This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contradictions, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

To
Our Grandchildren

Preface

This is the eleventh edition of *Kaplan & Sadock’s Synopsis of Psychiatry*, which was first published more than 40 years ago. During that time, it has gained the reputation of being an independent, consistent, accurate, objective, and reliable compendium of new events in the field of psychiatry. Since its beginning, the goal of this book has been to foster professional competence and ensure the highest quality care to those with mental illness. An eclectic, multidisciplinary approach has been its hallmark; thus, biological, psychological, and sociological factors are equitably presented as they affect the person in health and disease.

Synopsis serves the needs of diverse professional groups: psychiatrists and nonpsychiatric physicians, medical students, psychologists, social workers, psychiatric nurses, and other mental health professionals, such as occupational and art therapists, among others. *Synopsis* is also used by nonprofessionals as an authoritative guide to help them collaborate in the care of a family member or friend with mental illness. As authors and editors, we have been extremely gratified by the wide acceptance and use of *Synopsis*, both in the United States and around the world.

We are especially pleased that Pedro Ruiz, M.D., who joined us as third editor for the last (Tenth) edition of the *Comprehensive Textbook of Psychiatry*, is continuing his association with us as co-author of *Synopsis*. Dr. Ruiz is not only a close friend but is a distinguished academic psychiatrist, renowned as both an educator and clinician. He is past president of the American Psychiatric Association and serves as the current president of the World Psychiatric Association. Dr. Ruiz is Professor of Psychiatry and Executive Vice-Chair and Director of Clinical Programs at the University of Miami Miller School of Medicine.

HISTORY

This textbook evolved from our experience editing the *Comprehensive Textbook of Psychiatry*. That book is nearly 4,000 double-column pages long, with more than 450 contributions by outstanding psychiatrists and behavioral scientists. It serves the needs of those who require an exhaustive, detailed, and encyclopedic survey of the entire field. In an effort to be as comprehensive as possible, the textbook spans two volumes to cover the material, clearly rendering it unwieldy for some groups, especially medical students, who need a brief and more condensed statement of the field of psychiatry. To accomplish this, sections of the *Comprehensive Textbook of Psychiatry* were deleted or condensed, new subjects were introduced, and all sections were brought up to date, especially certain key areas, such as psychopharmacology. We wish to acknowledge our great and obvious debt to the more than 2,000 contributors to the current and previous editions of the *Comprehensive Textbook of Psychiatry*, all of whom have allowed us to synopsise their work. At the same time, we must accept responsibility for the modifications and changes in the new work.

COMPREHENSIVE TEACHING SYSTEM

This textbook forms one part of a comprehensive system developed by us to facilitate the teaching of psychiatry and the behavioral sciences. At the head of the system is the *Comprehensive Textbook of Psychiatry*, which is global in depth and scope; it is designed for and used by psychiatrists, behavioral scientists, and all workers in the mental health field. *Synopsis of Psychiatry* is a relatively brief, highly modified, and current version useful for medical students, psychiatric residents, practicing psychiatrists, and mental health professionals. Two special editions derived from *Synopsis*, *Concise Textbook of Clinical Psychiatry* and *Concise Textbook of Child and Adolescent Psychiatry*, contain descriptions of all psychiatric disorders, including their diagnosis and treatment in adults and children, respectively. They will be useful for clinical clerks and psychiatric residents who need a succinct overview of the management of clinical problems. Another part of the system, *Study Guide and Self-Examination Review of Psychiatry*, consists of multiple-choice questions and answers; it is designed for students of psychiatry and for clinical psychiatrists who require a review of the behavioral sciences and general psychiatry in preparation for a variety of examinations. The questions are modeled after and consistent with the format used by the American Board of Psychiatry and Neurology (ABPN), the National Board of Medical Examiners (NBME), and the United States Medical Licensing Examination (USMLE). Other parts of

the system are the various editions of the pocket handbooks: *Pocket Handbook of Clinical Psychiatry*, *Pocket Handbook of Psychiatric Drug Treatment*, *Pocket Handbook of Emergency Psychiatric Medicine*, and *Pocket Handbook of Primary Care Psychiatry*. Those books cover the diagnosis and treatment of psychiatric disorders, psychopharmacology, psychiatric emergencies, and primary care psychiatry, respectively, and are designed and written to be carried by clinical clerks and practicing physicians, whatever their specialty, to provide a quick reference. Finally, *Comprehensive Glossary of Psychiatry and Psychology* provides simply written definitions for psychiatrists and other physicians, psychologists, students, other mental health professionals, and the general public. Together, these books create a multiple approach to the teaching, study, and learning of psychiatry.

CLASSIFICATION OF DISORDERS

DSM-5

A fifth edition of the *American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders* was published in 2013 called DSM-5. It contains the official nomenclature used by psychiatrists and other mental health professionals in the United States; the psychiatric disorders discussed in the textbook are consistent with and follow that nosology. Every section dealing with clinical disorders has been updated thoroughly and completely to include the revisions contained in DSM-5. The reader also will find DSM-5 tables for most major mental disorders reprinted in this textbook as it has been in each of our editions.

The DSM is the “law of the land” and, as mentioned previously, is the nomenclature used throughout this textbook; however, some clinicians and researchers have reservations about various aspects of the DSM, which readers will find mentioned in *Synopsis*. As future editions of the DSM appear, this textbook, as always, will allow room for dissent before and especially after every new version appears. It will continue to provide a forum for discussion, evaluation, criticism, and disagreement, while duly acknowledging the official nomenclature.

ICD-10

Readers also should be aware of a parallel classification system developed by the World Health Organization (WHO) called the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). There are textual differences between DSM and ICD, but according to treaties between the United States and the WHO, the diagnostic code numbers must be identical to ensure uniform reporting of national and international psychiatric statistics. ICD diagnoses and numerical codes are accepted by Medicare, Medicaid, and private insurance companies for reimbursement purposes in the United States.

COVER ART AND ILLUSTRATIONS

Synopsis was one of the first modern psychiatric textbooks to use art and photographs to illustrate psychiatric subjects in order to enrich the learning experience, and we have continued that tradition through each edition.

The cover art is a detail of a painting entitled *Artist Surrounded by Masks* by the Belgian-born artist James Ensor (1860–1949), who was fascinated by masks, which for him represented the hypocrisy of humankind. Masks have played a role throughout human history. They both hide and reveal; they hide what we do not wish to show to others or to ourselves or what we wish to keep secret, and they reveal what we wish others to see. In the rehabilitation of psychiatric patients, making masks has been used by art therapists to help patients explore their feelings and to experience their creativity. The psychiatrist Hervey Cleckley coined the term “mask of sanity” to refer to the psychopath who manipulates others but who is, beneath the façade of normality, profoundly disturbed. Carl Jung wrote of the persona (derived from the Latin word for mask) as the image we wish to present to the world behind which lay other images of the self. We hope that the cover art enriches the learning experience for our readers.

As in all *Kaplan & Sadock* books, color plates of proprietary forms of commonly used psychiatric drugs including their dosage forms are pictured. All new drugs developed since the last edition was published are included. In addition, new illustrations and color plates have been added to many sections.

CASE HISTORIES

Case histories are an integral part of *Synopsis*. They are used extensively throughout the text to add clarity and bring life to the clinical disorders described. Cases come from various sources including the contributors to the current and previous editions of the *Comprehensive Textbook of Psychiatry* and our hospital colleagues, all of whom we thank for their contributions. Some also come from the authors’ clinical experience at Bellevue Hospital in New York. Cases appear in tinted type to help the reader find them easily.

NEW AND UPDATED SECTIONS

The introduction of DSM-5 in 2013 reframed psychiatric nosology, and the reader will find every section of *Synopsis* revised and updated to reflect those changes. The chapter on *Classification in Psychiatry* provides a concise overview and definition of every psychiatric disorder listed in DSM-5. In the rest of the book, each of these disorders is discussed in great detail in separate chapters and sections. In addition, almost every major mental disorder is accompanied by its corresponding DSM-5 diagnostic table.

The table of contents was reorganized starting with the chapter called *Neural Sciences*, in which three new sections were added: *Neural Development and Neurogenesis* reflects the important role of the developing nervous system in the causation of mental illness; *Applied Electrophysiology* describes the effects of electrical impulses in the brain and its relation to clinical psychiatry; and *Immune System and Central Nervous System Interactions* describes the complex effects of the immune system on the brain in health and disease.

A new section entitled *Normality and Mental Health* provides the reader with a framework within which to understand the boundaries of mental illness. Similarly, another new section, *Positive Psychology*, describes emerging theories and therapeutic approaches that contribute to mental health.

A chapter called *Contributions of the Sociocultural Sciences* contains three new sections entitled *Sociology and Ethology*, *Transcultural Psychiatry*, and *Culture-Bound Syndromes* that, taken together, reflect the tremendous impact that culture has on both the manifestations and prevalence of mental disorders around the world.

The chapter *End-of-Life Issues* covers death, dying, bereavement, and palliative care to reflect the important role psychiatrists have in the clinical specialty of palliative medicine. This chapter also covers pain control, which is a relatively new but important area in which psychiatrists play a significant role. In the chapter entitled *Gender Dysphoria*—a new diagnostic category included in DSM-5—special attention is given to issues that affect gay, lesbian, bisexual, and transgender persons. The chapter *Psychiatry and Reproductive Medicine* was revised extensively to keep pace with advances in women’s health issues. The chapter *Ethics in Psychiatry* was updated to include an extensive discussion of physician-assisted suicide. This topic is also given special attention in the section entitled *Euthanasia and Physician-Assisted Suicide*. In the last edition, the section on *Posttraumatic Stress Disorder* covered the tragic events of September 11, 2001, involving the World Trade Center in New York and the Pentagon in Washington. Regrettably, other disasters such as Hurricane Sandy and the Newtown killings have occurred since then. The psychological effects of those events are covered, as are the effects of the wars in Iraq and Afghanistan on the mental health of the veterans of those wars. Related to that is new coverage of the effects of terrorism and torture, two areas rarely covered in textbooks of psychiatry, but of extreme importance to psychiatrists who treat its victims.

Two new chapters, *Public Psychiatry* and *World Aspects of Psychiatry*, have been added to this edition, both of which reflect the national and global scope of psychiatry and the need for clinicians to understand disorders that appear around the world. A new section called *Brain Stimulation Methods* describes such new advances as transcranial magnetic and deep brain stimulation developed to restore health to those patients who have not responded to conventional therapies and who are among the most severely mentally ill.

The chapter on psychotherapy has been expanded to include newer treatments such as *Mentalization* and *Mindfulness*, both of which are covered in a newly written section. And, as in previous editions, the chapter *Pharmacological Treatment* covers every drug used by psychiatrists to treat mental illness. It has been completely updated to include all new drugs introduced since the last edition of this book was published.

Finally, every chapter in the behavioral sciences section has been revised and updated to reflect the latest advances in the field.

PSYCHOPHARMACOLOGY

The authors are committed to classifying drugs used to treat mental disorders according to their pharmacological activity and mechanism of action rather than using such categories as antidepressants, antipsychotics, anxiolytics, and mood stabilizers, which are overly broad and do not reflect, scientifically, the clinical use of psychotropic medication. For example, many antidepressant drugs are used to treat anxiety disorders; some anxiolytics are used to treat depression and bipolar disorders; and drugs from all categories are used to treat other clinical problems, such as eating disorders, panic disorders, and impulse-control disorders. Many drugs are also used to treat a variety of mental disorders that do not fit into any broad classification. Information about all pharmacological agents used in psychiatry, including pharmacodynamics, pharmacokinetics, dosages, adverse effects, and drug–drug interactions, was thoroughly updated to reflect recent research.

CHILDHOOD DISORDERS

The chapters covering childhood disorders were extensively revised to include important new material. DSM-5 introduced new childhood diagnostic categories and eliminated others. For example, diagnoses such as *Pervasive Developmental Disorder*, *Rett's Disorder*, and *Asperger's Disorder* are now subsumed under the rubric of *Autism Spectrum Disorder*, and *Disruptive Mood Dysregulation Disorder* and *Attenuated Psychosis Syndrome* were added as new diagnostic entities. These and other changes are reflected in the expanded coverage of disorders that usually begin in childhood and adolescence. The section dealing with the impact of terrorism has been updated to reflect new information about posttraumatic stress disorders in children, including the latest data on the psychological effects on children exposed to natural and man-made disasters. The section *Anxiety Disorders* was reorganized and updated thoroughly, and *Obsessive-Compulsive Disorder* is now a separate chapter. The section that deals with the use of pharmacological agents in children was updated extensively to reflect the many changes in the use of medications to treat disorders of childhood that have occurred since the last edition this book was published.

GLOSSARY

Unique to this edition is a new and updated comprehensive glossary of psychiatric signs and symptoms. Psychiatry is a descriptive science and the knowledge and accurate usage of the many terms available to the clinician is crucial to successful diagnosis and treatment. We hope readers find this new addition to the textbook of use.

REFERENCES

Each section in *Synopsis* ends with a number of citations that include reviews of the literature and up-to-date references in addition to relevant chapters in our larger textbook, *Comprehensive Textbook of Psychiatry*. References are limited in number; in part this was to conserve space, but more importantly, we are mindful that modern-day readers consult Internet databases such as *PubMed* and *Google Scholar* to stay abreast of the most current literature, and we encourage that trend.

ACKNOWLEDGMENTS

We deeply appreciate the work of our distinguished contributing editors, who gave generously of their time and expertise. Caroly Pataki, M.D., was responsible for updating and revising the section on childhood and adolescent disorders. She has served with distinction as Contributing Editor of child psychiatry in the *Comprehensive Textbook* for many editions, and we thank her for her tremendous help in this area. Norman Sussman, M.D., updated the section on psychopharmacology, enabling us to provide the reader with the current material in this ever-changing and rapidly expanding area. He also served as Contributing Editor for the *Comprehensive Textbook* in the area of psychopharmacology. We thank Dorice Viera, Associate Curator of the Frederick L. Ehrman Medical Library at the New York University School of Medicine, for her valuable assistance in the preparation of this and previous editions in which she participated.

We especially wish to express our deep thanks to our two project editors in New York: Nitza Jones-Sepulveda was with us for over a decade and worked on this and on many other *Kaplan & Sadock* books before moving into the private sector, and her vast knowledge of every aspect of book publishing was indispensable. She will be greatly missed. We also wish to thank Hayley Weinberg, who played a major role in the production of this book. She worked with enthusiasm, intelligence, and alacrity. We also wish to acknowledge and thank Gloria Robles in Miami, who was of invaluable assistance to all of the authors, especially Dr. Ruiz. Among the many others to thank are Seeba Anam, M.D., René Robinson, M.D., Nora Oberfield, M.D., Marissa Kaminsky, M.D., Caroline Press, M.D., Michael Stanger, M.D., Rajan Bahl, M.D., and Jay K. Kantor, Ph.D., all of whom contributed to various editions of *Synopsis*. Laura Erikson-Schroth, M.D., deserves special thanks for her help in the section on *Gender Dysphoria*. We especially want to thank Samoon Ahmad, M.D., who helped us tremendously as Consulting Editor in the area of psychopharmacology.

We also wish to acknowledge the contributions of James Sadock, M.D., and Victoria Sadock Gregg, M.D., for their help in their areas of expertise: emergency adult and emergency pediatric medicine, respectively.

We thank Alan and Marilyn Zublatt for their generous support of this and other *Kaplan & Sadock* textbooks. Over the years they have been unselfish benefactors to many educational, clinical, and research projects at the NYU Medical Center. We are deeply grateful for their help.

We want to take this opportunity to acknowledge those who have translated this and other *Kaplan & Sadock* books into foreign languages, including Chinese, Croatian, French, German, Greek, Indonesian, Italian, Japanese, Polish, Portuguese, Romanian, Russian, Spanish, and Turkish, in addition to a special Asian and international student edition.

Lippincott Williams & Wilkins has been our publisher for nearly half a century and as always, their staff was most efficient. Jamie Elfrank, Acquisitions Editor at LWW was extremely helpful in many aspects of our work and we value not only her assistance but her friendship as well. We also wish to thank Andrea Vosburgh, Production Editor at LWW who helped immeasurably in the many details involved in putting this book together. She went far beyond her role as production editor serving as part-time copy editor, picture editor, permissions editor and many other roles too numerous to mention. Her optimism and dedication to the project were extraordinarily helpful. Chris Miller at Aptara also deserves our thanks for her work on this and other *Kaplan & Sadock* titles. We especially wish to acknowledge Charley Mitchell, past Executive Editor at LWW, who encouraged and guided us for over 20 years before moving on to a career in academia. We value his friendship now as much as we did throughout the years he was at LWW.

Finally, we want to express our deep thanks to Charles Marmar, M.D., Professor and Chairman of Psychiatry at New York University School of Medicine, who gave us his full support throughout the project. He has guided the department into the 21st century with

dedication, skill, and enthusiasm. Under his leadership, NYU has become one of the leading centers of psychiatry and neuroscience both in this country and around the world.

Contents

1 Neural Sciences

- 1.1 Introduction
- 1.2 Functional Neuroanatomy
- 1.3 Neural Development and Neurogenesis
- 1.4 Neurophysiology and Neurochemistry
- 1.5 Psychoneuroendocrinology
- 1.6 Immune System and Central Nervous System Interactions
- 1.7 Neurogenetics
- 1.8 Applied Electrophysiology
- 1.9 Chronobiology

2 Contributions of the Psychosocial Sciences

- 2.1 Jean Piaget and Cognitive Development
- 2.2 Attachment Theory
- 2.3 Learning Theory
- 2.4 Biology of Memory
- 2.5 Normality and Mental Health

3 Contributions of the Sociocultural Sciences

- 3.1 Sociobiology and Ethology
- 3.2 Transcultural Psychiatry
- 3.3 Culture-Bound Syndromes

4 Theories of Personality and Psychopathology

- 4.1 Sigmund Freud: Founder of Classic Psychoanalysis
- 4.2 Erik H. Erikson
- 4.3 Other Psychodynamic Schools
- 4.4 Positive Psychology

5 Examination and Diagnosis of the Psychiatric Patient

- 5.1 Psychiatric Interview, History, and Mental Status Examination
- 5.2 The Psychiatric Report and Medical Record
- 5.3 Psychiatric Rating Scales
- 5.4 Clinical Neuropsychology and Intellectual Assessment of Adults
- 5.5 Personality Assessment: Adults and Children
- 5.6 Neuropsychological and Cognitive Assessment of Children
- 5.7 Medical Assessment and Laboratory Testing in Psychiatry
- 5.8 Neuroimaging
- 5.9 Physical Examination of the Psychiatric Patient

6 Classification in Psychiatry

7 Schizophrenia Spectrum and Other Psychotic Disorders

- 7.1 Schizophrenia
- 7.2 Schizoaffective Disorder
- 7.3 Schizophreniform Disorder
- 7.4 Delusional Disorder and Shared Psychotic Disorder
- 7.5 Brief Psychotic Disorder, Other Psychotic Disorders, and Catatonia

8 Mood Disorders

- 8.1 Major Depression and Bipolar Disorder
- 8.2 Dysthymia and Cyclothymia

9 Anxiety Disorders

- 9.1 Overview
- 9.2 Panic Disorder
- 9.3 Agoraphobia
- 9.4 Specific Phobia
- 9.5 Social Anxiety Disorder (Social Phobia)
- 9.6 Generalized Anxiety Disorder
- 9.7 Other Anxiety Disorders

10 Obsessive-Compulsive and Related Disorders

- 10.1 Obsessive-Compulsive Disorder
- 10.2 Body Dysmorphic Disorder
- 10.3 Hoarding Disorder
- 10.4 Hair-Pulling Disorder (Trichotillomania)
- 10.5 Excoriation (Skin-Picking) Disorder

11 Trauma- and Stressor-Related Disorders

- 11.1 Posttraumatic Stress Disorder and Acute Stress Disorder
- 11.2 Adjustment Disorders

12 Dissociative Disorders

13 Psychosomatic Medicine

- 13.1 Introduction and Overview
- 13.2 Somatic Symptom Disorder
- 13.3 Illness Anxiety Disorder
- 13.4 Functional Neurological Symptom Disorder (Conversion Disorder)
- 13.5 Psychological Factors Affecting Other Medical Conditions
- 13.6 Factitious Disorder
- 13.7 Pain Disorder
- 13.8 Consultation-Liaison Psychiatry

14 Chronic Fatigue Syndrome and Fibromyalgia

15 Feeding and Eating Disorders

- 15.1 Anorexia Nervosa
- 15.2 Bulimia Nervosa
- 15.3 Binge Eating Disorder and Other Eating Disorders
- 15.4 Obesity and the Metabolic Syndrome

16 Normal Sleep and Sleep-Wake Disorders

- 16.1 Normal Sleep
- 16.2 Sleep-Wake Disorders

17 Human Sexuality and Sexual Dysfunctions

- 17.1 Normal Sexuality
- 17.2 Sexual Dysfunctions
- 17.3 Paraphilic Disorders

18 Gender Dysphoria

19 Disruptive, Impulse-Control, and Conduct Disorders

20 Substance Use and Addictive Disorders

- 20.1 Introduction and Overview
- 20.2 Alcohol-Related Disorders
- 20.3 Caffeine-Related Disorders
- 20.4 Cannabis-Related Disorders
- 20.5 Hallucinogen-Related Disorders
- 20.6 Inhalant-Related Disorders
- 20.7 Opioid-Related Disorders
- 20.8 Sedative-, Hypnotic-, or Anxiolytic-Related Disorders
- 20.9 Stimulant-Related Disorders
- 20.10 Tobacco-Related Disorders
- 20.11 Anabolic-Androgenic Steroid Abuse
- 20.12 Other Substance Use and Addictive Disorders

20.13 Gambling Disorder

21 Neurocognitive Disorders

21.1 Introduction and Overview

21.2 Delirium

21.3 Dementia (Major Neurocognitive Disorder)

21.4 Major or Minor Neurocognitive Disorder Due to Another Medical Condition (Amnesic Disorders)

21.5 Neurocognitive and Other Disorders Due to a General Medical Condition

21.6 Mild Cognitive Impairment

22 Personality Disorders

23 Emergency Psychiatric Medicine

23.1 Suicide

23.2 Psychiatric Emergencies in Adults

23.3 Psychiatric Emergencies in Children

24 Complementary and Alternative Medicine in Psychiatry

25 Other Conditions that May be a Focus of Clinical Attention

26 Physical and Sexual Abuse of Adults

27 Psychiatry and Reproductive Medicine

28 Psychotherapies

28.1 Psychoanalysis and Psychoanalytic Psychotherapy

28.2 Brief Psychodynamic Psychotherapy

28.3 Group Psychotherapy, Combined Individual and Group Psychotherapy, and Psychodrama

28.4 Family Therapy and Couples Therapy

28.5 Dialectical Behavior Therapy

28.6 Biofeedback

28.7 Cognitive Therapy

28.8 Behavior Therapy

28.9 Hypnosis

28.10 Interpersonal Therapy

28.11 Narrative Psychotherapy

28.12 Psychiatric Rehabilitation

28.13 Combined Psychotherapy and Pharmacology

28.14 Genetic Counseling

28.15 Mentalization-Based Therapy and Mindfulness

29 Psychopharmacological Treatment

29.1 General Principles of Psychopharmacology

29.2 Medication-Induced Movement Disorders

29.3 α_2 -Adrenergic Receptor Agonists, α_1 -Adrenergic Receptor Antagonists: Clonidine, Guanfacine, Prazosin, and Yohimbine

29.4 β -Adrenergic Receptor Antagonists

29.5 Anticholinergic Agents

29.6 Anticonvulsants

29.7 Antihistamines

29.8 Barbiturates and Similarly Acting Drugs

29.9 Benzodiazepines and Drugs Acting on GABA Receptors

29.10 Bupropion

29.11 Buspirone

29.12 Calcium Channel Blockers

29.13 Carbamazepine and Oxcarbazepine

29.14 Cholinesterase Inhibitors and Memantine

29.15 Disulfiram and Acamprosate

29.16 Dopamine Receptor Agonists and Precursors

29.17 Dopamine Receptor Antagonists (First-Generation Antipsychotics)

29.18 Lamotrigine

29.19 Lithium

29.20 Melatonin Agonists: Ramelteon and Melatonin

29.21 Mirtazapine

29.22 Monoamine Oxidase Inhibitors

29.23 Nefazodone and Trazodone

29.24 Opioid Receptor Agonists

29.25 Opioid Receptor Antagonists: Naltrexone, Nalmefene, and Naloxone

- 29.26 Phosphodiesterase-5 Inhibitors
- 29.27 Selective Serotonin–Norepinephrine Reuptake Inhibitors
- 29.28 Selective Serotonin Reuptake Inhibitors
- 29.29 Serotonin–Dopamine Antagonists and Similarly Acting Drugs (Second-Generation or Atypical Antipsychotics)
- 29.30 Stimulant Drugs and Atomoxetine
- 29.31 Thyroid Hormones
- 29.32 Tricyclics and Tetracyclics
- 29.33 Valproate
- 29.34 Nutritional Supplements and Medical Foods
- 29.35 Weight Loss Drugs

30 Brain Stimulation Methods

- 30.1 Electroconvulsive Therapy
- 30.2 Other Brain Stimulation Methods
- 30.3 Neurosurgical Treatments and Deep Brain Stimulation

31 Child Psychiatry

- 31.1 Introduction: Infant, Child, and Adolescent Development
- 31.2 Assessment, Examination, and Psychological Testing
- 31.3 Intellectual Disability
- 31.4 Communication Disorders
 - 31.4a Language Disorder
 - 31.4b Speech Sound Disorder
 - 31.4c Child-Onset Fluency Disorder (Stuttering)
 - 31.4d Social (Pragmatic) Communication Disorder
 - 31.4e Unspecified Communication Disorder
- 31.5 Autism Spectrum Disorder
- 31.6 Attention Deficit/Hyperactivity Disorder
- 31.7 Specific Learning Disorder
- 31.8 Motor Disorders
 - 31.8a Developmental Coordination Disorder
 - 31.8b Stereotypic Movement Disorder
 - 31.8c Tourette's Disorder
 - 31.8d Persistent (Chronic) Motor or Vocal Tic Disorder
- 31.9 Feeding and Eating Disorders of Infancy or Early Childhood
 - 31.9a Pica
 - 31.9b Rumination Disorder
 - 31.9c Avoidant/Restrictive Food Intake Disorder
- 31.10 Elimination Disorders

About The Authors

BENJAMIN J. SADOCK, M.D.

