporal lobes (Mummery

(a)

(b)

Figure 55.1 MR scans of two patients with semantic dementia showing severe temporal lobe atrophy. In one case atrophy is more marked on the left side (a) and in the other case on the right (b).

et al., 2000; Chan *et al.*, 2001). Temporal atrophy is typically bilateral, although may be asymmetrical (Figure 55.1), the left or right predominance being associated with a clinical presentation emphasizing word meaning or face recognition disorder respectively. The inferolateral parts of the temporal lobe are most affected. The hippocampi are often relatively spared.

55.7.3 Functional brain imaging

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) show abnormalities in the anterior cerebral hemispheres, particularly the temporal regions (Plate 27). Appearances may be bilateral and symmetrical or markedly asymmetrical, affecting disproportionately the left or right hemisphere.

55.8 NEUROPATHOLOGY

Temporal lobe atrophy, usually bilateral but asymmetrical, is typically evident on gross examination of the brain. Histological changes chiefly affect the middle and inferior temporal gyri, with some involvement also of frontal cortex and relative sparing of the superior temporal gyrus, hippocampi, parietal and occipital cortex. The major histopathological feature is typically of a microvacuolar degeneration of the cortex, referred to as frontolobar degeneration (FLD)-type histology according to the Lund–Manchester consensus statement on frontotemporal dementia (Lund and Manchester Groups, 1994; see also Chapter 54). There is loss of large pyramidal nerve cells from affected areas of temporal and frontal cortex and a spongiform (microvacuolar) change due to neuronal fallout. Reactive astrocytosis is mild. Histopathological features of Alzheimer's disease are absent. No deposits of A β 4 amyloid protein are present in any cortical region, nor are there cells containing neurofibrillary tangles or Lewy-body-type inclusions. Pick-type inclusion bodies are also usually absent from surviving cortical nerve cells. Nevertheless, occasionally Pick-type (Lund and Manchester Groups, 1994) histological changes may occur, with severe astrocytic gliosis, and the presence of ballooned neurones and inclusion bodies. Semantic dementia has also been reported in association with ubiquitin-positive tau-negative inclusions, consistent with motor neurone disease (Rossor *et al.*, 2000).

55.9 NEUROCHEMISTRY

Neurochemical study of semantic dementia is limited. However, the evidence available indicates an absence of cholinergic deficits and similarities (A Procter, personal communication) with the findings of frontotemporal dementia (Francis *et al.*, 1993).

55.10 RELATIONSHIP BETWEEN SEMANTIC DEMENTIA AND OTHER FORMS OF FOCAL CEREBRAL DEGENERATION

The patterns of histology seen in semantic dementia are identical to those of the more common clinical syndrome of frontotemporal dementia, in which there is profound character change and breakdown in social conduct (see Chapters 52 and 54). Similar histological changes are also seen in progressive non-fluent aphasia (Snowden *et al.*, 1996a), in which the salient feature is a disorder of language expression and breakdown in phonological and syntactic aspects of language. These three distinct clinical syndromes appear to represent discrete clinical manifestations of a common underlying pathology, the clinical syndrome being determined by the anatomical distribution of pathological change within the frontal and temporal lobes. In the case of semantic dementia the pathology is dominant within the inferior and middle temporal lobes, whereas the frontal lobes and the traditional language areas of the superior temporal lobes (Wernicke's area) are relatively well preserved. By contrast, in frontotemporal dementia the frontal lobes and temporal poles are markedly affected, and in progressive non-fluent aphasia the perisylvian areas of the left hemisphere are preferentially involved. The link between the clinical syndromes of semantic dementia, frontotemporal dementia and progressive non-fluent aphasia is reinforced

- by clinical overlap between the syndromes in some patients;
- the presence of different syndromes in affected members of the same family, and
- by the co-occurrence of motor neurone disease in association with the prototypical syndromes (Neary *et al.*, 1990; Caselli *et al.*, 1993).

In prototypical semantic dementia patients do not show notable 'frontal lobe' behaviour. Nevertheless, an overlap between the clinical phenotypes of FTD and semantic dementia has been demonstrated in FTD patients who show mutations in the tau gene (Pickering-Brown *et al.*, 2002).

55.11 DIFFERENTIATION FROM FRONTOTEMPORAL DEMENTIA

Semantic dementia is unlikely to be confused with FTD on cognitive grounds (see Chapter 52). The problems in word and object recognition are quite distinct from the frontal executive failures of FTD. Nevertheless, both disorders involve behavioural change, which may appear superficially similar, leading to diagnostic confusion. Closer examination does, however, reveal differences between the 'temporal' behaviours of semantic dementia and the 'frontal' behaviours of FTD (Snowden *et al.*, 1996a, 2001) (Table 55.1).

Table 55.1 Behavioural differences between semantic dementia and frontotemporal dementia

Behaviour	Semantic dementia	Frontotemporal dementia
Affect	Restricted impairment, especially loss of fear Concern for illness	Pervasive loss of emotions Unconcern
Social behaviour	May show exaggerated sociability	Reduced sociability common
Interest and motivation	Narrowed interests	General loss of interest
Response to sensory stimuli	Exaggerated	Diminished
Eating	Food fads	Gluttony, indiscriminate eating
Wandering	No wandering	Wandering common
Pacing fixed route	Absent	May be present
Repetitive behaviours	Complex routines common Repetitive themes Clockwatches Compulsive quality	Simple motor stereotypies more likely No repetitive themes Unconcerned by time No compulsive quality

- In FTD behaviour tends to be unproductive and lacking in goal-direction, whereas in semantic dementia behavioural routines may be remarkably complex.
- In FTD there is poor mental application and impersistence whereas patients with semantic dementia frequently show dogged persistence, albeit on a narrowed range of activities.
- Patients with FTD show a lack of concern with personal appearance and hygiene, whereas the latter may become a source of preoccupation in patients with semantic dementia.
- FTD patients show generalized blunting of emotions, including a failure to show happiness, sadness and disgust. In semantic dementia affective changes are more selective, typically affecting particularly the capacity to show fear.
- FTD patients may show reduced sensitivity to pain, whereas semantic dementia patients are more likely to show an exaggerated response to sensory stimuli.
- FTD patients commonly exhibit gluttony and indiscriminate eating, whereas semantic dementia patients are more likely to show food fads.
- Perhaps the most striking difference is that repetitive behaviours have a much more compulsive quality in semantic dementia than FTD, suggesting an important role of the temporal lobes in obsessive-compulsive-type behaviour. The differences are most marked between semantic dementia and the apathetic form of FTD. Disinhibited FTD patients with more circumscribed atrophy of the orbitofrontal lobes and temporal pole may show some overlap with semantic dementia.

55.12 DIFFERENTIATION FROM ALZHEIMER'S DISEASE

Semantic dementia is most commonly misdiagnosed as Alzheimer's disease. This is unsurprising in view of the greater prevalence of Alzheimer's disease, the fact that presenting symptoms in both conditions are commonly of 'memory' problems and signs of semantic disorder may not be obvious at initial interview (Box 55.4). Nevertheless, the two conditions can be readily distinguished on clinical grounds (Table 55.2).

- In semantic dementia, 'memory loss' refers to loss of impersonal, conceptual knowledge about the world. Personal, autobiographical memories remain relatively well preserved. In Alzheimer's disease the converse is true. Memory is impaired predominantly for day-to-day events.
- Spatial abilities are well preserved in semantic dementia, whereas their breakdown is a frequent feature of Alzheimer's disease, manifest clinically by impaired localization of objects, inability to orientate clothing and objects correctly, and loss of topographical orientation within a familiar environment.
- Patients with both semantic dementia and Alzheimer's disease may have object recognition problems, yet the nature of the perceptual disorder is qualitatively different. In semantic dementia the difficulty lies in assigning meaning to objects that are perceived normally ('associative agnosia'). Patients can match stimuli on the basis of perceptual similarity, yet deny recognition of those stimuli, or make semantic errors (e.g. a camel identified as a 'dog'). They can copy accurately drawings of objects that they cannot recognize. In Alzheimer's disease, perceptual breakdown lies at the level of achieving an integrated percept ('apperceptive agnosia'). Misidentifications occur on the basis of interpretation of elements of a figure instead of the overall outline (e.g. a pair of scissors identified as a bowl on the basis of the circular handle). Patients have difficulty carrying out perceptual matching tasks, and are unable to reproduce line drawings, their copies often being fragmented with loss of the spatial relationships between elements of the figure.
- Language breakdown is a common feature of Alzheimer's disease, but is qualitatively distinct from that of semantic dementia. Whereas in semantic dementia speech is entirely effortless, in Alzheimer's disease speech it is typically hesitant and patients show evidence of actively searching for words, suggesting a difficulty in retrieval of words potentially within their vocabulary. Phonological errors may also occur. In Alzheimer's disease, moreover, sentences are unfinished and content broken, reflecting loss of train of thought and a reduced immediate memory span. Logoclonia, the festinating repetition of individual phonemes, may occur in moderate and advanced Alzheimer's disease, along with extrapyramidal

Box 55.4 Factors affecting poor recognition of semantic dementia

- Rare disorder
- Historical reports of 'memory' disorder
- Semantic disorder may not be evident at clinical interview
- Semantic impairments may be misinterpreted as classical amnesia
- Need explicit tests of word comprehension and naming, face and object recognition

Table 55.2 Clinical differences between semantic dementia and Alzheimer's disease

Characteristic	Semantic dementia	Alzheimer's disease
Age of onset	Most common in middle age	Most common in elderly
Language	Selective semantic disorder Impaired single word comprehension	No selective semantic disorder Impaired sentence comprehension
Perception	Associative agnosia	Apperceptive agnosia
Calculation	Preserved early in course	Impaired early in course
Spatial orientation	Preserved	Impaired early in course
Constructional skills	Preserved	Impaired early in course
Memory	Day-to-day memory preserved	Day-to-day memory impaired
Neurological signs	Akinesia and rigidity relatively late Myoclonus absent	Akinesia and rigidity relatively early Myoclonus may be present
Electroencephalography	Normal	Slowing of wave forms
Structural brain imaging	Focal temporal lobe atrophy typical Hippocampi relatively preserved Marked hemispheric asymmetry common	Focal atrophy rare Hippocampi atrophic Marked asymmetry rare
Functional brain imaging	Anterior hemisphere abnormalities Marked hemispheric asymmetry common	Posterior hemisphere abnormalities Marked asymmetry rare

neurological signs and myoclonus, suggestive of increasing basal ganglia involvement. It is not a feature of semantic dementia.

- In AD comprehension is better preserved for single nominal terms than for complex syntax, whereas in semantic dementia the reverse is the case. Although patients with Alzheimer's disease may acquire difficulties in reading, writing and spelling they do not

show the characteristic surface dyslexia and surface dysgraphia of semantic dementia.

- The presence of semantic impairment in Alzheimer's disease has been highlighted by a number of authors. However, whether this reflects a fundamental loss of knowledge (Hodges *et al.*, 1992b; Martin, 1992; Hodges and Patterson, 1995; Salmon *et al.*, 1999) as in semantic dementia or faulty access to information (Nebes, 1992; Nebes and Halligan, 1999; Ober and Shenaut, 1999) is controversial. In any event, in Alzheimer's disease semantic impairment is never a circumscribed deficit. It occurs typically as one component of a multifaceted disorder of language and invariably in the context of a demonstrable amnesia.
- Calculation difficulties are an early feature of Alzheimer's disease, whereas in semantic dementia preservation of numerical skills contrasts with the disorder of word meaning.

55.13 TREATMENT AND MANAGEMENT

Novel pharmacological therapies for Alzheimer's disease do not have a rational role in semantic dementia, because there is no demonstrated evidence of abnormalities in the cholinergic system. In patients with problematic behavioural changes, symptomatic treatment may be warranted. Repetitive, stereotypic behaviours may respond to serotonin reuptake inhibitors.

With regard to practical management of the disorder, it is of note that concepts (words, objects, etc.), relevant to the patient's daily life appear to be better retained than those which have no personal relevance (Snowden *et al.*, 1994, 1995; Westmacott *et al.*, 2003). Thus, for example, the word 'postman' may be understood better than the word 'milkman' if the patient has personal daily experience of the postman delivering letters to the home, but purchases milk from the supermarket. It has been argued that this feature results from patients' preserved autobiographical memory: concepts, which would otherwise be lost in their abstract sense, have some meaning to the patient if they are framed within the context of the patient's ongoing daily experience. By implication, input from speech therapists is more likely to be beneficial if this takes place in the patient's own surroundings using as referents patients' own belongings, than in the abstract setting of a clinical consulting room using standard pictorial materials.

There is clinical evidence in semantic dementia that some learning is possible. Patients may, for example, effectively learn the names of new acquaintances and the names of medicines prescribed to them. They may also succeed in relearning lost vocabulary (Graham *et al.*, 1999; Snowden and Neary, 2002). However, such reacquired knowledge is tenuous and vocabulary can be maintained only so long as those words are used regularly and are linked to patients' ongoing daily experience.

55.14 THEORETICAL ISSUES

Semantic dementia has attracted considerable theoretical interest from neuropsychologists in recent years. Because of its circumscribed nature it is a natural experimental model for understanding how the brain represents 'meaning'. Experimental studies are motivated by the fact that semantic knowledge does not break down in an all-or-none fashion. At any one stage of the disease patients know some words but not others, and recognize some objects and faces. Unearthing the factors that govern what is lost and retained ought to shed light on the cerebral representation of semantic knowledge. Contemporary issues include:

- *The role of the two hemispheres in meaning representation.* The traditional view has been that semantic memory is particularly dependent on the left hemisphere. However, patients with semantic dementia provide evidence that both hemispheres contribute and may have different roles (Thompson *et al.*, 2003, 2004; Snowden *et al.*, 2004). The left hemisphere appears to have a greater role in the knowledge of words and the right hemisphere in visual knowledge such as face recognition.
- *The representation of different categories of information.* Patients with semantic dementia may show disproportionate impairment in their knowledge of some categories (e.g. animals and vegetables) compared with others (e.g. household objects) (Basso *et al.*, 1988; Cardebat *et al.*, 1996). Such findings have been interpreted by some in terms of a distributed model of semantic memory, in which different properties of objects (e.g. sensory features, particularly important for discriminating between animals, and functional attributes, particularly important for discriminating between household objects) are represented separately (Warrington and Shallice, 1984; Warrington and McCarthy, 1987). It is assumed that cortical areas that have contributed to the development of various categories are also implicated in their representation (Gainotti, 2004). Other authors (Caramazza and Shelton, 1998) have argued that conceptual knowledge is truly organized by category.
- *The relationship between semantic memory and episodic memory.* Semantic memory is regarded as abstract knowledge independent of experience. However, findings in semantic dementia patients (Snowden *et al.*, 1994, 1995, 1996b; Westmacott *et al.*, 2003) suggest a closer relationship between knowledge and personal experience and interdependence between memory systems than generally recognized.

55.15 CONCLUSION

Semantic dementia is a striking disorder, clinically distinct from Alzheimer's disease and other forms of dementia.

Patients exhibit unique patterns of cognitive and behavioural symptomatology, which demand novel approaches to treatment and management. Neuropsychological studies are likely to further understanding of the cognitive characteristics of the disorder. Meanwhile, advances in molecular biological research ought to shed light on the underlying aetiology of this and other clinical manifestations of frontotemporal lobar degeneration.

The motor features of the cerebellar syndrome were crystallized by the great English neurologist Gordon Holmes soon after World War I. He did not ascribe any cognitive function to the cerebellum and, until the last decade or two, this view held general sway. However, a confluence of evidence from new neuroanatomical tracing techniques, functional neuroimaging experiments and careful clinical studies now points strongly to a significant role for the cerebellum in cognition, of which the clinician should be aware. This chapter aims to distil some of the important studies supporting a non-motor role for the cerebellum. The reader interested in a detailed exposition is referred to *The Cerebellum and Cognition*, edited by Jeremy Schmahmann (1997), while several shorter reviews have also been published (e.g. Leiner *et al.*, 1993; Fiez, 1996; Diamond, 2000; Rapoport *et al.*, 2000).

56.1 THE NEUROANATOMICAL BASIS OF CEREBELLAR COGNITIVE FUNCTION

The cerebellum, which contains more neurones than the entire remainder of the brain, has a regular and relatively simple modular structure. The 'corticonuclear microcomplex' is essentially a positive loop through the deep cerebellar nuclei, modulated by a variable negative side loop through the cerebellar cortex (Ito, 1993). The degree of inhibitory influence of the cerebellar cortical Purkinje cells on the deep cerebellar nuclei is governed by the development of long-term depression (LTD) at the excitatory parallel fibre-Purkinje dendrite synapses (Ito, 1993). LTD itself develops in response to near-simultaneous Purkinje cell activation by parallel

fibres, and by climbing fibres from the inferior olive. It may thus be considered to be analogous to associative long-term potentiation in the hippocampus. In the influential Marr–Albus–Ito model of cerebellar function, the climbing fibres are regarded as carrying the 'error signals' responsible for adaptive motor learning.

While there is no universally accepted model of the mechanism whereby LTD in the corticonuclear microcomplex might result in motor learning at the whole animal level, it is clear from its stereotyped modular structure that the cerebellum performs the same type of basic computation on whatever inputs it receives, and informs all its various efferent targets of the results of such computation. If different areas of the cerebellum differ in function, therefore, they do so by virtue of their differing inputs and outputs.

With this in mind, the evidence for cerebellar input from, and output to, non-motor areas can be considered. Such evidence is both indirect and direct. The former consists of the observation that, in primate phylogeny, and especially in hominids, the prefrontal portion of the frontal lobes and the lateral neocerebellum with its associated ventral macrogyric region of the dentate nucleus have undergone massive parallel selective enlargement, out of proportion to other brain areas (e.g. Matano, 2001; MacLeod *et al.*, 2003). More direct evidence has had to await the development of anterograde and retrograde trans-synaptic (viral) tracers (Middleton and Strick, 1997). Such tracers are necessary because cerebral cortical input to the cerebellum proceeds via corticopontine fibres synapsing on the pontine nuclei, which in turn project to the deep cerebellar nuclei and cerebellar cortex, while cerebellar output to the cortex proceeds via synaptic relays in the thalamus (Schmahmann and Pandya, 1997). Studies using such

tracers in primates have shown that a series of anatomically discrete parallel cortico-ponto-cerebello-thalamo-cortical loops exist, with prefrontal input predominantly to the ventral, macrogyric portion of the dentate nucleus and associated lateral neocerebellar cortex, and output via the ventrolateral and medial dorsal thalamic nuclei (Middleton and Strick, 2000, 2001). Motor and premotor cortex, in contrast, are reciprocally connected to the phylogenetically older dorso-lateral, microgyric portion of the dentate nucleus (Middleton and Strick, 2000, 2001). The analogy with separate, parallel corticobasal ganglionic circuits subserving motor and non-motor functions, as conceptualized by Alexander *et al.* (1986), is readily drawn (Middleton and Strick, 2000).

56.2 FUNCTIONAL NEUROIMAGING STUDIES

A large number of functional neuroimaging studies of cerebellar activation during tests of various cognitive domains have been reported over the last 15 years, using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). The typical design compares patterns of cerebellar activation on a cognitive task with that on what is thought to be a relevant control 'motor' and/or perceptual task. This section includes a broadly representative sample of such studies across various cognitive domains.

The cerebellum appears to play a role in language function. One of the earliest reports was that of Petersen *et al.* (1989), who used PET to study a verb association task (e.g. responding with 'bark' if shown the word 'dog'). The control tasks were reading aloud, and silently. Broca's area and the right lateral cerebellum were both activated. Hubrich-Ungureanu *et al.* (2002) extended these findings with an fMRI study of a silent verbal fluency task in left- and right-handed subjects. Fullbright *et al.* (1999) asked subjects to read silently. Their fMRI study showed that semantic comparison and judgement of non-word rhyming activated posterolateral (and especially right posterolateral) cerebellar cortex, compared with the control conditions of line orientation judgement, upper versus lower case print judgement, or judgement of real word rhyming. Xiang *et al.* (2003) recently confirmed the role of the right posterolateral cerebellum in semantic discrimination divorced from articulation. Such studies have led to the concept of the 'lateralized linguistic cerebellum', recently reviewed by Marien *et al.* (2001).

The cerebellum also appears to be involved in executive functioning and working memory. Cognitive processing during attempted solution of a pegboard puzzle task compared with simple peg movement was studied using fMRI estimation of dentate activation by Kim *et al.* (1994). The cognitively demanding task produced increased, and bilateral, dentate activation compared with the contralateral (to the moving hand) activation seen with simple peg movement. In as much as this task tapped visuospatial working memory, it is conceptually similar to the working memory fMRI study of Desmond *et al.* (1997), who found that delayed matching

of letter strings but not the control task activated the right inferolateral cerebellar hemisphere. The Wisconsin Card Sorting Test (WCST), a complex task often used to assess aspects of executive functioning, has also been found to activate the lateral cerebellum (e.g. Nagahama *et al.*, 1996).

An aspect of episodic memory was addressed by Andreasen *et al.* (1999) in a 'pure thought' PET experiment. Subjects were asked to recall a personal memory silently. The right lateral cerebellum was activated, in addition to several relevant supratentorial areas.

A further area of recent active study has been the role(s) of the cerebellum in attention. Allen *et al.* (1997) showed an anatomical double dissociation in cerebellar regional activation; a visual attention task activated the lateral cerebellum while the motor task activated more medial regions. Attention is, however, a multifaceted concept, placing a variety of different demands on the subject (e.g. sustained/directed attention, divided attention, attentional switching). Le *et al.* (1998) showed that shifting attention between stimulus dimensions (colour/shape) activated the right lateral cerebellum, while sustained attention did not. More recently, Bischoff-Grethe *et al.* (2002) have demonstrated that the lateral cerebellum's role in this paradigm may actually be in reassignment of a given motor response (e.g. pushing a button) to the new stimulus dimension, rather than in shifting attention *per se*.

It is clear that the weight of evidence from functional neuroimaging studies in favour of lateral cerebellar contributions to cognition is strong, as illustrated by the selected studies cited above. However, it is also clear that the exact role(s) of the lateral cerebellum in complex aspects of cognition such as language and attentional shifting still requires considerable clarification.

56.3 DIFFICULTIES IN STUDYING COGNITIVE FUNCTION IN SUBJECTS WITH CEREBELLAR DYSFUNCTION

The results of functional neuroimaging studies in normal people notwithstanding, the practising clinician is understandably primarily concerned with the potential impact of cerebellar disease or dysfunction on cognition. Unfortunately, several confounding factors must be borne in mind when interpreting such studies. The first problem is that performance on the neuropsychological tests used may be adversely affected by requirements for rapid verbal output, motor accuracy and speed, or by dependence on rapid visual scanning. A correlation between test results and ataxia severity will not necessarily indicate that such requirements are confounding the results, however; motor and cognitive function would be expected to decline in parallel in diffuse cerebellar degenerations, whether the observed cognitive dysfunction was secondary to the cerebellar disorder or was merely secondary to the resultant motor impairment.

Several types of neuropsychological task would be expected *a priori* to limit the potential for confounding of results. Some

tests are untimed, and do not require motoric or visual speed or accuracy. In the executive domain, these include the WCST, Raven's Progressive Matrices, and the Zoo Map subtest (of planning) from the Behavioural Assessment of the Dysexecutive Syndrome (BADS) battery. Most measures of verbal anterograde episodic memory also fall into this category, provided that dysarthria is not so severe as to compromise intelligibility. Other tests include a timed internal control condition involving similar scanning and output to the test condition. The effects of visual, verbal and motor dysfunction can therefore be subtracted out. Such tests within the executive function cognitive domain would include Trails B (versus A) and the Stroop test. Yet other tests requiring verbal output are timed, but empirical observation suggests that speed of articulation is not the rate-limiting factor. The controlled oral word association test (COWAT, FAS) appears to fall into this category (Storey *et al.*, 1999).

An indirect way of exploring the possibility that motor dysfunction might secondarily affect performance on cognitive tests is to study patients with Friedreich's ataxia (FA), whose motoric deficit is partly consequent upon disruption of afferent cerebellar input rather than direct disruption of the cerebellar microcorticonuclear units, although the deep cerebellar nuclei are also affected (Koeppen, 2002). While FA patients display impairments in a number of domains (Wollmann *et al.*, 2002), they have been shown to be less impaired on verbal working memory and visuospatial reasoning tasks than patients with assorted other cerebellar degenerations (Botez-Marquard and Botez, 1997). Indeed, White *et al.* (2000) demonstrated slowed processing speed and decreased cognitive inhibition on the Stroop test, but preserved planning, verbal fluency, and WCST performance.

The potential confounding factor of motor deficit has recently been explicitly addressed by Timmann *et al.* (2002), who correctly pointed out that even ataxic patients who cope well with the motor demands of a test may do so at the cost of attentional resources not required by control patients. These authors reported that subjects with pure cerebellar cortical atrophies (spinocerebellar ataxia [SCA] 6, other pure cerebellar dominant ataxias, or idiopathic cerebellar cortical atrophy) demonstrated impairments of visual association learning independent of the separately manipulated motor output requirements of the task.

The second problem affecting patient studies is that of choice of patient type. The ideal patient group for such a study would have widespread/diffuse involvement of cerebellar corticonuclear microcomplex units, with complete sparing of all other central nervous system structures. Unfortunately, such patients probably do not exist, at least to the extent of satisfying those sceptical of the idea of cerebellar contributions to cognition. Even relatively 'pure' cerebellar ataxias such as SCA 6 often have mild non-cerebellar features (e.g. pyramidal signs). Other degenerative cerebellar diseases studied in this context, such as SCAs 1, 2 and 3, are even more problematic, as they are known to manifest extracerebellar involvement of structures potentially or actually contributing

to cognition, such as the cerebral cortex, the striatum and the substantia nigra (Koeppen, 2002). On the other hand, focal cerebellar lesions such as infarcts and resected tumours may be 'pure', but there is no guarantee that cerebellar region(s) potentially important for cognition will be involved, unless a range of lesions in different locations are studied. Pooled results may then conceal regional differences in cognitive contribution unless sufficient subjects are available in each group for comparison. While this is difficult, such studies do perhaps provide the most convincing clinical evidence, as outlined in the next section.

56.4 ALTERED COGNITION IN ADULTS WITH FOCAL CEREBELLAR LESIONS

In a seminal report, Schmahmann and Sherman (1998) described the features of an entity that they named the 'cerebellar cognitive affective syndrome' in 20 adults with isolated cerebellar lesions: strokes, resected tumours not treated with radiotherapy, and post-viral cerebellitis. Posterior (roughly equivalent to lateral neocerebellar) lobe lesions produced executive dysfunction, with impairments of planning, set-shifting, verbal fluency by semantic category and abstract reasoning. There was also impairment of spatial cognition, including visual organization and visual memory. Lesions of the posterior vermis tended to produce personality change with blunting or disinhibition, while anterior lobe lesions resulted only in motor deficit.

Similar findings were reported by Malm *et al.* (1998) in 24 consecutive young adult patients with cerebellar infarcts who were compared with 14 age-matched controls. The patients performed less well on working memory and cognitive flexibility tasks, while intelligence (Wechsler Adult Intelligence Scale-Revised [WAIS-R] scores) and episodic memory were unaffected. Interestingly, while most made a good motor recovery, only half returned to work.

The broad conclusions of these studies have since been confirmed by Neau *et al.* (2000), who reported the neuropsychological profile of 15 consecutive patients with recent, isolated cerebellar infarcts, compared with 15 demographically matched controls. A further assessment was undertaken 1 year after the infarcts. These authors demonstrated impairments on a range of tasks tapping aspects of executive functioning, such as verbal fluency, working memory on the Paced Serial Addition Test (PASAT), and the Stroop colour/word interference test. These abnormalities were not accompanied by a clinically apparent 'frontal' neuropsychiatric syndrome. Block design was also affected; this deficit the authors likened to a mild parietal syndrome, although problems with block design can also be a feature of executive dysfunction (Lezak, 1995). Of interest is that infarcts in any of the three cerebellar arterial territories produced similar deficits, although the numbers in each group were small. As might be expected with infarcts, the deficits tended to have improved at the 1-year assessment.

The authors plausibly suggest that this improvement may have been partly responsible for the failure of Beldarrain *et al.* (1997) to demonstrate consistent deficits in a patient population including subjects with old cerebellar infarcts.

The specific role of the right lateral cerebellum in language, outlined in the section on functional neuroimaging above, was studied in control subjects and subjects with left lateral or right lateral cerebellar infarcts (Gebhart *et al.*, 2002). Those with right lateral cerebellar damage were impaired only on antonym generation, and not on semantic (category) noun fluency or verb selection. This argues in favour of a cerebellar role in producing word associations, and not just in 'imaging' verb action to a noun cue. Helmuth *et al.* (1997) also failed to demonstrate impaired noun-triggered verb generation in subjects with right cerebellar lesions, in contrast to the evidence from earlier functional neuroimaging studies.

Various attentional processes have also been studied in subjects with cerebellar lesions. Orienting of visuospatial attention has been found to be markedly delayed in such subjects, independent of motor responses (Townsend *et al.*, 1999). Most recently, Gottwald *et al.* (2003) compared 16 subjects with cerebellar tumours or haematomas to 11 matched control subjects and to demographically adjusted results from normative studies, and detected deficits in working memory and divided attention, but not in sustained directed attention. However, Helmuth *et al.* (1997) did not demonstrate deficits in spatial attention shifting or in intra- or interdimensional non-spatial attentional shifting, again failing to confirm functional neuroimaging studies in a clinical population. Moreover, Ravizza and Ivry (2001) found that, while patient groups with Parkinson's disease and with cerebellar lesions each showed impairment of attentional shifting, reducing the motor demands of the task improved the performance of the cerebellar patients only. It is obvious that the question of a cerebellar contribution to various forms of attention has generated conflicting results, and remains to be settled conclusively.

Studies in children with resected cerebellar tumours have produced similar results to those in adults (e.g. Levisohn *et al.*, 2000).

56.5 EVIDENCE FOR COGNITIVE IMPAIRMENT IN DEGENERATIVE CEREBELLAR DISEASE

Evidence for cognitive impairment in degenerative cerebellar disease comes from both neurophysiological and clinical neuropsychological studies. The best-known neurophysiological method of studying cognition involves measuring the latency of the P₃₀₀ event related cerebral potential. This occurs with conscious registration of an unusual stimulus, such as an occasional ('oddball') high-pitched tone inserted into a series of usual stimuli, such as many low-pitched tones. It may be regarded as a neurophysiological measure of selective attention and processing speed, and is delayed in various forms of dementia (reviewed by Goodin, 2003).

Tachibana *et al.* (1999) measured the P₃₀₀ during a visual discrimination task, and found it to be delayed in 15 subjects with idiopathic late-onset cerebellar ataxia, when compared with 10 controls. Single photon emission computed tomography (SPECT) scanning in the ataxic subjects showed correlated cerebellar/frontal cortex hypoperfusion (that is, reversed cerebellar/frontal diaschisis). Tanaka *et al.* (2003) did not find any differences in P₃₀₀ timing or scalp distribution to the classical auditory 'oddball' paradigm in 13 subjects with cerebellar cortical atrophy when compared with 13 demographically matched controls. However, P₃₀₀ latency was prolonged, and its peak attenuated frontally, in the 'No Go' condition of the 'Go/No Go' paradigm. The authors suggested that the cerebellum contributes to the frontal inhibitory system.

The neuropsychological consequences of degenerative cerebellar disease have been studied extensively. In one early study, Grafman *et al.* (1992) compared nine patients with 'pure cortical cerebellar atrophy' with 12 controls. There were no differences on paired associate learning, verbal fluency, or procedural (skill) learning. However, the ataxic subjects performed significantly less well on the Tower of Hanoi planning task, which is conceptually similar to the Tower of London test. Botez-Marquard and Botez (1997) showed that cerebellar degenerations resulted in impaired executive functioning, visuospatial organization, working memory, and spontaneous retrieval of episodic memories. Cerebellar strokes produced similar patterns of impairment, but these cognitive deficits resolved in 2–5 months. In both types of subjects, SPECT scanning showed reverse cerebellar/frontoparietal diaschisis.

Drepper *et al.* (1999) studied nine subjects with 'isolated' cerebellar degeneration, and 10 controls. The ataxic subjects showed a significant impairment in novel associative learning (colours with numbers) that did not correlate with either simple reaction time or visual scanning time.

Kish *et al.* (1994) studied the performance of 43 subjects with undefined dominant cerebellar degenerations of varying ataxia severity on a number of neuropsychological measures. Impaired performance on the WCST correlated with ataxia severity; none of those with mild ataxia showed deficits, while all of those with severe ataxia were impaired. Some of the latter also showed evidence of mild generalized cognitive deficit. The authors concluded that the dominant ataxias are not homogeneous with respect to cognitive involvement, and indeed the topography of extracerebral neuropathological involvement does vary considerably between these disorders (Koeppen, 2002).

Trojano *et al.* (1998) also studied a mixed population of subjects with dominant ataxias of varying severity, although 15 of their 22 subjects had SCA 2. They attempted to avoid confounding effects of motor impairment on performance by restricting their investigation to tests with untimed verbal response modes. The domains examined were predominantly verbal memory, and non-verbal reasoning (Raven's Progressive Matrices). None of the four genetically confirmed but asymptomatic subjects performed poorly on any of the tests, while most of the symptomatic subjects showed impairment

on at least one measure, most commonly the progressive matrices. Some showed more widespread deficits, but there was no correlation with ataxia severity. This might have reflected the small sample size, and the contaminating effects of inclusion of several SCA subtypes.

Several studies have assessed subjects with different SCA types singly or separately, thereby avoiding this particular confounding factor. Maruff *et al.* (1996) compared six patients with SCA 3 (Machado-Joseph disease) with 15 matched controls using a touch-screen testing system: the Cambridge Neuropsychological Test Automated Battery (CANTAB). Learning and visual memory were unaffected, but SCA 3 subjects displayed impaired visual information processing speed on high-demand tasks, and impaired attentional switching between visual stimulus dimensions. Executive dysfunction in SCA 3 was confirmed by Zawacki *et al.* (2002). Ishikawa *et al.* (2002) reported dementia with features of delirium including hallucinations in four young SCA 3 patients with severe disease, in the absence of MRI or pathological evidence of cortical neuronal loss.

SCA 2 may be associated with cortical atrophy and clinically obvious dementia in some pedigrees (Dürr *et al.*, 1995; Geschwind *et al.*, 1997). Although it is therefore not ideal for the purpose, it has been studied by several groups. Gambardella *et al.* (1998) and Storey *et al.* (1999) demonstrated impairments of executive function on the WCST and the Stroop test. Bürk *et al.* (1999) found that 25 per cent of their subjects were demented, while the others showed impairments of executive function and verbal memory that were independent of the severity of motor impairment. In contrast, Le Pira *et al.* (2002) reported that the impairments of executive function, attention and verbal memory in their SCA 2 patients were partly related to ataxia severity.

The pattern of neuropsychological impairment in SCA 1 patients compared with matched controls was reported by Bürk *et al.* (2001). Evidence of executive and verbal memory dysfunction was found, while visuospatial memory and attention were unaffected. The deficits did not correlate with CAG repeat length or with disease duration, which may be regarded as surrogate markers of disease severity in different dimensions.

While the studies on SCAs 1, 2 and 3 cited above paint a fairly consistent picture of executive dysfunction and verbal memory impairment, the effects of differences in the pattern and extent of extracerebellar neuropathological involvement, if any, can only be addressed adequately by direct comparison. This was undertaken by Bürk *et al.* (2003), who found that executive dysfunction was more marked in SCA 1 than in SCAs 2 or 3, while mild verbal memory impairment was present in all. On the basis of these findings, the authors suggested that the cognitive deficits were likely to result from disruption of cerebrotocerebellar circuitry at the pontine rather than at the cerebellar level. Given that SCA 2 causes more severe pontine atrophy than SCA 1, the reasons for this conclusion are unclear. A problem with this study is the lack of control for ataxia severity.

Perhaps the best way of clarifying the relative contributions of cerebellar and extracerebellar pathology to cognitive dysfunction in the SCAs would be to study those disorders characterized by relatively pure cerebellar involvement, such as SCA 6. To the author's knowledge, at least two such studies on SCA 6 are planned or in progress, but neither have been published as yet. Failing this, the conclusion that cerebellar degeneration itself is responsible for at least some of the cognitive changes observed in SCAs 1, 2 and 3 will remain contentious, although this conclusion is consonant with the results of functional neuroimaging and focal lesion studies.

56.6 CONCLUSION

There is now converging evidence from neuroanatomical, neuroimaging, and neurophysiological and neuropsychological patient studies that the lateral cerebellum is involved in network(s) subserving a range of cognitive functions, including aspects of language and executive functioning. The exact nature of the cerebellar contributions to cognition, and especially to attention (if any) are still being debated and elucidated. Nevertheless, the broad picture is well enough established that clinicians should consider the possibility of cognitive dysfunction in patients with overt cerebellar disorders. In this context, executive dysfunction is both the most likely to be overlooked in the structured clinical setting, and potentially the most disruptive to the patients' ability to compensate for impaired motor functioning. Clinicians should also bear in mind that obvious cognitive dysfunction may result from cerebellar disease, and that such dysfunction does not necessarily signify that a second, supratentorial disorder has been overlooked.

Progressive aphasia and other focal syndromes

JASON D WARREN, RICHARD J HARVEY AND MARTIN N ROSSOR

57.1 Progressive speech and language syndromes	720	57.5 Management	726
57.2 Progressive prosopagnosia	724	57.6 Conclusions	726
57.3 Progressive apraxia	725	References	727
57.4 Progressive visual syndromes	725		

Progressive cognitive syndromes with circumscribed deficits and preserved intellect have been recognized for many years (e.g. Serieux, 1893) and have attracted much recent interest. These focal forms of dementia (variously termed ‘focal cortical atrophies’, ‘lobar atrophies’ or ‘asymmetric cortical degenerations’) manifest in diverse cognitive domains including language, praxis, specific categories of knowledge and cortical visual functions. Many patients with focal presentations will ultimately suffer a generalized intellectual decline; however, this is not inevitable and is often delayed for a number of years (Mesulam, 1982).