Benjamin James Sadock, M.D., is the Menas S. Gregory Professor of Psychiatry in the Department of Psychiatry at the New York University (NYU) School of Medicine. He is a graduate of Union College, received his M.D. degree from New York Medical College, and completed his internship at Albany Hospital. He completed his residency at Bellevue Psychiatric Hospital and then entered military service as Captain US Air force, where he served as Acting Chief of Neuropsychiatry at Sheppard Air Force Base in Texas. He has held faculty and teaching appointments at Southwestern Medical School and Parkland Hospital in Dallas and at New York Medical College, St. Luke's Hospital, the New York State Psychiatric Institute, and Metropolitan Hospital in New York City. Dr. Sadock joined the faculty of the NYU School of Medicine in 1980 and served in various positions: Director of Medical Student Education in Psychiatry, Co-Director of the Residency Training Program in Psychiatry, and Director of Graduate Medical Education. Currently, Dr. Sadock is Co-Director of Student Mental Health Services, Psychiatric Consultant to the Admissions Committee, and Co-Director of Continuing Education in Psychiatry at the NYU School of Medicine. He is on the staff of Bellevue Hospital and Tisch Hospital and is a Consulting Psychiatrist at Lenox Hill Hospital. Dr. Sadock is a Diplomate of the American Board of Psychiatry and Neurology and served as an Associate Examiner for the Board for more than a decade. He is a Distinguished Life Fellow of the American Psychiatric Association, a Fellow of the American College of Physicians, a Fellow of the New York Academy of Medicine, and a member of Alpha Omega Alpha Honor Society. He is active in numerous psychiatric organizations and was president and founder of the NYU-Bellevue Psychiatric Society. Dr. Sadock was a member of the National Committee in Continuing Education in Psychiatry of the American Psychiatric Association, served on the Ad Hoc Committee on Sex Therapy Clinics of the American Medical Association, was a Delegate to the Conference on Recertification of the American Board of Medical Specialists, and was a representative of the American Psychiatric Association Task Force on the National Board of Medical Examiners and the American Board of Psychiatry and Neurology. In 1985, he received the Academic Achievement Award from New York Medical College and was appointed Faculty Scholar at NYU School of Medicine in 2000. He is the author or editor of more than 100 publications (including 49 books), a reviewer for psychiatric journals, and lectures on a broad range of topics in general psychiatry. Dr. Sadock maintains a private practice for diagnostic consultations and psychiatric treatment. He has been married to Virginia Alcott Sadock, M.D., Professor of Psychiatry at NYU School of Medicine, since completing his residency. Dr. Sadock enjoys opera, golf, skiing, traveling, and is an enthusiastic fly fisherman.

VIRGINIA A. SADOCK, M.D.

Virginia Alcott Sadock, M.D., joined the faculty of the New York University (NYU) School of Medicine in 1980, where she is currently Professor of Psychiatry and Attending Psychiatrist at the Tisch Hospital and Bellevue Hospital. She is Director of the Program in Human Sexuality at the NYU Langone Medical Center, one of the largest treatment and training programs of its kind in the United States. She is the author of more than 50 articles and chapters on sexual behavior and was the developmental editor of *The Sexual Experience*, one of the first major textbooks on human sexuality, published by Williams & Wilkins. She serves as a referee and book reviewer for several medical journals, including the *American Journal of Psychiatry* and the *Journal of the American Medical Association*. She has long been interested in the role of women in medicine and psychiatry and was a founder of the Committee on Women in Psychiatry of the New York County District Branch of the American Psychiatric Association. She is active in academic matters, served as an Assistant and Associate Examiner for the American Board of Psychiatry and Neurology for more than 20 years, and was also a member of the Test Committee in Psychiatry for both the American Board of Psychiatry and the Psychiatric Knowledge and Self-Assessment Program (PKSAP) of the American Psychiatric Association. She has chaired the Committee on Public Relations of the New York County District Branch of the American Psychiatric Association, has been a regional council member of the American Association of Sex Education Counselors and Therapists, a founding member of The Society of Sex Therapy and Research, and is President of the NYU Alumni Association of Sex Therapists. She has participated in the National Medical Television Network series *Women in Medicine* and the Emmy Award-winning PBS television

documentary *Women and Depression* and currently hosts the radio program *Sexual Health and Well-being* (Sirius-XM) at NYU Langone Medical Center. She lectures extensively both in this country and abroad on sexual dysfunction, relational problems, and depression and anxiety disorders. She is a Distinguished Fellow of the American Psychiatric Association, a Fellow of the New York Academy of Medicine, and a Diplomate of the American Board of Psychiatry and Neurology. Dr. Sadock is a graduate of Bennington College, received her M.D. degree from New York Medical College, and trained in psychiatry at Metropolitan Hospital. She lives in Manhattan with her husband, Dr. Benjamin Sadock, where she maintains an active practice that includes individual psychotherapy, couples and marital therapy, sex therapy, psychiatric consultation, and pharmacotherapy. She and her husband have two children, James and Victoria, both emergency physicians, and two grandchildren, Emily and Celia. In her leisure time, Dr. Sadock enjoys theater, film, golf, reading fiction, and travel.

PEDRO RUIZ, M.D.

Pedro Ruiz, M.D. is Professor and Interim Chair of the Department of Psychiatry and Behavioral Sciences at the University of Texas Medical School at Houston. He graduated from medical school at the University of Paris in France. He conducted his residency training in psychiatry at the University of Miami Medical School in Florida. He has held faculty appointments at a professorial level at Albert Einstein College of Medicine in New York City, and at Baylor College of Medicine and the University of Texas Medical School at Houston. He has served in various positions: Director of the Lincoln Hospital Community Mental Health Center, Director of the Bronx Psychiatric Center, Assistant Dean and Vice Chair of the Department of Psychiatry, all at Albert Einstein College of Medicine in New York City; Chief, Psychiatry Service at Ben Taub General Hospital and Vice Chair of the Department of Psychiatry at Baylor College of Medicine in Houston, Texas; Medical Director of the University of Texas Mental Sciences Institute and Vice Chair of the Department of Psychiatry at the University of Texas Medical School at Houston, in Houston, Texas. He is a Distinguished Life Fellow of the American Psychiatric Association, a Fellow of the American College of Psychiatrists, the American Association for Social Psychiatry, the Benjamin Rush Society and the American Group Psychotherapy Association, and an Honorary Fellow of the World Psychiatric Association. He is also a member of the American Academy of Addiction Psychiatry, the Group for the Advancement of Psychiatry, The American Association of Community Psychiatrists and the American Association of Psychiatric Administrators. He was President of the American College of Psychiatrists (2000–2001), the American Association for Social Psychiatry (2000–2002), the American Board of Psychiatry and Neurology (2002–2003), the American Psychiatric Association (2006–2007), and is currently President Elect of the World Psychiatric Association. He has served in more than 40 Editorial Boards, among them: The American Journal of Psychiatry, Psychiatric Services, The American Journal on Addictions, and World Psychiatry. He has received over 60 awards and honors, among them: The Administrative Psychiatry Award, Simon Bolivar Award, Tarjan Award, Nancy C.A. Roeske Certificate of Excellence, and the Irma J. Bland Award from the American Psychiatric Association; also, the Bowis Award from the American College of Psychiatrists. He is the author or editor of more than 600 publications; he has delivered worldwide more than 200 grand rounds and invited lectures; he has also made more than 400 worldwide scientific presentations. He and his wife Angela have two children, Pedro Pablo and Angela Maria, and four grandchildren, Francisco Antonio, Pedro Pablo, Jr., Omar Joseph, III, and Pablo Antonio. Dr. Ruiz enjoys reading literary novels, theater, films, traveling, and fishing.

1.1 Introduction

The human brain is responsible for our cognitive processes, emotions, and behaviors—that is, everything we think, feel, and do. Although the early development and adult function of the brain are shaped by multiple factors (e.g., epigenetic, environmental, and psychosocial experiences), the brain is the final integrator of these influences. Despite the many advances in neural sciences over the last several decades, including the “decade of the brain” in the 1990s, and the wide acceptance of the brain as the biological substrate for normal and abnormal mental functions, there has not been a true transformational advance in the treatment of mental disorders for more than half a century. The most obvious reason for the absence of more progress is the profound complexity of the human brain. A perhaps less obvious reason is the current practice of psychiatric diagnosis, which, for most clinicians, is based on syndrome-based classification systems.

The purpose of this chapter is to introduce the neural sciences sections, which describe the anatomy and function of the human brain, and then to discuss how an evolution of thinking toward a brain-based or biologically based diagnostic system for mental illness might facilitate our efforts to advance brain research, to develop better treatments, and to improve patient care.

In other fields of medicine, diagnosis is based on physical signs and symptoms, a medical history, and results of laboratory and radiological tests. In psychiatry, a diagnosis is based primarily on the clinician’s impression of the patient’s interpretation of his or her thoughts and feelings. The patient’s symptoms are then cross-referenced to a diagnostic or classification manual (e.g., *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5], *International Statistical Classification of Diseases and Related Health Problems* [ICD]) containing hundreds of potential syndromes, and one or more diagnoses are applied to the particular patient. These standard classification systems represent significant improvements in reliability over previous diagnostic systems, but there is little reason to believe that these diagnostic categories are valid, in the sense that they represent discrete, biologically distinct entities. Although a patient with no symptoms or complaints can be diagnosed as having diabetes, cancer, or hypertension on the basis of blood tests, X-rays, or vital signs, a patient with no symptoms cannot be diagnosed with schizophrenia, for example, because there are no currently recognized objective, independent assessments.

The goals of clinicians and researchers are to reduce human suffering by increasing our understanding of diseases, developing new treatments to prevent or cure diseases, and caring for patients in an optimal manner. If the brain is the organ of focus for mental illnesses, then it may be time to be more ambitious in building the classification of patients with mental illnesses directly from our understanding of biology, rather than only from the assessment of a patient’s symptoms.

THE HUMAN BRAIN

The following neural sciences sections each address a field of brain biology. Each of these fields could be relevant to the pathophysiology and treatment of mental illnesses. Although the complexity of the human brain is daunting compared with other organs of the body, progress can only be made if one approaches this complexity consistently, methodically, and bravely.

The neuronal and glial cells of the human brain are organized in a characteristic manner, which has been increasingly clarified through modern neuroanatomical techniques. In addition, our knowledge of normal human brain development has become more robust in the last decade. The human brain clearly evolved from the brain of lower animal species, allowing inferences to be made about the human brain from animal studies. Neurons communicate with one another through chemical and electrical neurotransmission. The major neurotransmitters are the monoamines, amino acids, and neuropeptides. Other chemical messengers include neurotrophic factors and an array of other molecules, such as nitric oxide. Electrical neurotransmission occurs through a wide range of ion channels. Chemical and electrical signals received by a neuron subsequently initiate various molecular pathways within other neurons that regulate the biology and function of individual neurons, including the expression of individual genes and the production of proteins.

In addition to the central nervous system (CNS), the human body contains two other systems that have complex, internal communicative networks: the endocrine system and the immune system. The recognition that these three systems communicate with each other has given birth to the fields of psychoneuroendocrinology and psychoneuroimmunology. Another property shared by the CNS, the endocrine system, and the immune system is the regular changes they undergo with the passage of time (e.g., daily, monthly), which is the basis of the field of chronobiology.

PSYCHIATRY AND THE HUMAN BRAIN

In the first half of the 20th century, the advances in psychodynamic psychiatry, as well as in social and epidemiological psychiatry, led to a separation of psychiatric research from the study of the human brain. Since the 1950s, the appreciation of the effectiveness of medications in treating mental disorders and the mental effects of illicit drugs, have reestablished a biological view of mental illness, which had already been seeded by the introduction of electroconvulsive therapy (ECT) and James Papez’s description of the limbic circuit in the 1930s. This biological view has been reinforced further by the development of brain imaging techniques that have helped reveal how the brain performs in normal and abnormal conditions. During this period, countless discoveries have been made in basic neural science research using experimental techniques to assess the development, structure, biology, and function of the CNS of humans and animals.

Psychopharmacology

The effectiveness of drugs in the treatment of mental illness has been a major feature of the last half-century of psychiatric practice. The first five editions of this textbook divided psychopharmacological treatment into four chapters on antipsychotic, antidepressant, anti-anxiety, and mood-stabilizing drugs. The prior division of psychiatric drugs into four classes is less valid now than it was in the past for the following reasons: (1) Many drugs of one class are used to treat disorders previously assigned to another class; (2) drugs from all four categories are used to treat disorders not previously treatable by drugs (for example, eating disorders, panic disorders, and impulse control disorders); and (3) drugs such as clonidine (Catapres), propranolol (Inderal), and verapamil (Isoptin) can effectively treat a variety of psychiatric disorders and do not fit easily into the aforementioned classification of drugs.

The primary motivation for this change was that the variety and application of the drug treatments no longer clearly fit a division of disorders into psychosis, depression, anxiety, and mania. In other words, the clinical applications of biologically based treatments did not neatly align with our syndrome-based diagnostic system. An implication of this observation could be that drug response might be a better indicator of underlying biological brain dysfunction than any particular group of symptoms. For example, although the DSM-5 distinguishes major depressive disorder from generalized anxiety disorder, most clinicians are aware that these are often overlapping symptoms and conditions in clinical practice. Moreover, the same drugs are used to treat both conditions.

The animal models that are used to identify new drug treatments may also have affected our ability to advance research and treatment. Many major classes of psychiatric drugs were discovered serendipitously. Specifically, the drugs were developed originally for nonpsychiatric

indications, but observant clinicians and researchers noted that psychiatric symptoms improved in some patients, which led to focused study of these drugs in psychiatric patients. The availability of these effective drugs, including monoaminergic antidepressants and antipsychotics, led to the development of animal models that could detect the effects of these drugs (e.g., tricyclic antidepressants increase the time mice spend trying to find a submerged platform in a “forced swim” test). These animal models were then used to screen new compounds in an attempt to identify drugs that were active in the same animal models. The potential risk of this overall strategy is that these animal models are merely a method for detecting a particular molecular mechanism of action (e.g., increasing serotonin concentrations), rather than a model for a true behavioral analog of a human mental illness (e.g., behavioral despair in a depressed patient).

Endophenotypes

A possible diagnosis-related parallel to how this textbook separated the four classes of psychotropic drugs into approximately 30 different categories is the topic of *endophenotypes* in psychiatric patients. An endophenotype is an internal phenotype, which is a set of objective characteristics of an individual that are not visible to the unaided eye. Because there are so many steps and variables that separate a particular set of genes from the final functioning of a whole human brain, it may be more tractable to consider intermediate assessments such as endophenotypes. This hypothesis is based on the assumption that the number of genes that are involved in an endophenotype might be fewer than the number of genes involved in causing what we would conceptualize as a disease. The nature of an endophenotype, as considered in psychiatry, is biologically defined on the basis of neuropsychological, cognitive, neurophysiological, neuroanatomical, biochemical, and brain imaging data. Such an endophenotype, for example, might include specific cognitive impairments as just one of its objectively measured features. This endophenotype would not be limited to patients with a diagnosis of schizophrenia because it might also be found in some patients with depression or bipolar disorder.

The potential role of an endophenotype can be further clarified by stating what it is not. An endophenotype is not a symptom, and it is not a diagnostic marker. A classification based on the presence or absence of one or more endophenotypes would be based on objective biological and neuropsychological measures with specific relationships to genes and brain function. A classification based on endophenotypes might also be a productive approach toward the development of more relevant animal models of mental illnesses, and thus the development of novel treatments.

PSYCHIATRY AND THE HUMAN GENOME

Perhaps 70 to 80 percent of the 25,000 human genes are expressed in the brain, and because most genes code for more than one protein, there may be 100,000 different proteins in the brain. Perhaps 10,000 of these are known proteins with somewhat identified functions, and no more than 100 of these are the targets for existing psychotherapeutic drugs.

The study of families with the use of population genetic methods over the last 50 years has consistently supported a genetic, heritable component to mental disorders. More recent techniques in molecular biology have revealed that specific chromosomal regions and genes are associated with particular diagnoses. A potentially very powerful application of these techniques has been to study transgenic models of behavior in animals. These transgenic models can help us understand the effects of individual genes as well as discover completely novel molecular targets for drug development.

It may be a natural response to resist “simple” genetic explanations for human features. Nonetheless, research on humans generally has found that approximately 40 to 70 percent of aspects of cognition, temperament, and personality are attributable to genetic factors. Because these are the very domains that are affected in mentally ill patients, it would not be surprising to discover a similar level of genetic influence on mental illness, especially if we were able to assess this impact at a more discrete level, such as with endophenotypes.

Individual Genes and Mental Disorders

Several types of data and observations suggest that any single gene is likely to have only a modest effect on the development of a mental disorder, and that when a mental disorder is present in an individual, it represents the effects of multiple genes, speculatively on the order of five to ten genes. This hypothesis is also supported by our failure to find single genes with major effects in mental illnesses. Some researchers, however, still consider it a possibility that genes with major effects will be identified.

“Nature” and “Nurture” within the CNS

In 1977, George Engel, at the University of Rochester, published a paper that articulated the biopsychosocial model of disease, which stressed an integrated approach to human behavior and disease. The biological system refers to the anatomical, structural, and molecular substrates of disease; the psychological system refers to the effects of psychodynamic factors; and the social system examines cultural, environmental, and familial influences. Engel postulated that each system affects and is affected by the others.

The observation that a significant percentage of identical twins are discordant for schizophrenia is one example of the type of data that support the understanding that there are many significant interactions between the genome and the environment (i.e., the biological basis of the biopsychosocial concept). Studies in animals have also demonstrated that many factors—including activity, stress, drug exposure, and environmental toxins—can regulate the expression of genes and the development and functioning of the brain.

Mental Disorders Reflect Abnormalities in Neuroanatomical Circuits and Synaptic Regulation

Although genes lead to the production of proteins, the actual functioning of the brain needs to be understood at the level of regulation of complex pathways of neurotransmission and intraneuronal signaling, and of networks of neurons within and between brain regions. In other words, the downstream effects of abnormal genes are modifications in discrete attributes such as axonal projections, synaptic integrity, and specific steps in intraneuronal molecular signaling.

Why Not a Genetic-Based Diagnostic System?

Some researchers have proposed moving psychiatry toward a completely genetic-based diagnostic system. This proposal, however, seems premature based on the complexity of the genetic factors presumably involved in psychiatric disorders, the current absence of sufficient data to make these genetic connections, and the importance of epigenetic and environmental influences on the final behavioral outcomes resulting from an individual’s genetic information.

LESSONS FROM NEUROLOGY

Clinical and research neurologists seem to have been able to think more clearly than psychiatrists about their diseases of interest and their causes, perhaps because the symptoms are generally nonbehavioral. Neurologists have biologically grounded differential diagnoses and treatment choices. This clarity of approach has helped lead to significant advances in neurology in the last two decades, for example, clarification of the amyloid precursor protein abnormalities in some patients with Alzheimer’s disease, the presence of trinucleotide repeat mutations in Huntington’s disease and spinocerebellar ataxia, and the appreciation of alpha-synucleinopathies, such as Parkinson’s disease and Lewy body dementia.

The continued separation of psychiatry from neurology is in itself a potential impediment to good patient care and research. Many

neurological disorders have psychiatric symptoms (e.g., depression in patients following a stroke or with multiple sclerosis or Parkinson's disease), and several of the most severe psychiatric disorders have been associated with neurological symptoms (e.g., movement disorders in schizophrenia). This is not surprising given that the brain is the organ shared by psychiatric and neurological diseases, and the division between these two disease areas is arbitrary. For example, patients with Huntington's disease are at much greater risk for a wide range of psychiatric symptoms and syndromes, and thus many different DSM-5 diagnoses. Because we know that Huntington's disease is an autosomal dominant genetic disorder, the observation that it can manifest with so many different DSM-5 diagnoses does not speak to a very strong biological distinction among the existing DSM-5 categories.

EXAMPLES OF COMPLEX HUMAN BEHAVIORS

The goal to understand the human brain and its normal and abnormal functioning is truly one of the last frontiers for humans to explore. Trying to explain why a particular individual is the way he or she is, or what causes schizophrenia, for example, will remain too large a challenge for some decades. It is more approachable to consider more discrete aspects of human behavior.

It is not the role of textbooks to set policies or to write diagnostic manuals, but rather to share knowledge, generate ideas, and encourage innovation. The authors believe, however, that it is time to reap the insights of decades of neural science and clinical brain research and to build the classification of mental illnesses on fundamental principles of biology and medicine. Regardless of official diagnostic systems, however, clinicians and researchers should fully understand the biological component of the biopsychosocial model, and not let research or patient care suffer because of a diagnostic system that is not founded on biological principles.

1.2 Functional Neuroanatomy

The sensory, behavioral, affective, and cognitive phenomena and attributes experienced by humans are mediated through the brain. It is the organ that perceives and affects the environment and integrates past and present. The brain is the organ of the mind that enables persons to sense, do, feel, and think.

Sensory systems create an internal representation of the external world by processing external stimuli into neuronal impulses. A separate map is formed for each sensory modality. *Motor systems* enable persons to manipulate their environment and to influence the behavior of others through communication. In the brain, sensory input, representing the external world, is integrated with internal drivers, memories, and emotional stimuli in *association units*, which in turn drive the actions of motor units. Although psychiatry is concerned primarily with the brain's association function, an appreciation of information processing of the sensory and motor systems is essential for sorting logical thought from the distortions introduced by psychopathology.

BRAIN ORGANIZATION

The human brain contains approximately 10^{11} *neurons* (nerve cells) and approximately 10^{12} *glial cells*. Neurons most classically consist of a *soma*, or cell body, which contains the nucleus; usually multiple *dendrites*, which are processes that extend from the cell body and receive signals from other neurons; and a single *axon*, which extends from the cell body and transmits signals to other neurons. Connections between neurons are made at *axon terminals*; there the axons of one neuron generally contact the dendrite or cell body of another neuron. Neurotransmitter release occurs within axon terminals and is one of the major mechanisms for intraneuronal communications, and also for the effects of psychotropic drugs.

There are three types of glial cells, and although they have often been thought of as having only a supportive role for neuronal functioning, glia have been increasingly appreciated as potentially involved in brain functions that may contribute more directly to both normal and disease mental conditions. The most common type of glial cell are the *astrocytes*, which have a number of functions, including nutrition of neurons, deactivation of some neurotransmitters, and integration with the blood-brain barrier. The *oligodendrocytes* in the central nervous system and the *Schwann cells* in the peripheral nervous system wrap their processes around neuronal axons, resulting in *myelin sheaths* that facilitate the conduction of electrical signals. The third type of glial cells, the *microglia*, which are derived from macrophages, are involved in removing cellular debris following neuronal death.

The neurons and glial cells are arranged in regionally distinct patterns within the brain. Neurons and their processes form groupings in many different ways, and these patterns of organization, or architecture, can be evaluated by several approaches. The pattern of distribution of nerve cell bodies, called *cytoarchitecture*, is revealed by aniline dyes called Nissl stains that stain ribonucleotides in the nuclei and the cytoplasm of neuronal cell bodies. The Nissl stains show the relative size and packing density of the neurons and, consequently, reveal the organization of the neurons into the different layers of the cerebral cortex.

SENSORY SYSTEMS

The external world offers an infinite amount of potentially relevant information. In this overwhelming volume of sensory information in the environment, the sensory systems must both detect and discriminate stimuli; they winnow relevant information from the mass of confounding input by applying filtration at all levels. Sensory systems first transform external stimuli into neural impulses and then filter out irrelevant information to create an internal image of the environment, which serves as a basis for reasoned thought. Feature extraction is the quintessential role of sensory systems, which achieve this goal with their hierarchical organizations, first by transforming physical stimuli into neural activity in the primary sense organs and then by refining and narrowing the neural activity in a series of higher cortical processing areas. This neural processing eliminates irrelevant data from higher representations and reinforces crucial features. At the highest levels of sensory processing, neural images are transmitted to the association areas to be acted on in the light of emotions, memories, and drives.

Somatosensory System

The *somatosensory system*, an intricate array of parallel point-to-point connections from the body surface to the brain, was the first sensory system to be understood in anatomical detail. The six somatosensory modalities are light touch, pressure, pain, temperature, vibration, and proprioception (position sense). The organization of nerve bundles and synaptic connections in the somatosensory system encodes spatial relationships at all levels, so that the organization is strictly *somatotopic* (Fig. 1.2-1).

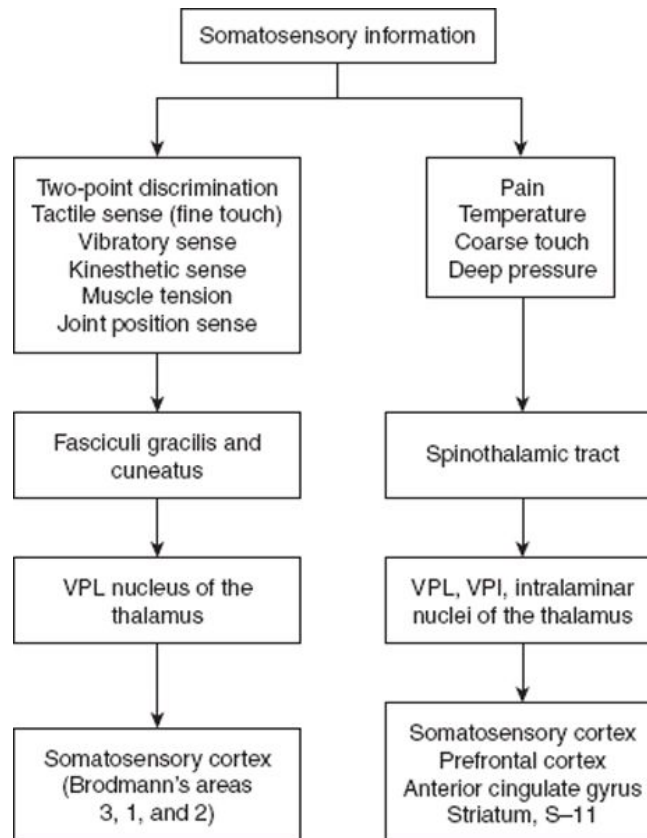

FIGURE 1.2-1

Pathway of somatosensory information processing. (Adapted from Patestas MA, Gartner LP. *A Textbook of Neuroanatomy*. Malden, MA: Blackwell; 2006:149.)

Within a given patch of skin, various receptor nerve terminals act in concert to mediate distinct modalities. The mechanical properties of the skin's mechanoreceptors and thermoreceptors generate neural impulses in response to dynamic variations in the environment while they suppress static input. Nerve endings are either fast or slow responders; their depth in the skin also determines their sensitivity to sharp or blunt stimuli. Thus the representation of the external world is significantly refined at the level of the primary sensory organs.

The receptor organs generate coded neural impulses that travel proximally along the sensory nerve axons to the spinal cord. These far-flung routes are susceptible to varying systemic medical conditions and to pressure palsies. Pain, tingling, and numbness are the typical presenting symptoms of peripheral neuropathies.