The focal dementias pose considerable nosological and neurobiological difficulties. While circumscribed lobar atrophy on structural brain imaging (especially magnetic resonance imaging, [MRI]) can support the impression of a focal cognitive syndrome, diagnosis remains essentially clinical. In this chapter, the focal dementias are classified according to clinical presentation and the various radiological and pathological correlates of each syndrome are outlined (see Table 57.1). The syndrome of semantic dementia, characterized by an early selective impairment of semantic memory, is discussed in Chapter 55.

57.1 PROGRESSIVE SPEECH AND LANGUAGE SYNDROMES

57.1.1 Primary progressive aphasia

Primary progressive aphasia (PPA) is a clinical syndrome of progressive language impairment with relative sparing of non-verbal cognitive and behavioural functions until late in the course. It may be the most common of the focal dementia syndromes. Although cases of the syndrome have been

described for over a century (Luzzatti and Poeck, 1991) the first comprehensive modern account was Mesulam’s (1982) series of six patients, five of whom had a progressive anomic aphasia. Diagnostic criteria have since been proposed (Mesulam, 2001). Non-fluent and fluent subtypes of PPA have been proposed on both clinical and anatomical grounds (Mesulam *et al.*, 2003); these subtypes are represented with approximately equal overall frequency in the literature (Mesulam and Weintraub, 1992; Black, 1996), however, ‘mixed’ forms are common (Grossmann, 2002; Mesulam *et al.*, 2003). The nosological status of fluent PPA is controversial: it is unclear whether this subtype should be considered a primary language disturbance, or rather subsumed within the semantic dementia spectrum. The heterogeneity of PPA reflects the distributed neuroanatomical networks and multiple cognitive operations that support language production and comprehension.

57.1.1.1 CLINICAL FEATURES

Difficulties in word-finding, naming or spelling and impoverished conversation are common presenting complaints; however, diagnosis is based on the form and content of the patient’s spontaneous speech. Non-fluent PPA is characterized by effortful, sparse or ‘telegraphic’ speech with grammatical and phonemic errors. Comprehension is generally retained until late in the course of the condition, although an early selective deficit in comprehending verbs and grammatical relations may be evident on neuropsychometry (Grossman, 2002). Stuttering and articulatory errors may occur, and associated features may include orofacial apraxia, dysphonia, and dysphagia (Mesulam and Weintraub, 1992; Kertesz and Orange, 2000; Mesulam, 2001). In contrast, fluent PPA is characterized by circumlocutory, ‘empty’ but grammatically correct speech, with relatively normal articulation, rate and phrase length (Mesulam, 2001);

Table 57.1 *Clinical, imaging and pathological features of the focal dementias*

Syndrome	Clinical features	Structural brain imaging (CT/MRI)	Functional brain imaging (SPECT/PET)	Pathology
Progressive aphasia				
Non-fluent	Anomia, sparse, effortful, telegraphic speech, phonemic paraphasias, agrammatism; may have orofacial apraxia, dysarthria, dysprosody, dysphagia	L perisylvian/inferior frontal atrophy	L > R frontal/ anterior temporal/ anterior insula hypometabolism/perfusion	Predominantly non-AD (varies between series) including non-specific histology, PD, CBD, PSP, MND
Fluent*	Anomia, circumlocutory, 'empty' speech, impaired comprehension, may have word-finding pauses	L anterolateral temporal atrophy	L > R temporal/parietal hypometabolism/perfusion	AD may be more frequent (unclear)
Other progressive speech/language syndromes*				
Orofacial apraxia	Severe early impairment of volitional facial, tongue, respiratory movements; associated speech production defect, dysarthria, dysgraphia; may have features MND	L > R frontotemporal atrophy	L > R frontal/anterior temporal hypometabolism/perfusion	PD, CBD
Anarthria	Prominent dysarthria; associated speech apraxia, dysprosody; late dysgraphia, dysphagia	L > R frontal opercular atrophy	L > R posterior-inferior frontal hypometabolism/perfusion	Non-specific histology
Aprosodia/amusia	Selective impairment of intonation and/or singing	R > L frontal/ anterior temporal atrophy	R > L frontal/ anterior temporal hypoperfusion	Uncertain
Conduction aphasia	Prominent difficulty with repetition; phonemic paraphasias	?L parietal atrophy	L parietotemporal hypometabolism/perfusion	Uncertain
Word deafness	Early impairment of auditory comprehension, acoustic processing; dysprosody, phonemic paraphasias	L superior temporal atrophy	L temporal hypoperfusion	CBD (limited information)
Dynamic aphasia	Selective impairment of propositional speech	L > R frontal atrophy	Uncertain	Uncertain
Agraphia	Early prominent impairment of writing; spelling variable; often associated apraxia, visuospatial deficits	Bilateral parietal atrophy	L > R parieto-occipital hypoperfusion	AD (limited information)
Progressive prosopagnosia	Facial recognition defect; may be associated with other defects of person-specific knowledge, impaired facial emotion processing and expression	R > L anterior temporal atrophy	R > L temporal/orbitofrontal hypometabolism/perfusion	Non-AD pathology (limited information)
Progressive apraxia	Selective impairment of volitional movements of limbs (often asymmetric), trunk; may have selective gait disturbance; may be associated orofacial apraxia, speech production defect	Asymmetric parietal atrophy	Posterior frontal/inferior parietal hypometabolism/perfusion; mesial frontal hypometabolism with gait apraxia	PD, AD, CBD
Progressive visual syndromes				
Visuospatial	Visual disorientation, impaired visually guided movements; often associated agraphia, other parietal signs	Bilateral parietal atrophy	Bilateral (often asymmetric) parieto-occipital hypometabolism/perfusion	Predominantly AD; also CJD, CBD, subcortical gliosis
Visual agnosia	Defective recognition of objects, written words, topography (apperceptive); alexia (without agraphia) for words or music	Bilateral parieto-temporo-occipital atrophy		
Primary visual dysfunction	Early impairments in colour and shape perception, visual fields, acuity	Bilateral posterior occipital atrophy		

* Nature of primary cognitive dysfunction uncertain.

AD, Alzheimer's disease; CBD, corticobasal degeneration; CJD, Creutzfeldt-Jakob disease; CT, computed tomography; L, left; MND, motor neurone disease; MRI, magnetic resonance imaging; PD, Pick's disease; PET, positron emission tomography; PSP, progressive supranuclear palsy; R, right; SPECT, single photon emission computed tomography

impaired comprehension is an early feature, not uncommonly ascribed to 'deafness' by the patient's family. Patients with prolonged word-finding pauses may represent a 'logopenic' subgroup (Mesulam and Weintraub, 1992). Repetition is often abnormal in non-fluent PPA, but may be relatively accurate in fluent PPA (Mesulam, 2001; Grossman, 2002). Although both fluent and non-fluent PPA typically manifest initially as a deterioration in spoken language, other language channels (reading, writing and gesture) generally show analogous deficits as the illness progresses (Snowden *et al.*, 1992; Mesulam, 2001). Mutism is an end-stage feature of both subtypes of PPA (Kertesz and Orange, 2000).

Relative preservation of memory, non-verbal cognitive domains and personality are core features distinguishing PPA from Alzheimer's disease and related dementias. Neuropsychometry has an important role to play in the clinical assessment, particularly in the evaluation of non-verbal cognitive domains; however, many neuropsychological tests and bedside instruments such as the Mini-Mental State Examination depend on verbal responses, and the extent of cognitive impairment in PPA should therefore always be interpreted with caution. Indeed, many patients remain able to care for themselves at home, to manage their financial affairs, and to drive safely, even as their language disintegrates, typically over the course of a decade or more. Eventually, non-verbal cognitive deficits such as executive dysfunction, limb apraxia, and dyscalculia may develop, and asymmetric (predominantly right-sided) pyramidal and extrapyramidal signs are not uncommon (Mesulam and Weintraub, 1992; Mesulam *et al.*, 2003). Few patients suffer a significant personality change, although frontal features (obsessionality, aggression, abulia or disinhibition) may emerge (Snowden *et al.*, 1992).

The age at onset of PPA ranges from the fifth to the eighth decade; males predominate among reported cases, and a variety of European and non-European languages are represented (Mesulam and Weintraub, 1992; Westbury and Bub, 1997). Patients with PPA not uncommonly have a personal or family history of developmental stuttering, dyslexia or other specific learning impairments (Mesulam and Weintraub, 1992), suggesting an underlying genetic or acquired vulnerability of brain language networks. Rarely, PPA is familial; an uncertain proportion of such families fall within the spectrum of dementia linked to chromosome 17, however relatively pure familial forms of PPA (with undetermined inheritance) have been described (Chapman *et al.*, 1997; Kreff *et al.*, 2003).

57.1.1.2 NEUROIMAGING

In PPA as in all the progressive focal syndromes, brain imaging should always be undertaken to exclude non-degenerative processes such as a cerebral tumour. Regional brain atrophy involving the posterior frontal/perisylvian region or temporal lobe can be identified on structural MRI in many cases of PPA (Westbury and Bub, 1997), however this is by no means invariable (Turner *et al.*, 1996; Catani *et al.*, 2003; Nestor *et al.*, 2003a). Atrophy may be restricted to the left hemisphere or it may be

bilateral. Focal changes frequently occur on a background of more diffuse atrophy, predominantly involving the frontal lobes. Patients with non-fluent presentations tend to have more severe inferior frontal/perisylvian atrophy (Figure 57.1a and b), while those with fluent presentations have predominantly anterolateral temporal involvement; however, a clear distinction has not been found in all series (Abe *et al.*, 1997; Sonty *et al.*, 2003). Proton magnetic resonance spectroscopy has documented asymmetric axonal injury within the arcuate fasciculus in PPA (Catani *et al.*, 2003), consistent with the focal involvement of white matter tracts linking cortical language areas.

Functional brain imaging techniques (single photon emission computed tomography [SPECT]; positron emission tomography [PET]; and functional MRI) have demonstrated dysfunction of left hemisphere language networks (Turner *et al.*, 1996; Westbury and Bub, 1997; Mesulam, 2001) that appears to pre-date the development of atrophy on structural imaging. The functional disturbance is more widespread than suggested by the distribution of structural changes, and there may be abnormal (possibly compensatory) activation beyond the classical language areas (Mesulam, 2001; Sonty *et al.*, 2003). Functional changes may be confined to the left hemisphere or they may be bihemispheric (Westbury and Bub, 1997; Soriani-Lefèvre *et al.*, 2003). Non-fluent phenotypes are associated with hypometabolism and decreased perfusion of frontal perisylvian language areas, while fluent phenotypes are associated with predominant temporal or temporoparietal dysfunction (Tyrrell *et al.*, 1990a; Snowden *et al.*, 1992; Abe *et al.*, 1997; Mesulam, 2001; Soriani-Lefèvre *et al.*, 2003). Involvement of the left anterior insula may disrupt speech production in non-fluent PPA (Nestor *et al.*, 2003a). These patterns (though non-diagnostic) are not typical of other frontotemporal dementia phenotypes or Alzheimer's disease (Westbury and Bub, 1997; Nestor *et al.*, 2003a) and correlate with neuropsychological profiles and clinical evolution (Tyrrell *et al.*, 1990a; Nestor *et al.*, 2003a). Selective right hemisphere hypometabolism has been documented in left-handed patients with PPA (Drzezga *et al.*, 2002).

57.1.1.3 OTHER INVESTIGATIONS

Other investigations are of limited clinical usefulness in PPA, but may assist in differential diagnosis. Electroencephalography (EEG) is generally unremarkable, but may show excess slow activity in the left frontotemporal region; the presence of diffuse abnormalities or loss of α rhythm suggests a generalized process such as Alzheimer's disease. Lumbar puncture may be indicated to exclude an inflammatory or other reversible process (for example, in younger patients or cases where disease evolution has been relatively rapid); the routine cerebrospinal fluid examination is normal. Electromyography may be useful in confirming a motor neurone disease-aphasia syndrome. No pathogenetic mutations have been identified in hereditary PPA (Kreff *et al.*, 2003); however, genetic screening may be indicated in younger patients to exclude atypical presentations of familial Alzheimer's disease or a familial tauopathy.

Figure 57.1(a–e) Brain imaging findings in focal dementias. Magnetic resonance imaging (MRI) findings in selected focal dementias. Structural T1-weighted images are presented in radiological convention (the left hemisphere is on the right). (a,b) Progressive non-fluent aphasia: asymmetric ($L > R$) perisylvian and bifrontal atrophy (coronal section, above; axial section, below); (c) progressive prosopagnosia: predominant right anterior temporal atrophy (coronal section); (d,e) progressive visual syndromes: bilateral parieto-occipital atrophy with relative sparing of anterior regions (coronal section, above; sagittal section, below). (With thanks to Dr Nick Fox for permission to reproduce the brain images.)

57.1.1.4 DISEASE BIOLOGY

A variety of neuropathological findings have been described in the relatively few patients with PPA who have come to post mortem or cerebral biopsy. In one review (Mesulam *et al.*, 2003), the most commonly reported pattern (approximately 60 per cent of cases) was a focal degeneration of the left frontal perisylvian and temporal cortex with neuronal loss, gliosis and mild spongiform changes within superficial cortical layers: 'dementia lacking distinctive histology'. Classical Pick's or Alzheimer's changes were less common (each approximately 20 per cent of cases). Other pathologies have been described infrequently: these include corticobasal degeneration (Ikeda *et al.*, 1996), progressive supranuclear palsy (Mochizuki *et al.*, 2003), and probable Creutzfeldt–Jakob disease (Mandell *et al.*, 1989), as well as less well characterized findings including glial cytoplasmic inclusions (Molina *et al.*, 1998). Cases of motor neurone disease-aphasia syndrome (Bak *et al.*, 2001) constitute a distinct subgroup.

Clinicopathological correlation in PPA remains problematic. There is general consensus that non-fluent PPA is rarely due to Alzheimer's disease (Snowden *et al.*, 1992; Kertesz *et al.*, 1994; Black, 1996; Turner *et al.*, 1996; Kramer and Miller, 2000; Mesulam *et al.*, 2003); however, this is not universally accepted (Hodges, 2001) and counter-examples are well documented (Galton *et al.*, 2000; Nestor *et al.*, 2003a). The situation is equally unclear for the fluent syndromes. Indeed, the pathological heterogeneity of PPA appears more in keeping with an anatomically determined neurolinguistic syndrome than a unitary disease. According to this view, the clinical and radiological features reflect the direction of spread of pathology from the dominant perisylvian region: if anteriorly, a predominantly non-fluent aphasia results; if posteriorly, a predominantly fluent syndrome with semantic disintegration (Kramer and Miller, 2000). Alternatively, PPA may represent a distinct anatomical variant of a common 'Pick's disease-tauopathy' spectrum of frontotemporal lobar degeneration (Kertesz *et al.*, 1994; Mesulam *et al.*, 2003). This concept could be extended to patients with corticobasal degeneration and motor neurone disease pathology (Kertesz *et al.*, 1994). The existence of familial forms of PPA, the apparent association between sporadic PPA and the *tau* H1/H1 genotype (Sobrido *et al.*, 2003) and the lack of association between PPA and the $\epsilon 4$ allele of apolipoprotein E (Mesulam *et al.*, 2003) are consistent with a distinct molecular pathogenesis; however, the significance of these observations remains uncertain. The recent discovery of the genetic basis for a developmental speech and language disorder (Vargha-Khadem *et al.*, 1998) raises the exciting prospect that a similar approach in familial PPA may transform our understanding of this condition.

57.1.2 Unusual syndromes

A number of progressive speech and language impairments that would not fulfil strict diagnostic criteria for PPA have been described. The extensive clinical and pathological overlap

within this group and the tendency of fragmentary syndromes to evolve over time and to develop features more typical of PPA suggest that these syndromes represent a neuroanatomical continuum reflecting the topography of pathological involvement, rather than discrete disease entities (Mesulam, 2001). Patients presenting with progressive orofacial apraxia and speech production impairment represent a clinically well defined (though pathologically heterogeneous) group (Tyrrell *et al.*, 1991; Cappa *et al.*, 1993; Chapman *et al.*, 1997). Orofacial apraxia manifests as an inability to cough, yawn or take a deep breath to command, although these actions are normal when performed spontaneously. The illness may evolve over several years into a frontotemporal dementia-motor neurone syndrome accompanied by prominent dysphagia, fasciculations (especially involving triceps and deltoids) and muscle wasting, and electrophysiological evidence of denervation (Tyrrell *et al.*, 1991). Other non-fluent syndromes include progressive aphemia (a severe apraxia of speech; Cohen *et al.*, 1993), cortical anarthria (the anterior opercular syndrome: Broussolle *et al.*, 1996; Silveri *et al.*, 2003), aprosodia ('prosoplegia'; Ghacibeh and Heilman, 2003) and expressive amusia (a selective impairment of singing; Confavreux *et al.*, 1992). Progressive agraphia (Grossman *et al.*, 2001; O'Dowd and de Zubicaray, 2003) and adynamic aphasia (Warren *et al.*, 2003) have also been reported. Uncommon fluent syndromes include progressive pure word deafness and auditory agnosia (Ikeda *et al.*, 1996; Otsuki *et al.*, 1998), and conduction aphasia (Hachisuka *et al.*, 1999). Atrophy tends to be predominantly anterior in the non-fluent syndromes and superior temporal or parietotemporal in the fluent syndromes. Progressive aprosodia and amusia appear to localize to the right frontal or anterior temporal lobes; these syndromes may be accompanied by a loss of facial expressivity, difficulty in comprehending facial or vocal emotion, and later development of a speech production deficit (Confavreux *et al.*, 1992; Ghacibeh and Heilman, 2003). Presentations dominated by progressive agraphia appear to correlate with dominant or bilateral parietal involvement (Grossman *et al.*, 2001; O'Dowd and de Zubicaray, 2003). For unknown reasons, certain phenotypes (for example, jargon aphasia and agraphia; Östberg *et al.*, 2001) occur much less commonly in degenerative than in vascular disease. Neuropathological studies indicate that the majority of patients presenting with unusual PPA variants (in particular, the non-fluent syndromes) have non-Alzheimer pathology, including Pick's disease, corticobasal degeneration and non-specific histology (Cappa *et al.*, 1993; Broussolle *et al.*, 1996; Chapman *et al.*, 1997).

57.2 PROGRESSIVE PROSOPAGNOSIA

In contrast to the well-characterized impairments of language and semantic memory that accompany focal degenerations of the left temporal lobe, the correlates of selective right temporal atrophy remain poorly defined. The apparent

rarity of focal right temporal degenerations may be due at least in part to the clinical silence of this region relative to the eloquent left temporal lobe, and indeed patients may not present to the neurologist until bilateral temporal lobe involvement produces a disturbance of semantic memory (Tyrrell *et al.*, 1990b). The best established clinical phenotype of right temporal lobe pathology is the syndrome of progressive prosopagnosia (Tyrrell *et al.*, 1990b; Evans *et al.*, 1995; Gainotti *et al.*, 2003). Patients present with a progressive inability to recognize faces; as the illness progresses, even famous and highly familiar faces (such as family members) may not be recognized, and generalization to other modalities (such as voices) may occur. Perceptual analysis of faces is generally normal (Tyrrell *et al.*, 1990b; Evans *et al.*, 1995; Gainotti *et al.*, 2003), and general semantic and autobiographical knowledge is typically preserved. These observations suggest that the core defect is loss of access to person-specific knowledge (Gainotti *et al.*, 2003). Focal right anterior temporal atrophy is observed on MRI (Figure 57.1c; p. 723); right temporal and orbitofrontal hypometabolism or hypoperfusion may be detected on functional imaging prior to the onset of structural change (Edwards-Lee *et al.*, 1997). Atrophy predominantly involving the right fusiform and parahippocampal gyri has been correlated with a variant prosopagnosia phenotype in which the core defect is an inability to form global perceptual representations of faces (Joubert *et al.*, 2003).

Some patients with selective right temporal atrophy have associated affective disturbances, personality change and sociopathy which may be due in part to an inability to interpret facial expressions, and the patient's own facial expressions frequently become blunted (Edwards-Lee *et al.*, 1997). Amygdala atrophy is often marked in these cases. Typical frontal behavioural features may develop. Associations between facial identity and emotion processing deficits and between prosopagnosia and other categories of perceptual deficit are variable (Evans *et al.*, 1995; Gentileschi *et al.*, 1999). Associative olfactory agnosia may accompany prosopagnosia (Mendez and Ghajarnia, 2001), perhaps illustrating a common mechanism of disconnection of right temporal cortex from mesial limbic structures. Based on limited evidence (Edwards-Lee *et al.*, 1997), the neuropathological correlates of progressive prosopagnosia may be similar to those of left temporal atrophy-semantic dementia and other frontotemporal dementias in the 'Pick-tauopathy' spectrum.

57.3 PROGRESSIVE APRAXIA

Primary progressive apraxia has been described only infrequently. Patients may complain initially of 'clumsiness' involving one hand (more commonly the left), and asymmetrical involvement is common as the illness evolves (Azouvi *et al.*, 1993). On examination, difficulty imitating gestures and meaningless hand positions, in pantomime and in the use of

objects may be evident; alien limb behaviour has been described (Ball *et al.*, 1993). Limb apraxia is often accompanied by deficits of buccofacial or truncal praxis. Aphasic and other cognitive deficits may develop later in the course. Structural MRI may demonstrate asymmetric parietal atrophy (Azouvi *et al.*, 1993; Kareken *et al.*, 1998), and PET has shown asymmetric posterior frontal and inferior parietal hypometabolism (Kareken *et al.*, 1998). Presentations dominated by a progressive frontal gait disorder ('gait apraxia') and fear of falling constitute a distinct clinical variant (Rossor *et al.*, 1999). There may be associated rigidity with the features of *gegenhalten* and initially few other signs; however, upper limb apraxia and more widespread cognitive dysfunction may develop later in the course. Structural brain imaging may be unremarkable; however, medial frontal hypometabolism may be evident on PET.

Progressive apraxia is a feature of corticobasal degeneration, in which limb apraxia is typically accompanied by asymmetric rigidity and other extrapyramidal or cortical sensory signs, and biparietal presentations of Alzheimer's disease, in which visuospatial impairments and other cognitive deficits are generally evident (Ball *et al.*, 1993; Mackenzie Ross *et al.*, 1996; Galton *et al.*, 2000). However, diagnostic and nosologic difficulties are posed by patients who have progressive apraxia with a paucity of associated neurological signs (Azouvi *et al.*, 1993; Kareken *et al.*, 1998). In support of a metabolic distinction from corticobasal degeneration, ¹⁸F-DOPA PET in such patients has demonstrated normal presynaptic dopaminergic uptake (Kareken *et al.*, 1998; Rossor *et al.*, 1999), suggesting that the dopaminergic nigrostriatal system is intact in at least a proportion of cases. However, neuropathological evidence remains limited and inconclusive. In patients with progressive apraxia and parietal dysfunction, Pick's disease (Cambier *et al.*, 1981) and Alzheimer's disease (Ball *et al.*, 1993) have been demonstrated at post mortem. A patient with complex limb apraxia associated with language disturbance and orofacial apraxia had focal atrophy involving the left frontal operculum and lower precentral gyrus with histological features of Pick's disease and typical inclusion bodies (Fukui *et al.*, 1996). In one case of progressive gait disturbance, mixed features of corticobasal degeneration and Alzheimer's disease were found at post mortem (Rossor *et al.*, 1999). By analogy with the progressive aphasias, progressive apraxia is likely to represent a clinical syndrome produced by a spectrum of pathological processes.

57.4 PROGRESSIVE VISUAL SYNDROMES

Three focal syndromes of progressive visual disturbance have been described (Galton *et al.*, 2000; Tang-Wai *et al.*, 2004): progressive visuospatial impairment, progressive visual agnosia and progressive primary visual dysfunction. Clinically and anatomically, these disorders fall within the broad group of posterior cortical atrophies (Benson *et al.*, 1988); this group overlaps with progressive syndromes in which parietal

dysfunction is prominent, including progressive apraxia, some fluent presentations of PPA, and biparietal presentations of Alzheimer's disease (Galton *et al.*, 2000). The progressive visual syndromes are likely to reflect differential involvement of the visual processing pathways of the posterior hemispheres (Mackenzie Ross *et al.*, 1996), and mixed features commonly appear as the illness evolves (Benson *et al.*, 1988; Attig *et al.*, 1993; Ardila *et al.*, 1997). Early involvement of the dorsal 'where' processing stream accounts for the majority of case reports (Attig *et al.*, 1993; Mackenzie Ross *et al.*, 1996; Goethals and Santens, 2001; Nestor *et al.*, 2003b). Patients with this syndrome typically present with difficulties in locating objects, planning visually-guided movements and reading lines of text. On examination, visual disorientation and/or optic ataxia, apraxia, agraphia and other parietal signs are frequent, and there may be difficulties in identifying fragmented figures; however, visual fields and early visual processing are intact. Initial disruption of the ventral 'what' processing stream (De Renzi, 1986; Ardila *et al.*, 1997) produces impairments in the recognition of objects, written words and topographical features; on examination, features of visual apperceptive agnosia are present. Variant syndromes include progressive pure alexia for words or music (Beverdors and Heilman, 1998) and hemiachromatopsia (Freedman and Costa, 1992). Rarely, early involvement of primary visual cortex produces impairments of early visual processing, which may include deficits or distortions of colour or shape perception, hallucinations or abnormal after-images (Levine *et al.*, 1993; Galton *et al.*, 2000; Chan *et al.*, 2001); visual field defects may develop, and visual acuity may be reduced. These different clinical syndromes broadly correspond to predominantly dorsal parietal, ventral parieto-temporo-occipital and posterior occipital patterns of atrophy on structural imaging (Figure 57.1d and e, p. 723) and pathological examination. Functional imaging generally shows bilateral (often asymmetric) parieto-occipital hypometabolism or hypoperfusion rather than the parieto-temporal pattern typical of Alzheimer's disease (Attig *et al.*, 1993; Victoroff *et al.*, 1994; Beverdors and Heilman, 1998; Goethals and Santens, 2001; Nestor *et al.*, 2003b).

The majority of progressive visual cases that have been studied pathologically have histological features of Alzheimer's disease (Pantel and Schroder, 1996; Galton *et al.*, 2000; Nestor *et al.*, 2003b; Tang-Wai *et al.*, 2004), suggesting that these syndromes should be regarded principally as variant Alzheimer phenotypes; this generalization may apply particularly to patients with prominent dorsal stream involvement (Nestor *et al.*, 2003b). More typical impairments of memory and other cognitive functions not uncommonly develop later in the course, though visual features may dominate for a number of years. Loss of α rhythm on EEG and evidence of hippocampal atrophy on MRI support the diagnosis of Alzheimer's disease, however routine investigations may be normal. Non-Alzheimer degenerative pathologies including corticobasal degeneration (Tang-Wai *et al.*, 2003), Creutzfeldt-Jakob disease (Victoroff *et al.*, 1994) and subcortical gliosis (Victoroff *et al.*, 1994) have been described in a small number of cases.

57.5 MANAGEMENT

No specific disease-modifying therapies are currently available for any of the focal dementias. After exclusion of reversible disease processes, the main priorities of management are the provision of information and the mobilization of support services for patients and their carers. The social and occupational consequences of these diseases are often profound; appropriate counselling may allow patients and families to plan for the future, and disease support groups may be helpful for some. Pharmacotherapy has a limited role. Concomitant depression should be treated; however, no additional cognitive benefit has been established for neuro-modulatory agents such as the serotonin reuptake inhibitors (Litvan, 2001; Deakin *et al.*, 2003; Pasquier *et al.*, 2003). Patients with frontotemporal lobar degenerations may be particularly vulnerable to dopaminergic blockade and neuroleptics should be avoided in this group (Pijnenburg *et al.*, 2003). Patients with posterior cortical atrophy who fulfil diagnostic criteria for Alzheimer's disease may derive symptomatic benefit from acetylcholinesterase inhibitors such as donepezil; however, anecdotal evidence suggests that these agents may worsen behavioural symptoms in the non-Alzheimer dementias and appropriate controlled trials are awaited. Specific cognitive rehabilitation programmes have been proposed in PPA (Louis *et al.*, 2001), however, their use has not been widely evaluated.

57.6 CONCLUSIONS

The focal dementias present challenges for clinicians and neurobiologists alike. Patients are often disabled by their deficits and stand in need of considerable clinical and social support; yet accurate diagnosis is difficult, and focal cognitive symptoms are not infrequently misinterpreted as non-organic. The clinical syndromes generally represent topographical signatures of the distribution of pathology rather than markers of specific diseases. Histopathological information remains limited: further detailed clinicopathological studies are needed in order to define the spectrum of pathological changes that may be associated with particular clinical phenotypes and to identify features that distinguish these unusual focal variants from the more common diffuse degenerations. Diagnostic and terminological inconsistencies and the conflation of clinical, anatomical and pathological levels of description have given rise to much confusion in the literature of these disorders. Ultimately, this confusion may be resolved only through an improved understanding of the neurobiological and molecular mechanisms whereby regional vulnerabilities of neuronal function are translated into clinical deficits. Such an approach will be essential for the development of rational therapies in these often devastating diseases. Current classification schemes (for example, the distinction between 'fluent' and 'non-fluent' PPA) may be refined as

more complete accounts of cognitive information processing become available. It is likely in turn that these rare disorders will provide fresh perspectives on human brain function (in particular, the operation of distributed neural networks) in both health and disease.

Depression with cognitive impairment

BINDU SHANMUGHAM AND GEORGE ALEXOPOULOS

58.1 Cognitive impairment in non-demented depressed patients	731	58.5 'Pseudodementia'	733
58.2 Depression in patients with dementing disorders	732	58.6 Prognosis of depression with cognitive impairment	733
58.3 Depression as a risk factor for dementia	732	58.7 Diagnostic assessment and treatment planning	734
58.4 Cognitive impairment and the course of geriatric depression	732	References	735

Depressed elders often have cognitive impairment. The number of community residents with both depressive symptoms and impaired cognition doubles at each 5-year interval after the age of 70 years. Depression accompanied by cognitive dysfunction occurs in 25 per cent of 85-year-old subjects (Arve *et al.*, 1999). Even non-demented depressed elders often have impairments in speed of processing and executive function (Kindermann *et al.*, 2000; Lockwood *et al.*, 2000). About 18–57 per cent of depressed elderly patients may present with dementia that resolves with remission of depression (Emery, 1988). Finally, dementing disorders are often complicated by depressive symptoms.

58.1 COGNITIVE IMPAIRMENT IN NON-DEMENTED DEPRESSED PATIENTS

A variety of neuropsychological impairments have been reported in late-life depression (Lockwood *et al.*, 2000, 2002). These include impairment in recall (Hart *et al.*, 1987), recognition memory, visuospatial skills (Boone *et al.*, 1995; Lesser *et al.*, 1996), verbal fluency, psychomotor speed (Hart *et al.*, 1987) and executive functions such as impaired planning, organizing, initiating, sequencing and attentional set shifting (Beats *et al.*, 1996; Lesser *et al.*, 1996; Butters *et al.*, 2000). Even moderately depressed middle-aged patients have deficits in planning, strategy development, spatial working memory, and verbal fluency despite unimpaired psychomotor speed (Elliot *et al.*, 1996). While tasks requiring development of performance strategies suffer in depressed patients,

automatic processes appear relatively preserved (Channon and Green, 1999).

Although focal deficits or even severe global impairment are observed in some depressed elderly patients, the cognitive functioning of others remains intact. Studies of cognitive response to psychopharmacological treatment of late-life depression indicate that a substantial number of patients continue to experience residual symptoms and neuropsychological deficits. Processing speed and working memory impairment persist after remission of geriatric depression (Butters *et al.*, 2000; Nebes *et al.*, 2000).

The neuropsychological dysfunctions of depression are consistent with frontal lobe abnormalities demonstrated by neuroimaging studies (Abrams and Taylor, 1987; Coffey, 1987; Sackeim and Steif, 1988; Deptula *et al.*, 1991; Lodewyk and Wong, 1993). Structural abnormalities have been identified in the frontal lobes (Krishnan *et al.*, 1993), the caudate (Krishnan *et al.*, 1992), and the putamen (Husain *et al.*, 1991). Hypometabolism has been reported in the dorsolateral prefrontal cortex (Baxter *et al.*, 1985; Martinot *et al.*, 1990; Bench *et al.*, 1992), inferior temporal areas (Lesser *et al.*, 1994), anterior cingulate (de Asis *et al.*, 1997; Drevets *et al.*, 1997; Mayberg *et al.*, 1997) and basal ganglia (Buchsbaum *et al.*, 1986). Notably, reduced metabolism of the rostral anterior cingulate may be associated with resistance to antidepressants in younger depressed patients (Mayberg *et al.*, 1997). In contrast, an increase in frontal hypometabolism has been reported following successful treatment with antidepressant medications (Mayberg *et al.*, 1999; Drevets, 2000). It has been proposed that abnormal function of the right dorsolateral prefrontal cortex is the biological substrate of poor sustained attention

noted in depressed patients, while metabolic abnormalities of the anterior cingulate cortex account for impaired selective attention of these patients (Liotti and Mayberg, 2001).

58.2 DEPRESSION IN PATIENTS WITH DEMENTING DISORDERS

Depressive symptoms are common among demented patients. Major depression or clinically significant depressive symptoms can be found in approximately 17 per cent of Alzheimer's patients (Wragg and Jeste, 1989). Patients with subcortical dementias, including vascular dementia, and Parkinson's disease, are more likely to experience depression than patients with Alzheimer's disease (Sobin and Sackeim, 1997).

Late-onset depression is often a prodrome of dementing disorders. Depressed mood was associated with an increased risk of incident dementia during a 5-year follow up of elderly community residents (Devanand *et al.*, 1996). Depressive symptoms predicted cognitive decline of elderly women during a 4-year follow up (Yaffe *et al.*, 1999). Among elderly individuals with subclinical cognitive dysfunction, those who developed dementia 3 years later had more depressive symptoms at baseline (Ritchie *et al.*, 1999). As subjects progressed to dementia, they exhibited fewer affective symptoms and more agitation and psychomotor slowing. These changes paralleled reduction of cerebral blood flow in the left temporal region. Finally, there is evidence that late-onset depression is associated with increased incidence of dementia in individuals without an apolipoprotein E (ApoE) $\epsilon 4$ allele (Steffens *et al.*, 1997).

Recently, the National Institute of Mental Health's Provisional Diagnostic Criteria for Depression of Alzheimer's Disease were developed with the goal to promote research on the mechanisms and treatment of this disorder (Olin *et al.*, 2002). The criteria require the presence of Alzheimer's disease diagnosis and 'clinically significant' depressive symptoms. Symptoms due to a medical condition other than Alzheimer's disease, or which are deemed to be a direct result of non-mood-related dementia symptoms (e.g. loss of weight due to difficulties with food intake) should not be used in making the diagnosis of depression of Alzheimer's disease.

58.3 DEPRESSION AS A RISK FACTOR FOR DEMENTIA

There is weak evidence that depression occurring in early life may be a risk factor for the later development of dementing disorders. In a meta-analytic study a past history of depression was associated with onset of Alzheimer's disease after the age of 70 years only when depressive symptoms had appeared within 10 years before the onset of dementia (Jorm *et al.*, 1991). Depressive symptoms occurring more than 10 years from the onset of dementia were found to be a risk factor

for Alzheimer's disease (Speck *et al.*, 1995). Lifetime history of depression may increase the risk of Alzheimer's disease, in patients with or without a family history of dementing disorders (van Duijn *et al.*, 1994).

Depression may promote the clinical expression of dementia in patients with Alzheimer's disease. Lifetime duration of depression was observed to correlate with hippocampal volume reduction, although some disagreement exists (Sheline *et al.*, 1999; Davidson *et al.*, 2002). Excessive secretion of stress-related hormones (glucocorticoids) may contribute to hippocampal atrophy. These hormones can reduce the secretion of neurotrophic factors, inhibit neurogenesis and render neurones vulnerable to the toxic effect of amyloid, thus compounding the neuropathological changes of Alzheimer's disease and accelerating the clinical expression of dementia. Once depression develops as part of these brain changes, it may accelerate the progression of Alzheimer's neuropathological changes. Several antidepressants elevate brain-derived neurotrophic factor (BDNF) in the rat hippocampus. Through this action, antidepressants may prevent stress-induced inhibition of neurogenesis and increase dendritic branching (Duman *et al.*, 1997). It remains to be investigated whether antidepressants delay the onset and inhibit the progression of Alzheimer's disease.

58.4 COGNITIVE IMPAIRMENT AND THE COURSE OF GERIATRIC DEPRESSION

Multiple pathways may lead to depression and cognitive impairment. Clinical as well as structural and functional neuroimaging studies suggest that depressive symptoms and executive impairment originate from related brain dysfunctions (Alexopoulos, 2001), at least in a subgroup of elderly patients. We described a 'depression-executive dysfunction syndrome' (DED), which is characterized by psychomotor retardation, reduced interest in activities, a rather mild vegetative syndrome, and pronounced functional disability disproportionate to the severity of the depression (Alexopoulos *et al.*, 1996; Kiosses *et al.*, 2000; Lockwood *et al.*, 2000). DED patients have impaired verbal fluency and visual naming, as well as poor performance on tasks of initiation and perseveration (Alexopoulos *et al.*, 1996). Psychomotor retardation, apathy and fluency deficits are symptoms often observed in frontal lobe syndromes. Yet, unlike patients with frontal lobe syndromes, patients with DED meet criteria for major depression, and have depressive symptomatology of comparable severity to that of geriatric major depression patients with unimpaired executive functions (Alexopoulos *et al.*, 2000).

There is evidence that impaired performance in some tests of executive function is associated with poor and/or slow antidepressant response (Alexopoulos, 2002a). In younger women, abnormal executive functions were associated with poor response to fluoxetine (Dunkin *et al.*, 2000). Abnormal scores in tests of initiation and perseveration were shown to

predict poor antidepressant response and low remission rate in non-demented elderly patients with major depression treated with 'adequate' dosages of various antidepressants (Kalayam and Alexopoulos, 1999). Furthermore, other studies demonstrated that the efficacy of antidepressants is not compromised by broad cognitive dysfunction (Alexopoulos, 1995; Nyth *et al.*, 1992; Katona *et al.*, 1998) or medical comorbidity (Small *et al.*, 1996). Along with slow and poor response to antidepressants, abnormal scores of initiation and perseveration have been shown to predict early relapse and recurrence of late-life depression in elderly patients treated with nortriptyline (Alexopoulos *et al.*, 2000), while neither memory impairment, nor disability, medical burden, social support, nor number of previous episodes influenced the long-term outcomes of late-life depression.