All somatosensory fibers project to, and synapse in, the thalamus. The thalamic neurons preserve the somatotopic representation by projecting fibers to the somatosensory cortex, located immediately posterior to the sylvian fissure in the parietal lobe. Despite considerable overlap, several bands of cortex roughly parallel to the sylvian fissure are segregated by a somatosensory modality. Within each band is the sensory "homunculus," the culmination of the careful somatotopic segregation of the sensory fibers at the lower levels. The clinical syndrome of *tactile agnosia (astereognosis)* is defined by the inability to recognize objects based on touch, although the primary somatosensory modalities—light touch, pressure, pain, temperature, vibration, and proprioception—are intact. This syndrome, localized at the border of the somatosensory and association areas in the posterior parietal lobe, appears to represent an isolated failure of only the highest order of feature extraction, with preservation of the more basic levels of the somatosensory pathway.

Reciprocal connections are a key anatomical feature of crucial importance to conscious perception—as many fibers project down from the cortex to the thalamus as project up from the thalamus to the cortex. These reciprocal fibers play a critical role in filtering sensory input. In normal states, they facilitate the sharpening of internal representations, but in pathological states, they can generate false signals or inappropriately suppress sensation. Such cortical interference with sensory perception is thought to underlie many psychosomatic syndromes, such as the hemisensory loss that characterizes conversion disorder.

The prenatal development of the strict point-to-point pattern that characterizes the somatosensory system remains an area of active study. Patterns of sensory innervation result from a combination of axonal guidance by particular molecular cues and pruning of exuberant synaptogenesis on the basis of an organism's experience. Leading hypotheses weigh contributions from a genetically determined molecular map—in which the arrangement of fiber projections is organized by fixed and diffusible chemical cues—against contributions from the modeling and remodeling of projections on the basis of coordinated neural activity. Thumbnail calculations suggest that the 30,000 to 40,000 genes in human deoxyribonucleic acid (DNA) are far too few to encode completely the position of all the trillions of synapses in the brain. In fact, genetically determined positional cues probably steer growing fibers toward the general target, and the pattern of projections is fine-tuned by activity-dependent mechanisms. Recent data suggest that well-established adult thalamocortical sensory projections can be gradually remodeled as a result of a reorientation of coordinated sensory input or in response to loss of part of the somatosensory cortex, for instance, in stroke.

Development of the Somatosensory System

A strict somatotopic representation exists at each level of the somatosensory system. During development, neurons extend axons to connect to distant brain regions; after arriving at the destination, a set of axons must therefore sort itself to preserve the somatotopic organization. A classic experimental paradigm for this developmental process is the representation of a mouse's whiskers in the somatosensory cortex. The murine somatosensory cortex contains a barrel field of cortical columns, each of which corresponds to one whisker. When mice are inbred to produce fewer whiskers, fewer somatosensory cortex barrels appear. Each barrel is expanded in area, and the entire barrel field covers the same area of the somatosensory cortex as it does in normal animals. This experiment demonstrates that certain higher cortical structures can form in response to peripheral input and that different input complexities determine different patterns of synaptic connectivity. Although

the mechanisms by which peripheral input molds cortical architecture are largely unknown, animal model paradigms are beginning to yield clues. For example, in a mutant mouse that lacks monoamine oxidase A and, thus, has extremely high cortical levels of serotonin, barrels fail to form in the somatosensory cortex. This result indirectly implicates serotonin in the mechanism of barrel field development.

In adults, the classic mapping studies of Wilder Penfield suggested the existence of a homunculus, an immutable cortical representation of the body surface. More recent experimental evidence from primate studies and from stroke patients, however, has promoted a more plastic conception than that of Penfield. Minor variations exist in the cortical pattern of normal individuals, yet dramatic shifts in the map can occur in response to loss of cortex from stroke or injury. When a stroke ablates a significant fraction of the somatosensory homunculus, the homuncular representation begins to contract and shift proportionately to fill the remaining intact cortex.

Moreover, the cortical map can be rearranged solely in response to a change in the pattern of tactile stimulation of the fingers. The somatotopic representation of the proximal and distal segments of each finger normally forms a contiguous map, presumably because both segments contact surfaces simultaneously. However, under experimental conditions in which the distal segments of all fingers are simultaneously stimulated while contact of the distal and proximal parts of each finger is separated, the cortical map gradually shifts 90 degrees to reflect the new sensory experience. In the revised map, the cortical representation of the proximal segment of each finger is no longer contiguous with that of the distal segment.

These data support the notion that the internal representation of the external world, although static in gross structure, can be continuously modified at the level of synaptic connectivity to reflect relevant sensory experiences. The cortical representation also tends to shift to fit entirely into the available amount of cortex.

These results also support the notion that cortical representations of sensory input, or of memories, may be holographic rather than spatially fixed: The pattern of activity, rather than the physical structure, may encode information. In sensory systems, this plasticity of cortical representation allows recovery from brain lesions; the phenomenon may also underlie learning.

Visual System

Visual images are transduced into neural activity within the retina and are processed through a series of brain cells, which respond to increasingly complex features, from the eye to the higher visual cortex. The neurobiological basis of feature extraction is best understood in finest detail in the visual system. Beginning with classic work in the 1960s, research in the visual pathway has produced two main paradigms for all sensory systems. The first paradigm, mentioned earlier with respect to the somatosensory system, evaluates the contributions of genetics and experience—or nature and nurture—in the formation of the final synaptic arrangement. Transplantation experiments, resulting in an accurate point-to-point pattern of connectivity, even when the eye was surgically inverted, have suggested an innate, genetically determined mechanism of synaptic pattern formation. The crucial role of early visual experience in establishing the adult pattern of visual connections, on the other hand, crystallized the hypothesis of activity-dependent formation of synaptic connectivity. The final adult pattern is the result of both factors.

The second main paradigm, most clearly revealed in the visual system, is that of highly specialized brain cells that respond exclusively to extremely specific stimuli. Recent work, for example, has identified cells in the inferior temporal cortex that respond only to faces viewed at a specific angle. An individual's response to a particular face requires the activity of large neural networks and may not be limited to a single neuron. Nevertheless, the cellular localization of specific feature extraction is of critical importance in defining the boundary between sensory and association systems, but only in the visual system has this significant question been posed experimentally.

In the primary visual cortex, columns of cells respond specifically to lines of a specific orientation. The cells of the primary visual cortex project to the secondary visual cortex, where cells respond specifically to particular movements of lines and to angles. In turn, these cells project to two association areas, where additional features are extracted and conscious awareness of images forms.

The inferior temporal lobe detects the shape, form, and color of the object—the *what* questions; the posterior parietal lobe tracks the location, motion, and distance—the *where* questions. The posterior parietal lobe contains distinct sets of neurons that signal the intention either to look into a certain part of visual space or to reach for a particular object. In the inferior temporal cortices (ITCs), adjacent cortical columns respond to complex forms. Responses to facial features tend to occur in the left ITC, and responses to complex shapes tend to occur in the right ITC. The brain devotes specific cells to the recognition of facial expressions and to the aspect and position of faces of others with respect to the individual.

The crucial connections between the feature-specific cells and the association areas involved in memory and conscious thought remain to be delineated. Much elucidation of feature recognition is based on invasive animal studies. In humans, the clinical syndrome of *prosopagnosia* describes the inability to recognize faces, in the presence of preserved recognition of other environmental objects. On the basis of pathological and radiological examination of individual patients, prosopagnosia is thought to result from disconnection of the left ITC from the visual association area in the left parietal lobe. Such lesion studies are useful in identifying necessary components of a mental pathway, but they may be inadequate to define the entire pathway. One noninvasive technique that is still being perfected and is beginning to reveal the full anatomical relation of the human visual system to conscious thought and memory is functional neuroimaging.

As is true for language, there appears to be a hemispheric asymmetry for certain components of visuospatial orientation. Although both hemispheres cooperate in perceiving and drawing complex images, the right hemisphere, especially the parietal lobe, contributes the overall contour, perspective, and right-left orientation, and the left hemisphere adds internal detail, embellishment, and complexity. The brain can be fooled in optical illusions.

Neurological conditions such as strokes and other focal lesions have permitted the definition of several disorders of visual perception. *Apperceptive visual agnosia* is the inability to identify and draw items using visual cues, with preservation of other sensory modalities. It represents a failure of transmission of information from the higher visual sensory pathway to the association areas and is caused by bilateral lesions in the visual association areas. *Associative visual agnosia* is the inability to name or use objects despite the ability to draw them. It is caused by bilateral medial occipitotemporal lesions and can occur along with other visual impairments. Color perception may be ablated in lesions of the dominant occipital lobe that include the splenium of the corpus callosum. *Color agnosia* is the inability to recognize a color despite being able to match it. *Color anomia* is the inability to name a color despite being able to point to it. *Central achromatopsia* is a complete inability to perceive color. *Anton's syndrome* is a failure to acknowledge blindness, possibly owing to interruption of fibers involved in self-assessment. It is seen with bilateral occipital lobe lesions. The most common causes are hypoxic injury, stroke, metabolic encephalopathy, migraine, herniation resulting from mass lesions, trauma, and leukodystrophy. *Balint's syndrome* consists of a triad of optic ataxia (the inability to direct optically guided movements), *oculomotor apraxia* (inability to direct gaze rapidly), and *simultanagnosia* (inability to integrate a visual scene to perceive it as a whole). Balint's syndrome is seen in bilateral parietooccipital lesions. *Gerstmann's syndrome* includes agraphia, calculation difficulties (acalculia), right-left disorientation, and finger agnosia. It has been attributed to lesions of the dominant parietal lobe.

Development of the Visual System

In humans, the initial projections from both eyes intermingle in the cortex. During the development of visual connections in the early postnatal period, there is a window of time during which binocular visual input is required for development of ocular dominance columns in the primary visual cortex. Ocular dominance columns are stripes of cortex that receive input from only one eye, separated by stripes innervated only by fibers from the other eye. Occlusion of one eye during this critical period completely eliminates the persistence of its fibers in the cortex and allows the fibers of the active eye to innervate the entire visual cortex. In contrast, when normal binocular vision is allowed during the critical development window, the usual dominance columns form; occluding one eye after the completion of innervation of the cortex produces no subsequent alteration of the ocular dominance columns. This paradigm crystallizes the importance of early childhood experience on the formation of adult brain circuitry.

Auditory System

Sounds are instantaneous, incremental changes in ambient air pressure. The pressure changes cause the ear's tympanic membrane to vibrate; the vibration is then transmitted to the ossicles (malleus, incus, and stapes) and thereby to the endolymph or fluid of the cochlear spiral. Vibrations of the endolymph move cilia on hair cells, which generate neural impulses. The hair cells respond to sounds of different frequency in a tonotopic manner within the cochlea, like a long, spiral piano keyboard. Neural impulses from the hair cells travel in a tonotopic arrangement to the brain in the fibers of the cochlear nerve. They enter the brainstem cochlear nuclei, are relayed through the lateral lemniscus to the inferior colliculi, and then to the medial geniculate nucleus (MGN) of the thalamus. MGN neurons project to the primary auditory cortex in the posterior temporal lobe. Dichotic listening tests, in which different stimuli are presented to each ear simultaneously, demonstrate that most of the input from one ear activates the contralateral auditory cortex and that the left hemisphere tends to be dominant for auditory processing.

Sonic features are extracted through a combination of mechanical and neural filters. The representation of sound is roughly tonotopic in the primary auditory cortex, whereas *lexical processing* (i.e., the extraction of vowels, consonants, and words from the auditory input) occurs in higher language association areas, especially in the left temporal lobe. The syndrome of *word deafness*, characterized by intact hearing for voices but an inability to recognize speech, may reflect damage to the left parietal cortex. This syndrome is thought to result from disconnection of the auditory cortex from Wernicke's area. A rare, complementary syndrome, *auditory sound agnosia*, is defined as the inability to recognize nonverbal sounds, such as a horn or a cat's meow, in the presence of intact hearing and speech recognition. Researchers consider this syndrome the right hemisphere correlate of pure word deafness.

Development of the Auditory System

Certain children are unable to process auditory input clearly and therefore have impaired speech and comprehension of spoken language. Studies on some of these children have determined that, in fact, they can discriminate speech if the consonants and vowels—the phonemes—are slowed twofold to fivefold by a computer. Based on this observation, a tutorial computer program was designed that initially asked questions in a slowed voice and, as subjects answered questions correctly, gradually increased the rate of phoneme presentation to approximate normal rates of speech. Subjects gained some ability to discriminate routine speech over a period of 2 to 6 weeks and appeared to retain these skills after the tutoring period was completed. This finding probably has therapeutic applicability to 5 to 8 percent of children with speech delay, but ongoing studies may expand the eligible group of students. This finding, moreover, suggests that neuronal circuits required for auditory processing can be recruited and be made more efficient long after language is normally learned, provided that the circuits are allowed to finish their task properly, even if this requires slowing the rate of input. Circuits thus functioning with high fidelity can then be trained to speed their processing.

A recent report has extended the age at which language acquisition may be acquired for the first time.

A boy who had intractable epilepsy of one hemisphere was mute because the uncontrolled seizure activity precluded the development of organized language functions. At the age of 9 years he had the abnormal hemisphere removed to cure the epilepsy. Although up to that point in his life he had not spoken, he initiated an accelerated acquisition of language milestones beginning at that age and ultimately gained language abilities only a few years delayed relative to his chronological age.

Researchers cannot place an absolute upper limit on the age at which language abilities can be learned, although acquisition at ages beyond the usual childhood period is usually incomplete. Anecdotal reports document acquisition of reading skills after the age of 80 years.

Olfaction

Odorants, or volatile chemical cues, enter the nose, are solubilized in the nasal mucus, and bind to odorant receptors displayed on the surface of the sensory neurons of the olfactory epithelium. Each neuron in the epithelium displays a unique odorant receptor, and cells displaying a given receptor are arranged randomly within the olfactory epithelium. Humans possess several hundred distinct receptor molecules that bind the huge variety of environmental odorants; researchers estimate that humans can discriminate 10,000 different odors. Odorant binding generates neural impulses, which travel along the axons of the sensory nerves through the cribriform plate to the olfactory bulb. Within the bulb, all axons corresponding to a given receptor converge onto only 1 or 2 of 3,000 processing units called *glomeruli*. Because each odorant activates several receptors that activate a characteristic pattern of glomeruli, the identity of external chemical molecules is represented internally by a spatial pattern of neural activity in the olfactory bulb.

Each glomerulus projects to a unique set of 20 to 50 separate columns in the olfactory cortex. In turn, each olfactory cortical column receives projections from a unique combination of glomeruli. The connectivity of the olfactory system is genetically determined. Because each odorant activates a unique set of several receptors and thus a unique set of olfactory bulb glomeruli, each olfactory cortical column is tuned to detect a different odorant of some evolutionary significance to the species. Unlike the signals of the somatosensory, visual, and auditory systems, olfactory signals do not pass through the thalamus but project directly to the frontal lobe and the limbic system, especially the pyriform cortex. The connections to the limbic system (amygdala, hippocampus, and pyriform cortex) are significant. Olfactory cues stimulate strong emotional responses and can evoke powerful memories.

Olfaction, the most ancient sense in evolutionary terms, is tightly associated with sexual and reproductive responses. A related chemosensory structure, the vomeronasal organ, is thought to detect *pheromones*, chemical cues that trigger unconscious, stereotyped responses. In some animals, ablation of the vomeronasal organ in early life may prevent the onset of puberty. Recent studies have suggested that humans also respond to pheromones in a manner that varies according to the menstrual cycle. The structures of higher olfactory processing in phylogenetically more primitive animals have evolved in humans into the limbic system, the center of the emotional brain and the gate through which experience is admitted into memory according to emotional significance. The elusive basic animal drives with which clinical psychiatry constantly grapples may therefore, in fact, originate from the ancient centers of higher olfactory processing.

Development of the Olfactory System

During normal development, axons from the nasal olfactory epithelium project to the olfactory bulb and segregate into about 3,000 equivalent glomeruli. If an animal is exposed to a single dominant scent in the early postnatal period, then one glomerulus expands massively within the bulb at the expense of the surrounding glomeruli. Thus, as discussed earlier with reference to the barrel fields of the somatosensory cortex, the size of brain structures may reflect the environmental input.

Taste

Soluble chemical cues in the mouth bind to receptors in the tongue and stimulate the gustatory nerves, which project to the nucleus solitarius in the brainstem. The sense of taste is believed to discriminate only broad classes of stimuli: sweet, sour, bitter, and salty. Each modality is mediated through a unique set of cellular receptors and channels, of which several may be expressed in each taste neuron. The detection and the discrimination of foods, for example, involve a combination of the senses of taste, olfaction, touch, vision, and hearing. Taste fibers activate the medial temporal lobe, but the higher cortical localization of taste is only poorly understood.

Autonomic Sensory System

The autonomic nervous system (ANS) monitors the basic functions necessary for life. The activity of visceral organs, blood pressure, cardiac output, blood glucose levels, and body temperature are all transmitted to the brain by autonomic fibers. Most autonomic sensory information remains unconscious; if such information rises to conscious levels, it is only as a vague sensation, in contrast to the capacity of the primary senses to transmit sensations rapidly and exactly.

Alteration of Conscious Sensory Perception through Hypnosis

Hypnosis is a state of heightened suggestibility attainable by a certain proportion of the population. Under a state of hypnosis, gross distortions of perception in any sensory modality and changes in the ANS can be achieved instantaneously. The anatomy of the sensory system does not change, yet the same specific stimuli may be perceived with diametrically opposed emotional value before and after induction of the hypnotic state. For example, under hypnosis a person may savor an onion as if it were a luscious chocolate truffle, only to reject the onion as abhorrently pungent seconds later, when the hypnotic suggestion is reversed. The localization of the hypnotic switch has not been determined, but it presumably involves both sensory and association areas of the brain. Experiments tracing neural pathways in human volunteers via functional neuroimaging have demonstrated that shifts in attention in an environmental setting determine changes in the regions of the brain that are activated, on an instantaneous time scale. Thus the organizing centers of the brain may route conscious and unconscious thoughts through different sequences of neural processing centers, depending on a person's ultimate goals and emotional state. These attention-mediated variations in synaptic utilization can occur instantaneously, much like the alteration in the routing of associational processing that may occur in hypnotic states.

MOTOR SYSTEMS

Body muscle movements are controlled by the lower motor neurons, which extend axons—some as long as 1 meter—to the muscle fibers. Lower motor neuron firing is regulated by the summation of upper motor neuron activity. In the brainstem, primitive systems produce gross coordinated movements of the entire body. Activation of the rubrospinal tract stimulates flexion of all limbs, whereas activation of the vestibulospinal tract causes all limbs to extend. Newborn infants, for example, have all limbs tightly flexed, presumably through the dominance of the rubrospinal system. In fact, the movements of an anencephalic infant, who completely lacks a cerebral cortex, may be indistinguishable from the movements of a normal newborn. In the first few months of life, the flexor spasticity is gradually mitigated by the opposite actions of the vestibulospinal fibers, and more limb mobility occurs.

At the top of the motor hierarchy is the corticospinal tract, which controls fine movements and which eventually dominates the brainstem system during the first years of life. The upper motor neurons of the corticospinal tract reside in the posterior frontal lobe, in a section of cortex known as the *motor strip*. Planned movements are conceived in the association areas of the brain, and in consultation with the basal ganglia and cerebellum, the motor cortex directs their smooth execution. The importance of the corticospinal system becomes immediately evident in strokes, in which spasticity returns as the cortical influence is ablated and the actions of the brainstem motor systems are released from cortical modulation.

Basal Ganglia

The *basal ganglia*, a subcortical group of gray matter nuclei, appear to mediate postural tone. The four functionally distinct ganglia are the striatum, the pallidum, the substantia nigra, and the subthalamic nucleus. Collectively known as the corpus striatum, the caudate and putamen harbor components of both motor and association systems. The caudate nucleus plays an important role in the modulation of motor acts. Anatomical and functional neuroimaging studies have correlated decreased activation of the caudate with obsessive-compulsive behavior. When functioning properly, the caudate nucleus acts as a gatekeeper to allow the motor system to perform only those acts that are goal directed. When it fails to perform its gatekeeper function, extraneous acts are performed, as in obsessive-compulsive disorder or in the tic disorders, such as Tourette's disorder. Overactivity of the striatum owing to lack of dopaminergic inhibition (e.g., in parkinsonian conditions) results in *bradykinesia*, an inability to initiate movements. The caudate, in particular, shrinks dramatically in Huntington's disease. This disorder is characterized by rigidity, on which is gradually superimposed choreiform, or "dancing," movements. Psychosis may be a prominent feature of Huntington's disease, and suicide is not uncommon. The caudate is also thought to influence associative, or cognitive, processes.

The globus pallidus contains two parts linked in series. In a cross section of the brain, the internal and external parts of the globus pallidus are nested within the concavity of the putamen. The globus pallidus receives input from the corpus striatum and projects fibers to the thalamus. This structure may be severely damaged in Wilson's disease and in carbon monoxide poisoning, which are characterized by dystonic posturing and flapping movements of the arms and legs.

The substantia nigra is named the black substance because the presence of melanin pigment causes it to appear black to the naked eye. It has two parts, one of which is functionally equivalent to the globus pallidus interna. The other part degenerates in Parkinson's disease. Parkinsonism is characterized by rigidity and tremor and is associated with depression in more than 30 percent of cases.

Finally, lesions in the subthalamic nucleus yield ballistic movements, sudden limb jerks of such velocity that they are compared to projectile movement.

Together, the nuclei of the basal ganglia appear capable of initiating and maintaining the full range of useful movements. Investigators have speculated that the nuclei serve to configure the activity of the overlying motor cortex to fit the purpose of the association areas. In addition, they appear to integrate proprioceptive feedback to maintain an intended movement.

Cerebellum

The cerebellum consists of a simple six-cell pattern of circuitry that is replicated roughly 10 million times. Simultaneous recordings of the cerebral cortex and the cerebellum have shown that the cerebellum is activated several milliseconds before a planned movement. Moreover, ablation of the cerebellum renders intentional movements coarse and tremulous. These data suggest that the cerebellum carefully modulates the tone of agonistic and antagonistic muscles by predicting the relative contraction needed for smooth motion. This prepared motor plan is used to ensure that exactly the right amount of flexor and extensor stimuli is sent to the muscles. Recent functional imaging data have shown that the cerebellum is active, even during the mere imagination of motor acts when no movements ultimately result from its calculations. The cerebellum harbors two, and possibly more, distinct "homunculi" or cortical representations of the body plan.

Motor Cortex

Penfield's groundbreaking work defined a motor homunculus in the precentral gyrus, Brodmann's area 4 (Fig. 1.2-2), where a somatotopic map of the motor neurons is found. Individual cells within the motor strip cause contraction of single muscles. The brain region immediately anterior to the motor strip is called the *supplementary motor area*, Brodmann's area 6. This region contains cells that when individually stimulated can trigger more complex movements by influencing a firing sequence of motor strip cells. Recent studies have demonstrated wide representation of motor movements in the brain.

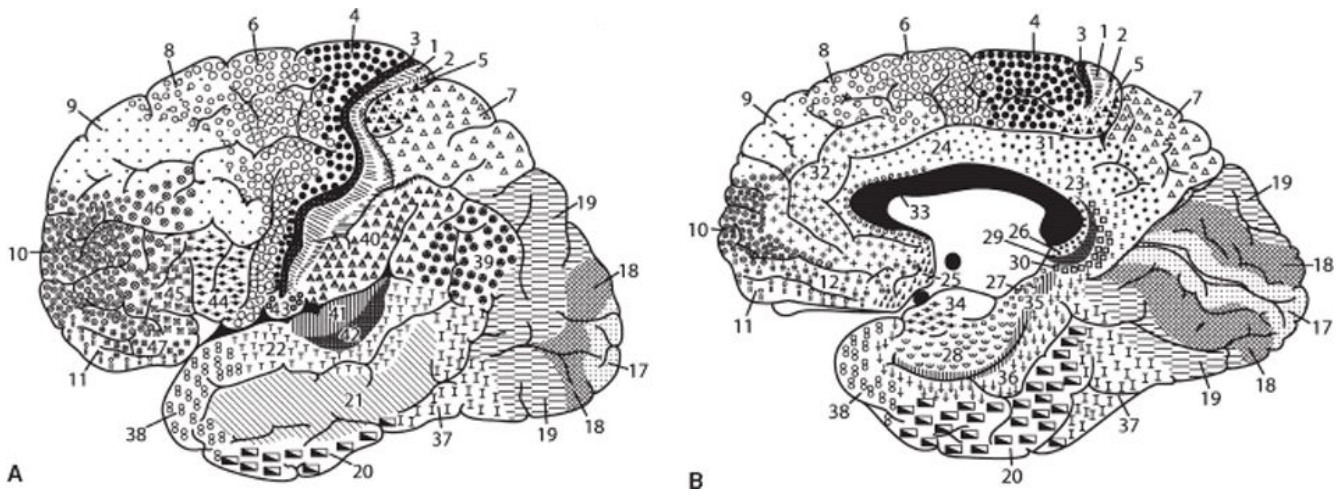

FIGURE 1.2-2 Drawing of the lateral view (A) and medial view (B) of the cytoarchitectonic subdivisions of the human brain as determined by Brodmann. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009.)

The skillful use of the hands is called *praxis*, and deficits in skilled movements are termed *apraxias*. The three levels of apraxia are limb-kinetic, ideomotor, and ideational. *Limb-kinetic apraxia* is the inability to use the contralateral hand in the presence of preserved strength; it results from isolated lesions in the supplementary motor area, which contains neurons that stimulate functional sequences of neurons in the motor strip.

Ideomotor apraxia is the inability to perform an isolated motor act on command, despite preserved comprehension, strength, and spontaneous performance of the same act. Ideomotor apraxia simultaneously affects both limbs and involves functions so specialized that they are localized to only one hemisphere. Conditions in two separate areas can produce this apraxia. Disconnection of the language comprehension area, Wernicke's area, from the motor regions causes an inability to follow spoken commands, and lesions to the left premotor area may impair the actual motor program as it is generated by the higher-order motor neurons. This program is transmitted across the corpus callosum to the right premotor area, which directs the movements of the left hand. A lesion in this callosal projection can also cause an isolated ideomotor apraxia in the left hand. This syndrome implies the representation of specific motor acts within discrete sections of the left premotor cortex. Thus just as some cells respond selectively to specific environmental features in the higher sensory cortices, some cells in the premotor cortex direct specific complex motor tasks.