Magnetic resonance imaging (MRI) studies have shown that white matter hyperintensities are associated both with executive dysfunction (Boone *et al.*, 1992; Lesser *et al.*, 1996) and with chronicity of geriatric depression (Coffey *et al.*, 1988; Hickie *et al.*, 1995). Severe hyperintensities in subcortical grey matter regions were associated with poor response of depressed elderly patients to electroconvulsive therapy (Steffens *et al.*, 2001). An electrical tomography analysis study suggests that anterior cingulate activity is a predictor of the extent of treatment response in depression (Pizzagalli *et al.*, 2001); functional integrity of the anterior cingulate cortex is required for the performance of executive functions.

Functional imaging studies of younger adults suggest that remission of depression is associated with metabolic increases in dorsal cortical regions (Mayberg *et al.*, 1999; Drevets, 2000) and metabolic decreases in ventral limbic and paralimbic structures (Mayberg *et al.*, 1999; Smith *et al.*, 1999; Liotti and Mayberg, 2001). Persistently elevated metabolism of the amygdala during remission of depression was associated with a high risk for relapse of depression in younger adults (Drevets, 1999). Reduced metabolism of the emotional subdivision of the anterior cingulate is associated with treatment resistance in depressed younger adults, while increased cingulate metabolism is a predictor of a good treatment response (Mayberg *et al.*, 1997). A diffusion tensor imaging study noted that microstructural abnormalities of the white matter lateral to the anterior cingulate are associated with poor or slow response of geriatric depression to citalopram (Alexopoulos *et al.*, 2002b). Disruption of white matter in this area may interfere with the dorsal cortical-ventral limbic reciprocal regulation and may contribute to adverse outcomes of geriatric depression.

58.5 'PSEUDODEMENTIA'

The concept of reversible dementia was introduced in the mid-nineteenth century (Berrios, 1985; Emery, 1988) and became the focus of clinical attention in the early 1960s when the term 'pseudodementia' was used to describe a broad range

of reversible cognitive impairments associated with psychiatric syndromes (Kiloh, 1961). The current concept of 'pseudodementia' is that of an initially reversible cognitive impairment that occurs in the context of diverse psychiatric disorders, which influence its course.

The clinical presentation of depression with cognitive impairment is heterogeneous. The signs and symptoms are principally influenced by the patients' ages and underlying psychiatric disorders (Kiloh, 1961; Wells, 1979; Rabins *et al.*, 1984; Alexopoulos, 1990; Emery and Oxman, 1992). In a non-geriatric series, 'pseudodementia' was reported in patients with Ganser syndrome, personality disorders, melancholic depression, hypomania, atypical psychosis, paraphrenia, catatonia, depersonalization and malingering (Kiloh, 1961, 1981; Wells, 1971). Non-geriatric patients with 'pseudodementia' often had a history of prior psychiatric disorders, a recent and abrupt onset of current illness, complained about their cognitive loss, experienced distress, and were able to both precisely identify the onset and describe in detail the course of their illness (Kiloh, 1961; Wells, 1979). On cognitive tests, these patients often said they did not know the correct answers even though the tasks were within their abilities. Performance on tasks of similar difficulty was markedly variable and accompanied by an overdramatization of their failures.

As many younger patients with 'pseudodementia' have psychiatric syndromes other than depression, their clinical presentation is dissimilar to that of geriatric patients with 'pseudodementia' in whom depression is the most common diagnosis. Depressed elders with 'pseudodementia' usually have a severe depression syndrome and a mild dementia. The clinical profile of major depression accompanying 'pseudodementia' of older adults is characterized by motor retardation, depressive delusions, hopelessness and helplessness (Alexopoulos and Abrams, 1991). Geriatric inpatients with major depression and 'pseudodementia' had a later age of onset of illness than patients who only had major depression (Alexopoulos *et al.*, 1993a). A study of elderly inpatients and outpatients noted that those with depression and 'pseudodementia' had more psychic and somatic anxiety, early morning awakening, and loss of libido than patients with Alzheimer's disease complicated by depression (Reynolds *et al.*, 1988). Unlike younger adults, depressed elders with 'pseudodementia' express limited cognitive complaints or 'I don't know' responses (Young *et al.*, 1985; Meyers, 1987; Emery, 1988). As a rule, the symptoms of depression preceded those of cognitive dysfunction in patients with depressive 'pseudodementia'.

58.6 PROGNOSIS OF DEPRESSION WITH COGNITIVE IMPAIRMENT

As a rule, cognitive impairment improves after amelioration of geriatric depression. However, this improvement is partial in most cases (Abas *et al.*, 1990; Nebes *et al.*, 2000, 2001).

Follow-up studies suggest that geriatric patients with depression and an initially reversible dementia ('pseudodementia') are at high risk for developing irreversible dementia (Reynolds *et al.*, 1986; Kral and Emery, 1989; Copeland *et al.*, 1992; Alexopoulos *et al.*, 1993a). Taken together, these studies suggest that 9–25 per cent of elderly patients with depression and an initially reversible dementia develop irreversible dementia each year. However, many such patients do not meet criteria for irreversible dementia for a period of 2 years after the initial episode of depression with 'pseudodementia' (Alexopoulos *et al.*, 1993b). However, some studies observed that there exists a population of elderly depressed people with reversible dementia who remain cognitively intact at least for a few years after resolution of the dementia syndrome (Rabins *et al.*, 1984; Pearlson *et al.*, 1989).

Differences in the course of cognitive dysfunction in depressed patients with an initially reversible dementia suggest that this syndrome is heterogeneous (Alexopoulos, 2002b). Some depressed people with an initially reversible dementia may already have an early dementing disorder. This view is supported by recent studies suggesting that depression is a prodrome of dementing disorders. Several explanations may account for depressed elderly patients with reversible dementia who remain cognitively intact on follow up. Disturbances in attention and motivation may interfere with the examination of higher intellectual functions in severely depressed elderly patients. Another possibility is that the cognitive dysfunction of depression may be prominent in patients with asymptomatic non-progressive brain lesions, e.g. silent stroke. Such patients may develop a dementia syndrome only during depression but not develop dementia during follow up. Such depression–lesion interaction is supported by the observation that neurological symptoms and signs are exacerbated when patients become depressed (Fogel and Sparadeo, 1985). Another possibility may be that severe cognitive dysfunction is an integral part of severe geriatric depression. There is evidence suggesting that cognitive dysfunction is an expression of the functional brain changes occurring during depression rather than a behavioural consequence of the affective symptoms. Memory and executive dysfunction often occur in depressed elderly patients (Butters *et al.*, 2000; Kindermann *et al.*, 2000; Lockwood *et al.*, 2000; Nebes *et al.*, 2001) who sometimes do not completely recover (Butters *et al.*, 2000; Nebes *et al.*, 2001). Dysnomia has been noted in depressed elderly patients compared with controls (Speedie *et al.*, 1990). Functional neuroimaging studies showed reduced glucose metabolism in the basal ganglia and the prefrontal areas (Drevets, 2000) of depressed patients, while structural neuroimaging studies documented reduced volumes of the putamen (Husain *et al.*, 1991) and the caudate (Krishnan *et al.*, 1992) in depressed patients compared with normal controls. These observations suggest that the spectrum of clinical manifestations of depression includes a wide range of cognitive impairments that may account for some of the subjects with reversible dementia who did not deteriorate on follow up.

58.7 DIAGNOSTIC ASSESSMENT AND TREATMENT PLANNING

Depressed elderly patients with cognitive impairment should have an evaluation both of their psychiatric symptoms and signs as well as their cognitive impairment. Since depression and cognitive impairment have a complex association, the diagnosis of depression and cognitive dysfunction or dementia should be made independently of each other. In some cases the syndromes of depression and dementia are caused by the same disorders, e.g. vascular dementias, Parkinson's disease, Alzheimer's disease, hypothyroidism, autoimmune diseases or steroid-induced depression with cognitive impairment. In other cases, depression and dementia simply may coexist.

Identifying and characterizing cognitive impairment of depressed elderly patients has important clinical implications. Depressed elders often develop delirium in response to drug side effects, dehydration, infections and other factors. Therefore, cognitive examination should focus on manifestations of delirium, including inattention, fluctuating state of consciousness and sleep-wake disturbances. Of course, making the diagnosis of delirium does not exclude the diagnosis of dementia. As dementing disorders predispose to delirium, delirious patients should be re-examined for an underlying dementing disorder after the resolution of delirium. Identifying treatable causes of dementia, e.g. dementia owing to drug intoxication, organ failure, endocrinopathies, B₁₂ deficiency, and space-occupying lesion is important as treatment of these conditions may reverse or arrest the progress of dementia.

When dementia is identified, the clinical characterization of the dementia syndrome can guide treatment. Among the dementia syndromes, subcortical dementia is the syndrome most likely to be complicated by depression. Subcortical dementia is characterized by significant memory impairment, executive dysfunction and psychomotor retardation. Disorders causing subcortical dementias include mixed Alzheimer's and vascular dementia, vascular dementia, Parkinson's disease, and dementia with Lewy bodies. These disorders require rather specific treatments, e.g. vascular dementia often is treated with aspirin and antioxidants, Parkinson's disease with dopamine acting agents, and dementia with Lewy bodies with cholinesterase inhibitors and anticonvulsants for behavioural control rather than antipsychotics. Unlike subcortical dementias, cortical dementias manifest broader impairment of cognitive functions, including memory impairment, apraxia, aphasia with paraphasic errors and graphomotor construction problems.

The most common cause of cortical dementia is Alzheimer's disease, a condition treated with cholinesterase inhibitors at least during the early and middle phase and with memantine during the advanced phase. Frontal lobe dementias are characterized by rather mild memory impairment and pronounced personality changes (apathy, socially inappropriate behaviour and disinhibition) often resulting in irritability. Frontal lobe dementia may be due to frontotemporal

dementia, head trauma and stroke, disorders for which there are no specific treatments.

Identification of executive dysfunction is important even in non-demented depressed elderly patients. Depressed patients with psychomotor retardation, reduced interest in activities, suspiciousness and disability are likely to have executive dysfunction (Alexopoulos *et al.*, 2002a). Depression with executive dysfunction may have a poor and unstable response to antidepressants (Kalayam and Alexopoulos, 1999; Alexopoulos *et al.*, 2000). For this reason, patients with the depression-executive dysfunction syndrome of late life require a carefully planned psychopharmacological treatment and vigilant follow up since they are at high risk for relapse or recurrence (Alexopoulos *et al.*, 2000). Non-pharmacological interventions need to be added, including problem-solving therapy aimed at remedying their behavioural deficits (Alexopoulos *et al.*, 2003).

Evaluation of depressive syndromes in cognitively impaired patients is complicated by the symptomatologic overlap with dementia, the instability of depressive manifestations over time and the poor ability of elderly patients to report their symptoms. If criteria for one of the depressive syndromes are met, an antidepressant treatment trial should be offered. Beyond the benefits of alleviating the problems and the complications of depression, remission of the depressive syndrome can increase the clinician's ability to evaluate the severity of the remaining cognitive impairment and plan for further treatment and follow up. The Expert Consensus Guideline recommends antidepressant drug therapy combined with a psychosocial intervention as the treatment of choice for geriatric depression (Alexopoulos *et al.*, 2001).

Variability in the course of elders with depressive 'pseudodementia' suggests the need for careful follow up. About 40 per cent of these patients are expected to receive the diagnosis of a dementing disorder within two years after the diagnosis of 'pseudodementia.' Prompt identification and treatment of the dementing disorder may increase the time during which the patient can function independently.

Alcohol-related dementia and the clinical spectrum of Wernicke–Korsakoff syndrome

STEPHEN C BOWDEN AND ALISON J RITTER

59.1 Cognitive impairment associated with alcohol dependence	738	59.4 Treatment recommendations	742
59.2 Diagnostic criteria for alcohol-related dementia	739	59.5 Conclusions	742
59.3 Broadening the definition of Wernicke–Korsakoff syndrome	740	References	742

Dementia associated with alcohol dependence has seen a dramatic increase in the number of clinical and experimental studies undertaken but also a plurality of views regarding aetiology, clinical course and optimal treatment modalities (Victor, 1994). When Butters and Cermak (1980) wrote their landmark work on the neuropsychology of the ‘alcoholic Korsakoff’s syndrome’ there were relatively few controlled studies of cognitive impairment associated with a diagnosis of alcohol dependence. The intervening period has seen a dramatic increase in our understanding of the prevalence of cognitive problems associated with long-term, and excessive, alcohol use that, in severe forms, is frequently interpreted as alcohol-related dementia. However, we have also witnessed a consonant increase in our understanding of the clinical spectrum of Wernicke–Korsakoff syndrome. While there is strong evidence that Wernicke–Korsakoff syndrome is caused by thiamin deficiency, it is most commonly reported in people with an associated diagnosis of alcohol dependence. The potential for Wernicke–Korsakoff syndrome to present as a dementia of fluctuating course and variable severity remains a concept unfamiliar to many clinicians. In this chapter, a diagnostic framework will be outlined for understanding dementia associated with alcohol dependence and important treatment and management considerations will be identified.

59.1 COGNITIVE IMPAIRMENT ASSOCIATED WITH ALCOHOL DEPENDENCE

Excessive alcohol consumption is a serious health problem in many countries with multiple direct and indirect social and

health costs (Gordis, 2000; Royal College of Physicians, 2001). As part of a wider perspective addressing health effects of alcohol dependence, there has been great interest in the hypothesis that excessive alcohol intake may affect the brain. Interest in this ethanol neurotoxicity hypothesis has spanned the spectrum of beverage alcohol intake from levels of alcohol consumption commonly regarded as ‘moderate’ or socially acceptable, up to levels of regular intake associated with disruption of occupational and social function and the multiple health risks of alcohol dependence (American Psychiatric Association, 1994).

Most studies reporting tangible effects on cognitive and broader psychological function have focused on levels of intake reported from individuals seeking professional help for their alcohol dependence (Bowden, 1987; Grant, 1987; Parsons, 1998). In general terms, reliably identifiable cognitive impairment associated with ethanol consumption is reported from samples of people whose alcohol dependence became established in late teenage years or early adulthood, and who have been consuming in excess of 80–100 mL of pure ethanol on a regular daily basis for some, usually many, years. By the time they seek professional help, many people with alcohol dependence have alcohol-induced multiple organ disease, and other complicating conditions such as poor nutrition and head injuries. In such samples, the prevalence of cognitive impairment has been estimated at a substantial minority or perhaps a majority (Parsons, 1994; Rourke and Loberg, 1996; Bates *et al.*, 2002).

In milder forms, this pattern of cognitive impairment was termed ‘subclinical psychological deterioration’ (Cutting, 1985), so named because in individual cases it may not be

apparent until elicited with objective assessment of cognition (Parsons, 1994). In more severe forms this clinical picture has been termed alcohol-induced persisting dementia (American Psychiatric Association, 1994: Code 291.2) or alcohol-related dementia (Oslin *et al.*, 1998).

Several reviews have provided a comprehensive overview of the many cognitive, neuroimaging, neurochemical, neurophysiological observations in alcohol-dependent patients (Lishman, 1998; Bates *et al.*, 2002; Harper *et al.*, 2003). Aetiological processes considered in the explanation of alcohol-related dementia include pre-existing learning disabilities, family history of alcohol dependence both as an early environmental and as genetic risk factors, childhood behaviour problems and comorbid psychopathology (Rourke and Loberg, 1996; Adams *et al.*, 1998; Lishman, 1998; Oslin *et al.*, 1998; Bates *et al.*, 2002; Oscar-Berman and Marinkovic, 2004). Medical risk factors that may predispose to cognitive impairment include multiple organ disease, particularly liver disease, head injury and multiple nutritional deficiencies (Parsons, 1994; Bates *et al.*, 2002; Harper *et al.*, 2003). Despite the complexity of the pathophysiological issues many authors have clearly favoured the concept of an alcohol-induced dementia. The most important caveat on this nosological inference is the fact that some neurological conditions may be relatively asymptomatic, the only important sign being cognitive impairment (Victor, 1994; Oslin *et al.*, 1998). These nosological issues will be discussed in detail below.

Many studies have examined parameters of alcohol intake with the view to identifying a dose–response relationship underlying alcohol-related dementia. In general the search for a clear dose–response relationship has been disappointing, with only occasional reports of correlations between parameters of intake and behavioural or neurophysiological outcome measures (Rourke and Loberg, 1996; Walton and Bowden, 1997; Oslin *et al.*, 1998). In terms of the specific pattern of cognitive impairment in alcohol-related dementia, some studies have focused on the deficits in core cognitive abilities such as working memory and fluid intelligence (sometimes labelled executive functions); other studies have reported deficits in most or all aspects of cognitive function including additional deficits in crystallized intelligence and anterograde memory or long-term retrieval (see Rourke and Loberg, 1996; Leckliter and Matarazzo, 1998; Bates *et al.*, 2002; Oscar-Berman and Marinkovic, 2004). Also there have been some interesting attempts to provide a characterization of cognitive impairment in alcohol-related dementia as a means by which to provide a differential diagnosis from other dementias (e.g. Saxton *et al.*, 2000). However, the variable pattern of cognitive function across individuals in all conditions, particularly in less severe forms, does not promise useful diagnostic efficiency.

An important issue in clinical management of patients suspected of alcohol-related dementia relates to stabilization of cognitive status and the timing of assessment of cognition after cessation of drinking. For this purpose, many neuropsychologists recommend refraining from assessment of cognitive

status until several weeks after withdrawal from alcohol (Goldman, 1985; Rourke and Loberg, 1996). However, this strategy may not always be practical and some evidence suggests that it may be possible to obtain a reasonable indication of cognitive function within a few days of cessation of drinking (Unkenstein and Bowden, 1990; Bowden *et al.*, 1995). Nevertheless, it is important to recognize that cognitive status may slowly improve after cessation of drinking, over a period of months or years, or worsen with resumption of alcohol abuse (Victor *et al.*, 1971; Sullivan *et al.*, 2000; Bates *et al.*, 2002; Oslin and Carey, 2003). Therefore, any assessment of cognitive status in detoxified alcohol-dependent persons, even in those patients showing a severe alcohol-related dementia, should be formulated on the assumption that cognitive status may evolve or resolve and may need to be reviewed regularly.

59.2 DIAGNOSTIC CRITERIA FOR ALCOHOL-RELATED DEMENTIA

A few years ago, Oslin and colleagues described provisional criteria for the diagnosis of alcohol-related dementia (Oslin *et al.*, 1998). Emulating consensus criteria for other dementias, Oslin and colleagues distinguished *possible*, *probable* and *definite* subcategories of alcohol-related dementia (*cf.* American Psychiatric Association, 1994: Code 291.2). The crux of their *probable* definition was a persisting dementia, not obviously attributable to any other condition, in the context of significant alcohol use defined as at least 35 standard drinks per week. Oslin and colleagues outlined a variety of inclusion and exclusion criteria for the various subcategories, and readily acknowledged that many of the diagnostic criteria were arbitrary and intended to stimulate debate and research. They also acknowledged that variants of Wernicke–Korsakoff syndrome or other unrecognized conditions may be the primary diagnosis in many cases of alcohol-related dementia.

Oslin and colleagues also acknowledged that there were no acceptable criteria for a *definite* diagnosis of alcohol-related dementia, in other words, no known neuropathological entity corresponding to the hypothesized clinical condition. This anomaly contrasts with other consensus criteria where, for example, a specific neuropathological condition provides the basis for a definite diagnosis of Alzheimer's disease (McKhann *et al.*, 1984). Despite the great interest, over recent decades, in identifying the pathophysiology, the anomaly persists, a specific neuropathological entity corresponding to alcohol-related dementia remains to be identified (Harper *et al.*, 2003; Oslin and Carey, 2003). In view of the ambiguities in diagnosis, it is not surprising that good prevalence figures are difficult to obtain. Nevertheless, clinical surveys suggest that alcohol dependence may be one of the most common apparent causes of dementia, after Alzheimer's and vascular dementia (Lishman, 1998; Oslin and Carey, 2003). In contrast many years ago Torvik and colleagues (Torvik *et al.*, 1982) inferred

from their large post-mortem surveys that most patients diagnosed clinically as having alcohol-related dementia usually will be found to have Wernicke–Korsakoff syndrome at post mortem.

Other conditions can give rise to cognitive deterioration in association with alcohol dependence, for example, pellagra, Marchiafava–Bignami disease, or hepatic encephalopathy (Victor, 1994; Lishman, 1998). Most interesting is the observation that, apart from Wernicke–Korsakoff syndrome, other pathological conditions are infrequently observed in the brains of patients who had a clinical diagnosis of dementia associated with alcohol dependence (Torvik *et al.*, 1982; Victor, 1994; Harper *et al.*, 2003). In addition, there is increasing evidence that many physiological derangements, worsened by excessive alcohol intake, may interact to diminish intracellular thiamin in the brain, even in the context of an adequate diet (Cook *et al.*, 1998; Crews *et al.*, 2000; Thomson *et al.*, 2002). The primary danger in giving a different name, for example alcohol-related dementia, to unrecognized clinical variants of known conditions, for example Wernicke–Korsakoff syndrome, is that appropriate treatment opportunities may be missed (Victor, 1994; Lishman, 1998; Thomson *et al.*, 2002).

59.3 BROADENING THE DEFINITION OF WERNICKE–KORSAKOFF SYNDROME

Wernicke–Korsakoff syndrome is reported with a prevalence of approximately 0.6–2 per cent of post-mortem studies and an incidence of approximately 1 per cent, making it one of the more common neurological diseases (Victor *et al.*, 1989; Torvik, 1991; Harper *et al.*, 2003; Thomson *et al.*, 2002). In addition, the classical diagnostic triad of neurological signs, namely eye signs, ataxia and cognitive impairment, is recognized as having high diagnostic specificity, but relatively low sensitivity, perhaps below 20 per cent, in the context of a disease that may have an acute onset, but also may be insidious and progressive with multiple episodes (Torvik *et al.*, 1982; Harper, 1983; Lishman, 1986; Victor *et al.*, 1989). While nystagmus and ataxia together have high specificity in the context of a history of alcohol dependence (Harper *et al.*, 1986; Victor *et al.*, 1989; Torvik, 1991), the one clinical sign that appears to have highest sensitivity, perhaps in excess of 80 per cent, is mental impairment observed on mental status examination (Torvik *et al.*, 1982; Harper *et al.*, 1986). As a consequence, it was recommended that any alcohol-dependent person showing signs of an organic brain syndrome, should be treated with parenteral thiamin (Schroeder *et al.*, 1991).

A few years ago Harper's group provided a reformulation of diagnostic criteria for Wernicke–Korsakoff syndrome, which included post-mortem confirmation with replication in a separate subsample using a quasi-prospective method (Caine *et al.*, 1997). On the basis of their results Caine and colleagues suggested that a diagnosis of Wernicke–Korsakoff syndrome should be made in any alcohol-dependent person

who shows any two of the following signs: ataxia, eye signs, nutritional deficiency or cognitive impairment (with or without selective amnesia). These clinical criteria were shown to have very high sensitivity and specificity (well in excess of 90 per cent in both cases), for the identification of both the acute and chronic phases of Wernicke–Korsakoff syndrome diagnosed at post mortem. On this basis, many of the patients conforming to the criteria for *probable* alcohol-related dementia (Oslin *et al.*, 1998), might be diagnosed instead with Wernicke–Korsakoff syndrome.

In addition, the variable course and clinical spectrum of Wernicke–Korsakoff syndrome are still not widely appreciated, although this disorder is a major confound regarding the diagnosis of alcohol-related dementia (Reuler *et al.*, 1985; Torvik, 1991; Thomson *et al.*, 2002). One of the major impediments to understanding the spectrum of cognitive manifestations of Wernicke–Korsakoff syndrome was the way in which a neuropsychological research strategy, used to identify patients with Wernicke–Korsakoff syndrome *and* a severe selective amnesia, was promulgated as a diagnostic criterion (for review see Bowden, 1990; Victor, 1994). The resulting diagnostic criterion assumed that a discrepancy between relatively preserved general intellectual function versus relatively impaired anterograde memory, operationalized as a large discrepancy between a Wechsler Scale Intelligence Quotient (IQ) versus Memory Quotient (MQ) in favour of IQ, had high diagnostic sensitivity to Wernicke–Korsakoff syndrome (Butters and Cermak, 1980; American Psychiatric Association, 1994). This restrictive definition of severe, selective memory impairment should not be confused with the apparently high sensitivity of *any* mental impairment, cited above.

The restrictive diagnostic criterion of selective memory impairment became widely accepted even though the criterion was never based on a study of either the epidemiology of the thiamin deficiency disorder, or representative samples of patients with the clinical diagnosis (see Bowden, 1990), and is reiterated in numerous research studies and reviews as though it corresponds to a discrete behavioural category or neuropathological entity (e.g. Kopelman, 1995; Harding *et al.*, 2000). Criticizing this narrow diagnostic focus on the IQ versus MQ discrepancy, Victor observed 'perhaps this notion of the Korsakoff amnesic syndrome is the conventional one, but if so, it is not consonant with the observed facts, clinical or pathologic' (Victor, 1994, p. 92). The narrow definition of the disorder, reinforced by the kind of patients often seen briefly in tertiary medical settings as an acute onset condition (the Wernicke's phase) with an apparently stable or slowly resolving chronic (Korsakoff's) phase, may be another example of what Cohen and Cohen termed the clinician's illusion (1984) and may be used inadvertently to exclude from consideration many patients with other variants of the thiamin deficiency disease (Homewood and Bond, 1999).

As a consequence of a failure to fully appreciate the variable clinical spectrum of Wernicke–Korsakoff syndrome, Torvik (1991) has inferred that perhaps only 1–20 per cent of patients with the disease are correctly diagnosed in life. Like

Figure 59.1 WAIS-R Full Scale IQ (FSIQ) plotted against the WMS-R General Memory Index (GMI) for 32 cases showing two or more signs of Wernicke-Korsakoff syndrome. Also shown is the best-fitting line for the regression of FSIQ on the GMI (see text for details).

Torvik (1982), Victor and colleagues (Victor *et al.*, 1989; Victor, 1994) were concerned to highlight the frequency with which patients with Wernicke-Korsakoff syndrome displayed a clinical profile of dementia. In a similar vein Reuler *et al.* (1985) concluded that most 'alcoholics that have been labelled demented will turn out to have inactive [chronic] Wernicke's encephalopathy' (p. 245).

To evaluate the hypothesis that a selective amnesia is a common accompaniment of Wernicke-Korsakoff syndrome (Butters and Cermak, 1980; American Psychiatric Association, 1994; Kopelman, 1995), we report in Figure 59.1 a consecutive series of 32 patients (30 male and 2 female) drawn from our clinical archive from a former State-run alcohol treatment centre. The average age of the patients was 44.6 years (SD = 11.9) with 9.0 years of education on average (SD = 2.9). All of these patients conformed to the clinical criterion shown to have high sensitivity and specificity to the neuropathology of Wernicke-Korsakoff syndrome (Victor *et al.*, 1989; Torvik, 1991; Caine *et al.*, 1997). Every patient had at least two of the requisite signs in addition to a history of alcohol dependence. Specifically, apart from their clinically obvious mental impairment, which was the motivation for referral, five (16 per cent) showed eye signs alone, 17 (53 per cent) showed ataxia alone, and 10 (31 per cent) showed eye signs and ataxia. Many also had poor diets, although this was not formally assessed. In this sample, mean duration of abstinence at testing was 20.3 days (SD = 12.0; range 8–60 days) and none of the patients were clinically confused or having delirium at the time of psychological assessment.

If the hypothesis of selective memory impairment (memory lower than intelligence) is correct then, the regression of intelligence on memory should produce a negative intercept,

that is, memory should be consistently poorer than intelligence. In the sample of 32 subjects (Figure 59.1), the Wechsler Memory Scale General Memory Index and Wechsler Full Scale IQ (Wechsler, 1981, 1987) were highly correlated ($r = 0.68$; $P < 0.01$) and the regression of Full Scale IQ on the General Memory Index produced a significant slope coefficient (slope = 0.88; standard error = 0.18; $P < 0.01$) but a non-significant intercept value (intercept = 11.17; standard error = 15.8; $P > 0.05$). There was no evidence of a non-linear component in this regression (quadratic term, $P > 0.1$). Despite a strong linear relationship, there was no evidence that memory was consistently poorer than intelligence.

A similar result was obtained when we regressed Full Scale IQ on the WMS-R Delayed Recall Index. These data have one important implication. In a sample of patients with clinical signs of Wernicke-Korsakoff syndrome known to have high sensitivity and specificity, the pattern of cognitive impairment is not one of selective amnesia, but rather a generalized cognitive impairment or dementia of variable severity. When memory is affected, intelligence is also. The present result is similar to that obtained by others (Talland, 1965; Jacobson and Lishman, 1987), although they tested similar hypotheses in patients selected for severe amnesia.

It might seem counter-intuitive to propose that Wernicke-Korsakoff syndrome be conceived as producing a dementia-like deterioration, in view of the striking amnesia seen in many patients. This inference may be better understood if it is appreciated that anterograde memory function is an instrumental daily-living skill, and deficits will be more striking than equivalent deficits in crystallized or fluid intellectual skills. We have seen many patients referred for assessment of a clinical amnesia who turn out, on objective assessment, to have equally severe intellectual impairment as well. This situation is not dissimilar to the pattern of intellectual impairment observed with irreversible degenerative conditions such as Alzheimer's disease. Although anterograde memory impairment is the clinical hallmark of Alzheimer's disease, broader intellectual impairment is often just as severe (e.g. Haxby *et al.*, 1992).

Two further points require special attention in broadening our understanding of Wernicke-Korsakoff syndrome. The first is the often overlooked potential for recovery. Current diagnostic guidelines suggest that 'once established the amnesia ... usually persists indefinitely' (American Psychiatric Association, 1994, p. 162). However, this was not a view shared by Korsakoff who observed '*memory often improves ... the intensity of the amnesia depends on the general course of the disease and on the depth of the affection, so that if the disease progresses toward improvement the amnesia diminishes and may entirely disappear; if the disease grows worse, however, the amnesia becomes deeper and deeper*' (Korsakoff, 1889, translated by Victor and Yakovlev, 1955, p. 398–399 – our emphasis added).

In addition, in the only large study of its type, Victor and colleagues (Victor *et al.*, 1971) reported that approximately three-quarters of a sample of 104 patients with an acute onset

variant Wernicke–Korsakoff syndrome and severe post-acute phase were observed to recover to some extent over long-term follow up: 46 per cent showed substantial or complete recovery. Numerous other studies of patients admitted to hospitals with Wernicke–Korsakoff syndrome report recovery (for review see Bowden, 1990), although the relationship to refeeding and specific thiamin treatment remains little studied (Ambrose *et al.*, 2001). Clinically, we have observed patients with Wernicke–Korsakoff syndrome who were severely demented, doubly incontinent, and dependent in all activities of daily living recover to independent living in a period of weeks.

A final aspect of Wernicke–Korsakoff syndrome that deserves further attention is the variable pattern of neuropathology, both in terms of local severity and distribution throughout the brain, including in the ‘classic’ periventricular and periaqueductal sites (Torvik, 1991; Harper *et al.*, 2003). In experimental studies of thiamin deficiency Langlais and colleagues have shown rapidly developing and reversible changes in diffuse regions of the cerebrum (Langlais *et al.*, 1996; Langlais and Zhang, 1997). Torvik (1991) discussed the potential clinical counterparts of the variable pattern of human pathology in cases of Wernicke–Korsakoff syndrome identified at post mortem, noting that, in view of the many mild and restricted lesions, the majority of patients exhibited much milder deficits than the Korsakoff’s psychosis. Although there is continuing interest in the neuropathological basis of Korsakoff’s amnesia, it may be that accentuated histological abnormalities in certain structures are best viewed as one extreme of a clinicopathological spectrum rather than a discrete pathological subtype (e.g. Harding *et al.*, 2000).

59.4 TREATMENT RECOMMENDATIONS

Behavioural management of cognitive impairment associated with alcohol dependence has been reviewed recently (Knight, 2001; Bates *et al.*, 2002; Oslin and Carey, 2003). At the present time, identification of Wernicke–Korsakoff syndrome in all its variants, remains a clinical diagnosis because there is no satisfactory laboratory test routinely available (Thomson *et al.*, 2002). Rather than waiting on some definitive diagnostic sign, it is more important to make a presumptive diagnosis and treat the patient as soon as possible (Cook *et al.*, 1998). The need for a more pro-active approach to treatment of known or suspected Wernicke–Korsakoff syndrome has been argued strongly by Cook *et al.* (1998). Current medical management of acute Wernicke–Korsakoff syndrome, in particular with aggressive vitamin B therapy has been reviewed by Thomson *et al.* (2002). Although these authors focused on medical management in the accident and emergency setting, many of the same principles should apply to treatment of cognitive impairment, including apparent dementia, in association with alcohol dependence irrespective of the setting. As Thomson and colleagues (2002) show, the risks of parenteral B vitamin therapy are low, and the potential to minimize long-term

disability may be greatly enhanced by early and effective treatment.

In the light of the potential recovery of cognitive function with effective treatment and abstinence from alcohol, clinicians also should be encouraged to intervene with efficacious treatments for alcohol dependence. Research demonstrates the effectiveness of brief interventions in both emergency and general medical settings and should be encouraged as standard practice (Bien *et al.*, 1993; Moyer *et al.*, 2002). Developments in more specialized treatments for alcohol dependence include improvements in withdrawal management (Mayo-Smith, 1997), medications such as naltrexone and acamprosate for relapse prevention (Garbutt *et al.*, 1999; Srisurapanont and Jarusuraisin, 2002) and cognitive behavioural interventions (Miller and Wilbourne, 2002). Every opportunity should be taken to actively treat any person with alcohol dependence.

59.5 CONCLUSIONS

Although Leevy (1982) invoked the term ‘thiamin dementia’ it may be simplest to retain the term Wernicke–Korsakoff syndrome to refer to all of the neurological and neuropsychological features of thiamin deficiency. The neurological usage of Wernicke–Korsakoff syndrome no longer applies only to those cases with the classical triad, but has broadened to encompass a highly variable neurological presentation (Torvik *et al.*, 1982; Reuler *et al.*, 1985; Victor *et al.*, 1989). It may be that the neuropsychology of Wernicke–Korsakoff syndrome is best conceived as an example of a potentially reversible dementia. The value of a broader approach to diagnosis is to heighten sensitivity to the prevalence of the disorder in certain populations, particularly in association with alcohol dependence.

60.1 DEMOGRAPHY OF DEMENTIA IN INTELLECTUAL DISABILITY

Early in the twentieth century children with intellectual disability (ID) in developed nations had a life expectancy of less than 20 years (Carter and Jancar, 1983). By the close of the twentieth century average life expectancy for people with ID had increased to 60 years. People with mild ID, few comorbid conditions and a protective life style have a life expectancy approaching and in some instances exceeding that of the general population (Patja *et al.*, 2000). People with Down syndrome (DS), cerebral palsy, greater levels of disability or comorbid physical conditions have lower life expectancies (Eyman *et al.*, 1989; Strauss and Eyman, 1996).

The number of people with ID aged 60 and over is expected to at least double and perhaps quadruple in the next two decades (Bigby *et al.*, 2001). The Edinburgh Principles promote the rights of people with ID and dementia to have access to the same standard of care provided to the general population and outline principles for the design of services to support people with ID with dementia and their carers (Wilkinson and Janicki, 2002). However, aged care and disability services have failed to develop coherent policy and programme responses to the rapidly increasing population of older people with ID.

60.2 DOWN'S SYNDROME AND ALZHEIMER'S DISEASE

The relationship between DS and the development of Alzheimer's disease (AD) in middle age is well established.

Post-mortem studies show neuropathological changes consistent with AD by 40 years of age (Wisniewski *et al.*, 1985). The average age of clinical diagnosis of dementia is about 50 years and prevalence may be as high as 75 per cent in those aged over 60 years (Holland, 1998).

DS, the commonest cause of ID, is due to trisomy 21 in 95 per cent of cases. The remainder are due to translocations, partial trisomies and mosaicism (Stoll *et al.*, 1998). Overexpression of a number of genes on chromosome 21 are implicated in the pathogenesis of AD in DS. Triplication of the amyloid precursor protein (APP) gene in trisomy 21, resulting in precocious and excessive amyloid production and cerebral deposition, is postulated to be the root cause of early onset AD in DS (Robakis *et al.*, 1987). Indeed, the expression of APP is 3–4 times higher than that expected from the 1.5 times increased gene load. Expression of APP is promoted by a transcriptional regulator that is also coded on chromosome 21 (Wolvetang *et al.*, 2003). A gene encoding for a β -secretase, located on chromosome 21, is overexpressed and cleaves APP to produce A β amyloid (Barbiero *et al.*, 2003). Serum levels of A β _{1–40} and A β _{1–42} are increased in DS and are associated with the development of dementia (Schupf *et al.*, 2001). A β amyloid contributes to neurofibrillary tangle formation as well as mediating inflammatory factors contributing to the rapid accumulation of neuropathology in the DS brain and may also trigger apoptotic pathways (Head *et al.*, 2001, 2002).

Overexpression of superoxide dismutase is thought to lead to excess free radical production and cell damage (Dickinson and Singh, 1993). In addition, at least 10 genes on chromosome 21 are involved in mitochondrial functioning (Hattori *et al.*, 2000). Mitochondrial dysfunction has been shown to increase oxidative stress that may lead to neuronal death and

altered metabolism of APP (Arbuzova *et al.*, 2002; Busciglio *et al.*, 2002).