Ideational apraxia occurs when the individual components of a sequence of skilled acts can be performed in isolation, but the entire series cannot be organized and executed as a whole. For example, the sequence of opening an envelope, removing the letter, unfolding it, and placing it on the table cannot be performed in order, even though the individual acts can be performed in isolation. The representation of the concept of a motor sequence may involve several areas, specifically the left parietal cortex, but it likely also relies on the sequencing and executive functions of the prefrontal cortex. This apraxia is a typical finding of diffuse cortical degeneration, such as Alzheimer's disease.

Autonomic Motor System

The *autonomic system* is divided into a sensory component (described earlier) and a motor component. The *autonomic motor system* is divided into two branches: the sympathetic and the parasympathetic. As a rule, organs are innervated by both types of fibers, which often serve antagonistic roles. The *parasympathetic system* slows the heart rate and begins the process of digestion. In contrast, the *sympathetic system* mediates the fight or flight response, with increased heart rate, shunting of blood away from the viscera, and increased respiration. The sympathetic system is highly activated by sympathomimetic drugs, such as amphetamine and cocaine, and may also be activated by withdrawal from sedating drugs such as alcohol, benzodiazepines, and opioids. Investigators who have found an increased risk of heart attacks in persons with high levels of hostility have suggested that chronic activation of the sympathetic fight or flight response, with elevated secretion of adrenaline, may underlie this association.

The brain center that drives the autonomic motor system is the *hypothalamus*, which houses a set of paired nuclei that appear to control appetite, rage, temperature, blood pressure, perspiration, and sexual drive. For example, lesions to the ventromedial nucleus, the satiety center, produce a voracious appetite and rage. In contrast, lesions to the upper region of the lateral nucleus, the hunger center, produce a profound loss of appetite. Numerous research groups are making intense efforts to define the biochemical regulation of appetite and obesity and frequently target the role of the hypothalamus.

In the regulation of sexual attraction, the role of the hypothalamus has also become an area of active research. In the 1990s, three groups independently reported neuroanatomical differences between certain of the hypothalamic nuclei of heterosexual and homosexual men. Researchers interpreted this finding to suggest that human sexual orientation has a neuroanatomical basis, and this result has stimulated several follow-up studies of the biological basis of sexual orientation. At present, however, these controversial findings are not accepted without question, and no clear consensus has emerged about whether the structure of the hypothalamus consistently correlates with sexual orientation. In animal studies, early nurturing and sexual experiences consistently alter the size of specific hypothalamic nuclei.

Primitive Reflex Circuit

Sensory pathways function as extractors of specific features from the overwhelming multitude of environmental stimuli, whereas motor pathways carry out the wishes of the organism. These pathways may be linked directly, for example, in the spinal cord, where a primitive reflex arc may mediate the brisk withdrawal of a limb from a painful stimulus, without immediate conscious awareness. In this loop, the peripheral stimulus activates the sensory nerve, the sensory neuron synapses on and directly activates the motor neuron, and the motor neuron drives the muscle to contract. This response is strictly local and all-or-none. Such primitive reflex arcs, however, rarely generate an organism's behaviors. In most behaviors, sensory systems project to association areas, where sensory information is interpreted in terms of internally determined memories, motivations, and drives. The exhibited behavior results from a plan of action determined by the association components and carried out by the motor systems.

Localization of Brain Functions

Many theorists have subdivided the brain into functional systems. Brodmann defined 47 areas on the basis of cytoarchitectonic distinctions, a cataloging that has been remarkably durable as the functional anatomy of the brain has been elucidated. A separate function, based on data from lesion studies and from functional neuroimaging, has been assigned to nearly all Brodmann's areas. At the other extreme, certain experts have distinguished only three processing blocks: The brainstem and the thalamic reticular activating system provide arousal and set up attention; the posterior cortex integrates perceptions and generates language; and, at the highest level, the frontal cortex generates programs and executes plans like an orchestra conductor.

Hemispheric lateralization of function is a key feature of higher cortical processing. The primary sensory cortices for touch, vision, hearing, smell, and taste are represented bilaterally, and the first level of abstraction for these modalities is also usually represented

bilaterally. The highest levels of feature extraction, however, are generally unified in one brain hemisphere only. For example, recognition of familiar and unfamiliar faces seems localized to the left inferior temporal cortex, and cortical processing of olfaction occurs in the right frontal lobe.

Hypotheses about the flow of thought in the brain are based on few experimental data, although this scarcity of findings has not impeded numerous theoreticians from speculating about functional neuroanatomy. Several roles have been tentatively assigned to specific lobes of the brain, on the basis of the functional deficits resulting from localized injury. These data indicate that certain regions of cortex may be necessary for a specific function, but they do not define the complete set of structures that suffices for a complex task. Anecdotal evidence from surface electrocorticography for the study of epilepsy, for example, suggests that a right parietal seizure impulse may shoot immediately to the left frontal lobe and then to the right temporal lobe before spreading locally to the remainder of the parietal lobe. This evidence illustrates the limitations of naively assigning a mental function to a single brain region. Functional neuroimaging studies frequently reveal simultaneous activation of disparate brain regions during the performance of even a simple cognitive task. Nevertheless, particularly in the processing of vision and language, fairly well-defined lobar syndromes have been confirmed.

Language

The clearest known example of hemispheric lateralization is the localization of language functions to the left hemisphere. Starting with the work of Pierre Broca and Karl Wernicke in the 19th century, researchers have drawn a detailed map of language comprehension and expression.

At least eight types of aphasias in which one or more components of the language pathway are injured have been defined. *Prosody*, the emotional and affective components of language, or “body language,” appears to be localized in a mirror set of brain units in the right hemisphere.

Because of the major role of verbal and written language in human communication, the neuroanatomical basis of language is the most completely understood association function. Language disorders, also called *aphasias*, are readily diagnosed in routine conversation, whereas perceptual disorders may escape notice, except during detailed neuropsychological testing, although these disorders may be caused by injury of an equal volume of cortex. Among the earliest models of cortical localization of function were Broca's 1865 description of a loss of fluent speech caused by a lesion in the left inferior frontal lobe and Wernicke's 1874 localization of language comprehension to the left superior temporal lobe. Subsequent analyses of patients rendered aphasic by strokes, trauma, or tumors have led to the definition of the entire language association pathway from sensory input through the motor output.

Language most clearly demonstrates hemispheric localization of function. In most persons, the hemisphere dominant for language also directs the dominant hand. Ninety percent of the population is right-handed, and 99 percent of right-handers have left hemispheric dominance for language. Of the 10 percent who are left-handers, 67 percent also have left hemispheric language dominance; the other 33 percent have either mixed or right hemispheric language dominance. This innate tendency to lateralization of language in the left hemisphere is highly associated with an asymmetry of the planum temporale, a triangular cortical patch on the superior surface of the temporal lobe that appears to harbor Wernicke's area. Patients with mixed hemispheric dominance for language lack the expected asymmetry of the planum temporale. That asymmetry has been observed in prenatal brains suggests a genetic determinant. Indeed, the absence of asymmetry runs in families, although both genetic and intrauterine influences probably contribute to the final pattern.

Language comprehension is processed at three levels. First, in *phonological processing*, individual sounds, such as vowels or consonants, are recognized in the inferior gyrus of the frontal lobes. Phonological processing improves if lip reading is allowed, if speech is slowed, or if contextual clues are provided. Second, *lexical processing* matches the phonological input with recognized words or sounds in the individual's memory. Lexical processing determines whether a sound is a word. Recent evidence has localized lexical processing to the left temporal lobe, where the representations of lexical data are organized according to semantic category. Third, *semantic processing* connects the words to their meaning. Persons with an isolated defect in semantic processing may retain the ability to repeat words in the absence of an ability to understand or spontaneously generate speech. Semantic processing activates the middle and superior gyri of the left temporal lobe, whereas the representation of the conceptual content of words is widely distributed in the cortex. Language production proceeds in the opposite direction, from the cortical semantic representations through the left temporal lexical nodes to either the oromotor phonological processing area (for speech) or the graphomotor system (for writing). Each of these areas can be independently or simultaneously damaged by stroke, trauma, infection, or tumor, resulting in a specific type of aphasia.

The garbled word salad or illogical utterances of an aphasic patient leave little uncertainty about the diagnosis of left-sided cortical injury, but the right hemisphere contributes a somewhat more subtle, but equally important, affective quality to language. For example, the phrase “I feel good” may be spoken with an infinite variety of shadings, each of which is understood differently. The perception of prosody and the appreciation of the associated gestures, or “body language,” appear to require an intact right hemisphere. Behavioral neurologists have mapped an entire pathway for prosody association in the right hemisphere that mirrors the language pathway of the left hemisphere. Patients with right hemisphere lesions, who have impaired comprehension or expression of prosody, may find it difficult to function in society despite their intact language skills.

Developmental dyslexia is defined as an unexpected difficulty with learning in the context of adequate intelligence, motivation, and education. Whereas speech consists of the logical combination of 44 basic phonemes of sounds, reading requires a broader set of brain functions and, thus, is more susceptible to disruption. The awareness of specific phonemes develops at about the age of 4 to 6 years and appears to be prerequisite to acquisition of reading skills. Inability to recognize distinct phonemes is the best predictor of a reading disability. Functional neuroimaging studies have localized the identification of letters to the occipital lobe adjacent to the primary visual cortex. Phonological processing occurs in the inferior frontal lobe, and semantic processing requires the superior and middle gyri of the left temporal lobe. A recent finding of uncertain significance is that phonological processing in men activates only the left inferior frontal gyrus, whereas phonological processing in women activates the inferior frontal gyrus bilaterally. Careful analysis of an individual's particular reading deficits can guide remedial tutoring efforts that can focus on weaknesses and thus attempt to bring the reading skills up to the general level of intelligence and verbal skills.

In children, developmental nonverbal learning disorder is postulated to result from right hemisphere dysfunction. Nonverbal learning disorder is characterized by poor fine-motor control in the left hand, deficits in visuospatial organization, problems with mathematics, and incomplete or disturbed socialization.

Patients with nonfluent aphasia, who cannot complete a simple sentence, may be able to sing an entire song, apparently because many aspects of music production are localized to the right hemisphere. Music is represented predominantly in the right hemisphere, but the full complexity of musical ability seems to involve both hemispheres. Trained musicians appear to transfer many musical skills from the right hemisphere to the left as they gain proficiency in musical analysis and performance.

Arousal and Attention

Arousal, or the establishment and maintenance of an awake state, appears to require at least three brain regions. Within the brainstem, the ascending reticular activating system (ARAS), a diffuse set of neurons, appears to set the level of consciousness. The ARAS projects to the intralaminar nuclei of the thalamus, and these nuclei in turn project widely throughout the cortex. Electrophysiological studies show that both the thalamus and the cortex fire rhythmical bursts of neuronal activity at rates of 20 to 40 cycles per second. During sleep, these bursts are not synchronized. During wakefulness, the ARAS stimulates the thalamic intralaminar nuclei, which in turn coordinate the oscillations of different cortical regions. The greater the synchronization, the higher the level of wakefulness. The absence of arousal produces stupor and

coma. In general, small discrete lesions of the ARAS can produce a stuporous state, whereas at the hemispheric level, large bilateral lesions are required to cause the same depression in alertness. One particularly unfortunate but instructive condition involving extensive, permanent, bilateral cortical dysfunction is the persistent vegetative state. Sleep–wake cycles may be preserved, and the eyes may appear to gaze; but the external world does not register and no evidence of conscious thought exists. This condition represents the expression of the isolated actions of the ARAS and the thalamus.

The maintenance of attention appears to require an intact right frontal lobe. For example, a widely used test of persistence requires scanning and identifying only the letter A from a long list of random letters. Healthy persons can usually maintain performance of such a task for several minutes, but in patients with right frontal lobe dysfunction, this capacity is severely curtailed. Lesions of similar size in other regions of the cortex usually do not affect persistence tasks. In contrast, the more generally adaptive skill of maintaining a coherent line of thought is diffusely distributed throughout the cortex. Many medical conditions can affect this skill and may produce acute confusion or delirium.

One widely diagnosed disorder of attention is attention-deficit/hyperactivity disorder (ADHD). No pathological findings have been consistently associated with this disorder. Functional neuroimaging studies, however, have variously documented either frontal lobe or right hemisphere hypometabolism in patients with ADHD, compared with normal controls. These findings strengthen the notion that the frontal lobes—especially the right frontal lobe—are essential to the maintenance of attention.

Memory

The clinical assessment of memory should test three periods, which have distinct anatomical correlates. *Immediate memory* functions over a period of seconds; *recent memory* applies on a scale of minutes to days; and *remote memory* encompasses months to years. Immediate memory is implicit in the concept of attention and the ability to follow a train of thought. This ability has been divided into phonological and visuospatial components, and functional imaging has localized them to the left and right hemispheres, respectively. A related concept, incorporating immediate and recent memory, is *working memory*, which is the ability to store information for several seconds, whereas other, related cognitive operations take place on this information. Recent studies have shown that single neurons in the dorsolateral prefrontal cortex not only record features necessary for working memory, but also record the certainty with which the information is known and the degree of expectation assigned to the permanence of a particular environmental feature. Some neurons fire rapidly for an item that is eagerly awaited, but may cease firing if hopes are dashed unexpectedly. The encoding of the emotional value of an item contained in the working memory may be of great usefulness in determining goal-directed behavior. Some researchers localize working memory predominantly to the left frontal cortex. Clinically, however, bilateral prefrontal cortex lesions are required for severe impairment of working memory. Other types of memory have been described: episodic, semantic, and procedural.

Three brain structures are critical to the formation of memories: the medial temporal lobe, certain diencephalic nuclei, and the basal forebrain. The *medial temporal lobe* houses the *hippocampus*, an elongated, highly repetitive network. The *amygdala* is adjacent to the anterior end of the hippocampus. The amygdala has been suggested to rate the emotional importance of an experience and to activate the level of hippocampal activity accordingly. Thus an emotionally intense experience is indelibly etched in memory, but indifferent stimuli are quickly disregarded.

Animal studies have defined a hippocampal place code, a pattern of cellular activation in the hippocampus that corresponds to the animal's location in space. When the animal is introduced to a novel environment, the hippocampus is broadly activated. As the animal explores and roams, the firing of certain hippocampal regions begins to correspond to specific locations in the environment. In about 1 hour, a highly detailed internal representation of the external space (a “cognitive map”) appears in the form of specific firing patterns of the hippocampal cells. These patterns of neuronal firing may bear little spatial resemblance to the environment they represent; rather, they may seem randomly arranged in the hippocampus. If the animal is manually placed in a certain part of a familiar space, only the corresponding hippocampal regions show intense neural activity. When recording continues into sleep periods, firing sequences of hippocampal cells outlining a coherent path of navigation through the environment are registered, even though the animal is motionless. If the animal is removed from the environment for several days and then returned, the previously registered hippocampal place code is immediately reactivated. A series of animal experiments have dissociated the formation of the hippocampal place code from either visual, auditory, or olfactory cues, although each of these modalities may contribute to place code generation. Other factors may include internal calculations of distances based on counting footsteps or other proprioceptive information. Data from targeted genetic mutations in mice have implicated both the *N-methyl-D-aspartate* (NMDA) glutamate receptors and the calcium-calmodulin kinase II (CaMKII) in the proper formation of hippocampal place fields. These data suggest that the hippocampus is a significant site for formation and storage of immediate and recent memories. Although no data yet support the notion, it is conceivable that the hippocampal cognitive map is inappropriately reactivated during a *déjà vu* experience.

The most famous human subject in the study of memory is H. M., a man with intractable epilepsy, who had both his hippocampi and amygdalae surgically removed to alleviate his condition. The epilepsy was controlled, but he was left with a complete inability to form and recall memories of facts. H. M.'s learning and memory skills were relatively preserved, which led to the suggestion that declarative or factual memory may be separate within the brain from procedural or skill-related memory. A complementary deficit in procedural memory with preservation of declarative memory may be seen in persons with Parkinson's disease, in whom dopaminergic neurons of the nigrostriatal tract degenerate. Because this deficit in procedural memory can be ameliorated with treatment with levodopa (Larodopa), which is thought to potentiate dopaminergic neurotransmission in the nigrostriatal pathway, a role has been postulated for dopamine in procedural memory. Additional case reports have further implicated the amygdala and the afferent and efferent fiber tracts of the hippocampus as essential to the formation of memories. In addition, lesional studies have suggested a mild lateralization of hippocampal function in which the left hippocampus is more efficient at forming verbal memories and the right hippocampus tends to form nonverbal memories. After unilateral lesions in humans, however, the remaining hippocampus may compensate to a large extent. Medical causes of amnesia include alcoholism, seizures, migraine, drugs, vitamin deficiencies, trauma, strokes, tumors, infections, and degenerative diseases.

The motor system within the cortex receives directives from the association areas. The performance of a novel act requires constant feedback from the sensory and association areas for completion, and functional neuroimaging studies have demonstrated widespread activation of the cortex during unskilled acts. Memorized motor acts initially require activation of the medial temporal lobe. With practice, however, the performance of ever-larger segments of an act necessary to achieve a goal become encoded within discrete areas of the premotor and parietal cortices, particularly the left parietal cortex, with the result that a much more limited activation of the cortex is seen during highly skilled acts, and the medial temporal lobe is bypassed. This process is called the *corticalization of motor commands*. In lay terms, the process suggests a neuroanatomical basis for the adage “practice makes perfect.”

Within the diencephalon, the dorsal medial nucleus of the thalamus and the mammillary bodies appear necessary for memory formation. These two structures are damaged in thiamine deficiency states usually seen in chronic alcoholics, and their inactivation is associated with Korsakoff's syndrome. This syndrome is characterized by severe inability to form new memories and a variable inability to recall remote memories.

The most common clinical disorder of memory is Alzheimer's disease. Alzheimer's disease is characterized pathologically by the degeneration of neurons and their replacement by senile plaques and neurofibrillary tangles. Clinicopathological studies have suggested that the cognitive decline is best correlated with the loss of synapses. Initially, the parietal and

temporal lobes are affected, with relative sparing of the frontal lobes. This pattern of degeneration correlates with the early loss of memory, which is largely a temporal lobe function. Also, syntactical language comprehension and visuospatial organization, functions that rely heavily on the parietal lobe, are impaired early in the course of Alzheimer's disease. In contrast, personality changes, which reflect frontal lobe function, are relatively late consequences of Alzheimer's disease. A rarer, complementary cortical degeneration syndrome, Pick's disease, first affects the frontal lobes while sparing the temporal and parietal lobes. In Pick's disease, disinhibition and impaired language expression, which are signs of frontal dysfunction, appear early, with relatively preserved language comprehension and memory.

Memory loss can also result from disorders of the subcortical gray matter structures, specifically the basal ganglia and the brainstem nuclei, from disease of the white matter, or from disorders that affect both gray and white matter.

Emotion

Individual emotional experiences occupy the attention of all mental health professionals. Emotion derives from basic drives, such as feeding, sex, reproduction, pleasure, pain, fear, and aggression, which all animals share. The neuroanatomical basis for these drives appears to be centered in the limbic system. Distinctly human emotions, such as affection, pride, guilt, pity, envy, and resentment, are largely learned and most likely are represented in the cortex (see [Color Plate 1.2-3](#)). The regulation of drives appears to require an intact frontal cortex. The complex interplay of the emotions, however, is far beyond the understanding of functional neuroanatomists. Where, for example, are the representations of the id, the ego, and the superego? Through what pathway are ethical and moral judgments shepherded? What processes allow beauty to be in the eye of the beholder? These philosophical questions represent a true frontier of human discovery.

Several studies have suggested that within the cortex exists a hemispheric dichotomy of emotional representation. The left hemisphere houses the analytical mind but may have a limited emotional repertoire. For example, lesions to the right hemisphere, which cause profound functional deficits, may be noted with indifference by the intact left hemisphere. The denial of illness and of the inability to move the left hand in cases of right hemisphere injury is called *anosognosia*. In contrast, left hemisphere lesions, which cause profound aphasia, can trigger a catastrophic depression, as the intact right hemisphere struggles with the realization of the loss. The right hemisphere also appears dominant for affect, socialization, and body image.

Damage to the left hemisphere produces intellectual disorder and loss of the narrative aspect of dreams. Damage to the right hemisphere produces affective disorders, loss of the visual aspects of dreams, and a failure to respond to humor, shadings of metaphor, and connotations. In dichotic vision experiments, two scenes of varied emotional content were displayed simultaneously to each half of the visual field and were perceived separately by each hemisphere. A more intense emotional response attended the scenes displayed to the left visual field that were processed by the right hemisphere. Moreover, hemisensory changes representing conversion disorders have been repeatedly noted to involve the left half of the body more often than the right, an observation that suggests an origin in the right hemisphere.

Within the hemispheres, the temporal and frontal lobes play a prominent role in emotion. The temporal lobe exhibits a high frequency of epileptic foci, and temporal lobe epilepsy (TLE) presents an interesting model for the role of the temporal lobe in behavior. In studies of epilepsy, abnormal brain activation is analyzed, rather than the deficits in activity analyzed in classic lesional studies. TLE is of particular interest in psychiatry because patients with temporal lobe seizures often manifest bizarre behavior without the classic grand mal shaking movements caused by seizures in the motor cortex. A proposed TLE personality is characterized by hyposexuality, emotional intensity, and a perseverative approach to interactions, termed *viscosity*. Patients with left TLE may generate references to personal destiny and philosophical themes and display a humorless approach to life. In contrast, patients with right TLE may display excessive emotionality, ranging from elation to sadness. Although patients with TLE may display excessive aggression between seizures, the seizure itself may evoke fear.

The inverse of a TLE personality appears in persons with bilateral injury to the temporal lobes after head trauma, cardiac arrest, herpes simplex encephalitis, or Pick's disease. This lesion resembles the one described in the Klüver-Bucy syndrome, an experimental model of temporal lobe ablation in monkeys. Behavior in this syndrome is characterized by hypersexuality, placidity, a tendency to explore the environment with the mouth, inability to recognize the emotional significance of visual stimuli, and constantly shifting attention, called *hypermetamorphosis*. In contrast to the aggression-fear spectrum sometimes seen in patients with TLE, complete experimental ablation of the temporal lobes appears to produce a uniform, bland reaction to the environment, possibly because of an inability to access memories.

The prefrontal cortices influence mood in a complementary way. Whereas activation of the left prefrontal cortex appears to lift the mood, activation of the right prefrontal cortex causes depression. A lesion to the left prefrontal area, at either the cortical or the subcortical level, abolishes the normal mood-elevating influences and produces depression and uncontrollable crying. In contrast, a comparable lesion to the right prefrontal area may produce laughter, euphoria, and *witzelsucht*, a tendency to joke and make puns. Effects opposite to those caused by lesions appear during seizures, in which occurs abnormal, excessive activation of either prefrontal cortex. A seizure focus within the left prefrontal cortex can cause gelastic seizures, for example, in which the ictal event is laughter. Functional neuroimaging has documented left prefrontal hypoperfusion during depressive states, which normalized after the depression was treated successfully.

Limbic System Function

The limbic system was delineated by James Papez in 1937. The Papez circuit consists of the hippocampus, the fornix, the mammillary bodies, the anterior nucleus of the thalamus, and the cingulate gyrus ([Fig. 1.2-4](#)). The boundaries of the limbic system were subsequently expanded to include the amygdala, septum, basal forebrain, nucleus accumbens, and orbitofrontal cortex.

FIGURE 1.2-4

Schematic drawing of the major anatomic structures of the limbic system. The cingulate and parahippocampal gyri form the “limbic lobe,” a rim of tissue located along the junction of the diencephalon and the cerebral hemispheres. (Adapted from Hendelman WJ. *Student's Atlas of Neuroanatomy*. Philadelphia: WB Saunders; 1994:179.)

Although this schema creates an anatomical loop for emotional processing, the specific contributions of the individual components other than the hippocampus or even whether a given train of neural impulses actually travels along the entire pathway is unknown.

The amygdala appears to be a critically important gate through which internal and external stimuli are integrated. Information from the primary senses is interwoven with internal drives, such as hunger and thirst, to assign emotional significance to sensory experiences. The amygdala may mediate learned fear responses, such as anxiety and panic, and may direct the expression of certain emotions by producing a particular affect. Neuroanatomical data suggest that the amygdala exerts a more powerful influence on the cortex, to stimulate or suppress cortical activity, than the cortex exerts on the amygdala. Pathways from the sensory thalamic relay stations separately send sensory data to the amygdala and the cortex, but the subsequent effect of the amygdala on the cortex is the more potent of the two reciprocal connections. In contrast, damage to the amygdala has been reported to ablate the ability to distinguish fear and anger in other persons' voices and facial expressions. Persons with such injuries may have a preserved ability to recognize happiness, sadness, or disgust. The limbic system appears to house the emotional association areas, which direct the hypothalamus to express the motor and endocrine components of the emotional state.

Fear and Aggression

Electrical stimulation of animals throughout the subcortical area involving the limbic system produces rage reactions (e.g., growling, spitting, and arching of the back). Whether the animal flees or attacks depends on the intensity of the stimulation.

Limbic System and Schizophrenia

The limbic system has been particularly implicated in neuropathological studies of schizophrenia. Eugen Bleuler's well-known four A's of schizophrenia—affect, associations, ambivalence, and autism—refer to brain functions served in part by limbic structures. Several clinicopathological studies have found a reduction in the brain weight of the gray matter but not of the white matter in persons with schizophrenia. In pathological as well as in magnetic resonance imaging (MRI) reports, persons with schizophrenia may have reduced volume of the hippocampus, amygdala, and parahippocampal gyrus. Schizophrenia may be a late sequela of a temporal epileptic focus, with some studies reporting an association in 7 percent of patients with TLE.

Functional neuroimaging studies have demonstrated decreased activation of the frontal lobes in many patients with schizophrenia, particularly during tasks requiring willed action. A reciprocal increase in activation of the temporal lobe can occur during willed actions, such as finger movements or speaking, in persons with schizophrenia. Neuropathological studies have shown a decreased density of neuropil, the intertwined axons and dendrites of the neurons, in the frontal lobes of these patients. During development, the density of neuropil is highest around age 1 year and then is reduced somewhat through synaptic pruning; the density plateaus throughout childhood and is further reduced to adult levels in adolescence. One hypothesis of the appearance of schizophrenia in the late teenage years is that excessive adolescent synaptic pruning occurs and results in too little frontolimbic activity. Some experts have suggested that hypometabolism and paucity of interneuronal connections in the prefrontal cortex may reflect inefficiencies in working memory, which permits the disjointed discourse and loosening of associations that characterize schizophrenia. At present, the molecular basis for the regulation of the density of synapses within the neuropil is unknown. Other lines of investigation aimed at understanding the biological basis of schizophrenia have documented inefficiencies in the formation of cortical synaptic connections in the middle of the second trimester of gestation, which may result from a viral infection or malnutrition. Neurodevelopmental surveys administered during childhood have found an increased incidence of subtle neurological abnormalities before the appearance of the thought disorder in persons who subsequently exhibited signs of schizophrenia.