Other factors modulate the risk of developing AD in DS. The presence of one or two apolipoprotein E (ApoE) $\epsilon 4$ alleles increases the risk of earlier onset AD in people with DS whilst the presence of ApoE $\epsilon 2$ is protective (Schupf *et al.*, 1996; Rubinsztein *et al.*, 1999). Serum levels of $A\beta_{1-42}$ are increased in DS subjects with the ApoE $\epsilon 4$ allele (Schupf *et al.*, 2001). Women with DS have early menopause. The earlier the menopause the greater the risk of AD and the earlier it develops. The bioavailability of endogenous oestradiol is thought to be associated with dementia (Cosgrave *et al.*, 1999; Schupf *et al.*, 2003; Patel *et al.*, 2004).

60.3 PREVALENCE OF AND RISK FACTORS FOR DEMENTIA IN OTHER PEOPLE WITH INTELLECTUAL DISABILITY

Less attention has been focused on dementia in people with ID not due to DS. Prevalence rates of 22 per cent have been reported (Lund, 1985; Cooper, 1997a) in epidemiological samples of people with ID over the age of 65 years. However, other studies have found rates of dementia not significantly different from that expected in the general population (Evenhuis, 1997; Zigman *et al.*, 2004). This considerable variance in the reported prevalence of dementia in ID reflects diagnostic challenges, choice of diagnostic criteria, sample selection, and other methodological differences. 'Dementia' and 'Alzheimer's disease' are often used interchangeably (Zigman *et al.*, 2004) and few researchers attempt to subtype dementia. Evenhuis (1997) reports cases of vascular and mixed dementia. However, the possibility of vascular dementia generally is overlooked. The presence of cerebrovascular disease or other major medical disorders may confound and therefore preclude a research diagnosis of dementia (Evenhuis, 1997; Zigman *et al.*, 2004).

Risk factors for dementia in people with ID not due to DS have not been a major focus for investigators. A large post-mortem series from an institutional population (Popovitch *et al.*, 1990) demonstrates the common presence of senile plaques and neurofibrillary tangles, increasing with age and correlated with a history of seizures, congenital malformations and head trauma. Neuropathological criteria for AD were fulfilled in 9.5 per cent of cases aged <50 years of age, increasing to 87 per cent for those >75 years. However, in most cases the plaques were not neuritic and substantial numbers of neurofibrillary tangles were found in the frontal lobes. Neither clinicopathological correlations nor the presence or absence of vascular pathology were reported.

In support of these findings Cooper (1997b) reported higher rates of poorly controlled epilepsy in those with dementia, raising questions about the cumulative effects of excitotoxic neurone death. Prevalence rates for epilepsy in people with ID are 30 per cent compared with 1 per cent for the general population (Ettinger and Steinberg, 2001). Head

injury is also associated with dementia in the general population and in people with ID. Head injury may be the cause of ID and people with ID are at risk of head injury due to falls and self-injurious behaviour such as head banging.

Low intellectual quotient (IQ) and low educational status are frequently quoted as being risk factors for AD and a low reserve hypothesis is invoked. Prenatal exposure to toxins such as alcohol (Dumas and Rabe, 1994) and microcephaly (Lee and Rabe, 1992) predispose to early cognitive decline in animal models, although the mechanism for this has not been elucidated. Is it the greater impact of age-related neurone loss on an already compromised brain or do prenatal insults affect some basic processes resulting in premature ageing?

The potential for vascular dementia in people with ID is high. The identification and management of vascular risk factors in people with ID is often overlooked by generic health care and health promotion (Wallace, 2004). High rates of pathological lipid profiles, obesity (Rimmer *et al.*, 1994), smoking (Tracy and Hosken, 1997), hypertension, other cardiovascular disease and cerebrovascular disease (Cooper, 1999) have been reported in people with ID. Certain genetic syndromes also predispose to hypertension, diabetes mellitus, obesity, hyperhomocysteinaemia, hyperlipidaemia and abnormalities in vasculature increasing the risk of vascular disease (Wallace, 2004).

60.4 DIAGNOSIS OF DEMENTIA IN PEOPLE WITH INTELLECTUAL DISABILITY

Currently there are no internationally recognized gold standard instruments for the diagnosis of dementia in people with intellectual disability. Standard tools such as the Mini-Mental State Examination and general neuropsychological assessments are not valid for use in people with ID because of substantial floor effects. A range of instruments have been used in dementia in ID research including tools for adaptive functioning, diagnosis of dementia and for testing specific cognitive domains. Measures of adaptive functioning were not specifically developed for use in dementia studies. A modified version of the CAMDEX informant interview has been shown to be a valid and reliable tool for use in the diagnosis of dementia in adults with DS (Ball *et al.*, 2004a). The Dementia Questionnaire for Persons with Mental Retardation (DMR; Evenhuis, 1996), an informant rated instrument and the Down Syndrome Dementia Scale (DSDS), completed by psychologist informant interview, both have good correlations with clinician diagnosis and correlate well with each other (Deb and Braganza, 1999).

The pattern and progression of cognitive decline in AD in people with DS follows the pattern in the general population with early memory impairment followed by declines in visual spatial skills and dyspraxia (Dalton *et al.*, 1999; Devenny *et al.*, 2000; Krinsky-McHale *et al.*, 2002). There are modified versions of the selective reminding test (Krinsky-McHale *et al.*, 2002) and cued recall test (Devenny *et al.*, 2002). Parietal

functioning can be tested by a dyspraxia scale (Dalton and Fedor, 1998).

Consensus diagnostic criteria for dementia for people with intellectual disability are given in Box 60.1. The clinical diagnosis of dementia in people with intellectual disability is complicated by the pre-existing impairments in intellectual and adaptive functioning. Decline from baseline functioning must be established. This is difficult if family members are not available for interview or when carers have not known the person over a sufficient period of time. In the clinical setting memory in people who are non-verbal can be tested by hiding three objects around the room and then testing delayed recall. Dyspraxia can be assessed by asking the person to take off and put back on shoes and jackets, but ability to complete these tasks needs to be measured against the person's baseline functioning. Comparison of current samples of writing and art work with earlier work is helpful in identifying decline in visuospatial skills.

Behavioural and psychological symptoms are common clinical features of dementia in people with intellectual disability. The onset of a variety of maladaptive behaviours may precede or coexist with the decline in adaptive functioning. Pre-existing levels of maladaptive behaviours tend to remain stable in the absence of a decline in functioning (Urv *et al.*, 2003). Mood changes, poor emotional control, irritability, onset of or increase in aggression, withdrawal, loss of interest, anhedonia, sleep and appetite disturbances have all been reported (Moss and Patel, 1995; Cooper, 1997a; Urv *et al.*, 2003). Psychotic symptoms include delusions of theft and persecution and visual hallucinations of strangers in the house (Cooper, 1997a). The earliest signs of AD in DS may be changes in executive functioning, behaviour and personality (Ball *et al.*, 2004b). Depression may precede or occur with AD and DS (Burt *et al.*, 1992; Sung *et al.*, 1997).

Decline in cognitive and adaptive function may be due to or complicated by a multitude of factors. Comorbid sensory impairment, mobility problems and medical conditions are common in people with intellectual disability, increase with

age and are more common in those with dementia (Cooper, 1997b). Conditions such as hypothyroidism are particularly common in people with DS. Delirium and depression, both common conditions, may present with cognitive and functional decline. Psychotropic polypharmacy is rife amongst people with intellectual disability, especially in the older group who are also prescribed greater amounts of anticholinergic medications (Pary, 1995). Psychotropic medications may result in significant cognitive impairment that could mimic dementia (Gedye, 1998).

Neuroimaging is important in establishing the presence of cerebrovascular disease or congenital abnormalities; however, its place in diagnosing AD in people with ID is less clear. Interpretation of neuroimages involves an understanding of the baseline differences in the brains of people with ID. People with DS and no AD have significantly smaller hippocampal volumes than cognitively normal adults even when smaller total brain volume is taken into account. In subjects with DS and AD, hippocampal and amygdala volumes decline (Aylward *et al.*, 1999). Serial MRI examinations maybe useful in individual patients with DS in tracking the development of AD; however, a single individual scan may not be particularly useful in establishing a diagnosis of AD (Prasher *et al.*, 1996). Cerebral single photon emission computed tomography (SPECT) scans of people with DS and clinical AD show reduced cerebral blood flow in the frontal, temporal, parietal and occipital regions of both hemispheres (Melamed *et al.*, 1987).

60.5 MANAGEMENT AND CARE OF PEOPLE WITH INTELLECTUAL DISABILITY AND DEMENTIA

The principles of care of people with ID and dementia are essentially the same as for all people with dementia. This includes the identification and management of coexistent medical conditions, attention to sensory impairments, immobility and nutrition. Medications need to be reviewed and limited to essential medications at the lowest effective dose. Alternatives to the use of medications with significant anticholinergic effects should be found. Careful assessment of the person's accommodation and care needs, the physical environment, routines and programmes as well as the expectations of others, needs to be conducted. Simple concrete explanations and visual aids can help co-residents to understand what is happening to their housemate (Lynggaard and Alexander, 2004). Carer education and support are essential. Training for carers is offered by the Down Syndrome Society in the United Kingdom and Alzheimer's Australia.

There is a small but growing body of evidence of the potential benefits of treating people with DS and AD with cholinesterase inhibitors. A small randomized controlled trial of donepezil in people with DS and AD found non-significant improvements in the treatment group (Prasher *et al.*, 2002). However, in an open label extension there was a

Box 60.1 DC-LD category IIIB1.1 unspecified dementia
(Royal College of Psychiatrists, 2001, with permission)

- A The symptoms/signs must be present for at least 6 months
- B They must not be a direct consequence of other psychiatric or physical disorders
- C The symptoms and signs must represent a change from the person's premorbid state
- D Impaired memory must be present
- E Impairment in other cognitive skills, judgement and thinking must be present
- F Items D and E must not be solely attributed to clouding of consciousness as in delirium
- G Reduced emotional control or motivation of change in social behaviour must be present

significant difference between the always-treated versus the never-treated group (Prasher *et al.*, 2003). A convenience sample of six patients with DS and AD treated with donepezil for 5 months showed significant improvement over nine closely matched historical control subjects (Lott *et al.*, 2002).

These studies found donepezil to be safe in people with DS, the main side effects being nausea, incontinence, agitation and listlessness. However, a case report of a person with DS and AD treated with donepezil 5 mg developing a bradycardia of 48 beats per minute and collapsing urges caution in the use of cholinesterase inhibitors in a population with high rates of major congenital cardiac defects. Relatively minor abnormalities such as generally low heart rates and conduction abnormalities may be overlooked (Torr, 2004).

There is no published guidance on the pharmacological treatments of behavioural and psychological symptoms of dementia (BPSD) in people with ID. However, it is known that people with ID are sensitive to psychotropic medications. In the absence of evidence to the contrary management of BPSD in people with ID should be the same as for the general population. Many older people with ID are already prescribed psychotropic medications that may not have been reviewed for many years. Psychotic disorders tend to be over-diagnosed and major mood disorders, especially bipolar disorder, are often unrecognized and untreated.

Schizophrenia, cognitive impairment and dementia

OSVALDO P ALMEIDA AND ROBERT HOWARD

61.1 Is the onset of schizophrenia associated with cognitive decline?	750	61.4 What is the association between schizophrenia and dementia?	752
61.2 Is schizophrenia associated with a specific pattern of cognitive impairment?	751	61.5 Conclusion	752
61.3 How do the cognitive deficits of schizophrenia evolve over time?	751	References	752

Kraepelin used the term ‘dementia praecox’ to describe what he believed to be two key features of what is now known as schizophrenia: functional and intellectual deterioration. Such a concept implies that people with schizophrenia experience some degree of functional and cognitive impairment, and that these deficits represent a decline from a previous level of function. Since Kraepelin’s seminal description of the key features of schizophrenia, research has been carried out with the aim of clarifying whether:

- the onset of schizophrenia is associated with cognitive decline;
- schizophrenia is associated with a specific pattern of cognitive deficits; and
- the cognitive deficits of schizophrenia are progressive and ultimately lead to the development of dementia.

This chapter will selectively review currently available evidence covering these three areas of research.

61.1 IS THE ONSET OF SCHIZOPHRENIA ASSOCIATED WITH COGNITIVE DECLINE?

Data on this topic remain sparse and come mostly from studies of people presenting to health services with first-episode psychosis (Bilder *et al.*, 2000). A recently published Canadian study exemplifies our current knowledge in this area (Addington *et al.*, 2003). The investigators recruited 312 subjects who were admitted to the Calgary Early Psychosis Programme with their first ever psychotic episode. The subjects’ mean age

was 24.7 years and 89.8 per cent were receiving treatment with atypical antipsychotic medication at the time of neuropsychological assessment. The most frequent diagnoses were schizophrenia (39.7 per cent), schizophreniform disorder (38.5 per cent), psychotic disorder not otherwise specified (14.1 per cent), brief psychotic disorder (3.9 per cent) and delusional disorder (1.6 per cent). Cognitive assessment included an estimate of premorbid cognitive abilities, verbal fluency, verbal and visual memory, working memory, attention, visual-constructional ability, visuomotor sequencing, psychomotor speed, and set-shifting ability. Subjects’ performance was significantly worse than that of non-psychiatric controls in all of the tests and subscores examined. The authors highlighted that patients’ performance was particularly poor on tests of verbal fluency and immediate and long delayed verbal recall (more than 1.5 standard deviations below the norm), but concluded that there was ‘no evidence to support differences in cognition among the different schizophrenia spectrum diagnostic groups’. Of note, such findings cannot be explained by the use of antipsychotic medication, as demonstrated by Ho *et al.* (2003a).

However, do the cognitive deficits observed among patients with first-episode psychosis represent a decline from a previous level of function? The results of volumetric magnetic resonance imaging (MRI) studies indicate that some of the brain abnormalities associated with schizophrenia precede the onset of the illness (Pantelis *et al.*, 2003), which suggests that cognitive deficits are also likely to be present prior to psychotic symptoms becoming apparent. Findings from the relatively small number of observational studies available to date are more or less consistent with such a hypothesis. Cannon *et al.*

(1999) used a nested case–control study design to investigate the premorbid elementary school performance of Finnish individuals born in Helsinki between 1951 and 1960. Subjects who received the diagnosis of schizophrenia up to the year 1991 ($n = 400$) did not have poorer academic performance in elementary school than controls ($n = 408$), but were significantly more likely to display difficulties in sports and handicrafts. In addition, a smaller number of subjects with schizophrenia than controls progressed to high school, which suggests that some level of premorbid dysfunction might already have been present before the onset of the illness.

A recent case–control study from Singapore (Ang and Tan, 2004) examined the academic progression of a sample of 30 young men with schizophrenia and 30 age- and sex-matched controls enlisted in the Singapore Armed Forces between January 1998 and December 2000. Subjects with schizophrenia showed objective evidence of academic decline 2–4 years before the onset of symptoms, as measured by differences in the results of the Primary School Leaving Examination (usually taken at around the age of 12 years) and the Cambridge General Certificate of Education Examination (usually taken at around the age of 16 years). Similar findings have been reported by others (Caspi *et al.*, 2003).

Taken together, these results suggest that cognitive deficits precede the onset of clinical symptoms in schizophrenia – i.e. the cognitive deficits are not triggered by the onset of the illness. They also indicate that such deficits represent a decline from a relatively normal previous level of function.

61.2 IS SCHIZOPHRENIA ASSOCIATED WITH A SPECIFIC PATTERN OF COGNITIVE IMPAIRMENT?

Schizophrenia is associated with pervasive cognitive deficits including memory, attention, set-shifting and visuospatial abilities, psychomotor speed and planning (Heinrichs and Zakzanis, 1998). Findings amongst young people presenting with a first-ever psychotic episode suggest that this pattern of generalized cognitive impairment is already present during the early stages of the illness, although some have chosen to highlight the potential clinical relevance of the executive dysfunction (Riley *et al.*, 2000; Weickert *et al.*, 2000; Joyce *et al.*, 2002). Emerging empirical data suggest that the parietal cortex and cerebellum, rather than the frontal lobes, are involved in the production of bizarre psychotic phenomena, such as delusions of control (Blakemore *et al.*, 2002, 2003).

Psychotic disorders with onset in later life are also associated with generalized cognitive impairment. For example, Almeida *et al.* (1995) examined a convenience sample of 47 non-demented older people with psychotic symptoms and 33 controls using a comprehensive neuropsychological battery of tests. Patients showed significantly lower scores than controls on general measures of cognitive functioning (Minimal State Examination – MMSE, Cambridge Cognitive

Examination, Wechsler Adult Intelligence Scale [Revised] verbal and performance scores), as well as on tests of delayed recall, working memory and executive function. Such findings have been replicated and extended by other studies, which have also shown that the pattern of cognitive impairment in schizophrenia with late onset is indistinguishable from the deficits displayed by patients with early illness onset (Sachdev *et al.*, 1999).

The clinical and social relevance of the neuropsychological deficits of schizophrenia become apparent when one examines their association with the functional capacity of patients. Evans *et al.* (2003) assessed 93 patients with diagnosis of schizophrenia or schizoaffective disorder (mean age = 57.2 ± 9.1 years) and 73 controls (mean age = 59.2 ± 11.2 years). The mean age at the onset of illness was 29.9 ± 13.7 years. Functional capacity, as measured by the Direct Assessment of Functional Status, was significantly correlated with processing speed, attention, abstract thinking, learning, delayed recall, verbal and motor skills ($P < 0.001$ for all correlations). Of note, psychotic patients presenting with functional impairment are less likely to be living independently (Twamley *et al.*, 2002). In addition, the level of functional impairment of elderly institutionalized patients with schizophrenia has been shown to be directly correlated to the severity of the cognitive deficits (Kurtz *et al.*, 2001).

In summary, young and old adults with schizophrenia display a non-specific pattern of generalized cognitive impairment compared with normal controls. The more severe the cognitive deficits, the greater the functional impairment and disability experienced by patients.

61.3 HOW DO THE COGNITIVE DEFICITS OF SCHIZOPHRENIA EVOLVE OVER TIME?

61.3.1 Schizophrenia with early onset

A fascinating recent development in schizophrenia research has been the demonstration that the brains of patients change significantly over time. For example, Ho *et al.* (2003b) reported the results of a 3-year MRI follow-up study of 73 young adults with schizophrenia (mean age = 24.5 ± 4.7 years) and 23 controls (mean age = 26.9 ± 5.3 years). They found that, compared with controls, the brains of patients displayed accelerated enlargement of the cortical sulcal cerebrospinal fluid spaces, progressive reduction in frontal lobe white matter volume and corresponding enlargement of frontal lobe cerebrospinal fluid volume. Such findings would suggest that the cognitive deficits of people with schizophrenia might also increase over time. However, the results of most follow-up studies investigating the progression of cognitive deficits in schizophrenia available to date do not support this hypothesis.

Hoff *et al.* (1999) reported the results of a 5-year longitudinal study of 42 patients with first-episode schizophrenia and

16 normal controls – they found that the cognitive performance of patients on tasks assessing language, executive function, verbal memory, spatial memory, concentration/speed and sensory-perception had remained relatively stable 1–1.5 standard deviations below the baseline level of performance of controls over the follow-up period. Another study by Gold *et al.* (1999) confirmed that the cognitive performance of patients does not deteriorate during the first 5 years of illness – in fact, it may actually improve with treatment. Other small-scale studies have confirmed that the overall cognitive performance of patients with schizophrenia tends to remain relatively stable over time (Stirling *et al.*, 2003).

61.3.2 Schizophrenia with late onset

Few studies have attempted to follow up patients with late-onset schizophrenia. Hymas *et al.* (1989) reported that patients with 'late paraphrenia' experienced a statistically significant, but clinically irrelevant, deterioration on the Mental Test Score. More recently, Palmer *et al.* (2003) have shown that the cognitive changes observed amongst patients with late-onset schizophrenia over a 2-year period are similar to those seen in people with early-onset schizophrenia and controls, which suggests that schizophrenia starting in later life is not associated with progressive cognitive decline.

In contrast, Brodaty *et al.* (2003) have argued that their 19 patients with onset of schizophrenia after the age of 50 years showed greater deterioration on MMSE scores over a 5-year follow-up period than 24 controls. However, patients recruited into this study had significantly fewer years of education and had lower baseline MMSE scores than controls (mean MMSE = 25.5 ± 3.5 versus 29.7 ± 1.0) – this is likely to have biased the overall results of the study significantly in favour of the control group.

In summary, there is no obvious evidence, at present, that schizophrenia with either early or late onset is associated with progressive cognitive decline. However, information on this topic remains sparse and conclusions are limited by small sample size, lack of sensitivity of the tests to change over time, and relative short follow-up periods.

61.4 WHAT IS THE ASSOCIATION BETWEEN SCHIZOPHRENIA AND DEMENTIA?

Preliminary evidence suggests that the risk of functional decline in schizophrenia may increase with increasing age after the age of 70 years. Friedman *et al.* (2001) followed up for 6 years a sample of 107 patients with schizophrenia aged 20–80 years. Functional decline, as measured by the Clinical Dementia Rating increased at around age 70 years and reached the same level as seen amongst patients with Alzheimer's disease at the age of 80 years. The authors concluded that the cognitive and functional status of institutionalized patients with schizophrenia is very stable until later in life, when a

progressive rate of cognitive and functional decline becomes apparent.

Histopathological investigations of the brains of patients with schizophrenia, however, have failed to show any sign of Alzheimer's disease-related pathology. Purohit *et al.* (1998) found no evidence of an excessive number of senile plaques, neurofibrillary tangles or neuronal loss amongst 100 consecutive autopsy brain specimens of subjects with chronic schizophrenia aged 52–101 years. Similarly, Arnold *et al.* (1998), who used a stereological counting method to quantify the presence of neurofibrillary tangles, amyloid plaques and Lewy bodies, found that their 23 elderly patients with schizophrenia did not present a larger number of neurodegenerative lesions than the 14 normal controls – both groups differed significantly in that respect from the 10 subjects with Alzheimer's disease.

More recently, Religa *et al.* (2003) have used specific antibodies against $A\beta_{40}$ and $A\beta_{42}$ to assist with the examination of the brains of 10 patients with Alzheimer's disease, 11 controls and 26 patients with schizophrenia (β -amyloid is thought to be central to the pathogenetic process that leads to the development of Alzheimer's disease). As expected, the levels of β -amyloid were highest amongst patients with Alzheimer's disease, and the mean concentration of $A\beta_{42}$ amongst patients with schizophrenia was similar to that of controls.

Taken together, these findings indicate that the mechanisms that lead to cognitive impairment in schizophrenia are different from those observed in common neurodegenerative disorders such as Alzheimer's disease.

61.5 CONCLUSION

Schizophrenia is a debilitating disorder that is associated with marked generalized cognitive impairment. These deficits are already present at the time of the onset of the illness and seem to remain relatively stable over time, although a small number of patients may experience significant cognitive and functional deterioration at follow up. There is no evidence that schizophrenia is a neurodegenerative disorder – in fact, all available evidence to date indicates that schizophrenia is not associated with any form of neurodegeneration. The use of the label 'dementia' to describe the cognitive deficits of patients with schizophrenia is misleading and should be avoided.

62.1 CLINICAL FEATURES

Huntington's disease (HD) is a hereditary progressive neurodegenerative disorder beginning classically in mid-life with the characteristic features of abnormal involuntary movements, mental impairment, psychiatric disorder, with death from complications of immobilization such as aspiration pneumonia (SuttonBrown and Suchowersky, 2003), occurring some 20–30 years after onset. In her monograph on HD, Folstein (Folstein, 1989) referred to the 'triad of clinical features' – motor disorder, cognitive disorder and emotional disorder. Within this characteristic triad, there is variety in the clinical phenotype with respect to onset timing, symptoms and progression.

62.1.1 Onset

The age of onset usually refers to the onset of typical motor symptoms, with the mean previously being reported from the late thirties to the early forties. Kremer (2003) argues that the median age of onset which is in the late forties or early fifties is the more accurate measure of onset age rather than the mean, due the fact that the onset age is not normally distributed, and that the truncated intervals of observation in many studies biases the results towards the younger onset group. Penney *et al.* (1990) introduced the term 'zone of onset', referring to the insidious onset of symptoms over many years before the definitive appearance of extrapyramidal signs such as chorea.

Various studies have indicated that the length of the trinucleotide repeats in the HD gene accounts for 50–70 per cent of the statistical variance in onset age (Duyao *et al.*, 1993). The phenomenon of anticipation whereby the disease

onset is earlier in successive generations has been observed in some families. In the majority of families, the age of onset has tended to be similar.

62.1.2 Motor disorder

Although chorea is usually the predominant feature, dystonia, athetosis, motor restlessness, myoclonus and voluntary movement abnormalities may also be present. The chorea consists typically of rapid, non-repetitive contractions involving the orofacial and truncal areas and the limbs, and worsens with anxiety. Common manifestations include lip pouting, twitching of the cheeks, irregular grimacing, alternate lifting of the eyebrows, head nodding from neck muscle involvement, irregular breathing, fingers and toes flexion and extension, crossing and uncrossing of the legs and truncal restlessness (Kremer, 2003). The choreoathetosis tends to be absent during sleep and present during the waking hours, when falling asleep or on wakening. The movements cannot be suppressed voluntarily, although early on the patient may be able to integrate some of these movements into purposeful actions or minimize them by holding onto a chair, for example. In this early stage, there is hypotonia with hyperreflexia (SuttonBrown and Suchowersky, 2003). In advanced cases, the diaphragm and vocal apparatus may be involved leading to dysarthria (SuttonBrown and Suchowersky, 2003).

Dystonia frequently accompanies chorea early in the illness or during the course of the condition but can be very severe in advanced cases, juvenile-onset patients or in the 'Westphal variant' of adult-onset cases. The dystonia may be manifest as abnormal posturing of the extremities and head, internal shoulder rotation, sustained fist clenching, excessive knee flexion and foot inversion (Kremer, 2003).

Abnormalities in saccadic eye movements, poor optokinetic nystagmus and slowness with refixation may also be found in the majority of patients. Saccadic abnormalities with an inability to suppress reflexive glances to sudden novel stimuli and delayed initiation of voluntary saccades and slow saccades, particularly in the vertical movements, are seen early in the majority of patients (Lasker and Zee, 1997).

As the condition progresses, voluntary movements are increasingly impaired by the occurrence of clumsiness, bradykinesia, rigidity, inability to sustain complex voluntary movement patterns leading to gait abnormalities and dysarthria. There is difficulty with tandem walking, turning, falls; eventually the patient is confined to a wheelchair. The dysarthria starts off as reduced clarity, which becomes worse as the rate and rhythm of speech becomes affected. Towards the late stage of the disease, rigidity and akinesia frequently overtake other aspects of the motor disorder accompanied by dysphagia and urinary incontinence. Frontal release reflexes such as snouting, sucking or grasping are seen when there is significant cognitive decline.

62.1.3 Cognitive disorder

62.1.3.1 NEUROPSYCHOLOGICAL DEFICITS

The cognitive changes in HD primarily reflect a form of subcortical dementia characterized by memory deficit, psychomotor slowing, apathy and depression. Cognitive domains affected include executive, language, perceptual and spatial skills, and memory functions. Executive function refers to a collection of higher order cognitive functions including the ability to plan and organize, monitor one's performance and self-correct, mental flexibility, shift attention set as circumstances change, and inhibit impulsive behaviours. Psychomotor slowing is evident in timed tasks such as digit symbol substitution and trail-making.

Intact verbal recognition memory, word recognition and object naming allows the person with HD to continue communicating initially despite mild dysarthria and dysprosody being present. In the advanced stages, language may be impaired leading to a mute state. This is due to a combination of motor disorder affecting phonation leading to severe dysarthria, impairment of comprehension of both affective and propositional prosody leading to failure to appreciate rhythm and changes of tone in normal speech and other cognitive deficits such as reduced verbal fluency, psychomotor slowing and apathy.

Visuospatial disorder in HD is evident early during performance in object assembly and block design tests (Craufurd and Snowden, 2003), as well as deficits in tests of pattern and spatial recognition memory, simultaneous and delayed matching-to-sample and spatial, which are complex tasks (Lawrence *et al.*, 2000) that also require planning and organization. Further studies are needed to determine whether these deficits represent 'true' deficits in visuospatial/visual object processing or reflect other processes such as deficits in context recognition/registration (Lawrence *et al.*, 2000).

Memory problems are a common complaint of patients with HD with studies indicating an inefficient memory strategy for acquiring and retrieving memories rather than a primary disorder of retention (Craufurd and Snowden, 2003). Craufurd and Snowden suggested that the memory deficits reflect executive dysfunction leading to ineffective information retrieval strategies. Performance on paired associated learning improved when a strategy was suggested (Craufurd and Snowden, 2003).

These cognitive deficits appear early in the course of the illness and may predate the motor signs. The rate of decline and cognitive domains affected in each individual are variable. Correlation between the rate of cognitive decline and CAG repeat length have been inconsistent (Craufurd and Snowden, 2003). The neural basis for these cognitive deficits is believed to be involvement of the basal ganglia and frontostriatal connections.

62.1.4 Psychiatric disorder

There is increasing awareness that the behavioural and psychological aspects of HD cause as much, if not more, distress to the person with HD and their carer as the motor and cognitive decline. Any treatments aiming to slow disease progression need to address all three aspects of Folstein's 'triad of clinical features'. Using DSM-III criteria, 30 per cent of the sample in Folstein's Maryland sample of 186 persons with HD were free from any psychiatric disorder, 33 per cent had affective disorder, and 30 per cent intermittent explosive disorder, 4.8 per cent had dysthymic disorder, 15.6 per cent alcoholism; 5.9 per cent antisocial personality and 5.9 per cent schizophrenia (Folstein, 1989). In a similar population based study, Watt and Sellar (1993) reported on a higher prevalence of depression (54 per cent), schizophrenia (12 per cent) and behavioural and personality disorder (42 per cent). The latter consisted of aggressiveness, which was the most frequent reported, followed by suspiciousness and temper. The prevalence of bipolar disorder, mania and hypomania is less clear, with reports ranging up to 10 per cent (Folstein, 1989).

The aetiology of affective disorder in HD is likely to be multifactorial. Depression can precede the onset of motor symptoms of HD by many years and can occur in those who may not be aware of being at-risk for the disorder (Craufurd and Snowden, 2003). It has also been postulated that the underlying neurodegenerative process in the caudate nucleus may also be responsible for the depressive symptoms. Craufurd *et al.* (2001) did not find a correlation between affective symptoms and severity of motor and cognitive symptoms. Several studies have shown that specific psychiatric symptoms such as psychosis (Tsuang *et al.*, 2000) and affective disorder (Folstein *et al.*, 1983) tended to cluster in certain families suggesting that other familial factors such as genetic heterogeneity at the HD locus, or a gene predisposing to the psychiatric disorder and closely linked to the HD gene may be responsible.

Irritability is reported frequently by family members who find such personality changes most difficult to tolerate. The potential role of alcohol and benzodiazepine side effects in precipitating such symptoms should not be ignored. Irritability as part of the symptoms complex of depressive illness should also be considered.

Other psychiatric manifestations such as obsessive-compulsive symptoms (Anderson *et al.*, 2001), excessive worrying and somatizations have been reported but often do not meet criteria to warrant a formal psychiatric diagnosis. The common obsessions reported have aggressive and contamination themes (Anderson *et al.*, 2001). Checking rituals were the most commonly reported (Anderson *et al.*, 2001). Psychotic symptoms in HD tend to be isolated and atypical rather than schizophreniform, with persecutory delusions being the most common. The psychotic symptoms are more common early on in the illness and decrease with the cognitive decline. Sleep disturbances of frequent nocturnal awakenings, reduced sleep efficiency and sleep phase disturbances have also been reported in HD (Nance and Westphal, 2002).

A high rate of suicide has been associated with HD in many studies (Di Maio *et al.*, 1993) and may be partially explained by a high prevalence of major affective disorder in this population. Undiagnosed or inadequately treated major depressive disorder can be uncovered by clinical examination and suicide can be prevented by energetic treatment with antidepressants or electroconvulsive therapy. Other symptoms in HD may increase the likelihood of suicide, including irritability, emotional lability and impulsiveness.

62.1.5 Advanced stage

A recent study by Foroud *et al.* (1999) reported the median duration of the disease as 21.4 years with a range of 1.2–40.8 years. In the late stages, the person with HD is usually confined to a wheelchair and reliant on care in a nursing home. Clinically, the bradykinesia, dystonia and rigidity dominate the clinical picture. Choreiform movements may still be evident in the orobuccal region and the extremities. Communication and swallowing are severely impaired. Nasogastric or percutaneous endoscopic gastric (PEG) feeds may be necessary to prevent aspiration and to offset the weight loss commonly seen in the advanced stage. Increased muscle tone may result in joint contractures. Pressure sores occur secondary to the immobility. Cognition is impaired and slow. It may be difficult to assess for psychiatric symptoms because of the limited communication. Sleep disturbance and agitation may be a problem. Some are incontinent of faeces and urine. Cachexia despite adequate intake may be seen during the latter part of the illness. The leading causes of death are from pneumonia, choking, nutritional deficiencies, skin ulcers and heart disease.

62.1.6 Clinical variants

Clinical variants of HD include the juvenile-onset, adult-onset Westphal variant and late-onset disease (Kremer, 2003).

Juvenile onset refers to the 10 per cent of all patients with HD who have onset before 20 years of age. Children with juvenile-onset HD often present with a decline in school performance and non-specific behavioural problems, with the motor disorder appearing a few years later. Other features of the juvenile onset are prominent rigidity and bradykinesia early on and minimal chorea, a rapidly progressive dementia, cerebellar abnormalities, myoclonus, epilepsy and long CAG repeats. The adult-onset Westphal variant refers to the cases with prominent rigidity earlier on rather than chorea. These patients are usually young with onset in their twenties or rarely in their thirties. Late-onset HD patients have a slower, milder form of HD with onset usually after age 50 years. Motor and cognitive symptoms are present but less severe while psychiatric symptoms are less common. Despite a more benign course, the number of years of survival after disease onset may still be similar to earlier-onset cases (James *et al.*, 1994).

62.2 EPIDEMIOLOGY

The prevalence of HD has been largely based on estimates of point prevalence and has shown wide variations between countries and studies due to differences in selection criteria, source population, and sampling methods. In the US most studies gave a rate between 5 and 7 per 100 000 of population (Folstein, 1989). The prevalence is much lower among non-European ethnic groups.

62.3 GENETICS

62.3.1 The HD gene

HD is transmitted as an autosomal dominant trait with high penetrance (Gusella *et al.*, 1993). In 1983, the linkage of a marker probe G8 (D4 S10) on the short arm of chromosome 4 to the HD gene was established (Gusella *et al.*, 1983). Presymptomatic testing of persons at risk of HD and prenatal diagnosis of at-risk pregnancies were thus first made available by the application of genetic linkage analysis.

Ten years later in March, 1993, the Huntington's Disease Collaborative Research Group (1993) announced the discovery of a novel gene, IT15 (interesting transcript), located at 4p16.3 (short arm of chromosome 4) which contains a polymorphic trinucleotide CAG repeat that is expanded and unstable. A (CAG)*n* repeat longer than the normal range was observed. The number of CAG repeats on normal chromosomes ranges from 11 to 34 (Gusella *et al.*, 1993). The zone of reduced penetrance (ZRP) refers to the CAG size range where the majority of persons will manifest the disease within their expected lifetime but a few will remain asymptomatic. In HD, the ZRP range is 36–38 (Andrew *et al.*, 1997). In the CAG size range 29–35 (intermediate alleles), individuals do not manifest signs of HD (Goldberg *et al.*, 1993) but their offspring are at risk of

inheriting an expanded CAG gene and therefore of developing HD (Andrew *et al.*, 1997). The estimate risk of an expansion to 36 or more repeats in the offspring of male intermediate HD gene carriers is between 2 and 10 per cent (Goldberg *et al.*, 1993). There is a bias towards increased number of CAG repeats especially in paternal transmission leading to anticipation (Duyao *et al.*, 1993) – earlier onset and greater severity of disease in later generations.

Mutation rate is very low, and variously calculated to be between 0.07×10^{-6} and 9.6×10^{-6} (Harper, 1991). Since the discovery of the gene, many suspected cases with no clinically affected parents were found to have parents in the intermediate allele range.

Increased number of CAG repeats is associated with an earlier age of onset (Duyao *et al.*, 1993; Illarioshkin *et al.*, 1994; Kiebertz *et al.*, 1994; Brandt *et al.*, 1996). However, the correlation is not sufficiently strong enough to predict the age of onset for a given individual (Gusella *et al.*, 1993). In the CAG repeat size range of 37–52 CAG units (88 per cent of all HD repeats), the variation around the predicted age of onset is ± 18 years (Gusella *et al.*, 1993). Late-onset HD has less correlation with the CAG repeat size (Kremer *et al.*, 1993) and increased likelihood of an intermediate CAG range (James *et al.*, 1994). Other factors aside from the number of CAG repeats clearly also have a role in determining the age of onset (Andrew *et al.*, 1997); possible contenders are modifying genes (Gusella *et al.*, 1993), environmental factors (Gusella *et al.*, 1993) or stochastic effects (Gusella *et al.*, 1993).

Severity of brain pathology as assessed by various measures such as striatal atrophy (Penney *et al.*, 1997) has been correlated with the size of the CAG repeat in the majority of studies. Some studies examining for correlation with regional brain atrophy have not found any correlation with the CAG repeat size (Sieradzan *et al.*, 1997). The relationship between CAG repeat size and rate of disease progression is controversial, partly due to the different markers of disease progression used in different studies and partly due to the confounding factor of age of onset, which may be related to disease progression. Illarioshkin *et al.* (1994) reported on a significant positive correlation between the rate of progression of neurological and psychiatric symptoms and CAG repeat size. In a 2-year longitudinal follow up, Brandt *et al.* (1996) found there was a greater decline in neurological and cognitive functioning in those with CAG repeats greater than 47. In contrast, Kiebertz *et al.* (1994) failed to find such a correlation between clinical progression of disease and CAG size. Similarly, no relationship has been found between size of CAG repeat, symptoms at onset (Sieradzan *et al.*, 1997) or psychiatric symptoms (Berrios *et al.*, 2001).