In one intriguing study, positron emission tomography (PET) scanning was used to identify the brain regions that are activated when a person hears spoken language. A consistent set of cortical and subcortical structures demonstrated increased metabolism when speech was processed. The researchers then studied a group of patients with schizophrenia who were experiencing active auditory hallucinations. During the hallucinations, the same cortical and subcortical structures were activated as were activated by the actual sounds, including the primary auditory cortex. At the same time, decreased activation was seen of areas thought to monitor speech, including the left middle temporal gyrus and the supplementary motor area. This study raises the questions of what brain structure is activating the hallucinations and by what mechanism do neuroleptic drugs suppress the hallucinations. Clearly, functional imaging has much to tell about the neuroanatomical basis of schizophrenia.

Frontal Lobe Function

The *frontal lobes*, the region that determines how the brain acts on its knowledge, constitute a category unto themselves. In comparative neuroanatomical studies, the massive size of the frontal lobes is the main feature that distinguishes the human brain from that of other primates and that lends it uniquely human qualities. There are four subdivisions of the frontal lobes. The first three—the motor strip, the supplemental motor area, and Broca's area—are mentioned in the preceding discussion of the motor system and language. The fourth, most anterior, division is the prefrontal cortex. The prefrontal cortex contains three regions in which lesions produce distinct syndromes: the *orbitofrontal*, the *dorsolateral*, and the *medial*. Dye-tracing studies have defined dense reciprocal connections between the prefrontal cortex and all other brain regions. Therefore, to the extent that anatomy can predict function, the prefrontal cortex is ideally connected to allow sequential use of the entire palette of brain functions in executing goal-directed activity. Indeed, frontal lobe injury usually impairs the executive functions: motivation, attention, and sequencing of actions.

Bilateral lesions of the frontal lobes are characterized by changes in personality—how persons interact with the world. The *frontal lobe syndrome*, which is most commonly produced by trauma, infarcts, tumors, lobotomy, multiple sclerosis, or Pick's disease, consists of slowed thinking, poor judgment, decreased curiosity, social withdrawal, and irritability. Patients typically display apathetic indifference to experience that can suddenly explode into impulsive disinhibition. Unilateral frontal lobe lesions may be largely unnoticed because the intact lobe can compensate with high efficiency.

Frontal lobe dysfunction may be difficult to detect by means of highly structured, formal neuropsychological tests. Intelligence, as reflected in the intelligence quotient (IQ), may be normal, and functional neuroimaging studies have shown that the IQ seems to require mostly parietal lobe activation. For example, during administration of the Wechsler Adult Intelligence Scale-Revised (WAIS-R), the highest levels of increased metabolic activity during verbal tasks occurred in the left parietal lobe, whereas the highest levels of increased metabolic activity during performance skills occurred in the right parietal lobe. In contrast, frontal lobe pathology may become apparent only under unstructured, stressful, real-life situations.

A famous case illustrating the result of frontal lobe damage involves Phineas Gage, a 25-year-old railroad worker. While he was working with explosives, an accident drove an iron rod through Gage's head. He survived, but both frontal lobes were severely damaged.

After the accident, his behavior changed dramatically. The case was written up by J. M. Harlow, M.D., in 1868, as follows: [George] is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires...His mind was radically changed, so decidedly that his friends and acquaintances said he was “no longer Gage.” (see Fig. 1.2-5)

FIGURE 1.2-5

The life mask and skull of Phineas Gage. Note damage to the frontal region. “A famous case illustrating the result of frontal lobe damage involves Phineas Gage, a 25-year-old railroad worker. While he was working with explosives, an accident drove an iron rod through Gage’s head. He survived, but both frontal lobes were severely damaged. After the accident, his behavior changed dramatically. The case was written up by J.M. Harlow, M.D., in 1868, as follows: [Gage] is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts his desires...His mind was radically changed, so decidedly that his friends and acquaintances said he was ‘no longer Gage.’” (Courtesy of Anthony A. Walsh, Ph.D.)

In one study of right-handed males, lesions of the right prefrontal cortex eliminated the tendency to use internal, associative memory cues and led to an extreme tendency to interpret the task at hand in terms of its immediate context. In contrast, right-handed males who had lesions of the left prefrontal cortex produced no context-dependent interpretations and interpreted the tasks entirely in terms of their own internal drives. A mirror image of the functional lateralization appeared in left-handed subjects. This test thus revealed the clearest known association of higher cortical functional lateralization with the subjects’ dominant hand. Future experiments in this vein will attempt to reproduce these findings with functional neuroimaging. If corroborated, these studies suggest a remarkable complexity of functional localization within the prefrontal cortex and may also have implications for the understanding of psychiatric diseases in which prefrontal pathology has been postulated, such as schizophrenia and mood disorders.

The heavy innervation of the frontal lobes by dopamine-containing nerve fibers is of interest because of the action of antipsychotic medications. At the clinical level, antipsychotic medications may help to organize the rambling associations of a patient with schizophrenia. At the neurochemical level, most typical antipsychotic medications block the actions of dopamine at the D₂ receptors. The frontal lobes, therefore, may be a major therapeutic site of action for antipsychotic medications.

DEVELOPMENT

The nervous system is divided into the central and peripheral nervous systems (CNS and PNS). The CNS consists of the brain and spinal cord; the PNS refers to all the sensory, motor, and autonomic fibers and ganglia outside the CNS. During development, both divisions arise from a common precursor, the neural tube, which in turn is formed through folding of the neural plate, a specialization of the ectoderm, the outermost of the three layers of the primitive embryo. During embryonic development, the neural tube itself becomes the CNS; the ectoderm immediately superficial to the neural tube becomes the neural crest, which gives rise to the PNS. The formation of these structures requires chemical communication between the neighboring tissues in the form of cell surface molecules and diffusible chemical signals. In many cases, an earlier-formed structure, such as the notochord, is said to *induce* the surrounding ectoderm to form a later structure, in this case the neural plate (see Color Plate 1.2-6). Identification of the chemical mediators of tissue induction is an active area of research. Investigators have begun to examine whether failures of the interactions of these mediators and their receptors could underlie errors in brain development that cause psychopathology.

Neuronal Migration and Connections

The life cycle of a neuron consists of cell birth, migration to the adult position, extension of an axon, elaboration of dendrites, synaptogenesis, and, finally, the onset of chemical neurotransmission. Individual neurons are born in proliferative zones generally located along the inner surface of the neural tube. At the peak of neuronal proliferation in the middle of the second trimester, 250,000 neurons are born each minute. Postmitotic neurons migrate outward to their adult locations in the cortex, guided by radially oriented astrocytic glial fibers. Glia-guided neuronal migration in the cerebral cortex occupies much of the first 6 months of gestation. For some neurons in the prefrontal cortex, migration occurs over a distance 5,000 times the diameter of the neuronal cell body. Neuronal migration requires a complex set of cell–cell interactions and is susceptible to errors in which neurons fail to reach the cortex and instead reside in ectopic positions. A group of such incorrectly placed neurons is called a *heterotopia*. Neuronal heterotopias have been shown to cause epilepsy and are highly associated with mental retardation. In a neuropathological study of the planum temporale of four consecutive patients with dyslexia, heterotopias were a common finding. Recently, heterotopic neurons within the frontal lobe have been postulated to play a causal role in some cases of schizophrenia.

Many neurons lay down an axon as they migrate, whereas others do not initiate axon outgrowth until they have reached their cortical targets. Thalamic axons that project to the cortex initially synapse on a transient layer of neurons called the *subplate neurons*. In normal development, the axons subsequently detach from the subplate neurons and proceed superficially to synapse on the true cortical cells. The subplate neurons then degenerate. Some brains from persons with schizophrenia reveal an abnormal persistence of subplate neurons, suggesting a failure to complete axonal pathfinding in the brains of these persons. This finding does not correlate with the presence of schizophrenia in every case, however. A characteristic branched dendritic tree elaborates once the neuron has completed migration. Synaptogenesis occurs at a furious rate from the second trimester through the first 10 years or so of life. The peak of synaptogenesis occurs within the first 2 postnatal years, when as many as 30 million synapses form each second. Ensheathment of axons by myelin begins prenatally; it is largely complete in early childhood, but does not reach its full extent until late in the third decade of life. Myelination of the brain is also sequential.

Neuroscientists are tremendously interested in the effect of experience on the formation of brain circuitry in the first years of life. As noted earlier, many examples are seen of the

impact of early sensory experience on the wiring of cortical sensory processing areas. Similarly, early movement patterns are known to reinforce neural connections in the supplemental motor area that drive specific motor acts. Neurons rapidly form a fivefold excess of synaptic connections; then, through a Darwinian process of elimination, only those synapses that serve a relevant function persist. This synaptic pruning appears to preserve input in which the presynaptic cell fires in synchrony with the postsynaptic cell, a process that reinforces repeatedly activated neural circuits. One molecular component that is thought to mediate synaptic reinforcement is the postsynaptic NMDA glutamate receptor. This receptor allows the influx of calcium ions only when activated by glutamate at the same time as the membrane in which it sits is depolarized. Thus, glutamate binding without membrane depolarization or membrane depolarization without glutamate binding fails to trigger calcium influx. NMDA receptors open in dendrites that are exposed to repeated activation, and their activation stimulates stabilization of the synapse. Calcium is a crucial intracellular messenger that initiates a cascade of events, including gene regulation and the release of trophic factors that strengthen particular synaptic connections. Although less experimental evidence exists for the role of experience in modulating synaptic connectivity of association areas than has been demonstrated in sensory and motor areas, neuroscientists assume that similar activity-dependent mechanisms may apply in all areas of the brain.

Adult Neurogenesis

A remarkable recent discovery has been that new neurons can be generated in certain brain regions (particularly the dentate gyrus of the hippocampus) in adult animals, including humans. This is in marked contrast to the previous belief that no neurons were produced after birth in most species. This discovery has a potentially profound impact on our understanding of normal development, incorporation of experiences, as well as the ability of the brain to repair itself after various types of injuries (see [Color Plates 1.2-7](#) and [1.2-8](#)).

Neurological Basis of Development Theories

In the realm of emotion, early childhood experiences have been suspected to be at the root of psychopathology since the earliest theories of Sigmund Freud. Freud's psychoanalytic method aimed at tracing the threads of a patient's earliest childhood memories. Franz Alexander added the goal of allowing the patient to relive these memories in a less pathological environment, a process known as a *corrective emotional experience*. Although neuroscientists have no data demonstrating that this method operates at the level of neurons and circuits, emerging results reveal a profound effect of early caregivers on an adult individual's emotional repertoire. For example, the concept of attunement is defined as the process by which caregivers "play back a child's inner feelings." If a baby's emotional expressions are reciprocated in a consistent and sensitive manner, certain emotional circuits are reinforced. These circuits likely include the limbic system, in particular, the amygdala, which serves as a gate to the hippocampal memory circuits for emotional stimuli. In one anecdote, for example, a baby whose mother repeatedly failed to mirror her level of excitement emerged from childhood an extremely passive girl, who was unable to experience a thrill or a feeling of joy.

The relative contributions of nature and nurture are perhaps nowhere more indistinct than in the maturation of emotional responses, partly because the localization of emotion within the adult brain is only poorly understood. It is reasonable to assume, however, that the reactions of caregivers during a child's first 2 years of life are eventually internalized as distinct neural circuits, which may be only incompletely subject to modification through subsequent experience. For example, axonal connections between the prefrontal cortex and the limbic system, which probably play a role in modulating basic drives, are established between the ages of 10 and 18 months. Recent work suggests that a pattern of terrifying experiences in infancy may flood the amygdala and drive memory circuits to be specifically alert to threatening stimuli, at the expense of circuits for language and other academic skills. Thus infants raised in a chaotic and frightening home may be neurologically disadvantaged for the acquisition of complex cognitive skills in school.

An adult correlate to this cascade of detrimental overactivity of the fear response is found in posttraumatic stress disorder (PTSD), in which persons exposed to an intense trauma involving death or injury may have feelings of fear and helplessness for years after the event. A PET scanning study of patients with PTSD revealed abnormally high activity in the right amygdala while the patients were reliving their traumatic memories. The researchers hypothesized that the stressful hormonal milieu present during the registration of the memories may have served to burn the memories into the brain and to prevent their erasure by the usual memory modulation circuits. As a result, the traumatic memories exerted a pervasive influence and led to a state of constant vigilance, even in safe, familiar settings.

Workers in the related realms of mathematics have produced results documenting the organizing effects of early experiences on internal representations of the external world. Since the time of Pythagoras, music has been considered a branch of mathematics. A series of recent studies has shown that groups of children who were given 8 months of intensive classical music lessons during preschool years later had significantly better spatial and mathematical reasoning in school than a control group. Nonmusical tasks, such as navigating mazes, drawing geometric figures, and copying patterns of two-color blocks, were performed significantly more skillfully by the musical children. Early exposure to music, thus, may be ideal preparation for later acquisition of complex mathematical and engineering skills.

These tantalizing observations suggest a neurological basis for the developmental theories of Jean Piaget, Erik Erikson, Margaret Mahler, John Bowlby, Sigmund Freud, and others. Erikson's epigenetic theory states that normal adult behavior results from the successful, sequential completion of each of several infantile and childhood stages. According to the epigenetic model, failure to complete an early stage is reflected in subsequent physical, cognitive, social, or emotional maladjustment. By analogy, the experimental data just discussed suggest that early experience, particularly during the critical window of opportunity for establishing neural connections, primes the basic circuitry for language, emotions, and other advanced behaviors. Clearly, miswiring of an infant's brain may lead to severe handicaps later when the person attempts to relate to the world as an adult. These findings support the vital need for adequate public financing of Early Intervention and Head Start programs, programs that may be the most cost-effective means of improving persons' mental health.

1.3 Neural Development and Neurogenesis

The human brain is a structurally and functionally complex system that exhibits ongoing modification in response to both experience and disease. The anatomical and neurochemical systems that underlie the cognitive, social, emotional, and sensorimotor functions of the mature nervous system emerge from neuronal and glial cell populations that arise during the earliest periods of development.

An understanding of molecular and cellular mechanisms mediating nervous system development is critical in psychiatry because abnormalities of developmental processes contribute to many brain disorders. Although a developmental basis may not be surprising in early childhood disorders, such as autism, fragile X mental retardation, and Rett syndrome, even mature diseases including schizophrenia and depression reflect ontogenetic factors. For example, evidence from brain pathology and neuroimaging indicates that there are reductions in forebrain region volumes, neuron and glial cell numbers, and some classes of interneurons in schizophrenia that are apparent at the time of diagnosis. Similarly, in autism, early brain growth is abnormally increased, and abnormalities of cellular organization are observed that reflect disturbances in the basic processes of cell proliferation and migration. When there is abnormal regulation of early brain development, a foundation of altered neuron populations that may differ in cell types, numbers, and positions is laid down, or abnormal connections, with consequences for interacting glial populations, may be elaborated. With progressive postnatal development, the maturing brain systems call upon component neurons to achieve increasing levels of complex information processing, which may be deficient should initial conditions be disturbed. New neural properties emerge during maturation as neuron populations elaborate additional functional networks based on and modified by ongoing experience. Given the brain's dynamic character, we may expect that developmental abnormalities in neural populations and systems, caused by genetic as well as environmental factors, will manifest at diverse times in a person's life.

OVERVIEW OF NERVOUS SYSTEM MORPHOLOGICAL DEVELOPMENT

In considering brain development, several overarching principles need to be considered. First, different brain regions and neuron populations are generated at distinct times of development and exhibit specific temporal schedules. This has implications for the consequences of specific developmental insults, such as the production of autism following fetal exposure to the drug thalidomide only during days 20 to 24 of gestation. Second, the sequence of cellular processes comprising ontogeny predicts that abnormalities in early events necessarily lead to differences in subsequent stages, although not all abnormalities may be accessible to our clinical tools. For example, a deficit in the number of neurons will likely lead to reductions in axonal processes and ensheathing white matter in the mature brain. However, at the clinical level, since glial cells outnumber neurons 8 to 1, the glial cell population, the oligodendrocytes, and their myelin appear as altered white matter on neuroimaging with little evidence of a neuronal disturbance. Third, it is clear that specific molecular signals, such as extracellular growth factors and cognate receptors or transcription factors, play roles at multiple developmental stages of the cell. For example, both insulin-like growth factor I (IGF-I) and brain-derived neurotrophic factor (BDNF) regulate multiple cellular processes during the developmental generation and mature function of neurons, including cell proliferation, survival promotion, neuron migration, process outgrowth, and the momentary synaptic modifications (plasticity) underlying learning and memory. Thus changes in expression or regulation of a ligand or its receptor, by experience, environmental insults, or genetic mechanisms, will have effects on multiple developmental and mature processes.

The Neural Plate and Neurulation

The nervous system of the human embryo first appears between 2½ and 4 weeks of gestation. During development, emergence of new cell types, including neurons, results from interactions between neighboring layers of cells. On gestational day 13, the embryo consists of a sheet of cells. Following gastrulation (days 14 to 15), which forms a two-cell-layered embryo consisting of ectoderm and endoderm, the neural plate region of the ectoderm is delineated by the underlying mesoderm, which appears on day 16. The mesoderm forms by cells entering a midline cleft in the ectoderm called the primitive streak. After migration, the mesodermal layer lies between ectoderm and endoderm and induces overlying ectoderm to become neural plate. Induction usually involves release of soluble growth factors from one group of cells, which in turn bind receptors on neighboring cells, eliciting changes in nuclear transcription factors that control downstream gene expression. In some cases, cell-cell contact-mediated mechanisms are involved. In the gene-patterning section below, the important roles of soluble growth factors and transcription factor expression are described.

The neural plate, the induction of which is complete by 18 days, is a sheet of columnar epithelium and is surrounded by ectodermal epithelium. After formation, the edges of the neural plate elevate, forming the neural ridges. Subsequently, changes in intracellular cytoskeleton and cell-extracellular matrix attachment cause the ridges to merge in the midline and fuse, a process termed neurulation, forming the neural tube, with a central cavity presaging the ventricular system (Fig. 1.3-1). Fusion begins in the cervical region at the hindbrain level (medulla and pons) and continues rostrally and caudally. Neurulation occurs at 3 to 4 weeks of gestation in humans, and its failure results in anencephaly rostrally and spina bifida caudally. Neurulation defects are well known following exposure to retinoic acid in dermatological preparations and anticonvulsants, especially valproic acid, as well as diets deficient in folic acid.

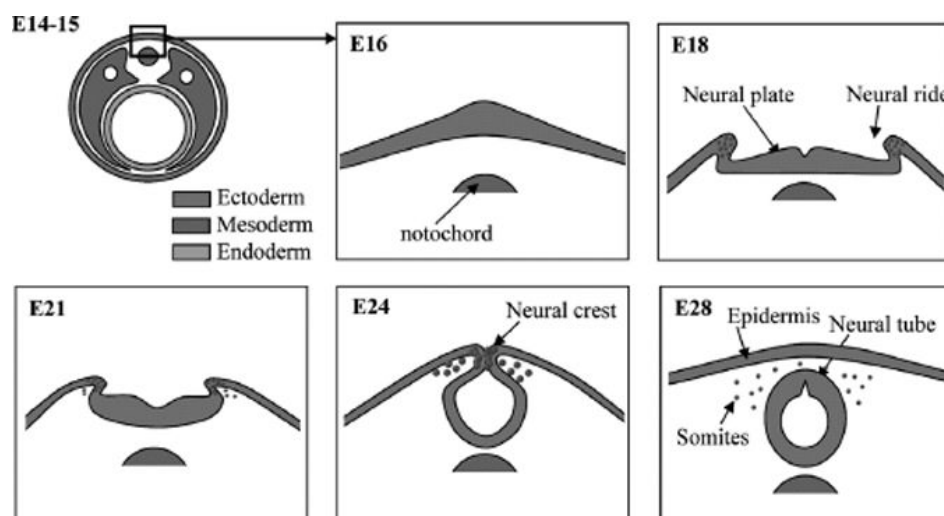

FIGURE 1.3-1

Mechanisms of neurulation. Neurulation begins with the formation of a neural plate in response to soluble growth factors released by the underlying notochord. The neural plate originates as a thickening of the ectoderm that results from cuboidal epithelial cells becoming columnar in shape. With further changes in cell shape and adhesion, the edges of the plate fold and rise, meeting in the midline to form a tube. Cells at the tips of the neural folds come to lie between the neural tube and overlying epidermis, forming the neural crest that gives

rise to the peripheral nervous system and other structures. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:44.)

Another product of neurulation is the neural crest, the cells of which derive from the edges of the neural plate and dorsal neural tube. From this position, neural crest cells migrate dorsolaterally under the skin to form melanocytes and ventromedially to form dorsal root sensory ganglia and sympathetic chains of the peripheral nervous system and ganglia of the enteric nervous system. However, neural crest gives rise to diverse tissues including cells of neuroendocrine, cardiac, mesenchymal, and skeletal systems, forming the basis of many congenital syndromes involving brain and other organs. The neural crest origin at the border of neural and epidermal ectoderm and its generation of melanocytes forms the basis of the neurocutaneous disorders, including tuberous sclerosis and neurofibromatosis. Finally, another nonneuronal structure of mesodermal origin formed during neurulation is the notochord found on the ventral side of the neural tube. As seen in subsequent text of this section, the notochord plays a critical role during neural tube differentiation, since it is a signaling source of soluble growth factors, such as sonic hedgehog (Shh), which affect gene patterning and cell determination.

Regional Differentiation of the Embryonic Nervous System

After closure, the neural tube expands differentially to form major morphological subdivisions that precede the major functional divisions of the brain. These subdivisions are important developmentally, because different regions are generated according to specific schedules of proliferation and subsequent migration and differentiation. The neural tube can be described in three dimensions, including longitudinal, circumferential, and radial. The longitudinal dimension reflects the rostrocaudal (anterior–posterior) organization, which most simply consists of brain and spinal cord. Organization in the circumferential dimension, tangential to the surface, represents two major axes: In the dorsoventral axis, cell groups are uniquely positioned from top to bottom. On the other hand, in the medial to lateral axis, there is mirror image symmetry, consistent with right–left symmetry of the body. Finally, the radial dimension represents organization from the innermost cell layer adjacent to the ventricles to the outermost surface and exhibits region-specific cell layering. At 4 weeks, the human brain is divided longitudinally into the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). These three subdivisions or “vesicles” divide further into five divisions by 5 weeks, consisting of the prosencephalon, which forms the telencephalon (including cortex, hippocampus, and basal ganglia) and diencephalon (thalamus and hypothalamus), the mesencephalon, (midbrain), and the rhombencephalon, yielding metencephalon (pons and cerebellum) and myelencephalon (medulla). Morphological transformation into five vesicles depends on region-specific proliferation of precursor cells adjacent to the ventricles, the so-called ventricular zones (VZs). As discussed later, proliferation intimately depends on soluble growth factors made by proliferating cells themselves or released from regional signaling centers. In turn, growth factor production and cognate receptor expression also depend on region-specific patterning genes. We now know that VZ precursors, which appear morphologically homogeneous, express a checkerboard array of molecular genetic determinants that control the generation of specific types of neurons in each domain (Fig. 1.3-2).

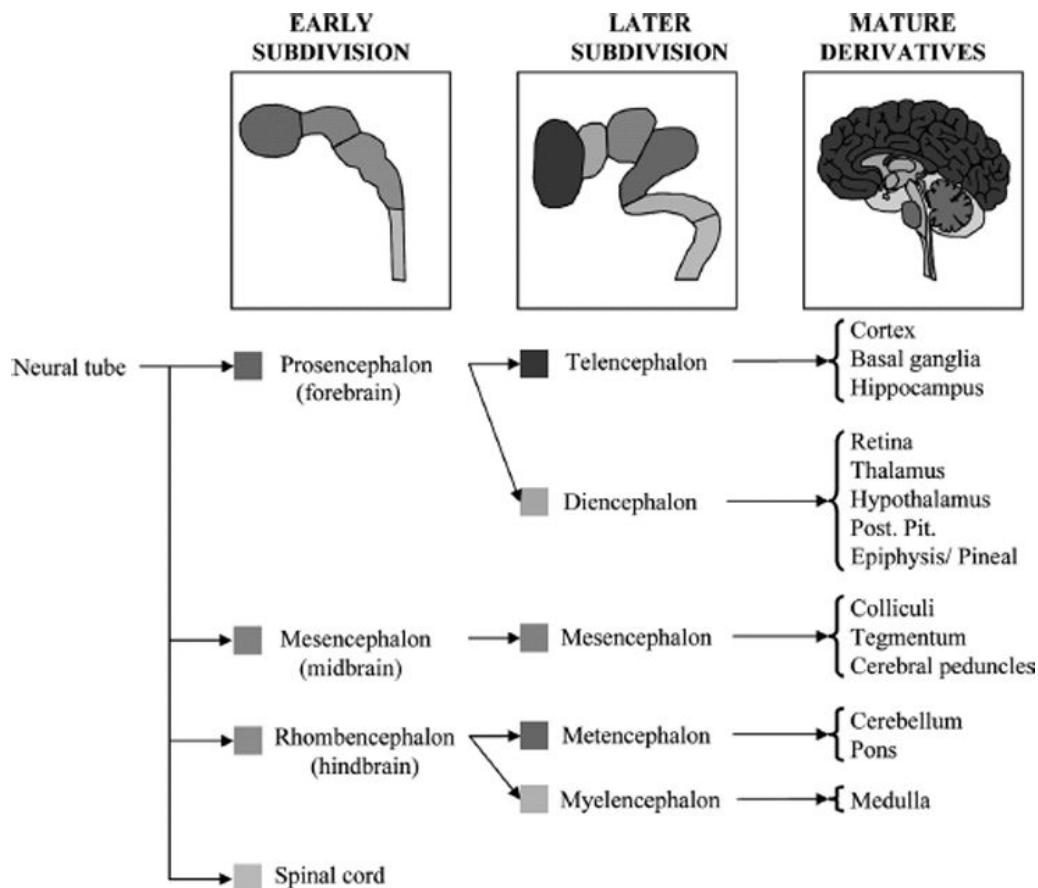

FIGURE 1.3-2

Progression of brain regional differentiation. Early after neurulation, the neural tube differentiates into four regions (forebrain, midbrain, hindbrain, and spinal cord) that give rise following later divisions and maturation to the different brain structures. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:45.)

In the circumferential dimension, organization begins very early and extends over many rostrocaudal subdivisions. In the spinal cord, the majority of tissue comprises the lateral plates, which later divide into dorsal or alar plates, composed of sensory interneurons, and motor or basal plates, consisting of ventral motor neurons. Two other diminutive plates, termed the roof plate and floor plate, are virtually absent in maturity; however, they play critical regulatory roles as growth factor signaling centers in the embryo. Indeed, the floor plate, in response to Shh from the ventrally located notochord, produces its own Shh, which in turn induces neighboring cells in ventral spinal cord and brainstem to express region-specific transcription factors that specify cell phenotype and function. For example, in combination with other factors, floor plate Shh induces midbrain precursors to differentiate into dopamine-secreting neurons of the substantia nigra. Similarly, the roof plate secretes growth factors, such as bone morphogenetic proteins (BMPs), which induce dorsal neuron cell fate in spinal cord. In the absence of roof plate, dorsal structures fail to form, such as cerebellum, and midline hippocampal structures are missing. Finally, in the radial dimension, the organization of layers is subdivision specific, produced by differential proliferation of VZ precursors and cell migration, as described later.

The Ventricular and Subventricular Proliferative Zones

The distinct patterns of precursor proliferation and migration in different regions generate the radial organization of the nervous system. In each longitudinal subdivision, the final population size of a brain region depends on the interplay of regulated neurogenesis with programmed cell death. Traditional concepts had suggested that there was excess cell production everywhere and that final cell number regulation was achieved primarily after neurogenesis through selective cell death mediated by target-derived survival (trophic) factors. We now know that the patterning genes discussed later play major roles in directing regional precursor proliferation that is coordinated with final structural requirements, and that programmed cell death occurs at multiple stages. Consequently, in diseases characterized by brain regions smaller than normal, such as schizophrenia, there may be a failure to generate neurons initially, as opposed to normal generation with subsequent cell loss.

Radial and Tangential Patterns of Neurogenesis and Migration

Of interest to psychiatry, the cerebral cortex is the paradigmatic model of inside-to-outside neurogenesis. A large number of studies now relate specific genetic mutations to distinct cortical malformations that alter neurogenesis, migration, and cellular organization, thereby increasing our knowledge of both normal and pathophysiologic cortical development. Derived from the embryonic forebrain telencephalic vesicles, the characteristic six-cell layers represent a common cytoarchitectural and physiological basis for neocortical function. Within each layer, neurons exhibit related axodendritic morphologies, use common neurotransmitters, and establish similar afferent and efferent connections. In general, pyramidal neurons in layer 3 establish synapses within and between cortical hemispheres, whereas deeper layer 5/6 neurons project primarily to subcortical nuclei, including thalamus, brainstem, and spinal cord. The majority of cortical neurons originate from the forebrain VZ. At the earliest stages, the first postmitotic cells migrate outward from the VZ to establish a superficial layer termed the preplate. Two important cell types comprise the preplate—Cajal–Retzius cells, which form outermost layer 1 or marginal zone, and subplate neurons, which lay beneath future layer 6. These distinct regions form when later-born cortical plate neurons migrate within and divide the preplate in two (Fig. 1.3-3).

FIGURE 1.3-3

Schematic drawing of radial and tangential migration during cerebral cortex development. **A.** A coronal section of one half of the developing rat forebrain. The dorsal forebrain gives rise to the cerebral cortex. Medial ganglionic eminences (MGEs) and lateral ganglionic eminences (LGEs) of the ventral forebrain generate neurons of the basal ganglia and the cortical interneurons. The *arrows* indicate the tangential migration route for γ -aminobutyric acid (GABA) interneurons to the cortex. The boxed area (enlarged in **B** and **C**) shows the developing cortex at early and late stages. **B.** In the dorsal forebrain, the first cohort of postmitotic neurons migrate out from the ventricular zone (VZ) and create a preplate (PP) below the pial surface. **C.** Subsequent postmitotic neurons will migrate along radial glia through the intermediate zone (IZ) and take position in the middle of the preplate, creating a cortical plate (CP) between the outer marginal zone (MZ) and inner subplate (SP). Ultimately, the CP will be composed of six layers that are born sequentially, migrating in an inside-to-outside pattern. Horizontal processes in the IZ represent axon terminals of thalamic afferents. (From Nadarajah B, Parnavelas JG. Modes of neuronal migration in the developing cerebral cortex. *Nat Neurosci.* 2002;3:423, with permission.)

A recent discovery, postulated for years, has changed the view of the origins of cortical neuron populations involved in human brain disease. Neuron tracing experiments in culture and in vivo demonstrate that the neocortex, a dorsal forebrain derivative, is also populated by neurons generated in the ventral forebrain (see Fig. 1.3-3). Molecular studies of patterning genes, especially *Dlx*, strongly support this model (see below). In contrast to excitatory pyramidal neurons, the overwhelming majority of inhibitory γ -aminobutyric acid (GABA)-secreting interneurons originate from mitotic precursors of the ganglionic eminences that generate the neurons of the basal ganglia. Subsets of interneurons also secrete neuropeptides, such as neuropeptide Y (NPY) and somatostatin, and express nitrous oxide (NOS)-generating enzyme. Not associated with cortical VZ radial glia, these GABA interneurons reach the cortical plate by migrating tangentially, in either the superficial marginal zone or a deep position above the VZ, the subplate region where thalamic afferents are also growing. Significantly, in brains from patients with schizophrenia, the prefrontal cortex exhibits a reduced density of interneurons in layer 2. In addition, there is upregulation of GABA_A-receptor binding, a potential functional compensation, as well as a relative deficiency of NOS-expressing neurons.

These observations have led to the hypothesis that schizophrenia is due to reduced GABAergic activity. The origin of GABA interneurons from the ganglionic eminences and their association with specific patterning genes raises new genetic models of disease causation and possible strategies for disease intervention. Thus, more broadly, normal cortical development depends on a balance of two principal

patterns of neurogenesis and migration, consisting of radial migration of excitatory neurons from the dorsal forebrain VZ and tangential migration of inhibitory neurons from the ventral forebrain.

In contrast to inside-to-outside neurogenesis observed in cortex, phylogenetically older regions, such as hypothalamus, spinal cord, and hippocampal dentate gyrus, exhibit the reverse order of cell generation. First-formed postmitotic neurons lie superficially, and last-generated cells localize toward the center. Although this outside-to-inside pattern might reflect passive cell displacement, radial glia and specific migration signaling molecules clearly are involved. Furthermore, cells do not always lie in direct extension from their locus of VZ generation. Rather, some groups of cells migrate to specific locations, as observed for neurons of the inferior olivary nuclei.

Of prime importance in psychiatry, the hippocampus demonstrates both radial and nonradial patterns of neurogenesis and migration. The pyramidal cell layer, Ammon's horn Cornu Ammonis (CA) 1 to 3 neurons, is generated in a typical outside-to-inside fashion in the dorsomedial forebrain for a discrete period, from 7 to 15 weeks of gestation, and exhibits complex migration patterns. In contrast, the other major population, dentate gyrus granule neurons, starts appearing at 18 weeks and exhibits prolonged postnatal neurogenesis, originating from several migrating secondary proliferative zones. In rats, for instance, granule neurogenesis starts at embryonic day 16 (E16) with proliferation in the forebrain VZ. At E18, an aggregate of precursors migrates along a subpial route into the dentate gyrus itself where they generate granule neurons in situ. After birth, there is another migration, localizing proliferative precursors to the dentate hilus, which persists until 1 month of life. Thereafter, granule precursors move to a layer just under the dentate gyrus, termed the subgranular zone (SGZ), which produces neurons throughout life in adult rats, primates, and humans. In rodents, SGZ precursors proliferate in response to cerebral ischemia, tissue injury, and seizures, as well as growth factors. Finally, the diminished hippocampal volume reported in schizophrenia raises the possibility that disordered neurogenesis plays a role in pathogenesis, as either a basis for dysfunction or a consequence of brain injuries, consistent with associations of gestational infections with disease manifestation.

Finally, a different combination of radial and nonradial migration is observed in cerebellum, a brain region recently recognized to play important functions in nonmotor tasks, with particular significance for autism spectrum disorders. Except for granule cells, the other major neurons, including Purkinje and deep nuclei, originate from the primary VZ of the fourth ventricle, coincident with other brainstem neurons. In rats, this occurs at E13 to E15, and in humans, at 5 to 7 weeks of gestation. The granule neurons, as well as basket and stellate interneurons, originate in the secondary proliferative zone, the external germinal cell layer (EGL), which covers newborn cerebellum at birth. EGL precursors originate in the fourth ventricle VZ and migrate dorsally through the brainstem to reach this superficial position. The rat EGL proliferates for 3 weeks, generating more neurons than in any other structure, whereas in humans, EGL precursors exist for at least 7 weeks and up to 2 years. When an EGL precursor stops proliferating, the cell body sinks below the surface and grows bilateral processes that extend transversely in the molecular layer, and then the soma migrates further down into the internal granule layer (IGL). Cells reach the IGL along specialized Bergmann glia, which serve guidance functions similar to those of the radial glia. However, in this case, cells originate from a secondary proliferative zone that generates neurons exclusively of the granule cell lineage, indicating a restricted neural fate. Clinically, this postnatal population in infants makes cerebellar granule neurogenesis vulnerable to infectious insults of early childhood and an undesirable target of several therapeutic drugs, such as steroids, well known to inhibit cell proliferation. In addition, proliferative control of this stem cell population is lost in the common childhood brain tumor, medulloblastoma (see Fig. 1.3-4).

FIGURE 1.3-4

Neurogenesis, migration, and differentiation of granule cells during cerebellar development. Granule cell precursors proliferate in the external germinal layer. After exiting the cell cycle, they migrate through the molecular layer and past the Purkinje neurons to reach the internal granule layer where they differentiate and make synapses. Neurons that do not migrate properly or that do not establish proper synaptic connections undergo apoptosis. EGL, external germinal cell layer; Mol, molecular layer; P, Purkinje cell layer; IGL, internal granule cell layer; Wm, white matter. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:48.)

Developmental Cell Death

During nervous system development, cell elimination is apparently required to coordinate the proportions of interacting neural cells. Developmental cell death is a reproducible, spatially and temporally restricted death of cells that occurs during the organism's development. Three types of developmental cell death have been described: (1) phylogenetic cell death that removes structures in one species that served evolutionarily earlier ones, such as the tail or the vomeronasal nerves; (2) morphogenetic cell death, which sculpts the fingers from the embryonic paddle and is required to form the optic vesicles, as well as the caudal neural tube; and (3) histogenetic cell death, a widespread process that allows the removal of select cells during development of specific brain regions. Numerous studies have focused on histogenetic cell death, the impact of which varies among brain regions but can affect 20 to 80 percent of neurons in some populations. A major role for developmental cell death was proposed in the 1980s based on the paradigm of nerve growth factor, suggesting that following neurogenesis, neurons compete for trophic factors. In this model, survival of differentiating neurons depended absolutely on establishing axonal connections to the correct targets in order to obtain survival-promoting (trophic) growth factors, such as the neurotrophins. Otherwise, they would be eliminated by programmed cell death. This competitive process was thought to ensure proper matching of new neuronal populations with the size of its target field. Although such interactions are involved in controlling cell degeneration, this model is overly simplistic: Developmental cell death also occurs in neural precursors and immature neurons, before any synaptic contacts are established.

Apoptosis. Apoptotic cell death, or apoptosis, is the major type of developmental cell degeneration. Apoptosis or "programmed cell

death” involves specific molecules that possess enzymatic activities such as cysteine-containing aspartate-specific proteases, also called “caspases,” which participate in complex intracellular mechanisms. A large number of signals (both proapoptotic and antiapoptotic) converge to regulate common signaling pathways. Of importance for psychiatry, both developmental as well as pathological cell death involve many of the same signaling cascades. A failure to inhibit apoptosis is involved in cancers and autoimmune diseases (multiple sclerosis), whereas excess stimulation of apoptosis is observed in neurodegenerative diseases during both development (Huntington’s disease, lysosomal diseases, and leukodystrophy) and aging (Alzheimer’s and Parkinson’s diseases). Massive apoptotic cell death is also observed during acquired developmental brain injuries such as hypoxia-ischemia, fetal alcohol syndrome, and exposure to ionizing radiations and neurotoxicants. Thus dysregulation of apoptotic cell death during development can lead to severe brain abnormalities, which may only manifest later as mature functional impairments.

Programmed cell death is a necessary process during neurodevelopment, as genetic deletion of caspases in embryonic mice produces enlarged and disorganized brains with marked regional specificity. Programmed cell death occurs at multiple stages of nervous system development, interacting with neurogenesis and differentiation with precise and complex mechanisms. As many neuropathologies also involve dysregulation of apoptosis, future studies hold promise for elucidation and treatment of neurological diseases.

THE CONCEPT OF NEURAL PATTERNING

Principles of Function

The morphological conversion of the nervous system through the embryonic stages, from neural plate through neural tube to brain vesicles, is controlled by interactions between extracellular factors and intrinsic genetic programs. In many cases, extracellular signals are soluble growth factors secreted from regional signaling centers, such as the notochord, floor, or roof plates, or surrounding mesenchymal tissues. The precursor’s ability to respond (competence) depends on cognate receptor expression, which is determined by patterning genes whose proteins regulate gene transcription. The remarkable new observation is that the subdivisions of the embryonic telencephalon that were initially based on mature differences in morphology, connectivity, and neurochemical profiles are also distinguished embryonically by distinct patterns of gene expression. Classical models had suggested that the cerebral cortex was generated as a fairly homogeneous structure, unlike most epithelia, with individual functional areas specified relatively late, after cortical layer formation, by the ingrowth of afferent axons from thalamus. In marked contrast, recent studies indicate that proliferative VZ precursors themselves display regional molecular determinants, a “protomap,” which the postmitotic neurons carry with them as they migrate along radial glia to the cortical plate. Consequently, innervating thalamic afferents may serve to modulate only intrinsic molecular determinants of the protomap. Indeed, in two different genetic mutants, *Gbx2* and *Mash1*, in which thalamocortical innervation is disrupted, expression of cortical patterning genes proceeds unaltered. On the other hand, thalamic afferent growth may be directed by patterning genes and subsequently play roles in modulating regional expression patterns. Thus experience-dependent processes may contribute less to cortical specialization than originally postulated.

The term patterning genes connotes families of proteins that serve primarily to control transcription of other genes, the products of which include other transcription factors or proteins involved in cellular processes, such as proliferation, migration, or differentiation. Characteristically, transcription factor proteins contain two principal domains, one that binds DNA promoter regions of genes and the other that interacts with other proteins, either transcription factors or components of intracellular second messengers. It is notable that transcription factors form multimeric protein complexes to control gene activation. Therefore, a single transcription factor will play diverse roles in multiple cell types and processes, according to what other factors are present, the so-called cellular environment. The combinatorial nature of gene promoter regulation leads to a diversity of functional outcomes when a single patterning gene is altered. Furthermore, because protein interactions depend on protein–protein affinities, there may be complex changes as a single factor’s expression level is altered. This may be one important mechanism of human variation and disease susceptibility, since polymorphisms in gene promoters, known to be associated with human disease, can alter levels of gene protein products. A transcription factor may associate primarily with one partner at a low concentration but with another at a higher titer. The multimeric nature of regulatory complexes allows a single factor to stimulate one process while simultaneously inhibiting another. During development, a patterning gene may thus promote one event, say generation of neurons, by stimulating one gene promoter, while simultaneously sequestering another factor from a different promoter whose activity is required for an alternative phenotype, such as glial cell fate. Finally, the factors frequently exhibit cross-regulatory functions, where one factor negatively regulates expression of another. This activity leads to the establishment of tissue boundaries, allowing the formation of regional subdivisions, such as basal ganglia and cerebral cortex in the forebrain.

In addition to combinatorial interactions, patterning genes exhibit distinct temporal sequences of expression and function, acting in hierarchical fashion. Functional hierarchies were established experimentally by using genetic approaches, either deleting a gene (loss of function) or over-/ectopically expressing it (gain of function), and defining developmental consequences. At the most general level, genetic analyses indicate that regionally restricted patterning genes participate in specifying the identity, and therefore function, of cells in which they are expressed. Subdivisions of the brain, and of cerebral cortex specifically, are identified by regionalized gene expression in the proliferative VZ of the neural tube, leading to subsequent differentiation of distinct types of neurons in each mature (postmitotic) region. Thus the protomap of the embryonic VZ apparently predicts the cortical regions it will generate and may instruct the hierarchical temporal sequence of patterning gene expression. It appears that the different genes underlie multiple stages of brain development including the following: (1) determining that ectoderm will give rise to nervous system (as opposed to skin); (2) defining the dimensional character of a region, such as positional identity in dorsoventral or rostrocaudal axes; (3) specifying cell class, such as neuron or glia; (4) defining when proliferation ceases and differentiation begins, (5) determining specific cell subtype, such as GABA interneuron, as well as projection pattern; and (6) defining laminar position in the region, such as cerebral cortex. Although investigations are ongoing, studies indicate that these many steps depend on interactions of transcription factors from multiple families. Furthermore, a single transcription factor plays regulatory roles at multiple stages in the developmental life of a cell, yielding complex outcomes, for instance, in genetic loss of function studies and human disease.

Recent advances in molecular biology have led to identification of another principle of nervous system organization, which if sustained by further studies, may provide a molecular basis for brain system diseases, such as Parkinson’s disease and autism. Using molecular techniques to permanently identify cells that had expressed during development of a specific gene, in this case the soluble growth factor, *Wnt3a*, investigators were able to determine where cells originated embryonically and could trace their path of migration along the neuraxis during development. These genetic-fate mapping studies indicate that cells that expressed *Wnt3a* migrated widely from the dorsal midline into the dorsal regions of the brain and spinal cord, thereby contributing to diverse adult structures in the diencephalon, midbrain, and brainstem and rostral spinal cord. Of interest, most of these structures were linked into a functional neural network, specifically the auditory system. The observation that a single functional system emerges from a specific group of fated cells would allow for restricted neurological-system–based disorders, such as deficits in dopamine or catecholamine neurons, or for the dysfunction of inter-related brain regions that subservise social cognition and interaction, a core symptom of the autism spectrum disorders. Other adult system degenerations may also be considered. This new observation may change the way that we consider temporal changes in patterning gene expression of specific brain regions during development.

Finally, patterning gene expression in nervous system subdivisions is not insensitive to environmental factors. To the contrary, expression is intimately regulated by growth factors released from regional signaling centers. Indeed, although a century of classical experimental embryology described morphologically the induction of new tissues between neighboring cell layers, we have only recently defined molecular identities of soluble protein morphogens and cell response genes underlying development. Signaling molecules from discrete centers establish tissue gradients that provide positional information (dorsal or ventral), impart cell specification, and/or control regional

growth. Signals include the BMPs, the Wingless-Int proteins (Wnts), Shh, fibroblast growth factors (FGFs), and epidermal growth factors (EGFs), to name a few. These signals set up developmental domains characterized by expression of specific transcription factors, which in turn control further regional gene transcription and developmental processes. The importance of these mechanisms for cerebral cortical development is only now emerging, altering our concepts of the roles of subsequent thalamic innervation and experience-dependent processes. In light of the temporal and combinatorial principles discussed earlier, brain development can be viewed as a complex and evolving interaction of extrinsic and intrinsic information.

SPECIFIC INDUCTIVE SIGNALS AND PATTERNING GENES IN DEVELOPMENT

Induction of the central nervous system (CNS) begins at the neural plate stage when the notochord, underlying mesenchyme, and surrounding epidermal ectoderm produce signaling molecules that affect the identity of neighboring cells. Specifically, the ectoderm produces BMPs that prevent neural fate determination by promoting and maintaining epidermal differentiation. In other words, neural differentiation is a default state that manifests unless it is inhibited. In turn, neural induction proceeds when BMP's epidermis-inducing activity is blocked by inhibitory proteins, such as noggin, follistatin, and chordin, which are secreted by Hensen's node (homologous to the amphibian Spemann organizer), a signaling center at the rostral end of the primitive streak. Once the neural tube closes, the roof plate and floor plate become new signaling centers, organizing dorsal and ventral neural tube, respectively. The same ligand/receptor system is used sequentially for multiple functions during development. BMPs are a case in point, since they prevent neural development at the neural plate stage, whereas after neurulation the factors are produced by the dorsal neural tube itself to induce sensory neuron fates.

The Spinal Cord

The spinal cord is a prime example of the interaction of soluble signaling factors with intrinsic patterning gene expression and function. The synthesis, release, and diffusion of inductive signals from signaling sources produce concentration gradients that impose distinct neural fates in the spinal cord (Fig. 1.3-5). The notochord and floor plate secrete Shh, which induces motoneurons and interneurons ventrally, whereas the epidermal ectoderm and roof plate release several BMPs that impart neural crest and sensory relay interneuron fates dorsally. Growth factor inductive signals act to initiate discrete regions of transcription factor gene expression. For instance, high concentrations of Shh induce winged helix transcription factor *Hnf3β* gene in floor plate cells and *Nkx6.1* and *Nkx2.2* in ventral neural tube, whereas the expression of more dorsal genes, *Pax6*, *Dbx1/2*, *Irx3*, and *Pax7*, is repressed. In response to Shh, ventral motoneurons express transcription factor gene *Isl1*, whose protein product is essential for neuron differentiation. Subsequently, ventral interneurons differentiate, expressing *En1* or *Lim1/2* independent of Shh signaling. In contrast, the release of BMPs by dorsal cord and roof plate induces a distinct cascade of patterning genes to elicit sensory interneuron differentiation. In aggregate, the coordinated actions of Shh and BMPs induce the dorsoventral dimension of the spinal cord. Similarly, other inductive signals determine rostrocaudal organization of the CNS, such as retinoic acid, an upstream regulator of *hox* patterning genes, anteriorly, and the FGFs posteriorly. The overlapping and unique expression of the many *hox* gene family members are important for establishing the segmental pattern in the anterior–posterior axis of the hindbrain and spinal cord, now classic models well described in previous reviews.

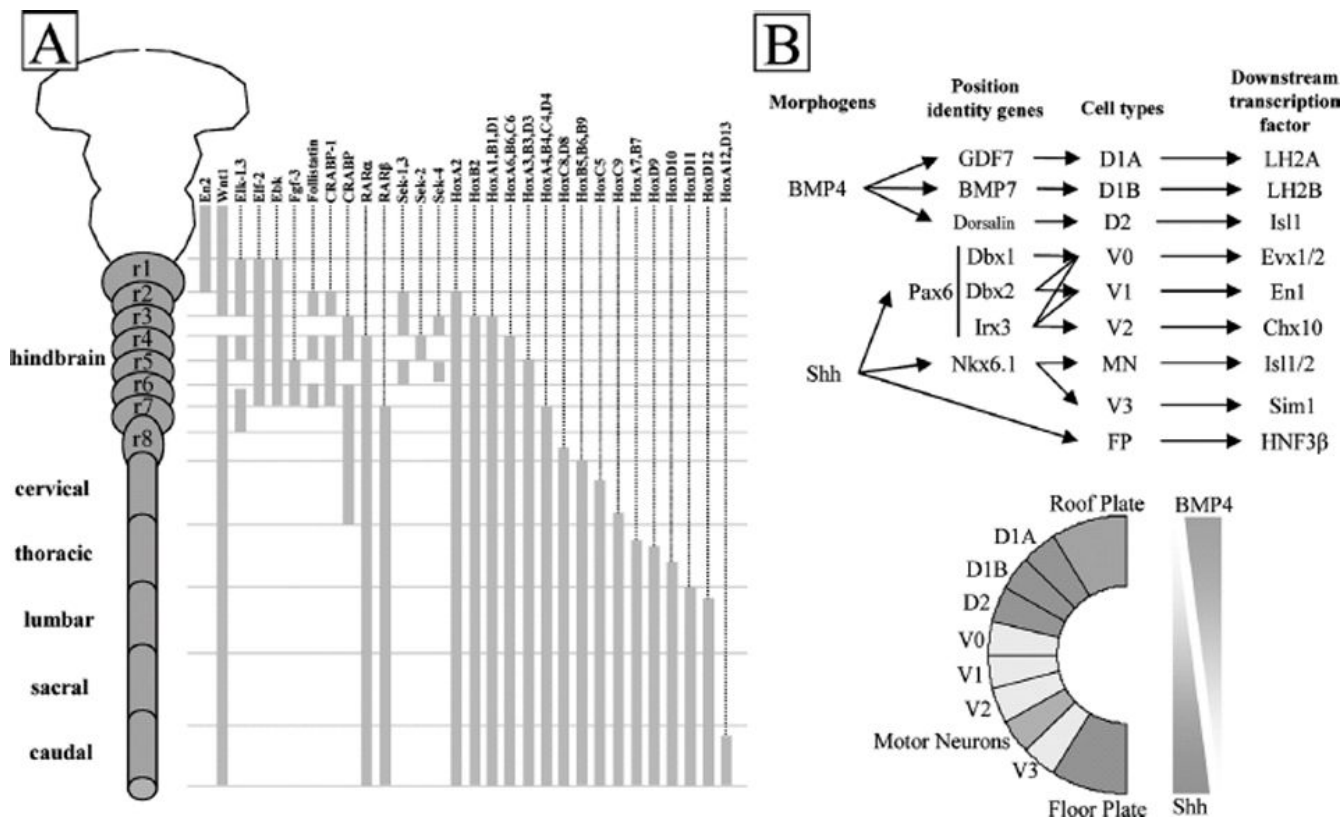

FIGURE 1.3-5 Patterning genes in the spinal cord. **A**, Diagram illustrating the localization of gene expression in the developing “trunk.” Rhombomere boundaries are specified by specific combinations of transcription factors. (Modified from Darnell, 2005.) **B**, Morphogen induction of spinal cord cell fate. Dorsoventral gradients of sonic hedgehog (Shh) and bone morphogenetic protein (BMP) induce expression of several position identity genes. Combinatorial effects of these factors establish progenitor domains and result in the expression of specific downstream molecular markers. D, dorsal neurons; V, ventral neurons. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock’s Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:51.)

Recent advances in spinal cord transcription factor expression and function support the principle that these factors play roles at multiple stages of a cell’s development, likely due to their participation in diverse protein regulatory complexes: The transcription factors Pax6, Olig2, and Nkx2.2, which define the positional identity of multipotent progenitors early in development, also play crucial roles in controlling the timing of neurogenesis and gliogenesis in the developing ventral spinal cord.