62.3.2 Mouse genetic models

The mouse genome can now be altered to produce transgenic mice. The term transgenic mice refers to mice generated

by pronuclear microinjection of recombinant DNA or modification of endogenous mouse genes. The three main models (Bates and Murphy, 2003) are:

- mice where transgenes expressing truncated or full length versions of the huntingtin in the form of genomic or cDNA constructs have been introduced into the mouse germline;
- ‘knockouts’ – transgenic animals where a specific gene has been deleted; and
- knock-ins – transgenic mice where the sequence in exon 1 of the Hdh gene (the mouse homologue for the IT15 gene) has been replaced with a CAG repeat that is pathogenic in humans (Bates and Murphy, 2003). In the knock-in mice, the Hdh gene in mice has been modified by inserting a pure mouse gene or a HD/Hdh chimera (SuttonBrown and Suchowersky, 2003).

There are several lines of transgenic mice with different phenotypes and ages of onset.

62.3.3 Huntingtin

The gene IT15 codes for huntingtin, a protein located in tissue throughout the body but which is concentrated in the brain (DiFiglia, 1997). The polymorphic CAG repeat encodes for glutamate. In HD, the increased number of CAG repeats in the IT15 gene results in an expanded polyglutamine tract at the N-terminus of the huntingtin protein. IT15 is expressed throughout the body and concentrated in the brain, ovaries, testes and lungs, and is not only present in the brain regions affected in HD (Gusella *et al.*, 1993). In HD, the distribution of the normal and abnormal huntingtin protein is heterogeneous throughout the brain (Gourfinkel-An *et al.*, 1997). The abnormal huntingtin is not limited to cerebral structures most affected by the neurodegenerative process (Sharp *et al.*, 1995). Within the brain, huntingtin is predominantly found in the neurones and to a smaller extent in the glial cells (Sharp *et al.*, 1995). It is present primarily in the cytoplasm and has been variably detected in the nucleus (Sharp *et al.*, 1995).

The normal function of IT15 and the mechanism by which the HD gene leads to neuronal loss and causes the symptoms of HD still remain unclear but is postulated to be more likely a gain rather than a loss of function. Recent studies suggest that the formation and accumulation of huntingtin aggregates in neuronal cells is crucial in the pathogenesis of HD (Wanker and Droge, 2002).

62.4 NEUROPATHOLOGY

Macroscopically, the brain is smaller and lighter in HD than in age-matched controls (MacMillan and Quarrell, 1996). Autopsy of brains of advanced HD patients demonstrate atrophy of the frontal lobes, caudate nucleus, putamen and

globus pallidus (MacMillan and Quarrell, 1996), thickened leptomeninges and white matter loss under the cortical mantle (Gutkunst *et al.*, 2002). The ventricles are enlarged to a greater extent than can be explained by the striatal loss. Under light microscopy, there are diagnostic findings of neuronal loss and gliosis in the striatum (putamen and caudate; MacMillan and Quarrell, 1996). The neuronal loss in the striatum primarily involves the medium sized neurones that are the major cell type in the striatum and act as the inhibitory projection neurones from the striatum to the globus pallidus and substantia nigra. As these medium sized neurones degenerate, there is a decrease in the neurotransmitter gamma-aminobutyric acid (GABA) and other neurochemicals such as substance P, glutamic acid decarboxylase, enkephalin, calcineurin, calbindin, adenosine and dopamine receptors (Gutkunst *et al.*, 2002). These neuropathological changes evolve with time with the major cell loss starting in the dorso-medial 'tail' of the caudate and dorsal putamen, progressing ventrally, posteriorly and laterally until there is widespread severe neuronal loss and gliosis in the caudate and putamen, and moderate loss in the nucleus accumbens.

62.5 NEUROIMAGING

62.5.1 Structural imaging studies in HD

Early computer-assisted tomography (CAT) imaging techniques and recent magnetic resonance imaging (MRI) have consistently revealed bicaudate atrophy. The bicaudate ratio (BCR) is the ratio CC/OT_{cc} where CC is the bicaudate diameter, the shortest distance between the indentations of the caudate nucleus, and OT_{cc} is the distance between the outer tables of the skull alone on the same plane as the bicaudate measurement. The BCR is increased in HD compared with normals. MRI studies have also demonstrated atrophy of the putamen, caudate and globus pallidus in HD patients (Aylward *et al.*, 1996). Frontal lobe atrophy, involving primarily the white matter and total brain atrophy have been noted (Aylward *et al.*, 1998). Age of onset of disease and CAG repeat length have been correlated with change in volume of caudate and total basal ganglia, even after controlling for length between scans, duration of illness and symptoms severity (Aylward *et al.*, 1997). Similar findings of increased BCR, smaller basal ganglia volume and caudate hypometabolism have also been found in the gene-positive HD group who were asymptomatic or had early choreiform movements (Grafton *et al.*, 1992).

62.5.2 Magnetic resonance spectroscopy (MRS) studies in HD

Studies using 1H -MRS in HD have found decreased N-acetylaspartate (NAA)/Cr in the putamen (Davie *et al.*, 1994),

lower concentration of NAA in the combined caudate head and anterior putamen (Sanchez-Pernaute *et al.*, 1999), decreased NAA and increased choline relative to creatine in the basal ganglia (Jenkins *et al.*, 1993), suggesting neuronal loss in these structures. Reduced creatine in the basal ganglia has also been reported (Sanchez-Pernaute *et al.*, 1999). Elevated lactate levels in the basal ganglia and occipital region have been noted in symptomatic HD patients (Jenkins *et al.*, 1993). Some of these findings have been extended to the presymptomatic gene-positive group.

62.5.3 Functional imaging

Single photon emission computed tomography (SPECT) studies of cerebral blood flow have consistently revealed reduced cerebral perfusion in the basal ganglia before evidence of atrophy on MRI (Sax *et al.*, 1996). Hypoperfusion in the cortical areas such as the prefrontal cortex (Sax *et al.*, 1996) has been reported although these findings have not always been replicable.

Initial positron emission tomography (PET) studies of cerebral glucose metabolism mirrored the hypoperfusion findings in SPECT studies. These findings were extended to some (Feigin *et al.*, 2001) but not all (Young *et al.*, 1987) considered at risk of developing HD. Cortical hypometabolism has been demonstrated in some (Kuwert *et al.*, 1990) but not all studies (Young *et al.*, 1986).

PET $H_2(15)O$ PET cerebral activation (Weeks *et al.*, 1997) and ^{99m}Tc -HMPAO SPECT (Deckel *et al.*, 2001) studies have examined the functional significance of the above findings. These results suggest that there is impairment of the output part of the basal ganglia-thalamo-cortical motor circuit and compensatory recruitment of additional accessory motor pathways in the cortex.

Decreased benzodiazepine receptor density in the caudate but not the putamen in early HD using ^{11}C -flumazenil PET has been reported (Holthoff *et al.*, 1993). ^{11}C -SCH23390 PET and ^{11}C -raclopride PET are used to study dopamine D1 and D2 receptor binding respectively. D1 (Sedvall *et al.*, 1994; Ginovart *et al.*, 1997) and D2 (Ginovart *et al.*, 1997) receptor binding is reduced in the striatum in symptomatic HD. Dopamine D1 receptors are reduced in the frontal (Sedvall *et al.*, 1994) and the temporal (Ginovart *et al.*, 1997) cortices in symptomatic HD subjects. Various studies have found some asymptomatic HD subjects with reduced dopamine D1 and D2 receptor binding in the putamen and caudate (Weeks *et al.*, 1996).

There have been few studies to date using functional MRI (fMRI) to examine neural activity in patients with HD. Clark *et al.* (2002) reported reduced fMRI signal in the three patients relative to the three controls in occipital, parietal and somato-motor cortex and in the caudate, while increased signal was found in HD in the left post-central and right middle frontal gyri during performance of the Porteus maze task.

62.6 MANAGEMENT

The main management issues in patients with diagnosed HD are:

- movement disorders causing involuntary movements, gait disorder, dystonia and rigidity;
- oral motor disorder affecting speech and eating;
- cognitive disorder;
- behavioural and psychiatric disorder of depression, psychosis, anxiety, obsessive-compulsive behaviours, irritability, agitation in late stage;
- medical issues of weight loss, sleep disturbance, complications in late-stage HD from infections, regurgitation, cachexia, delirium;
- social issues of work, finances, care and placement, driving ability;
- support for the caregiver and families; and
- education of the patient, family and other healthcare professionals (Nance and Westphal, 2002).

62.6.1 Genetic counselling

Guidelines of the International Huntington Association (IHA) and the World Federation of Neurology for HD (WFN; International Huntington Association and World Federation of Neurology Research Group on Huntington's Chorea, 1994), developed soon after the HD gene testing became available, have provided the framework for presymptomatic, prenatal and confirmatory testing. The presymptomatic predictive testing programmes include:

- helping the individual and accompanying person understand the diagnosis, probable course and current management available for HD;
- helping appreciation of the hereditary contribution to the disorder;
- pedigree analysis, which allows the risk to the individual to be assessed and some insight into the family dynamics;
- discussion of their personal experiences, goals, financial and social resources, coping styles and other support;
- reason for testing;
- psychological assessment of their coping ability; and
- possible neurological assessment for symptom onset.

Approximately 20 per cent of at-risk individuals worldwide have taken the opportunity to confirm their gene status through tests (SuttonBrown and Suchowersky, 2003). Despite initial concerns, with the appropriate support from pretest counselling, the risk of suicide and other events such as suicide attempts or hospitalization for psychiatric reasons have been low, with a worldwide risk reported at 0.97 per cent (Almqvist *et al.*, 1999). High risk factors include a positive gene test, psychiatric history <5 years prior to testing, and unemployment. All who committed suicide were symptomatic at the time of the suicide. Prenatal testing of the fetus

has had low uptake. Preimplantation genetic testing combines assisted reproduction and genetic testing, so that only HD negative embryos are implanted. This has become available only in recent years.

62.6.2 Pharmacological treatments

Currently pharmacological treatment is aimed at symptomatic control of the motor and psychiatric aspects of the disorder. Neuroleptics such as haloperidol, a dopamine antagonist, are used to suppress abnormal movements. In later stages of the illness, as dopamine receptors are destroyed with the neurones containing them, medication will gradually be less useful and may aggravate dystonia, bradykinesia and dysphagia, gait and balance problems. Given this natural progression of the chorea to decrease with time, antichoreic agents should be given only if the involuntary movements are severe and disabling. Low doses of haloperidol (less than 10 mg/day) have been shown to be most effective. Atypical neuroleptics such as risperidone and olanzapine are now preferred as they have a lower incidence of side effects. Tetrabenazine, a presynaptic dopamine-depleting agent is effective but may cause depression as a side effect (Gimenez-Roldan and Mateo, 1989). Trials of clozapine (doses up to 150 mg/day) have shown modest antichoreic effects but the side effects outweigh the potential benefits in most cases (van Vugt *et al.*, 1997). Benzodiazepines such as clonazepam may reduce anxiety and some of the motor symptoms (Peiris *et al.*, 1976).

The depression responds to the same treatments as it does in the general population but persons with HD may be more sensitive to the side effects such as sedation (Craufurd and Snowden, 2003) and anticholinergic-induced cognitive decline (Leroi and Michalon, 1998). HD patients have been reported to be sensitive to lithium toxicity owing to their high risk of dehydration (Leroi and Michalon, 1998). Management of irritability or behavioural disturbance should focus initially on any possible underlying cause such as depression or psychosis. Psychotic symptoms, irritability or behavioural disturbance respond to neuroleptics. Propranolol, serotonin reuptake inhibitors, carbamazepine and sodium valproate can be helpful in the management of irritability (Ranen *et al.*, 1996; Grove *et al.*, 2000; Craufurd and Snowden, 2003).

Specific treatments such as antioxidants and other neuroprotective drugs, which theoretically target the disease process to slow functional decline in manifest disease, are under trial. Drugs shown to be tolerated and which may slow the progression or improve the chorea include coenzyme Q (Feigin *et al.*, 1996), an antioxidant, and remacemide (Kiebertz *et al.*, 1996), a non-competitive *N*-methyl-D-aspartate (NMDA) receptor antagonist. Other drug trials reporting beneficial effects on chorea include tiapride, a highly selective striatal adenylate cyclase-independent dopamine-2 receptor antagonist (Dose and Lange, 2000), apomorphine (Albanese *et al.*, 1995), α -tocopherol (a free radical scavenger; Peyser

et al., 1995), lamotrigine (an antiepileptic drug that inhibits glutamate release; Kremer *et al.*, 1999), and riluzole (an antilglutamatergic agent; Rosas *et al.*, 1999).

62.6.3 Psychosocial and physical management

Supportive psychotherapy aims to deal with losses of health, work, independence for the individual, and their implications for the other family members. Cognitive assessment can assist in decision-making on employment, driving, self-care, and other legal and safety issues. As the disease progresses, assistance with personal care and other activities of daily living will become necessary. Day care and respite care programmes may need to be considered. Attention to nutrition is important as weight loss is an inherent feature of the disease. It may be compounded by dysphagia in the late stages of the disease, poor dentition, unusual food-related behaviours such as obsessive intake of sweet foods and food refusals, psychiatric disorders and medication side effects. The use of a gastrostomy feeding tube at the end stage of the disease should be discussed early on, when the patient is able to express his or her wishes on this matter. Local branches of the Huntington's Disease Association can provide valuable support, advice on local resources and educational material on HD. Finally, residential care may be needed for some HD patients.

62.6.4 Research into new therapies

Clinical research determining the early onset and progressive symptoms of HD are currently being undertaken by the Huntington Study Group, an international collaboration of researchers in HD. Restorative therapies that rejuvenate or replace malfunctioning neurones in order to restore functions are also being developed. Since 1989, there have been over 50 cases of cell transplantation using fetal striatal tissues (Dunnett and Rosser, 2002). Most reports have shown no major adverse effect with evidence of improved function and striatal graft viability in the short follow up of 12–33 months postoperatively (Dunnett and Rosser, 2002). However, there are many issues related to fetal striatal tissue transplantation in the ethical and practical domains that are likely to limit its availability. Another alternative is stem cells, which have the potential for self-renewal and are capable of forming at least one, sometimes, many, specialized cell types. Currently, the task is to control the differentiation potential of these cells in the adult brain environment.

Creutzfeldt–Jakob disease and other prion diseases

JOHN COLLINGE

63.1 Transmission and aetiology	763	References	773
63.2 Clinical features and diagnosis	765		

63.1 TRANSMISSION AND AETIOLOGY

The human prion diseases, also known as the transmissible spongiform encephalopathies, have been traditionally classified into Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler syndrome (GSS; also known as Gerstmann–Sträussler–Scheinker disease) and kuru. Remarkable attention has been recently focused on these diseases because of the unique biology of the transmissible agent or prion, and also because of the epidemic of bovine spongiform encephalopathy (BSE) and the evidence that BSE prions have infected humans, causing the new human prion disease known as variant CJD (vCJD). Human prion infection can be associated with extremely long incubation periods, which may span decades, and considerable uncertainty remains as to the eventual epidemic size of BSE-related human prion disease and the risks of its secondary transmission via medical and surgical procedures.

The transmissibility of the human diseases was demonstrated with the transmission (by intracerebral inoculation with brain homogenates) to chimpanzees of kuru and CJD in 1966 and 1968 respectively (Gajdusek *et al.*, 1966; Gibbs *et al.*, 1968). Transmission of GSS followed in 1981. Scrapie is a naturally occurring disease of sheep and goats, recognized in Europe for over 200 years (McGowan, 1922) and present in the sheep flocks of many countries. Scrapie was demonstrated to be transmissible in 1936 (Cuillé and Chelle, 1936) and the recognition that kuru, and then CJD, resembled scrapie in its histopathological appearances led to the suggestion that these diseases may also be transmissible (Hadlow, 1959). Kuru reached epidemic proportions amongst the Fore in the Eastern Highlands of Papua New Guinea and was transmitted by ritual cannibalism. Since the cessation of cannibalism in the 1950s, the disease has declined but a few cases still occur as

a result of the long incubation periods in this condition. The term Creutzfeldt–Jakob disease was introduced by Spielmeyer in 1922 bringing together the case reports published by Creutzfeldt and Jakob. Several of these cases would not meet modern diagnostic criteria for CJD and it was not until the demonstration of transmissibility allowing diagnostic criteria to be reassessed and refined that a clear diagnostic entity developed. All these diseases share common histopathological features; the classical triad of spongiform vacuolation (affecting any part of the cerebral grey matter), astrocytic proliferation and neuronal loss, which may be accompanied by the deposition of amyloid plaques (Beck and Daniel, 1987).

Prion diseases are associated with the accumulation of an abnormal, partially protease-resistant, isoform of a host-encoded glycoprotein known as prion protein (PrP). This disease-related isoform, PrP^{Sc}, is derived from its normal cellular precursor, PrP^C, by a post-translational process and involves a conformational change. PrP^C is rich in α -helical structure while PrP^{Sc} is predominantly composed of β -sheet. According to the 'protein-only' hypothesis (Griffith, 1967), an abnormal PrP isoform (Prusnier, 1990) is the principal, and possibly the sole, constituent of the transmissible agent or prion. It is hypothesized that PrP^{Sc} acts as a conformational template, promoting the conversion of PrP^C to further PrP^{Sc}. PrP^C may be poised between two radically different folding states: α - and β -forms of PrP can be interconverted in suitable conditions (Jackson *et al.*, 1999). Soluble β -PrP aggregates in physiological salt concentrations to form fibrils with morphological and biochemical characteristics similar to PrP^{Sc}. A molecular mechanism for prion propagation can now be proposed (Jackson *et al.*, 1999). Prion replication, with recruitment of PrP^C into the aggregated PrP^{Sc} isoform, may be initiated by a pathogenic mutation (resulting in a PrP^C predisposed to form β -PrP) in inherited prion diseases, by exposure to a 'seed' of PrP^{Sc} in acquired cases, or as a result

of the spontaneous conversion of PrP^C to β -PrP (and subsequent formation of aggregated material) as a rare stochastic event in sporadic prion disease.

The human PrP gene (designated PRNP) is located on chromosome 20p and was an obvious candidate for genetic linkage studies in the familial forms of CJD and GSS, which show an autosomal dominant pattern of disease segregation. A milestone in prion research was the identification of PRNP mutations in familial CJD and GSS in 1989. The first mutation to be identified in PRNP was in a family with CJD and consisted of a 144bp insertion (Owen *et al.*, 1989). A second mutation was reported in two families with GSS and genetic linkage was confirmed between this missense variant at codon 102 and GSS, confirming that GSS is an autosomal dominant Mendelian disorder (Hsiao *et al.*, 1989). These diseases are therefore both inherited and transmissible, a biologically unique feature. Approximately 15 per cent of prion diseases are inherited and around 30 coding mutations in PRNP are now recognized (Collinge 2001).

With the exception of rare iatrogenic CJD cases, most prion disease occurs as sporadic CJD where, by definition, there will not be a family history. However, PRNP mutations are seen in some apparently sporadic cases, since the family history may not be apparent, owing to late age of onset or non-paternity. Human prion diseases can therefore be subdivided into three aetiological categories: inherited, sporadic and acquired.

A common PrP polymorphism at residue 129, where either methionine or valine can be encoded, is, however, a key determinant of genetic susceptibility in acquired and sporadic forms of prion disease, the large majority of which occur in homozygotes (Collinge *et al.*, 1991a; Palmer *et al.*, 1991). This protective effect of PRNP codon 129 heterozygosity is also seen in some of the inherited prion diseases (Baker *et al.*, 1991; Hsiao *et al.*, 1992).

Sporadic CJD is thought to arise from somatic mutation of PRNP or spontaneous conversion of PrP^C to PrP^{Sc} as a rare stochastic event. The alternative hypothesis, that of exposure to an environmental source of either human or animal prions, is not supported by epidemiological studies to date (Brown *et al.*, 1987) but it remains possible that a minority of patients have an as yet unidentified environmental exposure to human or animal prions.

The existence of multiple isolates or strains of prions with distinct biological properties has provided a challenge to the 'protein-only' model of prion replication. Indeed, understanding how a protein-only infectious agent could encode phenotypic information is of considerable biological interest. However, it is now clear that prion strains can be distinguished by differences in the biochemical properties of PrP^{Sc}. Prion strain diversity appears to be encoded by differences in PrP conformation and pattern of glycosylation (Collinge *et al.*, 1996b). Molecular strain typing is now possible and has allowed the identification of four main types in CJD, sporadic and iatrogenic CJD being of PrP^{Sc} types 1–3, while all vCJD cases are associated with a type 4 PrP^{Sc} type (Collinge *et al.*, 1996b; Wadsworth *et al.*, 1999). That a similar PrP^{Sc} type to that seen

in vCJD is seen in BSE transmitted to several other species (Collinge *et al.*, 1996b) strongly supported the hypothesis that vCJD was human BSE. This conclusion was strengthened by transmission studies of vCJD into both transgenic and conventional mice, which indicated that cattle BSE and vCJD were caused by the same prion strain (Bruce *et al.*, 1997; Hill *et al.*, 1997). Molecular classification of human prion diseases is now possible and it is likely that additional PrP^{Sc} types will be identified (Hill *et al.*, 2003). Such studies, where patients are aetiologically classified by human prion strain, rather than by descriptive clinicopathological phenotype, allows re-evaluation of epidemiological risk factors and may provide new insights into causes of 'sporadic' CJD.

The ability of a protein to encode a disease phenotype has important implications in biology, as it represents a non-Mendelian form of transmission. It would be surprising if this mechanism had not been used more widely during evolution and may prove to be of wider relevance in pathobiology.

Transmission of prion diseases between different mammalian species is restricted by a 'species barrier' (Pattison, 1965). Early studies of the molecular basis of this barrier argued that it resided in differences in PrP primary structure between the species from which the inoculum was derived and the inoculated host. Transgenic mice expressing hamster PrP were, unlike wild type mice, highly susceptible to infection with hamster prions (Prusiner *et al.*, 1990). That most sporadic and acquired CJD occurred in individuals homozygous at PRNP polymorphic codon 129 supported the view that prion propagation proceeded most efficiently when the interacting PrP^{Sc} and PrP^C were of identical primary structure (Palmer *et al.*, 1991). However, prion strain type affects ease of transmission to another species. Interestingly, with BSE prions this strain component to the barrier seems to predominate, with BSE not only transmitting efficiently to a range of species, but maintaining its transmission characteristics even when passaged through an intermediate species with a distinct PrP gene (Bruce *et al.*, 1994; Hill *et al.*, 1997). The term 'species–strain barrier' or simply 'transmission barrier' may be preferable (Collinge, 1999). Both PrP amino acid sequence and strain type affect the 3D-structure of glycosylated PrP^{Sc} which will presumably affect the efficiency of the protein–protein interactions determining prion propagation. Other components to the species barrier are possible and may involve interacting cofactors, although no such factors have yet been identified.

The species barrier between cattle BSE and humans cannot be directly measured but can be modelled in transgenic mice expressing human PrP^C, which produce human PrP^{Sc} when challenged with human prions (Collinge *et al.*, 1995b). While classical CJD prions transmit efficiently to such mice at around 200 days, only infrequent transmissions at over 500 days were seen with BSE (and vCJD) prions, consistent with a substantial species barrier for this human PRNP genotype (Hill *et al.*, 1997). In transgenic mice expressing only human PrP methionine 129, while transmission assessed by onset of clinical disease was again inefficient, remarkably a large

proportion of the inoculated animals were subclinically infected (Asante *et al.*, 2002b) suggesting a considerably lower barrier to infection in this genotype. To date vCJD has only been recognized in humans of PRNP codon 129 methionine homozygous genotype. Interestingly, transmissions of BSE to mice expressing human PrP methionine 129 resulted in the generation of two distinct pathological and molecular phenotypes in these animals: one closely resembling vCJD (with type 4 PrP^{Sc} and the characteristic neuropathology of vCJD) and the other sporadic CJD with type 2 PrP^{Sc}. This raises the possibility that BSE infection of humans may result in phenotypes resembling classical CJD as well as the distinctive phenotype of vCJD (Asante *et al.*, 2002b).

63.2 CLINICAL FEATURES AND DIAGNOSIS

The human prion diseases can be divided aetiologically into inherited, sporadic and acquired forms, with CJD, GSS and kuru now seen as clinicopathological syndromes within a wider spectrum of disease. Kindreds with inherited prion disease have been described with phenotypes of classical CJD, GSS and other syndromes including fatal familial insomnia (Medori *et al.*, 1992b). Some kindreds show remarkable phenotypic variability which can encompass both CJD- and GSS-like cases as well as other cases that do not conform to either phenotype (Collinge *et al.*, 1992). Atypical cases (diagnosed by PRNP analysis) have been reported which entirely lack the classical histological features (Collinge *et al.*, 1990). There is significant clinical overlap with familial Alzheimer's disease, Pick's disease, frontal lobe degeneration of non-Alzheimer type and amyotrophic lateral sclerosis with dementia. It now seems sensible to designate the familial illnesses as inherited prion diseases and to subclassify according to PRNP mutation. Acquired prion diseases include iatrogenic CJD, kuru and vCJD. Sporadic prion diseases at present consist of CJD and atypical variants of CJD. As there are at present no equivalent aetiological diagnostic markers for sporadic prion diseases to those for the inherited diseases, it cannot yet be excluded that more diverse phenotypic variants of sporadic prion disease exist.

63.2.1 Sporadic prion disease

63.2.1.1 CREUTZFELDT-JAKOB DISEASE

The core clinical syndrome of classical CJD is a rapidly progressive multifocal dementia, usually with myoclonus. Most have onset between ages 45 and 75, with peak between 60 and 65 and a clinical progression to akinetic mutism and death in <6 months. Around one-third of cases have prodromal features including fatigue, insomnia, depression, weight loss, headaches, general malaise and ill-defined pain sensations. Frequent additional neurological features include extrapyramidal signs, cerebellar ataxia, pyramidal signs and cortical blindness.

Routine haematological and biochemical investigations are normal (although occasional patients have raised serum transaminases or alkaline phosphatase). There are no immunological markers and acute phase proteins are not elevated. Cerebrospinal fluid is normal, although neuronal specific enolase (NSE), and S-100 are usually elevated. However, they are not specific for CJD and represent markers of neuronal injury (Jimi *et al.*, 1992; Zerr *et al.*, 1995; Otto *et al.*, 1997). Estimation of CSF 14-3-3 protein, while again not a specific disease marker, appears useful in the appropriate clinical context (Collinge, 1996; Hsich *et al.*, 1996). It is also positive in recent cerebral infarction or haemorrhage and in viral encephalitis, which are unlikely to present diagnostic confusion with CJD, but more recent studies have found 14-3-3 positive in other non-prion related conditions (Sato *et al.*, 1999). While 14-3-3 is usually positive in typical CJD, its use in differential diagnosis in more challenging diagnostic contexts is less clear, as it may be negative in long duration atypical CJD and positive in patients with rapidly progressive Alzheimer's disease with myoclonus for example.

Neuroimaging with computed tomography (CT) is useful to exclude other causes of subacute neurological illness but there are no diagnostic features; cerebral and cerebellar atrophy may be present. However, magnetic resonance imaging (MRI) changes are increasingly recognized and may be extremely helpful diagnostically. Signal changes are frequently seen in the basal ganglia in T2-weighted images. More widespread signal changes may be seen in diffusion-weighted images, which appears more sensitive diagnostically and which may be present at an early clinical stage (Shiga *et al.*, 2004). The electroencephalogram (EEG) may show characteristic pseudo-periodic sharp wave activity, which is helpful in diagnosis but present only in around 70 per cent of cases. This finding may be intermittent and serial EEG is appropriate to try to demonstrate this appearance.

Neuropathological confirmation is by demonstration of spongiform change, neuronal loss and astrocytosis. PrP amyloid plaques are usually not present although PrP immunohistochemistry, with appropriate pretreatments (Budka *et al.*, 1995), will nearly always be positive. PrP^{Sc}, seen in all the currently recognized prion diseases, can be demonstrated by western blot. PRNP analysis is essential to exclude pathogenic mutations as a family history may not always be apparent. PRNP mutations should certainly be excluded prior to brain biopsy, which may be considered in some patients to exclude alternative, potentially treatable diagnoses. Tonsil biopsy (see below) is negative in sporadic CJD but may be considered in younger patients where a diagnosis of vCJD is being considered. Most cases of classical CJD are homozygous with respect to the codon 129 PRNP polymorphism (see the aetiology section above).

Sporadic CJD can now be subclassified by prion strain type using western blot analysis of brain tissue at biopsy or autopsy, although there is not as yet an international consensus on the number or nomenclature of these molecular types. Distinctive phenotypes are associated with different PrP^{Sc}

types (Parchi *et al.*, 1999; Hill *et al.*, 2003). For example, subacute patients whose illnesses have been of short clinical duration (several weeks) are associated with type 1 PrP^{Sc} in the brain (Wadsworth *et al.*, 1999; Hill *et al.*, 2003).

63.2.1.2 ATYPICAL CREUTZFELDT–JAKOB DISEASE

Atypical forms of CJD are well recognized. Around 10 per cent of CJD has a prolonged clinical course with duration of over 2 years (Brown *et al.*, 1984). Patients with a valine homozygous or methionine valine heterozygous genotype at PRNP codon 129 are more often atypical clinical forms than are methionine homozygotes (Collinge and Palmer, 1994) and may lack a characteristic EEG. It is unclear yet to what extent this represents propagation of different prion strains or a direct effect of the genotype on disease expression (Collinge, 2001). Approximately 10 per cent of CJD cases present with cerebellar ataxia rather than cognitive impairment – ataxic CJD (Gomori *et al.*, 1973). Heidenhain's variant refers to cases in which cortical blindness predominates, with severe involvement of the occipital lobes. In panencephalopathic CJD, predominately reported from Japan, there is extensive degeneration of the cerebral white matter in addition to spongiform vacuolation of the grey matter (Mizutani, 1981). Amyotrophic variants of CJD have been described with prominent early muscle wasting. However, most cases of dementia with amyotrophy are not experimentally transmissible (Salazar *et al.*, 1983) and their relationship with CJD is unclear. Most cases are probably variants of motor neurone disease with associated dementia. Amyotrophic features in CJD are usually seen in late disease when other features are well established. There are numerous individual case reports in the literature of other unusual presentations of CJD, mimicking many other neurological and psychiatric disorders.

63.2.2 Acquired prion diseases

While human prion diseases can be transmitted to experimental animals by inoculation, they are not contagious in humans. Documented case to case spread has only occurred by direct exposure to infected human tissues during ritual cannibalistic practices (kuru) or following accidental inoculation with prions during medical or surgical procedures (iatrogenic CJD).

63.2.2.1 KURU

Kuru reached epidemic proportions amongst a relatively isolated population (the Fore linguistic group and their neighbours with whom they intermarried) in the Eastern Highlands of Papua New Guinea. It predominantly affected women and children (of both sexes), with only 2 per cent of cases in adult males (Alpers, 1987) and was the commonest cause of death amongst women. It had been the practice in these communities to consume dead relatives, as a mark of respect and mourning. Women and children predominantly ate the brain

and internal organs, which is thought to explain the different age and sex incidence. Preparation of the cadaver was performed by the women and children such that other routes of exposure may also have been relevant. It is thought that the epidemic related to a single sporadic CJD case occurring in the region some decades earlier. Epidemiological studies provided no evidence for vertical transmission, since most of the children born after 1956 (when cannibalism had effectively ceased) and all of those born after 1959 of mothers affected with or incubating kuru were unaffected (Alpers, 1987). From the age of the youngest affected patient, the shortest incubation period is estimated as 4.5 years, although may have been shorter, since time of infection was usually unknown. Currently, two to three cases are occurring annually, all in individuals born prior to the cessation of cannibalism and indicating that incubation periods can be 40 years or more (Whitfield *et al.*, in preparation).

Onset of disease has ranged from age 5 to over 60 with a mean duration of 12 months (range 3 months to 3 years). The key clinical feature is progressive cerebellar ataxia. In sharp contrast to CJD, dementia is much less of a feature, even in the latter stages (Alpers, 1987).

Kuru typically begins with prodromal symptoms consisting of headache, aching of limbs and joint pains which can last for several months. Kuru was frequently self-diagnosed by patients at the earliest onset of unsteadiness in standing or walking, or of dysarthria or diplopia. At this stage there may be no objective signs of disease. Gait ataxia, however, worsens and patients develop a broad-based gait, truncal instability and titubation. A coarse postural tremor is usually present and accentuated by movement; patients characteristically hold their hands together in the mid-line to suppress this. Standing with feet together reveals clawing of toes to maintain posture. This marked clawing response is regarded as pathognomonic of kuru. Patients often become withdrawn at this stage and occasionally develop a severe reactive depression. Prodromal symptoms tend to disappear. Astasia and gait ataxia worsen and the patient requires a stick for walking. Intention tremor, dysmetria, hypotonia and dysdiadochokinesis develop. Strabismus, usually convergent, may occur particularly in children. Photophobia is common and there may be an abnormal cold sensitivity with shivering and piloerection even in a warm environment. Tendon reflexes are reduced or normal and plantar responses are flexor. Dysarthria usually occurs.

As ataxia progresses the patient passes from the first (ambulatory) stage to the second (sedentary) stage. At this stage patients are able to sit unsupported but cannot walk. Attempted walking with support leads to a high steppage, wide-based gait with reeling instability and flinging arm movements in an attempt to maintain posture. Hyperreflexia is seen, although plantar responses usually remain flexor with intact abdominal reflexes. Clonus is characteristically short lived. Athetoid and choreiform movements and parkinsonian tremors may occur. There is no paralysis, although muscle power is reduced. Obesity is common at this stage but may be present in early disease associated with bulimia.

Characteristically, there is emotional lability and bizarre uncontrollable laughter, which has led to the disease being referred to as 'laughing death'. There is no sensory impairment. In sharp contrast to CJD, myoclonic jerking is rarely seen. EEG is usually normal or may show non-specific changes. When truncal ataxia reaches the point where the patient is unable to sit unsupported, the third or tertiary stage is reached. Hypotonia and hyporeflexia develop and the terminal state is marked by flaccid muscle weakness. Plantar responses remain flexor and abdominal reflexes intact. Progressive dysphagia occurs and patients become incontinent of urine and faeces. Inanition and emaciation develop. Transient conjugate eye signs and dementia may occur. Primitive reflexes develop in occasional cases. Brain stem involvement and both bulbar and pseudobulbar signs occur. Respiratory failure and broncho-pneumonia eventually lead to death.

63.2.2.2 IATROGENIC CREUTZFELDT-JAKOB DISEASE

Iatrogenic transmission of CJD has occurred by inadvertent inoculation with human prions during medical procedures. Such iatrogenic routes include the use of inadequately sterilized neurosurgical instruments, dura mater and corneal grafting, and use of human cadaveric pituitary-derived growth hormone or gonadotrophin. Cases arising from intracerebral or optic inoculation manifest typically as classical CJD, with a rapidly progressive dementia, while those resulting from peripheral inoculation (pituitary-derived growth hormone exposure) typically present with a progressive cerebellar syndrome, and are in that respect reminiscent of kuru. Unsurprisingly, the incubation period in intracerebral cases is short (19–46 months for dura mater grafts) compared with peripheral cases (typically 15 years or more). There is evidence for genetic susceptibility to iatrogenic CJD with an excess of codon 129 homozygotes; heterozygosity appears protective with a more prolonged incubation period (Collinge *et al.*, 1991a; Brandel *et al.*, 2003).

Epidemiological studies have not shown association of CJD with occupations that may expose people to human or animal prions, although individual cases in two histopathology technicians, a neuropathologist and a neurosurgeon, have been documented. Similarly, extensive epidemiological analysis in the UK has found no evidence that blood transfusion is a risk factor (Esmonde *et al.*, 1993). It cannot be assumed that the same picture will hold for vCJD as this is caused by a distinct prion strain (Collinge *et al.*, 1996b) from those causing classical CJD and has a distinct pathogenesis (Hill *et al.*, 1999). Indeed, vCJD has now been reported in a recipient of blood from an infected donor (Llewelyn *et al.*, 2004). In addition, prion infection has been demonstrated in a second recipient of blood from an infected donor who died of an unrelated cause (Peden *et al.*, 2004). These early cases amongst a very small cohort of known exposed individuals is concerning, as the number of clinically silent individuals currently incubating vCJD, a proportion of whom will be blood donors, is unknown but may be substantial (Collinge, 1999).

63.2.3 Variant CJD

In late 1995, two cases of sporadic CJD were reported in the UK in teenagers (Bateman *et al.*, 1995; Britton *et al.*, 1995). Only four cases of sporadic CJD had previously been recorded in teenagers, and none of these cases occurred in the UK. In addition, both were unusual in having kuru-type plaques, seen in only around 5 per cent of CJD cases. Soon afterwards a third very young sporadic CJD case occurred (Tabrizi *et al.*, 1996). These cases caused considerable concern and the possibility was raised that they were BSE-related. By March 1996, further extremely young onset cases were apparent and review of the histology of these cases showed a remarkably consistent and unique pattern. These cases were named 'new variant' CJD (Will *et al.*, 1996). Review of neuropathological archives failed to demonstrate such cases. The statistical probability of such cases occurring by chance was vanishingly small and ascertainment bias seemed unlikely as an explanation. It was clear that a new risk factor for CJD had emerged and appeared to be specific to the UK. The UK Government Spongiform Encephalopathy Advisory Committee (SEAC) concluded that, while there was no direct evidence for a link with BSE, exposure to specified bovine offal (SBO) prior to the ban on its inclusion in human foodstuffs in 1989 was the most likely explanation. A case of vCJD was soon after reported in France (Chazot *et al.*, 1996). Direct experimental evidence that vCJD is caused by BSE was provided by molecular analysis of human prion strains and transmission studies in transgenic and wild type mice (see aetiology section above). While it is now clear that vCJD is the human counterpart of BSE, it is unclear why this particular age group should be affected and why none of these cases had a pattern of unusual occupational or dietary exposure to BSE. However, very little was known about which foodstuffs contained high-titre bovine offal. It is possible that certain foods containing particularly high titres were eaten predominantly by younger people. An alternative is that young people are more susceptible to BSE following dietary exposure or that they have shorter incubation periods. It is important to appreciate that BSE-contaminated feed was fed to sheep, pigs and poultry and that, although there is no evidence of natural transmission to these species, it would be prudent to remain open minded about other dietary exposure to novel animal prions.