The Cerebral Cortex

Recent evidence suggests that forebrain development also depends on inductive signals and patterning genes as observed in more caudal neural structures. In the embryo, the dorsal forebrain structures include the hippocampus medially, the cerebral cortex dorsolaterally, and the entorhinal cortex ventrolaterally, whereas in basal forebrain, the globus pallidus lies medially and the striatum laterally. On the basis of gene expression and morphological criteria, it has been hypothesized that the forebrain is divided into a checkerboard-like grid pattern of domains generated by the intersection of longitudinal columns and transverse segments, perpendicular to the longitudinal axis. The columns and segments (prosomeres) exhibit restricted expression of patterning genes, allowing for unique combinations of factors within each embryonic subdivision. Many of these genes, including *Hnf3 β* , *Emx2*, *Pax6*, and *Dlx2*, are first expressed even before neurulation in the neural plate and are then maintained, providing the “protomap” determinants of the VZ described earlier. As in spinal cord, initial forebrain gene expression is influenced by a similar array of signaling center soluble factors—Shh, BMP, and retinoic acid. As the telencephalic vesicles form, signaling centers localize to the edges of the cortex. In the dorsal midline there is the anterior neural ridge, an anterior cranial mesenchyme secreting FGF8, the roof plate, and, at the junction of the roof plate with the telencephalic vesicle, the cortical hem (Fig. 1.3-6). Other factors originate laterally from the dorsal–ventral forebrain junction, as well as from basal forebrain structures themselves.

FIGURE 1.3-6

Patterning genes and signaling centers in the developing cerebral cortex. This schematic diagram shows a lateral–superior view of the two cerebral hemispheres of the embryonic mouse, sitting above the midbrain and hindbrain (*broken lines*). The anterior–lateral extent of *Pax6* gene expression is indicated by circles. The posterior–medial domain of *Emx2* expression is indicated by stripes. The genes exhibit continuous gradients of expression that decrease as they extend to opposite poles. The signaling factor fibroblast growth factor 8 (FGF8) is produced by and released from mesenchymal tissue in the anterior neural ridge, which regulates *Pax6* and *Emx2* expression. In the midline, bone morphogenetic proteins (BMPs) and Wntless-Int proteins (Wnts) are secreted from other signaling centers, including the roof plate and the cortical hem. (Courtesy of E. DiCicco-Bloom and K. Forghash.)

Do molecular studies identify how different cortical regions interact with thalamic neurons to establish specific functional modalities, such as vision and sensation? And once regional identity is established, can it be modified by later developmental events? It has been proposed that initially there are no functional distinctions in the cortex but that they are induced by the ingrowth of extrinsic thalamic axons, which convey positional and functional specifications, the so-called “protocortex model.” However, in contrast, the abundant molecular evidence provided earlier suggests that intrinsic differences are established early in the neuroepithelium by molecular determinants that regulate areal specification, including the targeting of thalamic axons, termed the “protomap” model. The foregoing mutants now provide experimental tests of these two alternative models and indicate that neither model is completely correct. Although there is early molecular regionalization of the cortex, the initial targeting of thalamic axons to the cortex is independent of these molecular differences. In the rodent, thalamic afferents first target to their usual cortical regions prenatally in the late embryo. However, once thalamic afferents reach the cortex, which occurs several days after birth, interactions of thalamic axon branches with local regional cues leads to modifications of initial outgrowth and the establishment of connections that conform to areal molecular identities. Furthermore, the developing cortex exhibits a remarkable and unexpected level of flexibility in mediating modality-specific functions: In the ferret, surgical elimination of visual pathway (lateral geniculate nucleus) in postnatal pups results in the transfer of visual signaling to the auditory cortex, which successfully mediates vision! Thus the animal’s visual information is effectively processed by their auditory cortex.

The Hippocampus

The hippocampus is a region of major importance in schizophrenia, depression, autism, and other disorders, and defining mechanisms regulating hippocampal formation may provide clues to the developmental bases of these disorders. In mice, the hippocampus is located in the medial wall of the telencephalic vesicle. Where it joins the roof plate, the future roof of the third ventricle, there is a newly defined signaling center, the cortical hem, which secretes BMPs, Wnts, and FGFs (see Fig. 1.3-6). Genetic experiments have defined patterning genes localized to the cortical hem and hippocampal primordia, whose deletions result in a variety of morphogenetic defects. In mice lacking *Wnt3a*, which is expressed in the cortical hem, the hippocampus is either completely missing or greatly reduced, whereas neighboring cerebral cortex is mainly preserved. A similar phenotype is produced by deleting an intracellular factor downstream to Wnt receptor activation, the *Lef1* gene, suggesting that the *Wnt3a–Lef1* pathway is required for hippocampal cell specification and/or proliferation, issues remaining to be defined. When another cortical hem gene, *Lhx5*, is deleted, mice lack both the hem and neighboring choroid plexus, both sources of growth factors. However, in this case, the cortical hem cells may in fact proliferate in excess, and the hippocampal primordia may be present but disorganized, exhibiting abnormalities in cell proliferation, migration, and differentiation. A related abnormality is observed with *Lhx2* mutation. Finally, a sequence of bHLH transcription factors plays roles in hippocampal neurogenesis: Dentate gyrus differentiation is defective in *NeuroD* and *Mash1* mutants. Significantly, expression of all these hippocampal patterning genes is regulated by factors secreted by anterior neural ridge, roof plate, and the cortical hem, including FGF8, Shh, BMPs, and Wnts. Moreover, the basal forebrain region secretes an EGF-related protein, transforming growth factor α (TGF- α), which can stimulate expression of the classical limbic marker protein, lysosomal-associated membrane protein (LAMP). These various signals and genes now serve as candidates for disruption in human diseases of the hippocampus.

The Basal Ganglia

In addition to motor and cognitive functions, the basal ganglia take on new importance in neocortical function, since they appear to be the embryonic origin of virtually all adult GABA interneurons, reaching the neocortex through tangential migration. Gene expression studies have identified several transcription factors that appear in precursors originating in the ventral forebrain ganglionic eminences, allowing interneurons to be followed as they migrate dorsally into the cortical layers. Conversely, genetic deletion mutants exhibit diminished or absent interneurons, yielding results consistent with other tracing techniques. These transcription factors, including *Pax6*, *Gsh2*, and *Nkx2.1*, establish boundaries between different precursor zones in the ventral forebrain VZ, through mechanisms involving mutual repression. As a simplified model, the medial ganglionic eminence (MGE) expresses primarily *Nkx2.1* and gives rise to most GABA interneurons of the cortex and hippocampus, whereas the lateral ganglionic eminence (LGE) expresses *Gsh2* and generates GABA interneurons of the SVZ and olfactory bulb. The boundary between ventral and dorsal forebrain then depends on LGE interaction with the dorsal neocortex, which expresses *Pax6*. When *Nkx2.1* is deleted, LGE transcription factor expression spreads ventrally into the MGE territory, and there is a 50 percent reduction in neocortical and striatal GABA interneurons. In contrast, deletion of *Gsh2* leads to ventral expansion of the dorsal cortical molecular markers and concomitant decreases in olfactory interneurons. Finally, *Pax6* mutation causes both MGE and LGE to spread laterally and into dorsal cortical areas, yielding increased interneuron migration. The final phenotypic changes are complex, as these factors exhibit unique and overlapping expression and interact to control cell fate.

Neuronal Specification

As indicated for basal ganglia, throughout the nervous system transcription factors participate in decisions at multiple levels, including determining the generic neural cell, such as neuron or glial cell, as well as neuron subtypes. *Mash1* can promote a neuronal fate over a glial fate as well as induce the GABA interneuron phenotype. However, another bHLH factor, *Olig1/2*, can promote oligodendrocyte development, whereas it promotes motor neuron differentiation elsewhere, indicating that the variety of factors expressed in a specific cell leads to combinatorial effects and thus diverse outcomes for cell differentiation. The bHLH inhibitory factor, *Id*, is expressed at the transition from somatosensory to motor cortex, implying roles of family members in areal characteristics. In the hippocampus, granule neuron fate is dependent on *NeuroD* and *Math1*, with deficient cell numbers when either one is deleted. The role of specific factors in cortical cell layer determination remains an area of active investigation but likely includes *Tbr1*, *Otx1*, and *Pax6*.

A NEW MECHANISM FOR REGULATING GENE EXPRESSION: MIRNAS

Over the last decade a new mechanism for regulating messenger ribonucleic acid (mRNA) has been explored in simple to complex organisms that involves microRNAs (miRNAs). We now know that miRNAs contribute not only to normal development and brain function but also to brain disorders, such as Parkinson's and Alzheimer's disease, tauopathies, and brain cancer. miRNAs can affect the regulation of RNA transcription, alternative splicing, molecular modifications, or RNA translation. miRNAs are 21- to 23-nucleotide-long single-strand RNA molecules. Unlike mRNAs that encode the instructions for ribosome complex translation into proteins, miRNAs are noncoding RNAs that are not translated but are instead processed to form loop structures. miRNAs exhibit a sequence that is partially complementary to one or several other cellular mRNAs. By binding to target mRNA transcripts, the miRNAs serve to interfere with their function, thereby downregulating expression of these gene products. This gene silencing involves a complex mechanism: The larger miRNA primary transcript is first processed by the Microprocessor, an enzymatic complex consisting of the nuclease Drosha and the double-stranded RNA binding protein Pasha. The mature miRNA binds to its complementary RNA and then interacts with the endonuclease Dicer that is part of the RNA-induced silencing complex (RISC), resulting in the cleavage of the target mRNA and gene silencing (Fig. 1.3-7).

FIGURE 1.3-7

Processing and function of micro RNA (miRNA). After transcription, the primary miRNA forms a hairpin conformation. This structure allows the enzyme Drosha to cleave the transcript, producing a pre-miRNA that then exits the nucleus through nuclear pores. In the cytoplasm, Dicer cleaves the pre-miRNA stem loop, resulting in the formation of two complementary short RNA molecules. Only one of these molecules is integrated in the RNA-induced silencing complex (RISC) and serves as a guide strand that allows recognition and specificity for target RNA due to its sequence complementarity. After integration into the RISC complex, the miRNA matches with the complementary mRNA strand and induces mRNA duplex degradation by the argonaute protein, the catalytic enzyme of the RISC complex. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:55.)

Currently, 475 miRNAs have been identified in humans, and their total number is estimated to be between 600 and 3,441. Potentially, up to 30 percent of all genes might be regulated by miRNAs, a whole new layer of molecular complexity. A connection between miRNAs and several brain diseases has already been made. For example, miR-133b, which is specifically expressed in midbrain dopaminergic neurons, is deficient in midbrain tissue from patients with Parkinson's disease. Furthermore, the miRNAs encoding miR-9, miR-124a, miR-125b, miR-128, miR-132, and miR-219 are abundantly represented in fetal hippocampus, are differentially regulated in the aged brain, and are altered in Alzheimer's disease hippocampus. Similar RNA species termed short-interfering RNAs (siRNAs) have been discovered in plants where they prevent the transcription of viral RNA. The mechanisms involved in these effects are closely related to those of miRNA. Thus siRNAs are now being used in both basic and clinical research to downregulate specific cellular gene products, thereby advancing the study of pathways involved in neurodevelopment and providing new selective tools to regulate disease-causing genes or therapeutic molecular targets.

REGULATION OF NEURODEVELOPMENT BY EXTRACELLULAR FACTORS

The interaction of extracellular factors with intrinsic genetic determinants controlling region-specific neurogenesis includes signals that regulate cell proliferation, migration, differentiation, and survival (Table 1.3-1). Patterning genes control the expression of growth factor receptors and the molecular machinery of the cell division cycle. Extracellular factors are known to stimulate or inhibit proliferation of VZ precursors and originate from the cells themselves, termed autocrine, neighboring cells/tissues, or paracrine, or from the general circulation, as in endocrine, all sources known to affect proliferation in prenatal and postnatal developing brain. Although defined initially in cell culture, a number of mitogenic growth factors are now well-characterized in vivo, including those stimulating proliferation, such as basic FGF (bFGF), EGF, IGF-I, Shh, and signals inhibiting cell division, such as pituitary adenylate-cyclase-activating polypeptide (PACAP), GABA and glutamate, and members of the TGF-β superfamily. However, in addition to stimulating re-entry of cells into the cell cycle, termed a mitogenic effect, extracellular signals also enhance proliferation by promoting survival of the mitotic population, a trophic action. Stimulation of both pathways is necessary to produce maximal cell numbers. These mitogenic and trophic mechanisms during development parallel those identified in carcinogenesis, reflecting roles of c-myc and bcl-2, respectively. Several of the neurotrophins, especially BDNF and neurotrophin-3 (NT3), promote survival of mitotic precursors as well as the newly generated progeny.

Table 1.3-1
Regulation of Neurodevelopment by Extracellular Factors

(From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:55.)

The developmental significance of extracellular mitogens is demonstrated by the expression of the factors and their receptors in regions of neurogenesis, and by the profound and permanent consequences of altering their activities during development. For example, by administering growth factors to developing embryos or pups, one can induce changes in proliferation in prenatal cortical VZ, postnatal cerebellar EGL, and hippocampal dentate gyrus that produce lifelong modifications in brain region population size and cell composition. Such changes may be relevant to structural differences observed in neuropsychiatric disorders, such as depression, schizophrenia, and autism. Specifically, in the cerebral cortex VZ of the embryonic rat, proliferation is controlled by promitogenic bFGF and antimitogenic PACAP, which are expressed as autocrine/paracrine signals. Positive and negative effects were shown in living embryos in utero by performing intracerebroventricular (ICV) injections of the factors or antagonists. ICV injection of bFGF produced a larger adult cortex composed of 87 percent more neurons, which employed glutamate, thus increasing the ratio of excitatory pyramidal neurons to GABA inhibitory neurons, which were unchanged. Conversely, embryonic PACAP injection inhibited proliferation of cortical precursors by 26 percent, reducing the number of labeled layer 5/6 neurons in the cortical plate 5 days later. A similar reduction was accomplished by genetically deleting promitogenic bFGF or leukocyte inhibitory factor (LIF)/ciliary neurotrophic factor (CNTF)/gp130 signaling, diminishing cortical size. Furthermore, effects of mitogenic signals depended critically on the stage-specific program of regional development, since bFGF injection at later ages when gliogenesis predominates affected glial numbers selectively. Thus developmental dysregulation of mitogenic pathways due to genetic or environmental factors (hypoxia, maternal/fetal infection, or drug or toxicant exposure) will likely produce subtle changes in the size and composition of the developing cortex. Other signals likely to play proliferative roles include Wnt's, TGF-α, IGF-I, and BMPs. Although interactions between intrinsic cortical programs and extrinsic factors remain to be defined, a remarkable new study of mouse embryonic stem cells suggests that embryonic mammalian forebrain specification may be a developmentally ancestral intrinsic program that emerges in the absence of extrinsic signals. In specific culture conditions that block endogenous Shh signaling, mouse embryonic stem cells can sequentially generate the various types of neurons that display most salient features of genuine cortical pyramidal neurons. When grafted into the cerebral cortex, these cells differentiate into neurons that project to select cortical (visual and limbic regions) and subcortical targets, corresponding to a wide range of pyramidal layer neurons. Insight into precision control of neuronal differentiation will open new avenues to perform neuronal grafts in humans for cellular replacement in various acquired and neurodegenerative diseases.

Similar to cerebral cortex, later generated populations of granule neurons, such as in cerebellum and hippocampal dentate gyrus, are also

sensitive to growth factor manipulation, which is especially relevant to therapies administered intravenously to premature and newborn infants in the neonatal nursery. Like in humans, cerebellar granule neurons are produced postnatally in rats, but for only 3 weeks, whereas in both species dentate gyrus neurons are produced throughout life. Remarkably, a single peripheral injection of bFGF into newborn rat pups rapidly crossed into the cerebrospinal fluid (CSF) and stimulated proliferation in the cerebellar EGL by 30 percent as well as hippocampal dentate gyrus by twofold by 8 hours, consistent with an endocrine mechanism of action. The consequence of mitogenic stimulation in cerebellum was a 33 percent increase in the number of internal granule layer neurons and a 22 percent larger cerebellum. In hippocampus, mitotic stimulation elicited by a single bFGF injection increased the absolute number of dentate gyrus granule neurons by 33 percent at 3 weeks, defined stereologically, producing a 25 percent larger hippocampus containing more neurons and astrocytes, a change that persisted lifelong. Conversely, genetic deletion of bFGF resulted in smaller cerebellum and hippocampus at birth and throughout life, indicating that levels of the growth factor were critical for normal brain region formation. Other proliferative signals regulating cerebellar granule neurogenesis include Shh and PACAP, the disruption of which contributes to human medulloblastoma, whereas in hippocampus the Wnt family may be involved.

Clinical Implications

There are several clinical implications of these surprising growth factor effects observed in newborns. First, we may need to investigate possible neurogenetic effects of therapeutic agents we administer in the newborn nursery for long-term consequences. Second, because bFGF is as effective in stimulating adult neurogenesis (see subsequent text) as in newborns because of specific transport across the mature blood–brain barrier (BBB), there is the possibility that other protein growth factors are also preferentially transported into the brain and alter ongoing neurogenesis. Indeed, in rats, IGF-I also stimulates mature hippocampal dentate gyrus neurogenesis. Third, other therapeutics cross the BBB efficiently due to their lipid solubility, such as steroids, which inhibit neurogenesis across the age spectrum. Steroids are frequently used perinatally to promote lung maturation and treat infections and trauma, but effects on human brain formation have not been examined. Fourth, it is well known that neurological development may be delayed in children who experience serious systemic illness that is associated with numerous inflammatory cytokines, and one may wonder to what degree this reflects interference with neurogenesis and concomitant processes, potentially producing long-term differences in cognitive and motor functional development. Finally, maternal infection during pregnancy is a known risk factor for schizophrenia, and cytokines that cross the placental barrier may directly affect fetal brain cell proliferation and differentiation as well as cell migration, target selection, and synapse maturation, as shown in animal models, eventually leading to multiple brain and behavioral abnormalities in the adult offspring.

CELL MIGRATION

Throughout the nervous system, newly generated neurons normally migrate away from proliferative zones to achieve final destinations. If this process is disrupted, abnormal cell localization and function result. In humans, more than 25 syndromes with disturbed neuronal migration have been described. As noted earlier, neurons migrate in both radial and tangential fashions during development and may establish cell layers that are inside-to-outside, or the reverse, according to region. In developing cerebral cortex, the most well-characterized mechanism is radial migration from underlying VZ to appropriate cortical layers in an inside-to-outside fashion. In addition, however, the inhibitory GABA interneurons that are generated in ventrally located medial ganglionic eminences reach the cortex through tangential migration in the intermediate zone along axonal processes or other neurons. The neurons in developing cerebellum also exhibit both radial and tangential migration. Purkinje cells leave the fourth ventricle VZ and exhibit radial migration, whereas other precursors from the rhombic lip migrate tangentially to cover the cerebellar surface, establishing the EGL, a secondary proliferative zone. From EGL, newly generated granule cells migrate radially inward to create the internal granule cell layer. Finally, granule interneurons of the olfactory bulb exhibit a different kind of migration, originating in the SVZ of the lateral ventricles overlying the striatum. These neuroblasts divide and migrate simultaneously in the rostral migratory stream in transit to the bulb, on a path comprising chains of cells that support forward movements. The most commonly recognized disorders of human neuronal migration are the extensive lissencephalies (see subsequent text), although incomplete migration of more restricted neuron aggregates (heterotopias) frequently underlies focal seizure disorders.

Animal models have defined molecular pathways involved in neuronal migration. Cell movement requires signals to start and stop migration, adhesion molecules to guide migration, and functional cytoskeleton to mediate cell translocation. The best-characterized mouse model of aberrant neuronal migration is reeler, a spontaneous mutant in which cortical neuron laminar position is inverted, being generated in outside-to-inside fashion. Reelin is a large, secreted extracellular glycoprotein produced embryonically by the earliest neurons in the cortical preplate, Cajal–Retzius cells, and hippocampus and cerebellum. Molecular and genetic analysis has established a signaling sequence in reelin activity that includes at least two receptors, the very low-density lipoprotein receptor (VLDLR) and the apolipoprotein E receptor 2 (ApoER2), and the intracellular adapter protein, disabled 1 (Dab1), initially identified in the scrambler mutant mouse, a reelin phenocopy. Current thoughts consider the reelin system as one mediator of radial glia-guided neuron migration, although its specific functions in starting or stopping migration remain controversial. The roles of the VLDL and ApoE2 receptors are intriguing for their possible contributions to Alzheimer's disease risk. Recent studies have found human reelin gene (*RELN*) mutations associated with autosomal recessive lissencephaly with cerebellar hypoplasia, exhibiting a markedly thickened cortex with pachygyria, abnormal hippocampal formations, and severe cerebellar hypoplasia with absent folia. Additional studies suggest that reelin polymorphisms may contribute to autism spectrum disorder (ASD) risk as well.

With regard to cytoskeletal proteins, studies of the filamentous fungus *Aspergillus nidulans* surprisingly provided insight into the molecular machinery underlying the human migration disorder, Miller-Dieker syndrome, a lissencephaly associated with abnormal chromosome 17q13.3. Lissencephaly is a diverse disorder characterized by a smooth cortical surface lacking in gyri and sulci, with markedly reduced brain surface area. The absence of convolutions results from a migration defect: the majority of neurons fail to reach their final destinations. In classical lissencephaly (type I), cerebral cortex is thick and usually four-layered, whereas in cobblestone lissencephaly (type II), the cortex is chaotically organized with a partly smooth and partly pebbled surface and deficient lamination. The most severely affected parts of the brain are the cerebral cortex and hippocampus, with the cerebellum less affected. In fungus, the gene *NudF* was found to be essential for intracellular nuclear distribution, a translocation process also involved in mammalian cell migration. The human homologue of *NudF* is LIS-1 or PAFAH1B1, a mutation of which accounts for up to 60 percent of lissencephaly cases of type I pathology. The LIS-1 gene product interacts with microtubules and related motor components dynein and dynactin as well as doublecortin (DCX), which may regulate microtubule stability. Mutations in DCX gene result in X-linked lissencephaly in males and bands of heterotopic neurons in white matter in females, appearing as a “double cortex” on imaging studies, producing severe mental retardation and epilepsy. Other migratory defects occur when proteins associated with the actin cytoskeleton are affected, such as mutation in filamin 1 gene responsible for periventricular nodular heterotopias in humans and mutations of a regulatory phosphokinase enzyme, the CDK5/p35 complex.

Cell migration also depends on molecules mediating cellular interactions, which provide cell adhesion to establish neuron–neuron and neuron–glia relationships or induce attraction or repulsion. Astrotactin is a major glial protein involved in neuronal migration on radial glial processes, whereas neuregulins and their receptors, ErbB2–4, play roles in neuronal–glial migratory interactions. Recent genetic studies associate neuregulin polymorphisms with schizophrenia, suggesting that this developmental disease may depend on altered oligodendrocyte numbers and activities and synaptic functions. Furthermore, some work suggests that early appearing neurotransmitters themselves, GABA and glutamate, and platelet-derived growth factor (PDGF) regulate migration speed. In contrast to radial migration from cortical VZ, GABA interneurons generated in ganglionic eminences employ different mechanisms to leave the ventral forebrain and migrate dorsally into the cerebral cortex. Several signaling systems have been identified, including the Slit protein and Robo receptor, the semaphorins and their neuropilin receptors, and hepatocyte growth factor and its c-Met receptor, all of which appear to repel GABA interneurons from basal forebrain, promoting tangential migration into cortex. Significantly, the c-Met receptor has recently been associated with autism spectrum disorders, suggesting that altered GABA interneuron migration into cortex and deficits in inhibitory signaling may contribute to the phenotype, including seizures and abnormal cognitive processing. Finally, several human forms of congenital muscular dystrophy with

severe brain and eye migration defects result from gene mutations in enzymes that transfer mannose sugars to serine/threonine –OH groups in glycoproteins, thereby interrupting interactions with several extracellular matrix molecules and producing type II cobblestone lissencephalies.

DIFFERENTIATION AND NEURONAL PROCESS OUTGROWTH

After newly produced neurons and glial cells reach their final destinations, they differentiate into mature cells. For neurons, this involves outgrowth of dendrites and extension of axonal processes, formation of synapses, and production of neurotransmitter systems, including receptors and selective reuptake sites. Most axons will become insulated by myelin sheaths produced by oligodendroglial cells. Many of these events occur with a peak period from 5 months of gestation onward. During the first several years of life, many neuronal systems exhibit exuberant process growth and branching, which is later decreased by selective “pruning” of axons and synapses, dependent on experience, whereas myelination continues for several years after birth and into adulthood.

Although there is tremendous synapse plasticity in adult brain, a fundamental feature of the nervous system is the point-to-point or topographic mapping of one neuron population to another. During development, neurons extend axons to innervate diverse distant targets, such as cortex and spinal cord. The structure that recognizes and responds to cues in the environment is the growth cone, located at the axon tip. The axonal process is structurally supported by microtubules that are regulated by numerous microtubule-associated proteins (MAPs), whereas the terminal growth cone exhibits a transition to actin-containing microfilaments. The growth cone has rod-like extensions called filopodia that bear receptors for specific guidance cues present on cell surfaces and in extracellular matrix. Interactions between filopodial receptors and environmental cues cause growth cones to move forward, turn, or retract. Recent studies have identified the actin-modulating proteins and kinases involved in rapid growth cone movements, such as LIMK kinase that causes the language phenotype associated with Williams’ syndrome. Perhaps surprising is that activation of growth cone receptors leads to local mRNA translation to produce synaptic proteins, whereas traditional concepts assumed that all proteins were transported to axon terminals from distant neuronal cell somas. The region-specific expression of extracellular guidance molecules, such as cadherins, regulated by patterning genes *Pax6* and *Emx2*, results in highly directed outgrowth of axons, termed axonal pathfinding. These molecules affect the direction, speed, and fasciculation of axons, acting through either positive or negative regulation. Guidance molecules may be soluble extracellular factors or, alternatively, may be bound to extracellular matrix or cell membranes. In the latter class of signal is the newly discovered family of transmembrane proteins, the ephrins. Playing major roles in topographic mapping between neuron populations and their targets, ephrins act via the largest known family of tyrosine kinase receptors in brain, Eph receptors. Ephrins frequently serve as chemorepellent cues, negatively regulating growth by preventing developing axons from entering incorrect target fields. For example, the optic tectum expresses ephrins A2 and A5 in a gradient that decreases along the posterior to anterior axis, whereas innervating retinal ganglion cells express a gradient of Eph receptors. Ganglion cell axons from posterior retina, which possess high Eph A3 receptor levels, will preferentially innervate the anterior tectum because the low level ephrin expression does not activate the Eph kinase that causes growth cone retraction. In the category of soluble molecules, netrins serve primarily as chemoattractant proteins secreted, for instance, by the spinal cord floor plate to stimulate spinothalamic sensory interneurons to grow into the anterior commissure, whereas Slit is a secreted chemorepulsive factor that through its roundabout (Robo) receptor regulates midline crossing and axonal fasciculation and pathfinding.