There are considerable concerns that extensive human infection may have resulted from the widespread dietary exposure to BSE prions. Cattle BSE has now been reported, albeit at much lower levels than in the UK, in most member states of the EU, Switzerland, USA, Canada and Japan. Fortunately, the number of recognized cases of vCJD (up to 150 by early 2004) in the UK has been relatively small to date. Six patients have been identified in France and individual patients in Ireland, Italy, USA, Canada and Hong Kong. However, the number of infected individuals is unknown. Human prion disease incubation periods, as evidenced by kuru, are known to span decades. Furthermore, prion disease transmission

from one species to another is invariably associated with a considerable prolongation of mean incubation periods – the so called ‘species-barrier’ effect (Collinge, 1999). Recent estimates, based on mathematical modelling and clinically recognized vCJD, suggest the total epidemic may be relatively small (Ghani *et al.*, 2003) but key uncertainties, notably with respect to major genetic effects on incubation period (Lloyd *et al.*, 2001) suggest the need for caution; also such models cannot estimate the number of *infected* individuals and it is these that are most relevant to assessing risks of secondary transmission. Also, the possibility of subclinical carrier states of prion infection in humans, as recognized in several animal models, must also be considered (Hill *et al.*, 2000; Asante *et al.*, 2002b).

A recent attempt to estimate prevalence of vCJD prion infection in the UK by anonymous screen of archival, largely appendix, tissue, necessarily using a method of unknown sensitivity, found three positives in around 12 000 samples (Hilton *et al.*, 2004). The risk of secondary transmission via medical and surgical procedures is unquantifiable at present but continues to cause considerable concern. As discussed above, vCJD appears transmissible by blood transfusion; also prions are known to be resistant to conventional sterilization, and indeed iatrogenic transmission from neurosurgical instruments has long been documented (Bernoulli *et al.*, 1977). The wider tissue distribution of infectivity in vCJD (Wadsworth *et al.*, 2001), unknown prevalence of clinically silent infection, together with the recent experimental demonstration of the avid adherence to, and ease of transmission from, surgical steel surfaces (Flechsig *et al.*, 2001) highlight these concerns. From a public health standpoint, it is prudent therefore to operate on the basis that the majority of variant CJD cases are yet to occur and may not present clinically for many years (Collinge, 1999). Furthermore, studies in transgenic mouse models of human susceptibility to BSE prion infection suggest that BSE may also induce propagation of a prion strain indistinguishable from the commonest type of sporadic CJD (Asante *et al.*, 2002a), in addition to that causing variant CJD. Other novel prion disease phenotypes may be anticipated in alternative PRNP genotypes (Hill *et al.*, 1997).

Presentation of vCJD is with behavioural and psychiatric disturbances and, in some cases, sensory disturbance (Will *et al.*, 1996). Initial referral is often to a psychiatrist with depression, anxiety, withdrawal and behavioural change (Zeidler *et al.*, 1997a). Suicidal ideation is, however, infrequent and response to antidepressants poor. Delusions, which are complex and unsustained, are common. Other features include emotional lability, aggression, insomnia, and auditory and visual hallucinations. Dysaesthesiae, or pain in the limbs or face, which was persistent rather than intermittent and unrelated to anxiety levels, is a frequent early feature, sometimes prompting referral to a rheumatologist. A minority of cases have early memory loss or gait ataxia but in most such overt neurological features are not apparent until some months later (Zeidler *et al.*, 1997b). Typically, a progressive cerebellar syndrome then develops with gait and limb ataxia

followed with dementia and progression to akinetic mutism. Myoclonus is frequent, and may be preceded by chorea. Cortical blindness develops in a minority of patients in late disease. Upgaze paresis, an uncommon feature of classical CJD, has been noted in some patients (Zeidler *et al.*, 1997b). The age at onset has widened since the initial descriptions but remains dominated by young adults: range 12–74 years (mean 28 years) and the clinical course is relatively prolonged when compared with typical sporadic CJD (9–35 months, median 14 months). The EEG is nearly always abnormal, most frequently showing generalized slow wave activity, but without the pseudoperiodic pattern seen in most sporadic CJD cases. Neuroimaging by CT is either normal or shows only mild atrophy. However, a high signal in the posterior thalamus on T2-weighted MRI is seen in the majority but not all recognized cases (Zeidler *et al.*, 1997b; Hill *et al.*, 1999).

Recently, cases of sporadic CJD mimicking vCJD both clinically and on MRI have been described, with high signal from the pulvinar on FLAIR and diffusion-weighted imaging (Martindale *et al.*, 2003; Rossetti *et al.* 2004; Summers *et al.* 2004). Such a vCJD-like variant of sCJD appears to correlate with homozygosity for valine at codon 129 in the prion gene, or with methionine/valine heterozygosity. Cerebrospinal fluid (CSF) 14-3-3 protein may be elevated or normal.

No PRNP mutations are present in vCJD (Collinge *et al.*, 1996a) and gene analysis is important to exclude pathogenic mutations, as inherited prion disease presents in this age group and a family history is not always apparent. The codon 129 genotype has uniformly been homozygous for methionine at PRNP codon 129 to date.

Clear ante-mortem tissue based diagnosis of vCJD can now be made by tonsil biopsy with detection of characteristic PrP immunostaining and PrP^{Sc} type (Hill *et al.*, 1999). It has long been recognized that prion replication, in experimentally infected animals, is first detectable in the lymphoreticular system, considerably earlier than the onset of neurological symptoms. Importantly, PrP^{Sc} is only detectable in tonsil in vCJD, and not other forms of human prion disease studied. The PrP^{Sc} type detected on western blot in vCJD tonsil has a characteristic pattern designated type 4t (Hill *et al.*, 1999). A positive tonsil biopsy obviates the need for brain biopsy, which may otherwise be considered in such a clinical context to exclude alternative, potentially treatable, diagnoses. To date, tonsil biopsy has proved 100 per cent specific and sensitive for vCJD diagnosis and is well tolerated.

The neuropathological appearances of vCJD are striking and consistent. In addition to widespread spongiform change, gliosis and neuronal loss (most severe in the basal ganglia and thalamus), there are abundant PrP amyloid plaques in cerebral and cerebellar cortex. These consisted of kuru-like, ‘florid’ (surrounded by spongiform vacuoles) and multicentric plaque types. The ‘florid’ plaques, seen previously only in scrapie, were a particularly unusual but highly consistent feature. There is abundant pericellular PrP deposition in the cerebral and cerebellar cortex and, unusually, extensive PrP immunoreactivity in the molecular layer of the cerebellum.

In some respects, vCJD resembles kuru, in which behavioural changes and progressive ataxia predominate. Peripheral sensory disturbances are well recognized in the kuru prodrome and kuru plaques are seen in around 70 per cent of cases (and are especially abundant in younger kuru cases). That iatrogenic prion disease related to peripheral exposure to human prions has a more kuru-like than CJD-like clinical picture may well be relevant and would be consistent with a peripheral prion exposure in vCJD also.

This relatively stereotyped clinical presentation and neuropathology of vCJD contrasts sharply with sporadic CJD. This may be because vCJD is caused by a single prion strain and/or because a relatively homogeneous, genetically susceptible, subgroup with short incubation periods to BSE has been infected to date. It will be important to be alert to different clinical presentations.

63.2.4 Inherited prion diseases

63.2.4.1 GERSTMANN–STRÄUSSLER–SCHEINKER (GSS) SYNDROME

The first case was described by Gerstmann in 1928 and was followed by a more detailed report of seven other affected members of the same family in 1936 (Gerstmann *et al.*, 1936). The classical presentation is a chronic cerebellar ataxia accompanied by pyramidal features, with dementia occurring later. The histological hallmark is the presence of multicentric amyloid plaques. Numerous GSS kindreds from several countries have now been demonstrated to have PRNP mutations. GSS is an autosomal dominant disorder which can be classified within the spectrum of inherited prion disease.

63.2.4.2 INHERITED PRION DISEASES

The identification of a pathogenic PRNP mutation in a patient with neurodegenerative disease allows both diagnosis of inherited prion disease and its subclassification according to mutation. Around 30 pathogenic mutations in PRNP are described and consist of two groups:

- point mutations resulting in amino acid substitutions in PrP (or production of a stop codon);
- insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein.

An aetiological notation for these diseases (Collinge and Prusiner, 1992) is ‘inherited prion disease (PrP mutation)’; for instance: inherited prion disease (PrP 144bp insertion) or inherited prion disease (PrP P102L). Phenotypic descriptions of some of these mutations follow:

1. Missense mutations

- *PrP P102L*. This was first reported in 1989 in a UK and US family and is now demonstrated in many kindreds worldwide. Progressive ataxia is the dominant clinical feature, with dementia and pyramidal features. However,

marked variability both at the clinical and neuropathological level is apparent in some families (Hainfellner *et al.*, 1995). A family with marked amyotrophic features has also been reported (Kretzschmar *et al.*, 1992). Cases with severe dementia in the absence of prominent ataxia are also recognized. Neuropathological examination reveals PrP immunoreactive plaques in the majority of cases. Transmissibility to experimental animals has been demonstrated.

- *PrP P105L*. Reported in three Japanese families (Kitamoto *et al.*, 1993) with a history of spastic paraparesis and dementia, its clinical duration is around 5 years. There was no periodic synchronous discharge on EEG but MRI scans showed atrophy of the motor cortex. Neuropathological examination showed plaques in cerebral cortex (but not cerebellum) and neuronal loss but no spongiosis. Neurofibrillary tangles were variably present.
- *PrP A117V*. First described in a French family (Doh ura *et al.*, 1989) and subsequently in a US family of German origin (Hsiao *et al.*, 1991b), its clinical features are presenile dementia with pyramidal signs, parkinsonism, pseudobulbar features and cerebellar signs. Neuropathologically, PrP immunoreactive plaques are usually present. This mutation has also been identified in a large family in the UK (Mallucci *et al.*, 1999).
- *PrP Y145STOP*. This mutation was detected in a Japanese patient with a clinical diagnosis of Alzheimer’s disease. She developed memory disturbance at age 38 with a duration of illness of 21 years. Neuropathology revealed typical Alzheimer-like pathology without spongiform change (Kitamoto *et al.*, 1993a). Many amyloid plaques were seen in the cortex along with paired helical filaments. However, plaques were PrP immunoreactive. βA_4 immunocytochemistry was negative. These clinicopathological findings emphasize the importance of PRNP analysis in the differential diagnosis of dementia.
- *PrP D178N*. This was originally described in two Finnish families with a CJD-like phenotype (although without typical EEG appearances) (Goldfarb *et al.*, 1991b) and since demonstrated in CJD families in Hungary, Netherlands, Canada, Finland, France and UK. In the large Finnish kindred the mean onset was 47 and duration 27.5 months. Neuropathology showed spongiform change without amyloid plaques. This mutation was also reported in two families with fatal familial insomnia (FFI) (Lugaresi *et al.*, 1986; Medori *et al.*, 1992a). The first cases described had a rapidly progressive disease characterized clinically by untreatable insomnia, dysautonomia and motor signs, and neuropathologically by selective atrophy of the anteroventral and mediodorsal thalamic nuclei. There was marked thalamic astrocytosis. Mild spongiform change was seen in some cases and protease-resistant PrP demonstrated, albeit weakly, by immunoblotting. Proteinase-K treatment of extracted

PrP^{Sc} from FFI cases has shown a different sized PrP band on western blots than PrP^{Sc} from CJD cases (Monari *et al.*, 1994) suggesting that FFI may be caused by a distinct prion strain type. In a recent study Goldfarb *et al.* (1992) reported that, in all the codon 178 families studied with a CJD-like disease, the codon 178 mutation was encoded on a valine 129 allele, while all FFI kindreds encoded the same codon 178 mutation on a methionine 129 allele and suggested that the genotype at codon 129 determines phenotype. Recently an inherited case with the E200K mutation, which is normally associated with a CJD-like phenotype, has been reported with an FFI phenotype (Chapman *et al.*, 1996). An Australian family has also been reported with the FFI genotype but in which affected family members have a range of phenotypes encompassing typical CJD, FFI and an autosomal dominant cerebellar ataxia-like illness (McLean *et al.*, 1997). CJD-like codon 178 cases have frequently transmitted to experimental animals while the FFI type did not transmit to laboratory primates (Brown *et al.*, 1994). However, transmission of FFI to mice has been reported (Collinge *et al.*, 1995a; Tateishi *et al.*, 1995).

- *PrP V180I*. This was identified in two Japanese patients with subacute dementia and myoclonus (Kitamoto *et al.*, 1993b). The period from onset to akinetic mutism was 6–10 months. No family history was noted. EEG did not show pseudoperiodic sharp wave activity. Neuropathological examination demonstrated spongiform change, neuronal loss and astrocytosis. Interestingly, one of the patients with PrP Ile 180 also had PrP Arg 232.
- *PrP T183A*. This was reported in a single Brazilian family with frontotemporal dementia of mean onset 45 years and duration 4 years (Nitrini *et al.*, 1997). Parkinsonian features were also present in some patients. Neuropathological examination revealed severe spongiform change and neuronal loss in deep cortical layers and putamen with little gliosis. PrP immunoreactivity was demonstrated in putamen and cerebellum.
- *PrP F198S*. This was described in a single large Indiana kindred. Neuropathologically, there are widespread Alzheimer-like neurofibrillary tangles in cortex and subcortical nuclei in addition to PrP amyloid plaques (Dlouhy *et al.*, 1992). There is an apparent codon 129 effect with this mutation, in that individuals who were heterozygous at codon 129 had a later age of onset than homozygotes.
- *PrP E200K*. This was first described in families with CJD. Affected individuals develop a rapidly progressive dementia with myoclonus and pyramidal, cerebellar or extrapyramidal signs and a duration of illness usually <12 months. The average age of onset is 55. Neuropathological features are typical of CJD; plaques are absent but PrP^{Sc} can be demonstrated by immunoblotting. In marked contrast to other inherited prion diseases, the EEG usually shows pseudoperiodic activity. This mutation accounts for the three ethnogeographic clusters of CJD (amongst Libyan

Jews and in regions of Slovakia and Chile; Goldfarb *et al.*, 1990; Hsiao *et al.*, 1991a; Brown *et al.*, 1992). Atypical forms have now been identified. Peripheral neuropathy can occur in this disease (Neufeld *et al.*, 1992). Elderly unaffected carriers of the mutation have been reported. Penetrance is age dependent and thought to approach 100 per cent by the age 80 (Chapman *et al.*, 1994). There also appears to be a separate UK focus for this inherited prion disease (Collinge *et al.*, 1993). The codon 129 genotype does not appear to affect age at onset of this disorder. Transmission to experimental animals has been demonstrated.

- *PrP R208H*. Although reported in a single patient with CJD, no details of the family history or phenotype are as yet published (Mastrianni *et al.*, 1995).
- *PrP V210I*. This was reported in a single case in France (Davies *et al.*, 1993) with a rapidly progressive dementia, cerebellar signs and myoclonus and age of onset of 63. EEG showed pseudoperiodic sharp wave activity. The clinical duration was 4 months and neuropathological examination showed spongiform change, neuronal loss and astrocytosis. No amyloid plaques were seen. Parents had died at ages of 60 and 66 without dementia. A sister with the mutation had died of colon cancer at age 67. It is possible that this mutation produces a very late onset disease or is incompletely penetrant.
- *PrP Q217R*. Reported to date only in a single Swedish family, the presentation is with dementia followed by gait ataxia, dysphagia and confusion (Hsiao *et al.*, 1992). As with inherited prion disease (PrP F198S) there are prominent neurofibrillary tangles.
- *PrP M232R*. First found on the opposite allele to V180I mutation in a Japanese patient with prion disease (Kitamoto *et al.*, 1993b), it was further demonstrated in two additional Japanese patients with progressive dementia, myoclonus and periodic synchronous discharges in the EEG but without an apparent family history of neurological disease. The mean duration of illness was 3 months. Neuropathology showed spongiform change, neuronal loss and astrocytosis. PrP immunostaining revealed diffuse grey matter staining, but no plaques.

2. Insertional mutations

- *PrP 24bp insertion (one extra repeat)*. Reported in a single French individual, the patient presented at age 73 with dizziness followed by visual agnosia, cerebellar ataxia and intellectual impairment with diffuse periodic activity on EEG. Myoclonus and cortical blindness developed and he progressed to akinetic mutism. Disease duration was 4 months. The patient's father had died at age 70 from an undiagnosed neurological disorder. No neuropathological information is available.
- *PrP 48bp insertion (two extra repeats)*. Reported in a single US family (Goldfarb *et al.*, 1993), the proband had a CJD-like phenotype both clinically and pathologically with a typical EEG and an age at onset of 58. However,

the proband's mother had onset of cognitive decline at age 75 with a slow progression to a severe dementia over 13 years. The maternal grandfather had a similar late onset (at age 80) and slow progressive cognitive decline over 15 years.

- *PrP 96bp insertion (four extra repeats)*. This was first reported in an individual who died aged 63 of hepatic cirrhosis (Goldfarb *et al.*, 1991a) with no history of neurological illness, but it is unclear if this finding indicates incomplete penetrance of this mutation. This is the only recorded case of a PRNP insertional mutation other than in an affected or an at-risk individual. Two separate four octapeptide repeat insertional mutations have been reported in affected individuals, each differing in the DNA sequence from the original four repeat insertion, although all three of the mutations encode the same PrP. Laplanche *et al.* reported a 96bp insertion in an 82-year-old French woman who developed progressive depression and behavioural changes (Laplanche *et al.*, 1995). She progressed over 3 months to akinetic mutism with pyramidal signs and myoclonus. EEG showed pseudoperiodic complexes. Duration of illness was 4 months. There was no known family history of neurological illness. Another 96bp insertional mutation was seen in a patient with classical clinical and pathological features of CJD with the exception of the unusual finding of pronounced PrP immunoreactivity in the molecular layer of the cerebellum (Campbell *et al.*, 1996).
 - *PrP 120bp insertion (five extra repeats)*. This was reported in a US family with an illness characterized by progressive dementia, abnormal behaviour, cerebellar signs, tremor, rigidity, hyperreflexia and myoclonus. The age at onset was 31–45 with a clinical duration of 5–15 years (Goldfarb *et al.*, 1991a). EEG showed diffuse slowing only. Histological features were of spongiosis, neuronal loss and gliosis. Transmission has been demonstrated.
 - *PrP 144bp insertion (six extra repeats)*. This was the first PrP mutation to be reported in a small UK family with familial CJD (Owen *et al.*, 1989). The diagnosis in the family had been based on an individual who died in the 1940s with a rapidly progressive illness characteristic of CJD (Meyer *et al.*, 1954). Pathologically there was gross status spongiosis and astrocytosis affecting the entire cerebral cortex. However, other family members had a much longer duration GSS-like illness. Histological features were also extremely variable. This observation led to screening of various case of neurodegenerative disease and to the identification of a case classified on clinical grounds as familial Alzheimer's disease (Collinge *et al.*, 1989). More extensive screening work identified further families with the same mutation, who were then demonstrated by genealogical studies to form part of an extremely large kindred (Collinge *et al.*, 1992; Poulter *et al.*, 1992). Clinical information has been collected on
- around 50 affected individuals over seven generations. Affected individuals develop in the third to fourth decade onset of a progressive dementia associated with a varying combination of cerebellar ataxia and dysarthria, pyramidal signs, myoclonus and occasionally extrapyramidal signs, chorea and seizures. The dementia is often preceded by depression and aggressive behaviour. A number of cases have a long-standing personality disorder, characterized by aggression, irritability, antisocial and criminal activity, and hypersexuality, which may be present from early childhood, long before overt neurodegenerative disease develops. The histological features vary from those of classical spongiform encephalopathy (with or without PrP amyloid plaques) to cases lacking any specific features of these conditions (Collinge *et al.*, 1990). Age at onset in this condition can be predicted according to genotype at polymorphic codon 129. Since this pathogenic insertional mutation occurs on a methionine 129 PrP allele, there are two possible codon 129 genotypes for affected individuals, methionine 129 homozygotes or methionine 129/valine 129 heterozygotes. Heterozygotes have an age at onset that is about a decade later than homozygotes (Poulter *et al.*, 1992). Limited transmission studies to marmosets were unsuccessful. Transmission to transgenic mice expressing human prion protein has been achieved (Collinge *et al.*, in preparation). Further families with 144bp insertions, of different nucleotide sequence, have now been reported in the UK (Nicholl *et al.*, 1995) and Japan (Oda *et al.*, 1995).
- *PrP 168bp insertion (seven extra repeats)*. This has been reported in a US family. Clinical features were mood change, abnormal behaviour, confusion, aphasia, cerebellar signs, involuntary movements, rigidity, dementia and myoclonus. The age at onset was 23–35 years and the clinical duration 10 to over 13 years. The EEG was atypical. Neuropathology showed spongiform change, neuronal loss and gliosis to varying degrees (Goldfarb *et al.*, 1991a). Experimental transmission has been demonstrated.
 - *PrP 192bp insertion (eight extra repeats)*. Reported in a French family with clinical features including abnormal behaviour, cerebellar signs, mutism, pyramidal signs, myoclonus, tremor, intellectual slowing and seizures, the disease duration ranged from 3 months to 13 years. The EEG findings include diffuse slowing, slow wave burst suppression and periodic triphasic complexes. Neuropathological examination revealed spongiform change, neuronal loss, gliosis and multicentric plaques in the cerebellum (Goldfarb *et al.*, 1991a; Guioy *et al.*, 1993). Experimental transmission has been reported.
 - *PrP 216bp insertion (nine extra repeats)*. This was first reported in a single case from the UK (Owen *et al.*, 1992). The clinical onset was around 54 years with falls, axial rigidity, myoclonic jerks and progressive

dementia. Although there was no clear family history of a similar illness, the mother had died at age 53 with a cerebrovascular event. The maternal grandmother had died at age 79 with senile dementia. EEG was atypical. Neuropathological examination showed no spongiform encephalopathy but marked deposition of plaques, which in the cerebellum and the basal ganglia showed immunoreactivity with PrP antisera (Duchen *et al.*, 1993). In the hippocampus there were neuritic plaques positive for both β -amyloid protein and tau. Some neurofibrillary tangles were also seen. In some respects therefore the pathology resembled Alzheimer's disease. Experimental transmission studies have not been attempted. A second, German, family with a nine octapeptide repeat insertion of different sequence has also been reported (Krasemann *et al.*, 1995).

- *PrP 48bp deletion.* While deletion of a single octapeptide repeat element is a well recognized polymorphic variant of human PrP (with a frequency of around 1 per cent in the UK population), which does not appear to be associated with disease (Palmer *et al.*, 1993), a two repeat deletion has been described in two individuals with CJD (Beck *et al.*, 2001; Capellari *et al.*, 2002).

63.2.4.3 GENETIC COUNSELLING AND PRESYMPTOMATIC TESTING

PRNP analysis allows unequivocal diagnosis in patients with inherited prion disease. This has also allowed presymptomatic testing of unaffected, but at-risk, family members, as well as antenatal testing following appropriate genetic counselling (Collinge *et al.*, 1991b). The effect of codon 129 genotype on the age of onset of disease associated with some mutations also means it is possible to determine within a family whether a carrier of a mutation will have an early or late onset of disease. Most of the well-recognized pathogenic PRNP mutations appear fully penetrant; however, experience with some mutations is extremely limited. In families with the E200K mutation there are examples of elderly unaffected gene carriers who appear to have escaped the disease.

63.2.4.4 SECONDARY PROPHYLAXIS AFTER ACCIDENTAL EXPOSURE

Certain occupational groups are at risk of exposure to human prions, for instance neurosurgeons and other operating theatre staff, pathologists and morticians, histology technicians, as well as an increasing number of laboratory workers. Because of the prolonged incubation periods to prions following administration to sites other than the central nervous system (CNS), which is associated with clinically silent prion replication in the lymphoreticular tissue (Aguzzi, 1997), treatments inhibiting prion replication in lymphoid organs may represent a viable strategy for rational secondary prophylaxis after accidental exposure. A preliminary suggested regimen is a short course of immunosuppression with oral

corticosteroids in individuals with significant accidental exposure to human prions (Aguzzi and Collinge, 1997). Urgent surgical excision of the inoculum might also be considered in exceptional circumstances. There is hope that progress in the understanding of the peripheral pathogenesis will identify the precise cell types and molecules involved in colonization of the organism by prions. The ultimate goal will be to target the rate-limiting steps in prion spread with much more focused pharmacological approaches, which may eventually prove useful in preventing disease even after iatrogenic and alimentary exposure (Collinge and Hawke, 1998). A proof of principle of immunoprophylaxis by passive immunization using anti-PrP monoclonals has already been demonstrated in mouse models (White *et al.*, 2003).

63.2.4.5 PROGNOSIS AND POSSIBLE THERAPIES

All known forms of prion diseases are invariably fatal following a relentlessly progressive course and there is no effective therapy. The duration of illness in sporadic patients is very short with a mean duration of 3–4 months. However, in some of the inherited cases the duration can be 20 years or more (Collinge *et al.*, 1990). Symptomatic treatment of various neurological and psychiatric features can be provided and a range of supportive services are likely to be required in the later stages of the disease (see UK National Prion Clinic website for factsheets and specialist advice: <http://www.nationalprionclinic.org>).

While no effective treatment for the human disease is known, several drugs are currently being studied in patients. In the UK, a clinical trial protocol for evaluation of potential CJD therapeutics has been developed and is designated the MRC PRION-1 trial (<http://www.ctu.mrc.ac.uk/studies/cjd.asp>). Currently the drug quinacrine is being evaluated. Current agents are unlikely to stop prion propagation and may at best be expected to delay disease progression. Clearly, advances towards early diagnosis, to allow therapies to be used prior to extensive neuronal loss, will be important. While the challenge of interrupting this aggressive, non-focal and uniformly fatal neurodegenerative process is daunting, major advances are being made in understanding the basic processes of prion propagation and neurotoxicity. Considerable optimism is provided by the recent finding that onset of clinical disease in established neuroinvasive prion infection in a mouse model can be halted and indeed early pathology reversed (Mallucci *et al.*, 2003). A number of approaches to rational therapeutics are being studied in experimental models. Anti-PrP antibodies have been shown to block progression of peripheral prion propagation in mouse models and humanized versions of these antibodies could in principle be developed and used for both post-exposure prophylaxis or during established clinical disease. In the longer term, the development of drugs that selectively bind PrP^{Sc} or which bind to PrP^C to inhibit its conversion might be able to block prion propagation and allow natural clearance mechanisms to eradicate remaining PrP^{Sc} and so cure prion infection.

The latest reports indicate that since the beginning of 1980s, 60 million people have been infected with HIV (UNAIDS-WHO, 2001). Today, in certain parts of the world such as Sub-Saharan Africa, it is the leading cause of death amongst its population. In 1983 the Centers for Disease Control (CDC) issued the first classification of acquired immunodeficiency syndrome (AIDS), which was then revised in 1987 (CDC, 1987) and again in 1993 (MMWR). The 1983 and 1987 classifications were clinical symptom based, consisting of four groups of disorders:

- *Group I:* Acute infection (seroconversion)
- *Group II:* Asymptomatic infection
- *Group III:* Persistent generalized lymphadenopathy
- *Group IV:* with subgroups:
 - (A) constitutional disease with fever, weight loss, fatigue and night sweats
 - (B) neurological disease
 - (C) secondary infectious diseases
 - (D) secondary cancers
 - (E) other conditions.

In 1993 a second classification revision was accepted, which incorporated laboratory data and symptom-based classification as two parallel categories to rate the affected individual's condition (Table 64.1). The laboratory category is the CD4+ lymphocyte counts; this is the primary cell infected and destroyed by HIV and it is the loss of this population that results in severe immune suppression. For example, a person categorized as A3 will be clinically asymptomatic but has marked immunosuppression. The clinical

Table 64.1 Classification of AIDS (1993), using a combination of clinical features and laboratory investigations

Clinical features	Laboratory CD4+ counts (cells/mL)
Group A: asymptomatic	Group 1: 501–1000
Group B: constitutional symptoms	Group 2: 201–500
Group C: AIDS indicator illnesses	Group 3: <200

groups are progressive in that one proceeds from A through to C, but not back again. Thus, the category A3 means that this individual has never experienced any clinical symptoms. Since the mid-1990s the term HIV disease has tended to replace the term AIDS, which does not occur so frequently now that antiretroviral treatment is available.

Apart from CD4+ cells, the brain is a major target of infection resulting in cognitive dysfunction. The most severe neuropsychiatric manifestation is HIV dementia. In the last decade there has been significant progress in clarifying the brain pathology, clinical features, and more recently therapeutic strategies of this dementia. This chapter will cover these issues, including clarification of the range of brain pathology, correlation of which pathological events results in cognitive impairments, description of the clinical features and investigations, and finally the current treatment options for HIV dementia. This chapter will not address the secondary HIV-associated brain disorders that include opportunistic infections and neoplasms, which have been reviewed elsewhere (Everall and Lantos, 1991).

64.1 NEUROPATHOLOGICAL ABNORMALITIES ASSOCIATED WITH HIV

Since the mid-1980s a variety of virological, neuropathological and neuroscientific investigations have attempted to address: the characteristic features of the virus mediating cellular entry, the mechanism and timing of viral brain entry, which brain resident cells does HIV infect and replicate in, the spectrum of HIV-associated brain damage, the mechanism of neurotoxicity, and finally the relationship between this damage and the clinical onset of HIV-associated cognitive impairments. These will be discussed below.

64.1.1 Characteristics of HIV and the mechanism of cellular entry

HIV is a retrovirus and contains a single-stranded RNA genome with an RNA-dependent DNA polymerase, reverse transcriptase. When the viral genome enters the cell the reverse transcriptase synthesizes a double-stranded viral DNA copy. The DNA can remain unintegrated in the cytoplasm or enter the nucleus and become integrated with the host genome, a so-called provirus, which can replicate along with the host chromosomal DNA. The molecular structure of the HIV genome includes genes coding for structural, enzymatic and regulatory functions. The *env* gene codes for structural proteins of the viral envelope, such as gp120 and gp41. Gag codes for core structural viral proteins including matrix (p17), capsid (p24, p9 and p6). The enzymatic proteins are coded by the *pol* gene, and include reverse transcriptase, RNAase H, integrase and protease. The regulatory genes are *tat*, *nef*, *rev*, *vif*, *vpr* and *vpu* and their functions are gradually being elucidated. They are known to enhance every step of viral replication, including the early events of viral cellular entry, reverse transcription, nuclear transport and establishment of the provirus; or during the later events of provirus regulation during transcription, viral polyprotein processing and transport, and finally virion release and infectivity. Regulation of replication is also influenced by host factors such as cytokines and transcription factors. The regulation of viral replication is reviewed by Stevenson and O'Brien (1998).

HIV predominantly infects either CD4+ T lymphocytes or mononuclear phagocytes such as circulating monocytes or tissue macrophages. The ability to replicate in macrophages is due to genetic heterogeneity, which is greatest in the *env* gene (Hahn *et al.*, 1986; Koyanagi *et al.*, 1987; Saag *et al.*, 1988; Hwang *et al.*, 1991; Westervelt *et al.*, 1991). The cellular determinant of viral entry are the expression of an appropriate cell surface receptor. Thus, for lymphocytic strains, cell entry is mediated by not only binding to the CD4+ receptor but also to a coreceptor, CXCR-4. By comparison in monocyte-/macrophage-tropic strains the β -chemokine receptors, such as CCR-1, CCR-3 and CCR-5, are important cell receptors. These chemokine receptors are known to selectively act as coreceptors to CD4 to mediate HIV binding and entry (Dimitrov,

1997). Broadly speaking the ability to use either CXCR4 or CCR5 defines the tropism of the HIV strain, i.e. lymphocyte or macrophage tropic respectively. In the brain, microglia and macrophages, neurones and astrocytes all possess chemokine receptors. CXCR-4 is expressed by neurones and microglia (Lavi *et al.*, 1997), as well as reactive astrocytes (Miller and Meucci, 1999). CCR-1 has been reported in astrocytes, CCR-3 in microglia and CCR-5 in both microglia and neurones (Miller and Meucci, 1999). He *et al.* (1997) reported that both CCR3 and CCR5 are important for microglia infection, Ghorpade *et al.* (1998) found an essential role for only CCR5, while Shieh *et al.* (1998) observed that CCR5 was used for macrophage entry but failed to replicate the use of either CCR3 or CCR5 receptors for microglial infection. During recent years, a vast number of chemokine receptors have been discovered and the involvement of chemokine receptors in HIV is still being pursued. Attempts have also been made to identify viral features that would predict neurotropism. This is the property that facilitates entry into the nervous system. It has been suggested that the development of neurotropism is thought to be linked to alterations in the envelope glycoprotein gp120 (Cordonnier *et al.*, 1989; Power *et al.*, 1994; DiStefano *et al.*, 1998). To date the results have been intriguing but inconsistent; thus, the notion of a readily identifiable neurotropic strain has not been substantiated.

64.1.2 The timing of viral brain entry

HIV antigen and antibody (Ho *et al.*, 1985) can be identified in the cerebrospinal fluid during seroconversion but it remains unclear whether this represents a limited meningeal infection or indicative of widespread invasion of the central nervous system (CNS). Limited meningeal infection is most likely in the vast majority of individuals. Only a few isolated case reports have highlighted approximately three individuals who had documented fatal illnesses during seroconversion (for review see Gray *et al.*, 1996). Following seroconversion there is a prolonged and variable time interval of asymptomatic infection. Examination of the brain during this period is rare, unless an individual dies of an unrelated cause. The few studies on asymptotically infected individuals revealed only occasional detectable proviral DNA (Sinclair and Scaravilli, 1992; Donaldson *et al.*, 1994). As the duration of HIV infection was not known, it is possible that where proviral DNA was found the individuals may have had more advanced infection and more likely to develop HIV disease in the near future if they had lived.

In order to gain entry to the brain the virus has to cross the blood-brain barrier (BBB). It is widely believed that it does this through the systemic circulation either as cell-free virus, or through infected monocytes, macrophages or lymphocytes or through the choroid plexus (Kalams and Walker, 1995; Nottet *et al.*, 1996). The existence of the BBB and the low level of expression of major histocompatibility complex (MHC) molecules on cells within the brain, has led to the view that

the brain is an immunologically privileged site. However, in HIV infection and other inflammatory diseases inducible, adhesion molecules, selectins, chemokines and cytokines are expressed by the immune system and BBB, which promote adhesion of immune cells to endothelial cells and then transmigration across the BBB.

64.1.3 Cellular localization of HIV in the brain

Demonstration of the virus within cells can be performed by detecting HIV DNA, messenger RNA (mRNA), or viral protein. Immunohistochemistry of viral proteins has demonstrated that macrophages, microglia and multinucleated giant cells are the major cellular reservoirs of HIV in the brain (Koenig *et al.*, 1986; Wiley *et al.*, 1986). However, recent application of *in situ* polymerase chain reaction (PCR) and reverse transcriptase-PCR has provided evidence that the DNA and RNA may be present in a wider variety of cell types, including oligodendrocytes (Albright *et al.*, 1996) and even neurones (Nuovo *et al.*, 1994; Bagasra *et al.*, 1996). Evidence for a 'restrictive infection' in astrocytes is now emerging (Canki *et al.*, 2001; Galey *et al.*, 2003) in which regulatory proteins such as nef are produced (Saito *et al.*, 1994). However, full replication of structural HIV proteins is absent. So, while there is evidence of HIV DNA and RNA in a wide population of brain cells, full replicative infection only occurs in microglia, macrophages and multinucleated giant cells.

64.1.4 Primary neuropathological damage associated with HIV

This is a consequence of HIV brain infection, and is distinct from the myriad of opportunistic infections and neoplasms that can arise secondarily to immune compromise (for review see Cohen and Berger, 1998). The primary damage consists of a range of neuropathologically recognized disorders, dendritic and synaptic damage, and neuronal loss. These can occur together, and are pathological phenomena, which can only be diagnosed by examination of the brain. The development of these events does not necessarily imply onset of clinical symptoms (Price *et al.*, 1991). These disorders will be considered below.

64.1.4.1 NEUROPATHOLOGICALLY RECOGNIZED DISORDERS

These disorders are discrete inflammatory and degenerative disorders (Budka, 1991), whose frequencies are derived from several autopsy series from various European and North and South American countries (Budka, 1998; Table 64.2). These disorders are summarized below.

- *HIV encephalitis (HIVE)*. This is characterized histologically by inflammatory foci of microglia, macrophages and multinucleated giant cells. The latter are the histological hallmark of HIVE. These tend to be

Table 64.2 *HIV-related brain pathology, and their observed frequencies in several studies (data from Budka, 1998)*

Type of lesion	Frequency in several series (%)
HIV-specific lesions	21.5
HIV encephalitis (HIVE)	16
HIV leukoencephalopathy (HIVL)	12
HIVE combined with HIVL	14
HIV meningoventriculoencephalitis	0.6
HIV-associated lesions	46
Diffuse poliodystrophy (DPD)	44
Lymphocytic meningitis	4
Multifocal vacuolar leukoencephalopathy	1
Vacuolar myelopathy	8

widely distributed throughout the brain but may be more common in the deep grey structures (basal ganglia and thalamus), as well as the cortical white matter (Budka, 1991). Viral proteins can often be demonstrated. The clinical consequence of developing HIVE is not clear and potential clinicopathological correlations will be discussed in Section 64.3 (p. 781). Recently, Davies *et al.* (1998) examined the neuropathological findings of 1144 brains collected over a 10-year period from six centres throughout Europe and the United States. HIVE comprised 26 per cent of the overall observed pathology, which is similar to the 16 per cent estimated by Budka (1998). However, the frequency varied between centres, from 13 to 44 per cent, and between those cases collected before and after 1988. This date was the approximate general introduction date for zidovudine, after which the rate of HIVE declined. This has also been reported by Gray *et al.* (1994). In a UK national neuroepidemiological survey, Davies *et al.* (1997) similarly revealed that the frequency of HIVE was 25 per cent but, more importantly, that it varied among risk groups, with intravenous drug users having a rate over 50 per cent. This indicated that brain pathology can be influenced by risk group.

- *HIV leukoencephalopathy (HIVL)*. In this disorder there is diffuse damage to the white matter with myelin loss, reactive astrocytosis, macrophages and multinucleated giant cells (Kleihues *et al.*, 1985). The white matter is usually affected symmetrically and the cerebellar white matter can also be affected. In addition to the myelin damage axonal shrinkage has also been reported (Kaus *et al.*, 1991). While HIVE and HIVL are presented as two distinct entities they have inflammatory features in common and may represent a spectrum disorder. A rare variant of the leukoencephalopathy has been noted with numerous vacuolar myelin swellings and macrophages. This is called *vacuolar leukoencephalopathy*. Recently, a severe form of HIVL has been described by Langford *et al.* (2002) in AIDS patients who had undergone antiretroviral therapy prior to death. This may indicate

the identification of a new form of neuropathology since the introduction of highly active antiretroviral therapy (HAART).

- *Diffuse poliodystrophy*. This refers to a picture diffuse reactive astrocytosis, gliosis, microglial activation and presumed neuronal loss in the grey matter of the cortex, basal ganglia and brain stem (Budka, 1990).
- *Lymphocytic meningitis*. The leptomeninges, including the perivascular spaces are infiltrated with lymphocytes. No opportunistic pathogens are ever identified, and clinically this is presumed to be associated with the aseptic meningitis that can occur during primary systemic infection.
- *Cerebral vasculitis*. Blood vessel walls are infiltrated with multinucleated giant cells and lymphocytes. There may be accompanying necrosis, and so clinically this may produce focal neurological deficits. Vascular lesions are more common in those with haemophilia (Davies *et al.*, 1997).

64.1.4.2 NEURONAL INJURY AND LOSS

This consists of the following:

- *Dendritic and synaptic damage*. There is significant dendritic and synaptic damage in the cortex of those who die of AIDS. There is a significant 10–40 per cent decrease in the microscopic area occupied by microtubule-associated protein-2 (MAP2) immunolabeled dendrites (Masliah *et al.*, 1992a), a decrease in the complexity of synaptophysin-immunoreactive presynaptic terminals (Wiley *et al.*, 1991; Masliah *et al.*, 1992a, 1996a), and a notable dendritic simplification with decreased dendritic length and loss of spines (Masliah *et al.*, 1992b). Ultrastructurally, there is dendritic vacuolization with disruption of the neuritic endomembrane system (Wiley *et al.*, 1991). The extent of dendritic and synaptic damage is closely correlated with the amount of envelope viral protein, gp41, in the brain (Masliah *et al.*, 1992a, 1997; Everall *et al.*, 1998). A transgenic mouse model over-expressing the HIV envelope protein gp120 (Toggas *et al.*, 1994) has similar dendritic alterations to those observed in HIV encephalitis. This indicates that active damage to synapses is a primary pathogenic event of this disorder, and that gp120 is involved in this process (Masliah *et al.*, 1996a, b).
- *Neuronal loss*. While the majority of neuronal loss studies have been on those who died of AIDS, a stereological study of a previously described French series of individuals who died while asymptotically infected (Gray *et al.*, 1993) did not reveal neuronal loss (Everall *et al.*, 1992). This is consistent with the observation that there are low levels of provirus found in some but not all asymptomatic brains, compared with the high levels of provirus reported in brains from those who died of AIDS (Donaldson *et al.*, 1994; Sinclair *et al.*, 1994). In contrast,

those who died of AIDS have significant cortical neuronal loss, which disproportionately affects larger pyramidal neurones (Ketzler *et al.*, 1990; Wiley *et al.*, 1991; Weis *et al.*, 1993; Asare *et al.*, 1996). The frontal cortex, with nearly 40 per cent decrease in neuronal number, is more greatly affected than other cortical areas (Everall *et al.*, 1991, 1993). There is degeneration of the striatocortical, corticocortical and limbic intrinsic/inhibitory circuitries (Masliah *et al.*, 1996a, b). Neocortical width is reduced by approximately 20 per cent (Wiley *et al.*, 1991), and mean neuronal volume was also altered in the regions with the most marked neuronal loss (Everall *et al.*, 1993). Loss has also been observed in extracortical regions, including the putamen, globus pallidus and hippocampus (Spargo *et al.*, 1993; Masliah *et al.*, 1995, 1996a), substantia nigra (Reyes *et al.*, 1991), and cerebellum (Grauss *et al.*, 1990). These observations suggest that neuronal loss develops during symptomatic disease when viral load is increased.

64.2 POTENTIAL MECHANISM OF HIV-ASSOCIATED NEURONAL INJURY AND LOSS

There is evidence that the mechanism of neuronal damage and clinical onset of cognitive impairment probably involves two main groups of potential pathogenic factors: *viral proteins* and *cytokines*.

64.2.1 Viral proteins

A variety of the HIV proteins have been shown to be neurotoxic. The envelope glycoprotein gp120 causes a toxic calcium influx by stimulating the glutamate *N*-methyl-D-aspartate (NMDA) receptors (Dreyer *et al.*, 1990), which *in vitro* results in cell death (Brenneman *et al.*, 1988). This can be prevented by applying either calcium channel antagonists (e.g. nimodipine) or NMDA antagonists (e.g. MK801 or memantine). Similarly, the viral regulatory protein tat affects membrane permeability causes depolarization (Sabatier *et al.*, 1991), and stimulates the α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate receptors. AMPA receptors are decreased in AIDS (Everall *et al.*, 1995). Interactions with the cellular surface of ion channels have been demonstrated for the envelope protein gp41 (Werner *et al.*, 1991) and the regulatory protein nef has recently been shown to be neurotoxic (Trillo-Pazos *et al.*, 1998).

64.2.2 Cytokines

A wide range of cytokines are involved in the immunological response to inflammatory disease. Microglia and macrophages are capable, for example, of producing tumour necrosis factor

(TNF)- α , interleukin-1 (IL-1) and transforming growth factor β (TGF- β ; Wahl *et al.*, 1991; Tyor *et al.*, 1992). Both gp120 and gp41 are able to induce cytokine production, especially TNF- α and IL-1 β (Merrill and Chen, 1991). A number of other cytokines have been demonstrated to be produced when HIV is present. Importantly, cytokines (TNF- α and IL-1 β) activate gene expression and so induce productive infection (Swingler *et al.*, 1992). Thus, a positive cycle is set up with viral products inducing cytokines, which in turn induce viral replication and therefore increase the viral load in the brain. In addition TNF- α can activate programmed cell death, also called apoptosis. Other cytokines that have been implicated are TGF- β , produced by mononuclear cells and found in areas of tissue pathology (Wahl *et al.*, 1991) and IL-6 which affects HIV expression (Tesmer *et al.*, 1993). Another cytokine CD23 expressed by astrocytes was found extensively in HIV brains and additionally involved in the activation of nitric oxide pathway and IL-1 β (Dugas *et al.*, 2001).

64.2.3 Other potential factors

In the HIV-infected brain both the gp120-mediated NMDA-activated calcium influx and the excess cytokines can induce oxidative stress. For example, glutamate receptor activation can stimulate nitric oxide synthase production of nitric oxide (Dawson *et al.*, 1994), and cytokines can induce macrophages and microglia to produce nitric oxide in more prolonged bursts. Nitric oxide and superoxide radicals produce the peroxynitrite radical, resulting in lipid peroxidation and demyelination. Brain antioxidant mechanisms include glutathione peroxidase, superoxide dismutase, ascorbic acid, vitamin E and glutathione. However, the brain is still susceptible to oxidative damage (Floyd and Carney, 1992), which is exacerbated by a 60 per cent reduction in the levels of ascorbic acid in the frontal cortex in HIV disease (Everall *et al.*, 1997). Platelet-activating factor (PAF) and arachidonic acid may also contribute to the pathogenic mechanism (reviewed by Griffin, 1998). PAF receptors in the nervous system are present at synapses, and PAF's effects include upregulation of TNF- α synthesis, release of glutamate, increases in intracellular calcium and death of neurones in tissue culture.

64.3 CORRELATION OF PRIMARY NEUROPATHOLOGICAL DAMAGE WITH ONSET OF HIV-RELATED COGNITIVE DISORDERS AND DEMENTIA

The pathogenesis of HIV-related cognitive impairments is not clear. When HIV was first recognized it was thought that this may underlie cognitive deficits. However, Glass *et al.* (1993) found that less than 50 per cent of cases with known HIV-associated dementia during life had HIV. In fact multinucleated giant cells, which are regarded as the histological hallmark of HIV are poor indicators for dementia. The number of

macrophages and microglia correlate more closely with cognitive abnormalities (Glass *et al.*, 1993, 1995). *In vitro* soluble factors secreted from peripheral blood macrophages of individuals with HIV dementia are far more toxic than those from symptom-free or uninfected individuals (Pulliam *et al.*, 1996). These observations support the notion that macrophages and microglia are the site of toxin production resulting in neuronal damage and death.

Subtle cognitive impairments are accompanied by dendritic and synaptic damage, and this damage is also related to rising brain viral load (Masliah *et al.*, 1997; Everall *et al.*, 1998). In those who are developing dementia the severity correlates with particular neuronal populations. In mild HIV-associated dementia there is loss affecting large pyramidal neurones, and in those who have progressed to severe dementia the loss also affects small interneurones (Asare *et al.*, 1996). The relationship between cognitive impairments and selective neuronal damage and loss provides insight into the pathogenic mechanism. The pyramidal neurones are likely to bear glutamate receptors and have low levels of calcium-binding proteins (Everall *et al.*, 1995; Masliah *et al.*, 1995), while the interneurones often express cytokines receptors (Masliah *et al.*, 1996a) and high levels of calcium-binding proteins (Masliah *et al.*, 1995). There is a significant decrease in the calcium-binding protein calbindin-immunoreactive pyramidal neurones and interneurones in the neocortex, which correlates with viral burden, while calbindin-positive neurones in the basal ganglia and hippocampus are unaffected (Masliah *et al.*, 1995). Similarly, neocortical parvalbumin containing interneurones are not lost, while those in CA3 region of the hippocampus showed marked loss (Masliah *et al.*, 1992c). In the basal ganglia, the calbindin-positive cells that appear to be resistant to neurodegeneration are gamma-aminobutyric acid (GABA) containing spiny cells (Wilson, 1990). These regional differences in the patterns of selective damage to neurones in the HIV-infected brain suggest different pathogenic mechanisms may be operating. In the neocortex neurones may be more vulnerable to HIV-1-mediated damage, e.g. gp120, tat etc., while in the hippocampus and basal ganglia cytokines might play a significant role.

There is indirect evidence to support the role of viral proteins in the pathogenesis of HIV-associated dementia. Gp120 administered to neonatal rats causes cognitive and motor impairments, and pathologically dystrophic dendritic changes of pyramidal neurones in all cortical areas and the development of behavioural retardation (Hill *et al.*, 1993). In the cerebrospinal fluid of patients with AIDS and cognitive and motor abnormalities there are elevated levels of quinolinic acid (Heyes *et al.*, 1991), an endogenous NMDA agonist, suggesting it is involved in excitotoxic-mediated neuronal damage.

64.4 CLINICAL FEATURES OF HIV-ASSOCIATED COGNITIVE IMPAIRMENTS

A variety of cognitive impairments can occur in HIV-infected individuals. They can be classified as follows (for review see

Box 64.1 *HIV-1 minor cognitive motor disorder (MCMD)*
(data from American Academy of Neurology AIDS Taskforce, 1991)

Probable – must have each of the following:

1. Acquired cognitive/motor/behavioural abnormalities, verified by clinical history, neurological and neuropsychological examination
2. Mild impairment of ability to work or other activities of daily living
3. Not of sufficient degree to meet the criteria for HIV dementia or HIV myelopathy
4. No other aetiology

Possible – must have one of the following:

1. Conditions 1, 2 and 3 above are present but an alternative aetiology is present and the cause of condition 1 is not certain
2. Conditions 1, 2 and 3 above are present but the aetiology of condition 1 cannot be determined because of incomplete clinical evaluation

McArthur and Grant, 1998):

- *Neuropsychological deficit*. There is an abnormality on one cognitive domain during neuropsychological testing.
- *Neuropsychological impairment (NPI)*. Here an individual has underperformed on two or more cognitive domains during neuropsychological testing.
- *HIV minor cognitive/motor disorder (MCMD)*. This differs from the previous two categories in that the neurocognitive impairment is sufficient to affect day-to-day functioning at least in a mild degree. Confusingly, there are currently two sets of criteria for the diagnosis of MCMD. The American Academy of Neurology AIDS Taskforce (1991) developed the first criteria to recognize the disorder (Box 64.1), while the latter by Grant and Atkinson (1995) has a more detailed specification (Box 64.2).
- *HIV dementia*. There is marked cognitive impairment of sufficient degree to interfere markedly with activities of daily living.

64.4.1 Stage of onset of cognitive impairment

There have been various studies investigating when cognitive impairment or the more disabling dementia occur. However, study design has varied between investigations, which has hampered comparisons. White *et al.* (1995) reviewed 57 neuropsychological studies and summarized that 35 per cent of asymptotically infected individuals had neuropsychological impairment, compared with 12 per cent in seronegative controls, and concluded that the more detailed the test battery the more likely to find impairment. However, Heaton

Box 64.2 *HIV-1 associated mild neurocognitive disorder*
(data from Grant and Atkinson, 1995)

1. Acquired impairment in cognitive functioning, involving at least two ability domains in which the performance is at least 1 standard deviation below the mean for age-educated-appropriate norms on standardized neuropsychological tests. The neuropsychological assessment must survey at least the following abilities: verbal/language, attention/speeded processing, abstraction/executive, memory, complex perceptual-motor performance, motor skills
2. The cognitive impairment results in at least mild interference in daily functioning (at least on the following):
 - self-report of reduced mental acuity, inefficiency in work, homemaking or social functioning
 - observation by knowledgeable others that the individual has undergone at least mild decline in mental acuity, with resultant inefficiency in work, homemaking or social functioning
3. The cognitive impairment has been present for at least 1 month
4. The cognitive impairment does not meet criteria for delirium or dementia
5. There is no other pre-existing cause of the mild neurocognitive disorder

et al. (1994) showed that these preclinical abnormalities probably had a subtle effect on an individual's daily performance, as almost 27 per cent of those with neurocognitive abnormalities were unemployed compared with just under 10 per cent of asymptotically infected individuals without impairment.

It is unclear whether these impairments remain static or worsen over time. In the Multicentre AIDS Cohort Study (MACS) Sacktor *et al.* (1996) showed that transient changes in neuropsychological function were relatively frequent, whereas sustained abnormalities only affected 15 per cent of asymptomatic individuals. Newman *et al.* (1995), in a meta-analysis of neuropsychological studies, identified four previous longitudinal studies in which neurocognitive decline had been observed. The HIV Neurobehavioural Research Center (HNRC) showed that over a 1-year period 2 per cent of those who were cognitively normal had developed MCMD, while 11 per cent of those who had had previous neurocognitive impairment deteriorated to MCMD (McArthur and Grant, 1998). The HNRC data also revealed that a number of individuals with neuropsychological impairment improved: 47 per cent became cognitively normal, while of those with MCMD 36 per cent improved to only mild impairment and a further 21 per cent became cognitively normal. These observations highlight the fact that cognitive impairments are not necessarily permanent or progressive.

64.4.2 Diagnostic criteria for HIV dementia

As with other dementias, HIV dementia is primarily a disorder of cognition in which the functions involved in processing new information, recalling information, and being able to perform the activities of daily living are severely curtailed. Additionally, there may also be concurrent problems of motor function and behavioural problems including personality change. During the description and definition of this new disease, four classification systems have evolved, they are:

- AIDS dementia complex (ADC) – described by Navia *et al.* (1986);
- HIV-associated dementia complex (HAD) – formulated by the American AIDS Neurology Taskforce (1991);
- HIV dementia – defined by Grant and Atkinson (1995);
- HIV-1-associated dementia – defined by the World Health Organization (1990).

The first to be described was ADC by Navia *et al.* in 1986. Importantly, this classification described the dementia as a 'complex' thus recognizing the triad of cognitive, motor and behavioural features. The ADC system also provided a rating scale from mild to severe ADC (Box 64.3). However, there is apparently equal importance given to all three features, so theoretically an individual could be diagnosed as having severe ADC because of marked motor abnormalities, such as inability to walk or incontinence, and not because of cognitive changes (Catalan, 1991).

This potential problem may have provided the impetus for another classification system. The American AIDS Neurology Taskforce (1991) set forward operational criteria for HIV-1 Associated Dementia Complex (HAD). This system restated cognitive changes as the core feature. Prominent motor changes in the absence of cognitive changes are termed HIV myelopathy. Cognitive impairment was to be newly acquired,

Box 64.3 *Classification of AIDS dementia complex (data from Price and Brew, 1988)*

Stage 0 (Normal): Normal mental and motor function

Stage 0.5 (Subclinical): Minimal or equivocal neurocognitive symptoms without impairment of work or activities of daily living (ADL)

Stage 1 (Mild): Definite impairment present, but able to perform all, but the more demanding aspects of work or ADL

Stage 2 (Moderate): Unable to work, but can perform basic activities of self-care, ambulatory but may require some assistance

Stage 3 (Severe): Major intellectual or motor impairment, cannot follow commands or sustain complex conversation, unable to walk without support

Stage 4 (End-stage): Nearly vegetative, rudimentary intellectual function, nearly mute, paraplegic, incontinent

not constitutional, and they could not be explained by alternative aetiologies such as systemic illness, effects of medications or other drugs, or even other brain infections. Thus, it was highlighted that HAD was a diagnosis of exclusion. To this end a diagnosis of *possible* HAD could be applied if it was not possible to exclude other causes, because of incomplete clinical or investigative evaluation; or *probable* HAD if other causes were ruled out by clinical investigations (Box 64.4). The definitive diagnosis could only be confirmed if the brain itself could be examined microscopically, which is not possible during life. Grant and Atkinson (1995) have attempted to refine these operational criteria by stipulating the assessment of cognitive abnormalities.

The World Health Organization (1990) proposed the concept of HIV-1 associated dementia derived from the ICD-10 classification of dementia. This is reviewed by Catalan and Burgess (1996) who remark that this definition encompassed three broad areas. The first was the presence of recorded decline in memory and cognitive function for at least 1 month duration, the second was evidence of HIV-1 infection, and the third was the absence of other potential causes of the dementia. With these various classification systems in existence it would seem prudent to use those which offer the most consistent operational criteria for diagnosis of HIV dementia. The American Academy of Neurology AIDS Taskforce (1991) definition is gaining acceptance, as are the modifications

Box 64.4 *Classification of HIV associated dementia complex (data from American Academy of Neurology AIDS Taskforce, 1991)*

Probable – must have each of the following:

1. Acquired abnormality in two or more cognitive domains, which have been present for a minimum of 1 month's duration, AND cognitive dysfunction of sufficient degree to impair activities of daily living and/or ability to work. **N.B.** These symptoms must not be attributable to systemic illness or other factors
2. Acquired abnormality in motor function as verified by clinical examination and/or neuropsychological tests, AND/OR decline in motivation, emotional control or change in social behaviour
3. Absence of clouding of consciousness
4. Exclusion, by various clinical and laboratory investigations of other potential aetiological causes, e.g. opportunistic central nervous system infections or neoplasm, systemic illness, psychiatric illness, treatment side effects and substance misuse

Possible – must have one of the following:

1. Conditions 1, 2 and 3 above are present, but an alternative aetiology is present and so the actual cause of 1 is not clear
2. Conditions 1, 2 and 3 above are present, but the aetiology of 1 is not clear owing to an incomplete clinical and laboratory investigation

proposed by Grant and Atkinson (1995) based upon the work carried out by the HIV Neurobehavioural Research Center (Heaton *et al.*, 1995; Box 64.5).

The variety of motor and behavioural changes that can occur can be varied and progressive. Motor changes may start with minor alterations such as the patient becoming more clumsy, including being more likely to trip up while walking and dropping things, as well as deteriorating handwriting. More serious changes include difficulty walking without assistance and falling over, to loss of power in the legs, paraplegia, and urinary and faecal incontinence. Behavioural changes can also be varied and broadly include changes in behaviour and the person's previous personality. Thus, some may become socially withdrawn apathetic, talking less or even mute. In this situation the presence of *depression*, or other treatable psychiatric conditions must be excluded. Other individuals can become disinhibited resulting in behaviour that can put them in vulnerable and potentially dangerous situations. Such disinhibition can be accompanied with features seen in *mania* with elevated or irritable mood, grandiosity, pressure of speech, flight of ideas and inappropriate behaviour. It is now recognized that mania can be a presenting feature of HIV-associated dementia. However, this is not clear cut as those who have either a past personal or family history of manic illness may develop a coincidental manic illness. Those individuals without this history are more likely to be developing mania in the setting of dementia (Lyketsos *et al.*, 1993, 1997). It is beginning to be recognized that some individuals continue with a predominantly manic type illness that is often difficult to control. Whether HIV-related mania becomes

recognized as a discrete disorder will only become clear by future research.

64.4.3 Epidemiology of HIV dementia

As early as 1983, Snider *et al.* recognized that individuals with AIDS could develop frank cognitive deficits, a disorder that they labelled subacute encephalopathy. Navia *et al.* (1986) further described the clinical features, applied the term AIDS dementia complex, and also realized that the dementia can occur as a first presenting feature of AIDS (Navia *et al.*, 1987). It is now accepted that HIV dementia is very rare in those with asymptomatic HIV infection, affecting less than 1 per cent. In 3 per cent of those who develop AIDS, dementia is the first AIDS-defining illness. While those with symptomatic HIV disease have a prevalence of 7–10 per cent, and in those with advanced HIV disease (AIDS) this rises to 15–20 per cent (McArthur *et al.*, 1993). It has been reported that, when dementia develops in those with less advanced immunodeficiency, the course is less rapid than in those with advanced disease (Bouwman *et al.*, 1996). There is less consistency in reporting the incidence of HIV dementia. Day *et al.* (1992) observed an annual incidence of 14 per cent in symptomatically infected individuals, compared with 7 per cent by McArthur *et al.* (1993), and 9 per cent in a study from Edinburgh (Pretsell *et al.*, 1996). Dore *et al.* (1999) reported that, although AIDS dementia complex reduced with the introduction of HAART, the reduction was less marked compared with other AIDS-defining illnesses.

The incidence and prevalence of HIV dementia have been effected by the introduction of antiretroviral therapy. After the introduction of azidothymidine (AZT) a decline in the frequency of the dementia was reported (Portegies *et al.*, 1989; Chiesi *et al.*, 1990), while the MACS were not able to demonstrate a neuroprotective effect (Day *et al.*, 1992; McArthur *et al.*, 1993; Bacellar *et al.*, 1994). It is possible that this discrepancy is in part explained by a dose effect. Following its introduction AZT was used at a high dose of 1200–1500 mg/day, compared with the current daily dose of 500–600 mg. It is possible that this lower dose is suboptimal. However, this issue has now been complicated by the recent arrival within the last 2 years of the new generation of antiretroviral agents. The issue of treatment for HIV dementia will be discussed below. The introduction of HAART has resulted in a reduction of HIV-associated dementia; however, the prevalence rate is increasing as the number of HIV patients survive longer.

64.4.4 Risk factors for dementia

Wang *et al.* (1995) reported a higher risk of dementia in those of increasing age, following the diagnosis of AIDS, and intravenous drug use. Similarly data from the MACS (McArthur *et al.*, 1993) revealed several variables: lower haemoglobin up to 6 months prior to the onset of AIDS, lower body mass up to 6 months prior to the onset of AIDS, more constitutional

Box 64.5 HIV-1-associated dementia (data from Heaton *et al.*, 1995)

1. Marked acquired impairment in cognitive functioning, involving at least two ability domains (e.g. memory, attention): typically the impairment is in multiple domains, especially in learning of new information, slowed information processing, and defective attention/concentration. The cognitive impairment can be ascertained by history, mental status examination, or neuropsychological testing
2. The cognitive impairment produces marked interference with day-to-day functioning (work, home life, social activities)
3. The marked cognitive impairment has been present for at least 1 month. The pattern of cognitive impairment does not meet criteria for delirium (i.e. clouding of consciousness is not a prominent feature); or, if delirium is present, criteria for dementia had been met on a prior examination before delirium was present
4. There is no evidence of another pre-existing aetiology that could explain the dementia, e.g. CNS infection or neoplasm, cerebrovascular disease, coincidental neurological disease, substance misuse, etc.

symptoms up to 12 months before the onset of AIDS, and older age of onset of AIDS. However, specific AIDS indicator illnesses, use of AZT before AIDS, and CD4 count before AIDS were not significant indicators.

64.5 CLINICAL AND LABORATORY INVESTIGATION OF HIV DEMENTIA

As stated previously, HIV dementia is a diagnosis of exclusion, in which other potential aetiologies are ruled out. Typically, three groups of investigations can be performed: neuropsychological testing, neuroimaging, and examination of the CSF. These will be briefly outlined below.

64.5.1 Neuropsychological testing

This should be performed in conjunction with the neurological examination, and is useful in assessing both the severity and pattern of cognitive impairment. HIV dementia has the clinical features typical of a 'subcortical dementia' with abnormalities on information processing speed, motor speed, attentional set shifting and new information acquisition. By contrast the usual features of a 'cortical dementia', such as accelerated forgetting, intrusion errors, naming problems and constructional dyspraxia, are uncommon. It must be remembered that the division of 'subcortical' and 'cortical' dementias is descriptive of a constellation of clinical symptoms and does not mean that in the former there are no cortical neuropathological lesions and in the latter no subcortical pathology.

There is no correct approach to which battery of neuropsychological tests are performed. McArthur and Grant (1998) stated general guidelines that the tests should be sensitive to a wide range of impairments, robust to the effect of serial repetition, sensitive to known abnormalities in HIV dementia, and the length of the battery kept as short as is feasible. The confounding effects of age, years of education, and culture are beyond the scope of this chapter, but they add to the complexity of this area so that development and implementation of neuropsychological testing remains confined to expert neuropsychologists. Both the MACS (Selnes and Miller, 1994) and the HNRC (Heaton *et al.*, 1995) study groups have comprehensive test batteries, with modified, shorter or 'step-down' versions for those who are too ill or cognitively impaired to complete the full test battery. The respective test batteries are outlined in Box 64.6 and Table 64.3.

In the absence of access to a psychologist to perform neuropsychological testing, quick and easy to apply bedside tests have been suggested. One of the most widely used bedside tests is the Mini-Mental State Examination (MMSE). However, it is limited in the assessment of HIV-infected individuals as it does not have timed tests, which is important in a disorder with motor/psychomotor slowing. This has recently been addressed by Power *et al.* (1995), who modified the MMSE to encompass timed tasks (Table 64.4). It can be administered in about 5 minutes.

Box 64.6 Neuropsychological Battery of Multicentre AIDS Cohort Study (MACS)

Employment Questionnaire	

Table 64.4 HIV Dementia Rating Scale (data from Power et al., 1995)

Maximum score on each test	Test score achieved	Domain tested
4		Memory – Registration Give four words to recall (dog, hat, green peach) – 1 second to say each. Then ask patient to repeat all four words after you have said them
6		Attention Antisaccadic eye movements:* 20 commands ____ errors of 20 trials ≤3 errors = 4; 4 errors = 3; 5 errors = 2; 6 errors = 1; >6 errors = 0
4		Psychomotor speed Ask patient to write the alphabet (uppercase letters) horizontally across the page, and record the time taken: ____ seconds ≤21 s = 6; 21.1–24 s = 5; 24.1–27 s = 4; 27.1–30 s = 3; 30.1–33 s = 2; 33.1–36 secs = 1; >36 s = 0
	Give one point for each correct remembered word. For words not recalled, prompt with a 'semantic' clue, as follows: animal (dog), piece of clothing (hat), colour (green), fruit (peach). Give ½ point for each correct response after prompting	Memory – Recall Ask patient to repeat the four words from the Memory – Registration above
2		Construction Ask patient to copy the cube below, and record the time taken: ____ seconds <25 s = 2; 5–35 s = 1; >35 s = 0 A score of <10 is used as the cut-off for indicating the presence of HIV-associated dementia
	Total score: ____ /16	

* Ask the patient to initially focus on the examiner's nose, and then to look to and from the examiner's moving index finger and nose. This is done with alternating hands, with the examiner's hands held at the patient's shoulder width and eye height. When the patient is comfortable looking at the finger that moved, he/she is asked to look at the index finger not moving. The task is practised until the patient is familiar with the task. The patient is then asked to perform 20 serial antisaccades. An error is noted if the patient looked towards the finger that moved

64.5.2 Neuroimaging investigations

Computed tomography (CT) and magnetic resonance imaging (MRI) scans can detect atrophy, which is more often ventricular but can affect sulci. MRI is the more sensitive imaging modality. T2-weighted images are sensitive to oedematous changes, such as the bilateral diffuse white matter hyperintensities that can be observed throughout the cortical white matter. While T1-weighted images can detect anatomical changes such as atrophy. These changes can occasionally be observed in asymptomatic individuals but are more common in those with symptomatic disease and dementia. Focal changes or mass effects are more consistent with the presence of opportunistic infections or a tumour.

Single photon emission computed tomography (SPECT) perfusion studies with HMPAO (Tc^{99m} -hexamethylpropyleneamine oxine) can show multiple scattered perfusion deficits,

though the specificity of this observation is low as many conditions can produce a similar picture. Positron emission tomography (PET) have shown changes in regional metabolic rates for glucose, especially in the prefrontal area in asymptomatic infected individuals compared with seronegative individuals (Pascal *et al.*, 1991). In those with AIDS, hypermetabolism in the basal ganglia and thalamus has been reported (van Gorp *et al.*, 1992), and increasingly hypometabolism with worsening HIV dementia has been noted (van Gorp *et al.*, 1992). Interestingly an increase in regional cerebral blood volume in the basal ganglia in HIV-infected individuals has been observed using functional MRI (Gonzalez *et al.*, 1998).

Proton magnetic resonance spectroscopy (MRS) studies have demonstrated a global reduction in *N*-acetylaspartate (NAA), which is a neuronal marker (Salvan *et al.*, 1997), and an increase in choline, a cell membrane component, in

HIV dementia (Chong *et al.*, 1993, 1994). Phosphorus-MRS has also revealed lower ATP/inorganic phosphate ratios in asymptomatic infected individuals (Deicken *et al.*, 1991). All of these findings support the notion of metabolic dysfunction during HIV infection, which worsens with deteriorating cognitive function. However, the specificity and sensitivity of these observations is still unclear.

64.5.3 Examination of the CSF

Assessment of the CSF is useful for excluding opportunistic infections and clarifying abnormalities associated with HIV infection. The latter include pleiocytosis, the presence of both viral antibodies and antigen (p24, a core protein), raised cytokine levels, such as TNF- α , IL-1 β and -6; and the MHC I associated protein β_2 -microglobulin. Our understanding of the relationship between these factors and disease progression is not clear, except that it has been reported that in the absence of opportunistic infections a raised β_2 -microglobulin supports a diagnosis of HIV-associated dementia (Brew *et al.*, 1992).

In the last few years CSF viral RNA has also been assessed, allowing the relationship between viral load and cognitive performance to be examined. CSF viral RNA levels have been observed to rise over time in otherwise healthy infected individuals studied over a 3-year period (Gisslen *et al.*, 1998). This was not accompanied by a similar rise in serum levels, which appear to be associated with clinical disease progression. CSF viral RNA levels are influenced by the number of mononuclear cells in the CSF (Martin *et al.*, 1998). Furthermore, higher levels of CSF HIV-1 RNA are associated neuropathologically with the presence of HIV encephalitis. The severity of the encephalitis, as rated by increasing numbers of microglia, correlates with increasing viral load (Cinque *et al.*, 1998). However, no correlation was observed between CSF viral load and assumed HIV encephalitis in living patients using radiological and other laboratory markers (Bossi *et al.*, 1998). This may indicate the unreliability of these investigations in accurately predicting underlying brain pathology.

Generally it has been found that CSF viral load is high in patients with a range of AIDS-related neurological disorders (DiStefano *et al.*, 1998). Ellis *et al.* (1997) have found that in asymptomatic infected individuals the viral load in the CSF is correlated with plasma viral load, while in symptomatic disease the CSF viral load was noted to be higher in those with neuropsychological impairments. Similarly, the CSF viral load was found to be higher in individuals with dementia and to correlate with the severity of dementia (Brew and Portegies, 1997; McArthur *et al.*, 1997; McCutchan *et al.*, 1997).

64.6 TREATMENT OF HIV DEMENTIA

The synaptic and dendritic abnormalities, which occur before the onset of obvious neuronal loss and correlate with the onset of mild cognitive deficits, are potentially reversible.

Table 64.5 Antiretroviral agents

Initial designation	Drug name	Proprietary name
Nucleoside reverse transcriptase inhibitors		
Azidothymidine (AZT)	Zidovudine (ZDV)	Retrovir
3TC	Lamivudine	Epivir
ddl	Didanosine	Videx
ddC	Zalcitabine	Hivid
d4T	Stavudine	Zerit
AZT and 3TC		Combivir
Adefovir*		
Non-nucleoside reverse transcriptase inhibitors		
DMP 266**	Efavirenz	Stocrin
	Nevirapine	Viramune
	Delavirdine**	Rescriptor
Protease inhibitors

	Nelfinavir	Viracept
	Saquinavir	Fortavase
	Ritonavir	Norvir
	Indinavir	Crixavan

* Currently undergoing Phase III Clinical Trials in UK

** Available on open-label expanded access

This has relevance to the advent of a new generation of anti-retroviral agents, including the use of protease inhibitors, and the introduction of plasma viral load testing to monitor response to treatment. There are three groups of agents: nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, and protease inhibitors. A list of these agents is presented in Table 64.5. Ideally an antiretroviral agent will fully penetrate all tissue compartments of the body including the central nervous system, and be 100 per cent effective in suppressing viral replication, which in turn will alleviate viral persistence and the emergence of resistant strains. No single agent is totally effective, hence the establishment of combination therapy, which, if it incorporates a protease inhibitor or at least three agents, is termed HAART.

64.6.1 Central nervous system penetration of antiretrovirals

In animal models it has been shown that AZT can pass into the brain passively by diffusion (Thomas and Segal, 1997), and that both AZT and d4T (stavudine) rapidly distribute, probably passively, within the central nervous system following intravenous administration (Yang *et al.*, 1997). The ratio of brain to plasma concentrations was higher for d4T and the drugs did not interfere with one another. Nevirapine has been demonstrated to cross an experimental bovine blood-brain barrier model (Glynn and Yazdanian, 1997). In the human brain AZT has been demonstrated in individuals who died of AIDS (Artigas *et al.*, 1991). However, theoretical models to calculate drug levels in the human brain indicate that clinically effective doses may not be achieved (Groothuis and Levy,

1997), although clinical response is apparently at variance with this.

More information is available with regard to CSF penetration, which is taken to be a marker for entry into the brain. Brew and Portegies (1997) and Portegies and Rosenberg (1998) have summarized information regarding a number of anti-retroviral agents. Of the nucleoside reverse transcriptase inhibitors, AZT has a steady state CSF level of 0.3 μM following an oral dose of 200 mg, although the CSF concentration of AZT is independent of dose (Burger *et al.*, 1993); d4T has a concentration of 0.24 μM and 3TC 0.28 μM , while didanosine (ddI) and zalcitabine (ddC) are lower at 0.17 μM and 0.01 μM respectively. As no brain penetration data are available on these latter two agents, the low CSF levels suggest that they may not be as effective as AZT and d4T. In our own studies we assessed the direct effects of AZT, d4T and abacavir (ABC) on brain cells with the aid of a human brain aggregate model infected with an HIV-1 macrophage tropic strain. We observed neuroprotection and a reduction in astrocyte proliferation by all three agents, whereas the rate of decrease in viral replication was superior with d4T (Kandaneeratchi *et al.*, 2002a, b, 2004). Peripheral neuropathy is a dose-dependent complication of both d4T and ddC, especially in individuals with advanced HIV disease. The new agent ABC is also known to penetrate the CSF.

With regard to the non-nucleoside reverse transcriptase inhibitors no CSF concentrations are currently available though the CSF to serum ratio for nevirapine is stated to be 0.45. A protease inhibitor such as indinavir, even though highly protein bound, is present in the CSF at a level of 0.23 μM (Stahle *et al.*, 1997). Saquinavir CSF concentrations are very low, and there are no reports for ritonavir. In a bovine microvascular model the permeability was highest for amprenavir (141W94), followed by indinavir and then saquinavir (Glynn and Yazdanian, 1998). Saquinavir was a substrate for the *p*-glycoprotein efflux pump, which may explain the poor results seen with this drug, and possibly other protease inhibitors, in penetrating the central nervous system.

There are a number of antiretroviral drugs that are still at developmental stages or in clinical trials and their potential therapeutic effects in the central nervous system is yet to be evaluated. These include entry inhibitors (T20, PRO 542) targeted to prevent binding of gp120 to CD4 receptor (More and Doms, 2003). Other forms of treatment strategies include vaccines for the prevention of persistent infection or to control infection.

64.6.2 Antiviral therapy and CSF viral load

It is known that AZT reduces CSF levels of viral antigen and β_2 -microglobulin levels (Royal *et al.*, 1994). Now it is becoming clear that initiation of combination antiretroviral therapy can have a dramatic effect on viral RNA load in the CSF. HIV RNA was undetectable after approximately 5 months treatments in 10 patients, eight of whom were taking a protease inhibitor, and seven were taking AZT, and three d4T (Gisslen

et al., 1997). Sereni *et al.* (1998) have observed similar findings in nine individuals taking a combination of amprenavir, AZT and 3TC for up to 32 weeks. McArthur *et al.* (1998) assessed HAART in 36 HIV-infected individuals and found undetectable levels in the CSF at 3 months, but at 6 months 50 per cent of the subjects showed a rise in both plasma and CSF viral load, indicating 'escape' from therapeutic control of viral replication. Ellis *et al.* (1998) by serial examination of the CSF in five patients noted a decline in viral load but that it was slower than in the plasma. A one log drop in viral load took a mean of 4 days in plasma and 20 days in the CSF.

While combination therapy has a significant impact on viral load in the CSF, the issue of whether a protease inhibitor or which composition of the combination of antiretroviral agents is superior in terms of duration of the effective suppression of viral replication is still to be clarified. Nevertheless, as higher CSF viral loads are associated with deteriorating cognitive performance, the ability to reduce CSF viral replication is an important marker in preventing or treating HIV-related cognitive disorder.

64.6.3 Effect of therapy on cognitive symptoms

AZT is the only agent that has been assessed on its own. In individuals without neurological problems it was found that after 1 year's AZT 500 mg/day treatment electrophysiological event-related potentials (EVP) were maintained within normal limits, whereas in an untreated group they became prolonged (Evers *et al.*, 1998). Prolongation of EVPs has been proposed as a possible early marker for HIV-associated dementia. There have been a few studies demonstrating that AZT protects against the development of HIV-associated dementia (Portegies *et al.*, 1989; Chiesi *et al.*, 1996). For the treatment of HIV-related cognitive dysfunction and dementia there have been a number of studies demonstrating the efficacy of AZT in improving neurological and cognitive status (Yarchoan *et al.*, 1987; Schmitt *et al.*, 1988; Portegies *et al.*, 1993). However, reports are conflicting as to the optimal dose, with some investigators reporting greater improvement with high doses: 800–1200 mg/day in the Nordic Medical Research Council's HIV Therapy trial (1992), and 2000 mg/day in the Sidtis *et al.* study (1993), while others suggested that levels as low as 500 mg/day can be effective (Tozzi *et al.*, 1993). Benefits of AZT are not permanent and symptoms tend to reappear after 6–12 months of therapy. There is little evidence available for other antiretroviral agents as monotherapy. Didanosine was not observed to have a significant effect in protecting against the development of HIV-related cognitive impairment (Darbyshire and Aboulker, 1992). Aterviridine, in a small pilot study of five individuals with HIV-associated dementia, produced improvement in four (Brew *et al.*, 1996).

Attention is now on the effectiveness of combination antiretroviral therapy in preventing and treating HIV-associated cognitive impairments and dementia. Evidence is now being gathered that the inclusion of a protease inhibitor into the

combination may be even more beneficial. Galgani *et al.* (1998) showed that individuals taking a protease inhibitor and two nucleoside analogues (AZT and ddi, AZT and ddC, AZT and d4T) had less neurological impairment than those just taking two nucleoside analogues. Tozzi *et al.* (1999) also reported that combination of two nucleoside analogue with one protease inhibitor improved minor cognitive motor disorder. Similarly, Sacktor *et al.* (1998) found that HAART was superior than combination therapy without a protease inhibitor in improving various measures of neuropsychological performance. Suarez *et al.* (2001) confirmed these results by reporting that HAART improved subcortical cognitive functions. A proton MRS study on HIV-infected patients with cognitive and motor dysfunctions showing cerebral metabolite abnormalities were found to improve following HAART treatment (Chang *et al.*, 1999). However, as stated previously Dore *et al.* (1999) reported that, although AIDS dementia complex declined with the introduction of HAART, this decline was less marked compared with other AIDS-defining illnesses. There was also an increase in CD4 cell count at diagnosis of ADC at the beginning of HAART. They concluded that HAART produced less protection against ADC compared with ADI. Combination therapies, including HAART, are exciting and powerful treatment options but studies have yet to establish which combinations are the most effective. Factors such as brain and CSF penetration, the combined agents' ability to reduce viral load and the development of viral resistance and mutations will all have to be taken into account when therapeutic management is planned.

64.6.4 Adjunctive therapy

A variety of therapeutic strategies have been proposed in addition to antiretroviral therapy for treatment of HIV dementia. These are based on interfering with the known mechanism of HIV-related cellular brain pathology. For instance, calcium channel antagonist agents, such as nimodipine, can block the excitotoxic gp120-mediated calcium current *in vitro*, and similarly it has been proposed that memantine can be used to block the glutamate channel. Furthermore, pentoxifylline has been proposed as a TNF- α antagonist. However, to date clinical trials on memantine and pentoxifylline are either still in progress or the results are not widely known. Other forms of protection includes the blocking of signalling pathways such as the wnt signalling pathway with the regulation of GSK-3 β . Both lithium and fibroblast growth factor 1 (FGF1) were observed to be neuroprotective against HIV-1 gp120 by regulating GSK-3 β (Everall *et al.*, 2001, 2002).

64.7 TREATMENT OF MOTOR AND BEHAVIOURAL PROBLEMS

In assessing potential HIV-associated cognitive impairments, it is important to recognize and treat and comorbid psychiatric conditions such as hypomania, depression or anxiety.

64.7.1 Motor problems

These are often problems with mobility or incontinence, which may be important in planning a care package to maintain independence. Assisted care by providing a carer for a number of hours per week may be necessary, even if the person has a partner/carer, in order to relieve the burden of care. Similarly a buddy, a volunteer from a HIV voluntary agency, may be appropriate if the person is socially isolated. If high levels of care are needed then regular respite care at a residential unit may be useful, if acceptable to the person concerned. This will provide a break from care, and help prevent stress amongst carers, hopefully allowing community care to continue for longer.

64.7.2 Behavioural and psychological problems

As outlined above, behavioural and psychological problems can sometimes be the first presenting symptoms of a developing dementia and require thorough psychiatric and neurological evaluation. Hypomania will usually require medication with antipsychotic agents. As a general rule these should be given initially at low doses and titrated up as required to improve the mental state. Use of two or more antipsychotics should be avoided and vigilance for the development of side effects including extrapyramidal side effects should be maintained. The possibility of drug interactions may be increased as the patient is often taking multiple medications, and onset of neuroleptic malignant syndrome should be borne in mind if the patient's physical health deteriorates without other cause apparent. Depression can occasionally develop in individuals with cognitive impairments, especially if they have insight in to their condition. In this situation the depression requires a thorough assessment and appropriate management with antidepressant medication, supportive psychotherapy, or both.

Depending on symptom severity the patient may be cared for in the community or may require inpatient admission, including compulsory detention under (in the UK) the Mental Health Act 1983. Close liaison between medical and mental health teams with planning of nursing care plans should identify which is the optimal setting (medical or psychiatric) for assessment and treatment, and minimize the possibility of transfer between medical and psychiatric wards. This is often distressing to the patient and adversely affects their response to treatment.

64.8 PROGNOSIS OF HIV DEMENTIA

The prognosis is currently unclear. It is known that without treatment, as occurred in earlier years, the survival rate was very poor with progression from mild to severe dementia occurring within a few months, while those with severe dementia often died within weeks or a few months. However, the use

of combination antiretroviral therapy appears to have significantly improved prognosis although, until longer term studies with the new therapies have been fully assessed, their full impact is difficult to determine.

Uncommon forms of dementia

ANOOP VARMA

65.1 Dementias associated with neurodegenerative disorders	795	65.4 Conclusion	801
65.2 Dementias associated with inherited metabolic diseases	797	References	801
65.3 Other uncommon dementias	799		

The preceding chapters have discussed the common types of dementias including Alzheimer's disease (AD), vascular dementia (VaD), dementia with Lewy bodies (DLB), fronto-temporal dementia (FTD), etc. In 1–5 per cent of patients with dementia the underlying disorders are uncommon. Many of these patients develop dementia as part of a more prominent neurological syndrome (e.g. corticobasal degeneration). However, awareness of these disorders may lead to effective treatments (e.g. Whipple's disease), or lead to better care from the knowledge of evolution of the disease and its attendant symptoms and signs. Patients whose disorders have an underlying genetic basis may require genetic counselling. This chapter attempts to summarize the clinical, diagnostic and therapeutic aspects of these disorders.

65.1 DEMENTIAS ASSOCIATED WITH NEURODEGENERATIVE DISORDERS

65.1.1 Progressive supranuclear palsy (PSP; Steele–Richardson–Olszewski syndrome)

PSP is characterized by supranuclear ophthalmoplegia (especially downgaze), pseudobulbar palsy, dysarthria, retrocollis, parkinsonism and dementia (Steele *et al.*, 1964; Steele, 1972). Patients are commonly affected in the seventh decade with no significant difference between the sexes (Maher and Lees, 1986). The disorder is often misdiagnosed (Osaki *et al.*, 2004) and initial diagnoses include Parkinson's disease, balance disorders and stroke (Burn and Lees, 2002). Presenting complaints include abrupt falls, unsteadiness of gait, slurred speech or memory impairment. As the disease progresses, marked and relatively symmetrical rigidity (pronounced in the neck) and

the characteristic downgaze palsy emerge. Cerebellar and pyramidal signs and pseudobulbar palsy may be observed.

Although severe dementia is uncommon, subcortical cognitive impairment and depression are common. Mentation is slowed and difficulty in switching set, perseveration, apathy and poor abstraction are prominent neuropsychological features (Albert *et al.*, 1974). Significant depression may occur in addition to emotional lability that often accompanies the pseudobulbar syndrome.

The diagnosis rests on clinical history and examination. Mid-brain atrophy on magnetic resonance imaging (MRI) and/or signal changes in the mid-brain, red nucleus or globus pallidus are supportive (Asato *et al.*, 2000; Warmuth-Metz *et al.*, 2001). Functional imaging studies including blood flow single photon emission computed tomography (SPECT), dopamine transporter and dopamine (D2) receptor imaging are not diagnostically specific to PSP (Brooks, 1993; Kim *et al.*, 2002).

Treatment with levodopa, dopamine agonists, amantadine, tricyclic antidepressants and anticholinergics has proved disappointing.

Over a period of 5–7 years severe physical decline leads to loss of ambulation and eventually to death. Autopsy reveals tau positive neurofibrillary tangles, neuronal loss and tau-positive glial inclusions in the substantia nigra, globus pallidus, subthalamic nucleus and mid-brain (Jellinger and Blancher, 1992).

65.1.2 Corticobasal degeneration (CBD)

CBD is a striking parkinsonian syndrome characterized by grossly asymmetrical dystonia, alien limb phenomenon, apraxia and myoclonus (Ribeiz *et al.*, 1968; Gibb *et al.*, 1989; Stover and Watts, 2001).

Patients usually present in late middle life, often with a useless arm. The asymmetry is marked and eventually the disorder spreads contralaterally. The involved arm may be initially apraxic but rigidity and dystonia supervene. Myoclonus may be reported or elicited at action. Patients may describe alien limb phenomenon and intermanual conflict. Rigidity, corticospinal signs, cortical sensory loss, supranuclear gaze palsy and dysarthria may occur. Dementia is not severe but includes subcortical deficits, apraxia, constructional and spatial impairment (Gibb *et al.*, 1989; Stover and Watts, 2001).

MRI may show severe asymmetrical posterior frontal and parietal atrophy (Savoirdo, 2003). Regional cerebral blood flow (rCBF) SPECT shows reduced uptake in the affected posterior frontal, superior, anterior, inferior and posterior parietal cortices with less prominent changes in the thalamus and basal ganglia (Markus *et al.*, 1995). A recent study suggests a more widespread rCBF change (Hossain *et al.*, 2003).

The characteristically asymmetrical cortical (apraxia and myoclonus) and basal (dystonia, with akinesia and rigidity) signs are the hallmark of the syndrome. Even when a limb is severely rigid and postured due to dystonia, it is usually possible to elicit apraxia in the contralateral limb or orofacial musculature.

Sustained benefit with levodopa, dopamine agonists or amantadine is unusual. The disorder is relentlessly progressive leading to a severe akinetic-rigid syndrome with dysarthria, dysphagia and eventually a wheelchair and bed-bound state. The life span from the onset of symptoms ranges from 6 to 9 years.

Pathological features (Gibb *et al.*, 1989) include neuronal loss in the thalamus, basal ganglia, brain stem and the frontoparietal cortex. Swollen achromatic neurones in the frontoparietal region are pathologically characteristic. The nosology of corticobasal degeneration is debated between lumpers (Kertesz, 1997) and splitters (Neary, 1997). However, it seems an eminently sensible suggestion to carefully document the clinical, histopathological (Hachinski, 1997) and genetic features of all reported cases, regardless of one's position.

65.1.3 Multiple system atrophy (MSA)

The term MSA was proposed in 1969 (Graham and Oppenheimer, 1969) and has gained wide acceptance over the years (Quinn, 1989; Gilman *et al.*, 1999). The disorder affects both sexes in the sixth decade. The main features include autonomic dysfunction, parkinsonism, cerebellar ataxia and pyramidal signs in varying combinations (Wenning *et al.*, 2004). The two main subtypes are the parkinsonian (MSA-P) and the ataxic (MSA-C) variants, depending on the major motor feature. Patients may also develop inspiratory stridor or rapid eye movement (REM) sleep behaviour disorder. Dementia is usually mild and neuropsychological tests reveal deficits in tests sensitive to frontosubcortical dysfunction. Cognitive dysfunction is heterogeneous with some patients revealing no impairment even when severely physically disabled (Robbins *et al.*, 1992).

MRI may show putaminal or olivopontocerebellar atrophy, sometimes with hyperintensities in the pons and middle cerebellar peduncles (Schrag *et al.*, 2000). Hypointensities in the putamen with a hyperintense rim are thought to be characteristic of MSA (Kraft *et al.*, 1999). Denervation on sphincter electromyography (EMG) may be diagnostically helpful if other causes of sphincter denervation have been ruled out (Vodusek, 2001).

Most patients are levodopa unresponsive and symptomatic treatment centres around relief from dysautonomic symptoms. MSA progresses relentlessly and most patients are severely disabled in 5 years. Argyrophilic glial cytoplasmic inclusions are the pathological hallmark of MSA. The distribution of pathology varies with the predominance of parkinsonian or cerebellar features (Wenning *et al.*, 2004).

65.1.4 Autosomal dominant cerebellar ataxias (ADCAs)

ADCAs cause progressive ataxia of gait typically presenting in the third to fifth decades (Harding, 1982). The underlying genetic heterogeneity includes various different genetic loci with CAG/polyglutamine expansions (SCA – spinocerebellar ataxia) 1–13 genes (Durr and Brice, 2000). No clinical sign can be confidently attributed to a genotype in most forms of ADCA. Nonetheless several signs occur more commonly in one genotype than in another. SCA1 is associated with gait spasticity and a more aggressive course. SCA2 may present with slowed saccades and hyporeflexia with axonal neuropathy. These patients have prominent and early cognitive dysfunction (Burk *et al.*, 1999). Patients with SCA3 may have gaze-evoked nystagmus and parkinsonism. SCA7 uniquely causes reduced visual acuity owing to progressive macular degeneration (Durr and Brice, 2000).

Burk *et al.* (1999) found approximately 25 per cent of SCA2 patients to be clinically demented; the remaining patients had neuropsychological evidence of memory impairment and executive dysfunction. Another study has replicated these findings and additionally reported attentional deficits (Le Pira *et al.*, 2002). Cognitive dysfunctions have also been described in other varieties of ADCA, e.g. SCA1 (Trojano *et al.*, 1998), and there is some suggestion that these deficits are related to disease severity (Trojano *et al.*, 1998; Le Pira *et al.*, 2002). It is possible that cognitive impairment in these patients is due to dysfunction of less well-known cognitive functions of the cerebellum (Leiner *et al.*, 1993), and/or disruption of frontoponto-cerebellar pathways (Le Pira *et al.*, 2002).

MRI may reveal cerebellar hemispheric or vermian atrophy (especially in SCA6), or brain stem atrophy (especially in SCA2; Durr and Brice, 2000). Molecular analyses identify CAG/polyglutamine expansions in approximately 50–90 per cent of all cases with a demonstrable autosomal dominant pattern of inheritance. Conversely the diagnostic yield is very low in patients without family histories (Pujana *et al.*, 1999; Durr and Brice, 2000).

65.2 DEMENTIAS ASSOCIATED WITH INHERITED METABOLIC DISEASES

A wide variety of inherited metabolic diseases, usually thought to be limited to infancy or childhood, may manifest in adolescence or young adulthood (Coker, 1991). They may present with predominantly neurological disease or with associated systemic involvement (Box 65.1). Although the brunt of pathology may vary from dominant grey matter involvement (seizures, dementia) to white matter disease (motor weakness, spasticity, ataxia), most of these disorders, if untreated, eventually lead to severe mental and physical disability.

65.2.1 Metachromatic leukodystrophy (MLD)

MLD is an autosomal recessive disorder owing to arylsulphatase deficiency. Sulphatide accumulation, especially in the brain and peripheral nerves is accompanied with central and peripheral demyelination. Late infantile, juvenile and adult forms are recognized. The adult form usually presents in the second decade, although late onset cases in the sixth decade have been described (Duyff and Weinstein, 1996). These patients usually present with personality change and intellectual deterioration (Hageman *et al.*, 1995), although mainly motor forms (pyramidal, extrapyramidal and cerebellar involvement with peripheral neuropathy) are also recognized (Baumann *et al.*, 2002). Some of these patients may

Box 65.1 *Dementia associated with inherited metabolic diseases*

Predominantly neurological disease

- Predominantly white matter
 - metachromatic leukodystrophy
 - adrenoleukodystrophy
 - cerebrotendinous xanthomatosis
- Predominantly grey matter
 - GM2 gangliosidosis
 - Kufs' disease
 - Lafora body disease

Associated systemic disease

- Gaucher's disease
- Niemann–Pick disease type C
- Wilson's disease

Prominent extrapyramidal signs

- Wilson's disease
- Hallervorden–Spatz disease
- Metachromatic leukodystrophy
- Kufs' disease
- GM2 gangliosidosis
- Niemann–Pick disease type C
- Gaucher's disease

have psychotic features and could be misdiagnosed as schizophrenia (Hyde *et al.*, 1992).

The disease progresses over 20+ years and in the terminal stages patients become quadriparetic and mute. The diagnosis is confirmed by demonstration of reduced arylsulphatase activity in peripheral blood white cells. Cerebrospinal fluid (CSF) studies reveal raised protein. T2-weighted MRI brain scans show bilaterally symmetrical, predominantly periventricular high signal changes in the deep white matter (Faerber *et al.*, 1999). Stem cell gene therapy has met with limited success in mouse models (Matzner *et al.*, 2002).

65.2.2 Adrenoleukodystrophy (ALD)

ALD is an X-linked disorder (gene locus on Xq28) characterized by impaired ability to oxidize very long chain fatty acids (VLCFA), leading to their accumulation in the brain and adrenal glands (Igarashi *et al.*, 1976). Moser (1997) and colleagues (Moser *et al.*, 1984) found that cerebral forms occur alone in 30 per cent, adrenomyeloneuropathy alone in 20 per cent and combined childhood cerebral and myelopathic forms in the remainder. Most cases present in the first decade with decline in intellect, change in personality with inappropriate laughter and crying. Unsteadiness, incoordination and intention tremor soon develop. Vomiting, circulatory collapse, oral mucosal and skin pigmentation may occur. In the late stage blindness, deafness, pseudobulbar paralysis and bilateral hemiplegia supervene. Adult patients usually present with mild cerebral symptoms and spastic myelopathy with neuropathy. Some patients may present with dementia, behavioural changes and/or psychosis (Kitchin *et al.*, 1987).

Brain MRI shows widespread white matter changes with a predilection for the parieto-occipital white matter and may, therefore, be confused with multiple sclerosis. The diagnosis is confirmed by the demonstration of an excess of VLCFA in blood (plasma, red and white cells). Markers of adrenal insufficiency support the diagnosis. Dietary supplementation with monounsaturated fatty acids and bone marrow transplantation have been shown to stabilize disability (van Geel *et al.*, 1997).

65.2.3 Cerebrotendinous xanthomatosis (CTX)

CTX is a rare autosomal recessive disorder with accumulation of cholestanol and cholesterol. Patients usually present in the second and third decades. Cataracts, diarrhoea and tendon xanthomas may be noted from an early age. With progression, intellectual deficit and inattentiveness give way to progressive dementia, spasticity, ataxia, pseudobulbar palsy and peripheral neuropathy (Moghadasian *et al.*, 2002).

Computed tomography (CT) and MRI demonstrate diffuse brain and spinal cord atrophy, white matter changes and occasionally focal lesions (Kaye, 2001). Laboratory investigations reveal elevated levels of plasma and bile cholestanol (normally cholestanol is 0.1–0.2 per cent of total cholesterol;

in CTX there is a 10–100-fold rise) and increased urinary excretion of bile alcohol glucuronides (Koopman, *et al.*, 1988). Treatment with chenodeoxycholic acid may reverse neurological deficits, especially when started in young patients (Berginer *et al.*, 1984).

65.2.4 Adult GM2 gangliosidosis

GM2 gangliosidosis is due to deficiency of hexosaminidase A, which leads to accumulation of gangliosides in neurones (Argov and Navon, 1984). Partial deficiency of hexosaminidase A (<15 per cent) is associated with later (juvenile and adult) onset syndromes. Patients may present with slowly progressive motor neurone disorder, with or without pyramidal and cerebellar signs. Some patients have psychiatric disturbances, personality changes and intellectual deterioration. Dystonia, myoclonus, seizures and ocular motor disorders may also be observed (Hund *et al.*, 1997).

The diagnosis is confirmed by enzyme assays in white cells. MRI shows generalized atrophy with particularly severe cerebellar involvement (Clarke, 2002). Electromyography reveals denervation even in patients without overt clinical signs.

65.2.5 Kufs' disease (neuronal ceroid lipofuscinosis, NCL)

Kufs' disease is the juvenile/adult form of NCL, a group of lysosomal storage disorders. Unlike the early onset forms, Kufs' disease develops later (15–25 years) and is unattended by retinal and visual changes (Berkovic *et al.*, 1988). Most cases are autosomal recessive although autosomal dominant patterns have been described (Josephson *et al.*, 2001). Varying combinations of progressive myoclonic epilepsy, generalized tonic clonic epilepsy, dysarthria, ataxia and dystonia may be observed. Some patients have prominent neuropsychiatric symptoms including behavioural changes, psychosis and dementia (Berkovic *et al.*, 1988; Hinkebein and Callahan, 1997).

The diagnosis may prove difficult and involves demonstration of accumulation of autofluorescent ceroid and lipofuscin in nerve-containing tissue (Goebel and Braak, 1989). Skin biopsies can be positive and are easier to obtain than brain tissue. The disease is relentlessly progressive and results in death in 10–15 years.

65.2.6 Lafora body disease

Lafora body disease is autosomal recessive and one of the genes responsible has been mapped to chromosome 6q24 (Serratosa *et al.*, 1995; Minassian *et al.*, 1998). These patients usually present with intractable seizures in the second decade of life. Myoclonus and occipital seizures are characteristic. Dysarthria, ataxia, emotional disturbances, confusion and dementia develop gradually. Patients eventually become severely demented, mute, quadriparetic and bed-bound. Death occurs within 10 years of onset (Minassian, 2001).

The electroencephalogram (EEG) shows generalized epileptiform discharges with photomyoclonus. Background EEG is persistently slow. Skin, liver, muscle or brain biopsies may reveal the pathognomonic periodic-acid-Schiff (PAS) positive Lafora bodies. At pathology Lafora bodies, composed of polyglucosans, are present throughout the brain, especially in the cerebral and cerebellar cortices, basal ganglia, thalamus and the spinal cord. Similar accumulations are also found in skin, muscle, heart and liver.

65.2.7 Hallervorden–Spatz disease

The original description dates back to 1922 (Hallervorden and Spatz, 1922). Over the years deviations from the original description have been included within the term Hallervorden–Spatz syndrome. Halliday (1995) suggests reserving the term Hallervorden–Spatz disease for the paediatric neurodegenerative disorder and Hallervorden–Spatz syndrome to include disorders with the pallidal triad of iron deposition, axial spheroids and gliosis.

The onset is usually before the age of 10 years and death occurs in the early twenties (Dooling *et al.*, 1974). Adult-onset cases (atypical disease) are reported and develop progressive dementia, quadriparesis and extrapyramidal features including parkinsonism, dystonia and/or chorea (Halliday, 1995); the course may be more prolonged over 15–40 years.

The disorder is autosomal recessive and many cases with the syndrome result from mutations in a gene called PANK2 (encoding the enzyme pantothenate kinase, which regulates biosynthesis of coenzyme A) on chromosome 20p13 (Hayflick *et al.*, 2003). All patients with classical Hallervorden–Spatz syndrome and a third with atypical disease have PANK2 mutations. The atypical cases have prominent psychiatric features, palilalia, dysarthria, dystonia and cognitive decline including personality change, impulsivity and emotional lability. Patients with PANK2 mutations show bilateral hyperintensity surrounded by hypointensity in the medial globus pallidus on T2-weighted MRI scans ('eye of the tiger' sign).

The globus pallidus shows a rusty discoloration. Microscopy reveals axonal spheroids in the basal ganglia, cerebellum and brain stem. Neurofibrillary tangles and Lewy bodies may be seen in some patients with Hallervorden–Spatz syndrome (Halliday, 1995).

65.2.8 Gaucher's disease

Gaucher's disease is an autosomal recessive inherited lysosomal storage disorder owing to glucocerebrosidase deficiency. Glucocerebroside accumulates in visceral organs, reticulo-endothelial tissue and the nervous system.

The clinical manifestations of Gaucher's disease vary enormously. Many patients remain asymptomatic all their lives; at the opposite end of the spectrum some patients with the rare acute neuronopathic form die by the age of 18 months.

Type I Gaucher's disease is without neurological manifestations and visceral manifestations include hepatosplenomegaly, anaemia, thrombocytopenia and skeletal abnormalities. The adult forms are stable and slowly progressive. Type II Gaucher's disease is characterized by early-onset neurological and visceral disease. Severe neck rigidity and arching, bulbar signs, appendicular rigidity, chorea and dystonia follow eye movement disorders and strabismus. Type III Gaucher's disease is the intermediate form with onset between 0.1 and 14 years (usually 1 year). Eye movement disorders, ataxia, spasticity, and slowly progressive dementia may be accompanied by visceral involvement (Balicki and Beutler, 1995).

Investigations show a rise in acid phosphatase, characteristic histiocytes (Gaucher cells) in marrow smears and liver or spleen biopsies. The diagnosis is confirmed by detecting reduced glucocerebrosidase activity in peripheral white cells. Type I Gaucher's disease responds to enzyme replacement therapy with recombinant glucocerebrosidase (Charrow *et al.*, 2004).

65.2.9 Niemann–Pick disease type C (NPD-C)

NPD-C is a lipid storage disorder with hepatosplenomegaly and a variety of neurological and psychiatric symptoms and signs (Patterson, 2003). The diagnosis should be considered in any individual with unexplained dementia or psychiatric impairment, especially when accompanied by ataxia, dystonia or vertical supranuclear gaze palsy. The absence of organomegaly, normal imaging or bone marrow biopsy does not rule out the diagnosis.

NPD-C can present at any age. Psychiatric and cognitive dysfunction predominate later-onset presentations. Dysarthria, dementia and ataxia may be accompanied by vertical supranuclear gaze palsy. Psychosis may be the occasional presenting feature and rarely choreoathetosis may occur. A mixture of partial and generalized seizures may occur. Gelastic cataplexy (ranging from subtle head nodding to profound atonia, usually provoked by humorous situations) may be seen in approximately 20 per cent of patients (Shulman *et al.*, 1995a, b).

Most patients with NPD-C have mutations in the NPC1 gene located on chromosome 18q11. Although genotyping may be helpful in diagnosis, the frequency of polymorphisms makes detection and interpretation of changes in the DNA sequence difficult in some cases. The diagnosis is strongly supported by detecting polymorphous cytoplasmic bodies on electron microscopic examination of skin, rectal or conjunctival biopsies (Patterson, 2003). There is no definitive therapy for NPD-C.

65.2.10 Wilson's disease

Wilson's disease is an autosomal recessive disorder of copper homeostasis. The responsible gene has been identified on chromosome 13. Most clinical manifestations can be directly attributed to copper accumulation, especially in the brain and liver (Jones and Weissenborn, 1997; Gitlin, 2003).

Thirty-five per cent of all patients may present with neurological Wilson's disease in the second or third decades of life, without overt liver disease. Incoordination, clumsiness, tremor, dysarthria, excess salivation, dysphagia and movement disorders (a variety of tremors, dystonia, bradykinesia, chorea) produce a prominent motor syndrome. Psychiatric symptoms may dominate the clinical picture in a third of all patients and include behavioural and personality changes, psychosis, depression and/or cognitive impairment (Jones and Weissenborn, 1997; Gitlin, 2003). T2-weighted MRI may reveal the 'face of the giant panda' sign consisting of high signal in the mid-brain tegmentum except the red nucleus, preservation of signal in the substantia nigra and hypointensity of the superior colliculus (Hitoshi *et al.*, 1991). Slit lamp examination reveals Kayser–Fleischer rings and peripheral blood ceruloplasmin concentration is <20 mg/dl. Urinary copper excretion is >100 µg/24 hours (normal <40). Treatment requires lifelong chelation with D-penicillamine, trientine or tetrathiomolybdate. Advanced liver failure may require hepatic transplantation (Jones and Weissenborn, 1997; Gitlin, 2003).

65.3 OTHER UNCOMMON DEMENTIAS

65.3.1 Mitochondrial cytopathy (MC)

Mitochondrial encephalomyopathies (ME) are a group of multisystem disorders characterized by biochemical and genetic mitochondrial defects with a variable mode of inheritance. Oxidative phosphorylation (ATP synthesis by oxygen consuming respiratory chain [RC]) supplies most organs and tissues with energy. RC components originate from nuclear DNA and mitochondrial DNA. Patients with a defect of oxidative phosphorylation may present with:

- an unexplained combination of neuromuscular/non-neuromuscular symptoms;
- a progressive course;
- involvement of seemingly unrelated organs or tissues (Munnich and Rustin, 2001).

The central and/or peripheral nervous system may be involved. Patients may present with a range of manifestations, i.e. encephalopathy, brain stem involvement (ophthalmoplegia), cerebellar disorders (ataxia), myoclonus, seizures, pyramidal dysfunction, leukodystrophy, poliodystrophy or peripheral neuropathy and/or myopathy. MELAS (mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes), MERRF (myoclonic epilepsy with ragged red fibres), subacute necrotizing encephalomyopathy (Leigh syndrome), MNGIE (mitochondrial myopathy, peripheral neuropathy, encephalopathy and gastrointestinal disease) are commonly recognized ME, whereas progressive external ophthalmoplegia (PEO) and Kearns–Sayre syndrome (KSS) are mitochondrial myopathies (Rahman and Schapira, 1999).

Cognitive impairment and dementia are commonly recorded features of MC. However, the neuropsychological deficits in MC have not been studied in detail. Many reports of cognitive deficits in MC could be attributed to focal deficits from strokes (e.g. MELAS) or seizures. Turconi *et al.* (1999) reported memory and constructional impairment in MC (PEO, KSS and one patient with MERRF). Bosbach *et al.* (2003) studied similar patients (PEO and KSS) with rigorous neuropsychological assessment including executive functions. They reported executive dysfunction, constructional impairment and attentional difficulties suggesting fronto-subcortical dysfunction.

Combinations of clinical features like deafness, diabetes mellitus, cardiomyopathy, myopathy and encephalopathy are strongly suggestive of MC. Diagnostic approaches are tailored to the clinical presentation (for details see Finsterer, 2004). T2-weighted MRI may show high signal changes in the deep white matter or grey–white interface, especially posteriorly, in patients with MELAS. Electrophysiology may reveal neuropathy in a third of cases; electromyography may be normal, neurogenic and/or myogenic. EEG may be slow and reflect encephalopathy. CSF protein is raised in KSS; CSF lactate may be elevated e.g. in MELAS, MERRF or Leigh syndromes. Muscle biopsy may show ragged red fibres (MELAS, MERRF) on light microscopy; further immunohistochemical and electron microscopy studies may detail mitochondrial abnormalities. Negative genetic tests require cautious interpretation. Mitochondrial deletions are usually not detected in blood. Further DNA analysis from muscle tissue may be required (Rahman and Schapira, 1999; Munnich and Rustin, 2001; Finsterer, 2004). Treatment remains symptomatic.

65.3.2 Whipple's disease

Whipple's disease is a systemic infectious disorder usually presenting with weight loss, arthralgia, diarrhoea and abdominal pain. Small intestinal biopsy confirms the diagnosis by demonstrating PAS-positive inclusions in the lamina propria. These inclusions represent the causative bacteria, *Tropheryma whipplei* (Marth and Raoult, 2003). Neurological symptoms occur in approximately 15 per cent of patients and may present without prominent gastrointestinal disorder (Louis *et al.*, 1996; Marth and Raoult, 2003).

Eighty per cent of patients with central nervous system (CNS) Whipple's disease have systemic signs. Cognitive changes with or without neuropsychiatric manifestations are frequent. Patients may develop frank dementia. Supranuclear gaze palsy, myoclonus, oculomasticatory myorhythmia or oculo-facial-skeletal myorhythmia are characteristically present in a third to half of all such patients. Ataxia and/or seizures are not infrequent (Louis *et al.*, 1996).

Tissue biopsy (small bowel, brain, lymph node or vitreous fluid) is positive in about 75 per cent of patients. Polymerization chain reaction (PCR) gene amplification may be positive for *T. whipplei* in gastric fluid, small bowel, synovial or saliva samples (Louis *et al.*, 1996; Delanty *et al.*, 1999).

Currently recommended treatment regimes include 2 weeks of parenteral ceftriaxone followed by long-term oral trimethoprim-sulfamethoxazole administration (Marth and Raoult, 2003).

65.3.3 Hashimoto's encephalopathy (HE)

HE characteristically presents with a fluctuating confusional state, tremor and myoclonus (Shaw *et al.*, 1991). Seizures, stroke like episodes, pyramidal weakness, extrapyramidal rigidity and ataxia may emerge over the ensuing weeks and months. The onset may be abrupt or insidious and the evolution is typically subacute (Kothbauer-Margreiter *et al.*, 1996).

The EEG is usually slow. MRI and SPECT scans may be normal or show non-specific changes. CSF protein is usually raised with a normal cell count. High titre of antithyroid antibodies with normal thyroid function clinches the diagnosis (Neary and Snowden, 2003).

The disorder responds to steroids and often prolonged courses are required. Remissions and relapses necessitate appropriate adjustments in steroid therapy. HE is most likely to be confused with fluctuating encephalopathies including DLB, Creutzfeldt–Jakob disease (CJD), metabolic encephalopathy, cerebral vasculitis and paraneoplastic limbic encephalitis (PLE) (Box 65.2).

65.3.4 Cerebral vasculitis

Cerebral vasculitis may occur as part of a systemic vasculitis, e.g. systemic lupus erythematosus (SLE). However, occasionally a neurological syndrome may be the presenting feature of systemic vasculitis or less commonly due to an isolated primary vasculitis of the central nervous system, i.e. without peripheral clinical or laboratory (absence of autoantibodies, normal erythrocyte sedimentation rate and C-reactive protein) markers of systemic vasculitis. The latter condition poses diagnostic difficulties and detection requires a high degree of clinical suspicion and experience. Patients may develop multifocal symptoms and signs with stepwise progression. Headache and confusion (subacute encephalopathy), usually with focal signs and myoclonus, may raise suspicion of an underlying cerebral vasculitis. Investigations including MRI, EEG and CSF studies may be normal. Cerebral angiography and leptomeningeal biopsies may also be falsely negative. The diagnosis is sometimes established after repeated investigations (vascular changes on MRI, CSF pleocytosis and raised

protein, multifocal narrowing of blood vessels on angiography and vasculitic lesions on leptomeningeal biopsy). Treatment is aggressive with immunosuppression (cyclophosphamide) and steroids (Scolding, 1997; Joseph and Scolding, 2002).

65.3.5 Paraneoplastic limbic encephalitis (PLE)

Paraneoplastic syndromes represent remote effects of cancer rather than direct effects such as metastatic invasion. PLE is characterized by personality changes, behavioural changes including irritability and depression, seizures (complex partial, generalized or a combination), memory impairment and even frank dementia (Corsellis *et al.*, 1968; Gultekin *et al.*, 2000). Memory loss and confusion are the commonest presenting symptoms. Neurological dysfunction may develop 0.5–33 months (median 3.5 months) before tumour detection. Other parts of the nervous system may also be involved (sensory neuronopathy, cerebellar ataxia, brain stem diplopia and dizziness). The course is subacute and may fluctuate with progression over weeks or months (Newman *et al.*, 1990).

MRI shows unilateral/bilateral high signal changes in mesial temporal lobes on T2-weighted image that may enhance with contrast (Dirr *et al.*, 1990; Gultekin *et al.*, 2000). The CSF may show pleocytosis, raised protein or oligoclonal bands. Paraneoplastic antibodies are detected in 60 per cent of patients, most commonly anti-Hu (associated with small cell lung cancer) or anti-Ta (associated with testicular tumours). Seventy-eight per cent of patients have positive MRI findings and/or CSF abnormalities (Gultekin *et al.*, 2000).

It is thought that tumour expression triggers autoimmunity against the nervous system (Newman *et al.*, 1990; Gultekin *et al.*, 2000). Although a variety of treatments including steroids, intravenous immunoglobulins and plasma exchange have been tried, none is of proven value. Early identification of the tumour and prompt treatment appears to offer the greatest chance for neurological improvement (Gultekin *et al.*, 2000).

Box 65.3 Myoclonic dementias

- Alzheimer's disease
- Dementia with Lewy bodies
- Creutzfeldt–Jakob disease
- Metabolic encephalopathy
- Hashimoto's encephalopathy
- Cerebral vasculitis

- Corticobasal degeneration
- Lafora body disease
- Kufs' disease
- GM2 gangliosidosis
- HIV encephalopathy

65.4 CONCLUSION

An awareness of the clinical syndromes (Boxes 65.1–65.3) and a high index of suspicion make accurate diagnosis of uncommon dementias possible. Some of these disorders can be conclusively diagnosed with the help of biological markers (biochemical or genetic) or radiological findings. Since effective treatments are available for some conditions (Wilson's disease, Hashimoto's encephalopathy, Whipple's disease, etc.), knowledge of these dementias, though uncommon, is essential.