THE NEURODEVELOPMENTAL BASIS OF PSYCHIATRIC DISEASE

An increasing number of neuropsychiatric conditions are considered to originate during brain development, including schizophrenia, depression, autism, and attention-deficit/hyperactivity disorder. Defining when a condition begins helps direct attention to underlying pathogenic mechanisms. The term neurodevelopmental suggests that the brain is abnormally formed from the very beginning due to disruption of fundamental processes, in contrast to a normally formed brain that is injured secondarily or that undergoes degenerative changes. However, the value of the term neurodevelopmental needs to be reconsidered, because of different use by clinicians and pathologists. In addition, given that the same molecular signals function in both development and maturity, altering an early ontogenetic process by changes in growth factor signaling, for instance, probably means that other adult functions exhibit ongoing dysregulation as well. For example, clinical researchers of schizophrenia consider the disorder neurodevelopmental because at the time of onset and diagnosis, the prefrontal cortex and hippocampus are smaller and ventricles enlarged already at adolescent presentation. In contrast, the neuropathologist uses the term neurodevelopmental for certain morphological changes in neurons. If a brain region exhibits a normal cytoarchitecture but with neurons of smaller than normal diameter, reminiscent of “immature” stages, then this may be considered an arrest of development. However, if the same cellular changes are accompanied by inflammatory signs, such as gliosis and white blood cell infiltrate, then this is termed neurodegeneration. These morphological and cellular changes may no longer be adequate to distinguish disorders that originate from development versus adulthood, especially given the roles of glial cells, including astrocytes, oligodendrocytes, and microglia, as sources of neurotrophic support during both periods of life. Thus abnormalities in glial cells may occur in both epochs to promote disease or act as mechanisms of repair. Many neurodegenerative processes such as in Alzheimer’s and Parkinson’s diseases are associated with microglial cells. On the other hand, neuronal dysfunction in adulthood such as cell shrinkage may occur without inflammatory changes. In animal models, interruption of BDNF neurotrophic signaling in adult brain results in neuron and dendrite atrophy in cerebral cortex without eliciting glial cell proliferation. Thus finding small neurons without gliosis in the brains of patients with schizophrenia or autism does not necessarily mean that the condition is only or primarily developmental in origin. In turn, several etiological assumptions about clinical brain conditions may require reexamination.

Because the same processes that mediate development, including neurogenesis, gliogenesis, axonal growth and retraction, synaptogenesis, and cell death, also function during adulthood, a new synthesis has been proposed. All of these processes, although perhaps in more subtle forms, contribute to adaptive and pathological processes. Successful aging of the nervous system may require precise regulation of these processes, allowing the brain to adapt properly and counteract the numerous intrinsic and extrinsic events that could potentially lead to neuropathology. For example, adult neurogenesis and synaptic plasticity are necessary to maintain neuronal circuitry and ensure proper cognitive functions. Programmed cell death is crucial to prevent tumorigenesis that can occur as cells accumulate mutations throughout life. Thus dysregulation of these ontogenetic processes in adulthood will lead to disruption of brain homeostasis, expressing itself as various neuropsychiatric diseases.

Schizophrenia

The neurodevelopmental hypothesis of schizophrenia postulates that etiologic and pathogenetic factors occurring before the formal onset of the illness, that is, during gestation, disrupt the course of normal development. These subtle early alterations in specific neurons, glia, and circuits confer vulnerability to other later developmental factors, ultimately leading to malfunctions. Schizophrenia is clearly a multifactorial disorder, including both genetic and environmental factors. Clinical studies using risk assessment have identified some relevant factors, including prenatal and birth complications (hypoxia, infection, or substance and toxicant exposure), family history, body dysmorphism, especially structures of neural crest origin, and presence of mild premorbid deficits in social, motor, and cognitive functions. These risk factors may affect ongoing developmental processes such as experience-dependent axonal and dendritic production, programmed cell death, myelination, and synaptic pruning. An intriguing animal model using human influenza-induced pneumonia of pregnant mice shows that the inflammatory cytokine response produced by the mother may directly affect the offspring’s brain development, with no evidence of the virus in the fetus or placenta.

Neuroimaging and pathology studies identify structural abnormalities at disease presentation, including smaller prefrontal cortex and

hippocampus and enlarged ventricles, suggesting abnormal development. More severely affected patients exhibit a greater number of affected regions with larger changes. In some cases, ventricular enlargement and cortical gray matter atrophy increase with time. These ongoing progressive changes should lead us to reconsider the potential role of active degeneration in schizophrenia, whether due to the disease or its consequences, such as stress or drug treatment. However, classic signs of neurodegeneration with inflammatory cells are not present.

Structural neuroimaging strongly supports the conclusion that the hippocampus in schizophrenia is significantly smaller, perhaps by 5 percent. In turn, brain morphology has been used to assess etiological contributions of genetic and environmental factors. Comparisons of concordance for schizophrenia in monozygotic and dizygotic twins support roles for both factors. Among monozygotic twins, only 40 to 50 percent of both twins have the illness, indicating that genetic constitution alone does not ensure disease and suggesting that the embryonic environment also contributes. Neuroimaging, pharmacological, and pathological studies suggest that some genetic factors allow for susceptibility and that secondary insults, such as birth trauma or perinatal viral infection, provide the other. This model is consistent with imaging studies showing small hippocampus in both affected and unaffected monozygotic twins. Moreover, healthy, genetically at risk individuals show hippocampal volumes (smaller) more similar to affected probands than normal controls. Thus hippocampal volume reduction is not pathognomonic of schizophrenia but rather may represent a biological marker of genetic susceptibility. It is not difficult to envision roles for altered developmental regulators in producing a smaller hippocampus, which in turn limits functional capacity. A smaller hippocampus may result from subtle differences in the levels of transcription factors, such as *NeuroD*, *Math1*, or *Lhx*, signaling by *Wnt3a* and downstream mediator *Lef1*, or proliferative control mediated by bFGF, the family members of which exhibit altered expression levels in schizophrenia brain samples. Such genetic limitations may only become manifest following another developmental challenge, such as gestational infection, stressors, or toxicant exposure.

A regional locus of schizophrenia pathology remains uncertain but may include hippocampus, entorhinal cortex, multimodal association cortex, limbic system, amygdala, cingulate cortex, thalamus, and medial temporal lobe. Despite size reductions in specific regions, attempts to define changes in cell numbers have been unrewarding, since most studies do not quantify the entire cell population but assess only regional cell density. Without assessing a region's total volume, cell density measures alone are limited in revealing population size. Most studies have found no changes in cell density in diverse regions. A single study successfully examining total cell number in hippocampus found normal neuron density and a 5 percent volume reduction on the left and 2 percent on the right, yielding no significant change in total cell number.

In contrast to total neuron numbers, using neuronal cell-type-specific markers, many studies have found a decreased density of nonpyramidal GABA interneurons in cortex and hippocampus. In particular, parvalbumin-expressing interneurons are reduced, whereas calretinin-containing cells are normal, suggesting a deficiency of an interneuron subtype. These morphometric data are supported by molecular evidence for decreased GABA neurons, including reduced mRNA and protein levels of the GABA-synthesizing enzyme, GAD67, in cortex and hippocampus. Another product of the adult GABA-secreting neurons, reelin, which initially appears in Cajal-Retzius cells in embryonic brain, is reduced 30 to 50 percent in schizophrenia and bipolar disorder with psychotic symptoms. Such a deficiency, leading to diminished GABA signaling, may underlie a potential compensatory increase in GABA_A receptor binding detected in hippocampal CA 2 to 4 fields by both pyramidal and nonpyramidal neurons, apparently selective since benzodiazepine binding is unchanged. More generally, deficiency in a subpopulation of GABA interneurons raises intriguing new possibilities for schizophrenia etiology. As indicated in the preceding gene patterning section, different subpopulations of forebrain GABA interneurons originate from distinct precursors located in the embryonic basal forebrain. Thus cortical and hippocampal GABA interneurons may derive primarily from the MGE under control of the patterning gene *Nkx2.1*, whereas SVZ and olfactory neurons derive from *Gsh2*-expressing LGE precursors. Furthermore, the timing and sequence of GABA interneuron generation may depend on a regulatory network including *Mash1*, *Dlx1/2*, and *Dlx5/6*, all gene candidates for schizophrenia risk. Indeed, *DLX1* gene expression is reduced in the thalamus of patients with psychosis. Thus abnormal regulation of these factors may diminish selectively GABA interneuron formation, which in turn may represent a genetically determined vulnerability, and may contribute to diminished regional brain size and/or function.

The most compelling neuropathological evidence for a developmental basis is the finding of aberrantly localized or clustered neurons especially in lamina II of the entorhinal cortex and in the white matter underlying prefrontal cortex and temporal and parahippocampal regions. These abnormalities represent alterations of developmental neuronal migration, survival, and connectivity. In addition, in hippocampus and neocortex, pyramidal neurons appear smaller in many studies, exhibiting fewer dendritic arborizations and spines with reduced neuropil, findings that are associated with reductions in neuronal molecules, including MAP2, spinophilin, synaptophysin, and SNAP25. Although the genes associated with schizophrenia are reviewed extensively in other chapters, worth mentioning here is a particularly intriguing candidate gene *DISC1*, whose protein has roles during development including regulating cell migration, neurite outgrowth, and neuronal maturation as well as in adult brain, where it modulates cytoskeletal function, neurotransmission, and synaptic plasticity. *DISC1* protein interacts with many other proteins intimately involved in neuronal cell migration and forms a protein complex with *Lis1* and *NudEL* that is downstream of reelin signaling.

Autism Spectrum Disorders

Another condition that is clearly neurodevelopmental in origin is autism spectrum disorders (ASDs), a complex and heterogeneous group of disorders characterized by abnormalities in social interaction and communication and the presence of restricted or repetitive interests and activities. In the last edition of DSM (DSM-IV) the ASDs included classic autistic disorder, Asperger's syndrome, and pervasive developmental disorder not otherwise specified. These three disorders were grouped together due to their common occurrence in families, indicating related genetic factors and shared signs and symptoms. Recent conceptualizations of ASDs propose that there are multiple "autisms" differing in underlying pathogenetic mechanisms and manifestations. It is likely that the different core symptom domains (or other endophenotypes) will be more heritable than the syndromic diagnosis, which was constructed to be inclusive. The large diversity of ASD signs and symptoms reflects the multiplicity of abnormalities observed in pathological and functional studies and include both forebrain and hindbrain regions. Forebrain neurons in the cerebral cortex and limbic system play critical roles in social interaction, communication, and learning and memory. For example, the amygdala, which connects to prefrontal and temporal cortices and fusiform gyrus, plays a prominent role in social and emotional cognition. In ASDs, the amygdala and fusiform gyrus demonstrate abnormal activation during facial recognition and emotional attribution tasks. Some investigators hypothesize that ASDs reflect dysfunctions in specific neural networks, such as the social network. On the other hand, neurophysiological tests of evoked cortical potentials and oculomotor responses indicate normal perception of primary sensory information but disturbed higher cognitive processing. The functional impairments in higher-order cognitive processing and neocortical circuitry suggest a developmental disorder involving synaptic organization, a mechanism that may be uniformly present throughout the brain, a model in distinct contrast to abnormalities of specific neural networks. Earlier reference to the expression of *Wnt3a* in cells that migrated widely during development and appear in auditory systems is one example of how developmental changes may affect single functional networks, whereas changes in common and widely expressed synaptic molecules, such as the neuroligins, would represent the other mechanism.

The most important recent discovery in ASD pathogenesis has been the widely reported and replicated brain growth phenotype: Starting with probably normal size at birth, the brain exhibits an accelerated increase in volume by the end of the first year compared to the typically developing child, and this process continues from ages 2 to 4 years. These data derive from both neuroimaging studies as well as measures of head circumference performed by multiple labs. It is not known whether this reflects an acceleration of normal developmental processes or, alternatively, a disease-specific aberration in postnatal development, including changes in cell numbers, neuronal processes, synapse formation and modifications, or glial cell dysfunction, to name a few. The most prominent differences are observed in frontal and parietal cortex, cerebellar hemispheres, as well as the amygdala. These findings are also consistent with recent reports of macrocephaly in up to ~20 percent of ASD cases in brain and DNA banks. These findings raise many questions to be addressed by developmental neuroscientists.

Functional neuroimaging studies indicate broad forebrain but also cerebellar dysfunctions in ASD, and classical pathological studies have suggested abnormalities restricted to limbic and cerebellar structures. However, classical studies were hampered by small sample sizes, poor control for comorbidities such as epilepsy and mental retardation that affect

neuroanatomy, and the use of tissue cell density measures as opposed to unbiased stereological methods to estimate regional neuron numbers. Although previous studies described increased densities of small neurons in interconnecting limbic nuclei, including CA fields, septum, mammillary bodies, and amygdala, these results have not been replicated by other laboratories. In contrast, the most consistent neuropathology has been observed in the cerebellum (21 of 29 brains), showing reductions in the number of Purkinje neurons without signs of acquired postnatal lesions, such as gliosis, empty baskets, and retrograde loss of afferent inferior olive neurons, suggesting prenatal origins.

A more recent study identifies widespread and nonuniform abnormalities, suggesting dysregulation of many processes, including neuron proliferation, migration, survival, organization, and programmed cell death. Four of six brains were macrocephalic, consistent with increased size defined by numerous pathology and neuroimaging studies. In cerebral cortex, there was thickened or diminished gray matter, disorganized laminar patterns, misoriented pyramidal neurons, ectopic neurons in both superficial and deep white matter, and increased or decreased neuron densities. This evidence of abnormal cortical neurogenesis and migration accords well with the deficits in cognitive functions. In brainstem, neuronal disorganization appeared as discontinuous and malpositioned neurons in olivary and dentate nuclei, ectopic neurons in medulla and cerebellar peduncles, and aberrant fiber tracts. There were widespread patchy or diffuse decreases of Purkinje neurons, sometimes associated with increased Bergmann glia, or ectopic Purkinje neurons in the molecular layer. Hippocampal neuronal atrophy was not observed, and quantitative stereology found no consistent change in neuron density or number. Moreover, a single recent neuropathological study using multiple immunological indices has reported increased levels of immune cytokines in the cerebrospinal fluid of patients and in brain tissues as well as astrocytes expressing high levels of glial fibrillary acidic protein in frontal and cingulate cortex, white matter, and cerebellum, all suggesting potential immune activation without evidence of an inflammatory process. We await confirmation of these important findings.

Although seemingly incompatible, these various data support a model of developmental abnormalities occurring at different times, altering regions according to specific schedules of neurogenesis and differentiation. It is notable that a similar range of abnormalities was found in classical studies but was excluded, since these abnormalities did not occur in every brain examined. Moreover, in 15 children exposed to the teratogen thalidomide during days 20 to 24 of gestation, when cranial and Purkinje neurogenesis occurs in brainstem, four cases exhibited autism. On the basis of these data, autism is associated with insults at 3 weeks for thalidomide, 12 weeks when inferior olivary neurons are migrating, and ~30 weeks when olivary axons make synapses with Purkinje cells. These diverse abnormalities in cell production, survival, migration, organization, and differentiation in both hindbrain and forebrain indicate disturbed brain development over a range of stages. Recent genetic studies have defined two genetic polymorphisms associated reproducibly with ASD in several datasets, both of which influence brain developmental processes. The first is *ENGRAILED-2*, the cerebellar patterning gene whose dysregulation causes deficits in Purkinje and granule neurons in animal models and acts to control proliferation and differentiation. The second is the hepatocyte growth factor receptor *cMET*, whose function affects tangential migration of GABA interneurons from the ventral forebrain ganglionic eminences, potentially leading to imbalances of excitatory and inhibitory neurotransmission. Furthermore, although the cellular derangements may be directly responsible for the core symptoms of autism, there is an alternative hypothesis: Disturbed regulation of developmental processes produces an as-yet unidentified biochemical cellular lesion that may be associated with autism. This proposal is supported by the currently known genetic causes of autism that account for 10 percent of cases, including tuberous sclerosis, neurofibromatosis, Smith-Lemli-Opitz syndrome, Rett syndrome, and fragile X mental retardation. These genetic etiologies interfere with cell proliferation control, cholesterol biosynthesis and Shh function, and synaptic and dendrite protein translation and function, fundamental processes in the sequence of development. An intriguing potential link in these monogenetic causes of autism symptoms is their participation in protein synthesis in the synapse, especially as regulated via the PI3K/Akt signaling pathway and the mammalian target of rapamycin (mTOR) complex, an area of active research.

THE REMARKABLE DISCOVERY OF ADULT NEUROGENESIS

In the last decade, there has been a fundamental shift in paradigm regarding the limits of neurogenesis in the brain, with important implications for neural plasticity, mechanisms of disease etiology and therapy, and possibilities of repair. Until recently, it has generally been maintained that we do not produce new neurons in the brain after birth (or soon thereafter, considering cerebellar EGL); thus brain plasticity and repair depend on modifications of a numerically static neural network. We now have strong evidence to the contrary: new neurons are generated throughout life in certain regions, well documented across the phylogenetic tree, including birds, rodents, primates, and humans. As an area of intense interest and investigation, we may expect rapid progress over the next two decades, likely altering models described herein.

The term neurogenesis has been used inconsistently in different contexts, indicating sequential production of neural elements during development, first neurons then glial cells, but frequently connoting only neuron generation in adult brain, in contrast to gliogenesis. For this discussion, we use the first, more general meaning, and distinguish cell types as needed. The first evidence of mammalian neurogenesis, or birth of new neurons, in adult hippocampus was reported in the 1960s in which ³H-thymidine-labeled neurons were documented. As a common marker for cell production, these studies used nuclear incorporation of ³H-thymidine into newly synthesized DNA during chromosome replication, which occurs before cells undergo division. After a delay, cells divide, producing two ³H-thymidine-labeled progeny. Cell proliferation is defined as an absolute increase in cell number, which occurs only if cell production is not balanced by cell death. Because there is currently little evidence for a progressive increase in brain size with age, except perhaps for rodent hippocampus, most neurogenesis in adult brain is apparently compensated for by cell loss. More recent studies of neurogenesis employ the more convenient thymidine analog BrdU, which can be injected into living animals and then detected by immunohistochemistry.

During embryonic development, neurons are produced from almost all regions of the ventricular neuroepithelium. Neurogenesis in the adult, however, is largely restricted to two regions: the SVZ lining the lateral ventricles and a narrow proliferative zone underlying the dentate gyrus granule layer (subgranular zone) in hippocampus. In mice, rodents, and monkeys, newly produced neurons migrate from the SVZ in an anterior direction into the olfactory bulb to become GABA interneurons. The process has been elegantly characterized at both ultrastructural and molecular levels. In the SVZ, the neuroblasts (A cells) on their way to olfactory bulb create chains of cells and migrate through a scaffold of glial cells supplied by slowly dividing astrocytes (B cells). Within this network of cell chains, there are groups of rapidly dividing neural precursors (C cells). Evidence suggests that the B cells give rise to the C cells, which in turn develop into the A cells, the future olfactory bulb interneurons. The existence of a sequence of precursors with progressively restricted abilities to generate diverse neural cell types makes defining mechanisms that regulate adult neurogenesis *in vivo* a great challenge.

As in developing brain, adult neurogenesis is also subject to regulation by extracellular signals that control precursor proliferation and survival and in many cases the very same factors. After initial discovery of adult neural stem cells generated under EGF stimulation, other regulatory factors were defined including bFGF, IGF-I, BDNF, and LIF/CNTF. Although the hallmark of neural stem cells includes the capacity to generate neurons, astrocytes, and oligodendroglia, termed multipotentiality, specific signals appear to produce relatively different profiles of cells that may migrate to distinct sites. Intraventricular infusion of EGF promotes primarily gliogenesis in the SVZ, with cells migrating to olfactory bulb, striatum, and corpus callosum, whereas bFGF favors the generation of neurons destined for the olfactory bulb. Both factors appear to stimulate mitosis directly, with differential effects on the cell lineage produced. In contrast, BDNF may increase neuron formation in SVZ as well as striatum and hypothalamus, though effects may be primarily through promoting survival of newly generated neurons that otherwise undergo cell death. Finally, CNTF and related LIF may promote gliogenesis or, alternatively, support self-renewal of adult stem cells rather than enhancing a specific cell category.

Remarkably, in addition to direct intraventricular infusions, adult neurogenesis is also affected by peripheral levels of growth factors, hormones, and neuropeptides. Peripheral administration of both bFGF and IGF-I stimulate neurogenesis, increasing selectively mitotic labeling in the SVZ and hippocampal subgranular zone, respectively, suggesting that there are specific mechanisms for factor transport across the BBB. Of interest, elevated prolactin levels, induced by peripheral injection or natural pregnancy, stimulate proliferation of progenitors in the mouse SVZ, leading to increased olfactory bulb interneurons, potentially playing roles in learning new infant scents. This may be relevant to changes in prolactin seen in psychiatric disease. Conversely, in behavioral paradigms of social stress, such as territorial challenge by male intruders, activation of the hypothalamic-pituitary-adrenal axis with increased glucocorticoids leads to reduced neurogenesis in the hippocampus, apparently through local glutamate signaling. Inhibition is also observed after

peripheral opiate administration, a model for substance abuse. Thus neurogenesis may be one target process affected by changes of hormones and neuropeptides associated with several psychiatric conditions.

The discovery of adult neurogenesis naturally leads to questions about whether new neurons can integrate into the complex cytoarchitecture of the mature brain and to speculation about its functional significance, if any. In rodents, primates, and humans, new neurons are generated in the dentate gyrus of the hippocampus, an area important for learning and memory. Some adult-generated neurons in humans have been shown to survive for at least 2 years. Furthermore, newly generated cells in adult mouse hippocampus indeed elaborate extensive dendritic and axonal arborizations appropriate to the neural circuit and display functional synaptic inputs and action potentials. From a functional perspective, the generation and/or survival of new neurons correlates strongly with multiple instances of behavioral learning and experience. For example, survival of newly generated neurons is markedly enhanced by hippocampal-dependent learning tasks and by an enriched, behaviorally complex environment. Of perhaps greater importance, a reduction in dentate gyrus neurogenesis impairs the formation of trace memories, that is, when an animal must associate stimuli that are separated in time, a hippocampal-dependent task. Finally, in songbirds, neurogenesis is activity dependent and is increased by foraging for food and learning new song, whether it occurs seasonally or is induced by steroid hormone administration.

From clinical and therapeutic perspectives, fundamental questions are whether changes in neurogenesis contribute to disease and whether newly formed neurons undergo migration to and integration into regions of injury, replacing dead cells and leading to functional recovery. A neurogenetic response has now been shown for multiple conditions in the adult, including brain trauma, stroke, and epilepsy. For instance, ischemic stroke in the striatum stimulates adjacent SVZ neurogenesis with neurons migrating to the injury site. Furthermore, in a highly selective paradigm not involving local tissue damage, degeneration of layer 3 cortical neurons elicited SVZ neurogenesis and cell replacement. These studies raise the possibility that newly produced neurons normally participate in recovery and may be stimulated as a novel therapeutic strategy. However, in contrast to potential reconstructive functions, neurogenesis may also play roles in pathogenesis: In a kindling model of epilepsy, newly generated neurons were found to migrate to incorrect positions and participate in aberrant neuronal circuits, thereby reinforcing the epileptic state. Conversely, reductions in neurogenesis may contribute to several conditions that implicate dysfunction or degeneration of the hippocampal formation. Dentate gyrus neurogenesis is inhibited by increased glucocorticoid levels observed in aged rats and can be reversed by steroid antagonists and adrenalectomy, observations potentially relevant to the correlation of elevated human cortisol levels with reduced hippocampal volumes and the presence of memory deficits. Similarly, stress-induced increases in human glucocorticoids may contribute to decreased hippocampal volumes seen in schizophrenia, depression, and posttraumatic stress disorder.

A potential role for altered neurogenesis in disease has gained the most support in recent studies of depression. A number of studies in animals and humans suggest a correlation of decreased hippocampal size with depressive symptoms, whereas clinically effective antidepressant therapy elicits increased hippocampal volume and enhanced neurogenesis, with causal relationships still being defined. For example, postmortem and brain imaging studies indicate cell loss in corticolimbic regions in bipolar disorder and major depression. Significantly, mood stabilizers, such as lithium ion and valproic acid, as well as antidepressants and electroconvulsive therapy activate intracellular pathways that promote neurogenesis and synaptic plasticity. Furthermore, in a useful primate model, the adult tree shrew, the chronic psychosocial stress model of depression elicited ~15 percent reductions in brain metabolites and a 33 percent decrease in neurogenesis (BrdU mitotic labeling), effects that were prevented by coadministration of antidepressant, tianeptine. More importantly, although stress exposure elicited small reductions in hippocampal volumes, stressed animals treated with antidepressant exhibited increased hippocampal volumes. Similar effects have been found in rodent models of depression.

In addition to the foregoing structural relationships, recent evidence has begun defining the roles of relevant neurotransmitter systems to antidepressant effects on behavior and neurogenesis. In a most exciting finding, a causal link between antidepressant-induced neurogenesis and a positive behavioral response has been demonstrated. In the serotonin 1A receptor null mouse, fluoxetine, a selective serotonin reuptake inhibitor [SSRI], produced neither enhanced neurogenesis nor behavioral improvement. Furthermore, when hippocampal neuronal precursors were selectively reduced (85 percent) by X-irradiation, neither fluoxetine nor imipramine induced neurogenesis or behavioral recovery. Finally, one study using hippocampal cultures from normal and mutant rodents strongly supports a neurogenetic role for endogenous NPY, which is contained in dentate gyrus hilar interneurons. NPY stimulates precursor proliferation selectively via the Y1 (not Y2 or Y5) receptor, a finding consistent with the receptor-mediating antidepressive effects of NPY in animal models and the impact of NPY levels on both hippocampal-dependent learning and responses to stress. In aggregate, these observations suggest that volume changes observed with human depression and therapy may directly relate to alterations in ongoing neurogenesis. More generally, the discovery of adult neurogenesis has led to major changes in our perspectives on the regenerative capacities of the human brain.

1.4 Neurophysiology and Neurochemistry

The study of chemical interneuronal communication is called neurochemistry, and in recent years there has been an explosion of knowledge in understanding chemical transmission between neurons and the receptors affected by those chemicals. Similarly, advances in the science of physiology as applied to the brain and how the brain functions have been equally influenced. This chapter focuses on the complex heterogeneity of both these areas to help explain the complexity of thoughts, feelings, and behaviors that make up the human experience.

MONOAMINE NEUROTRANSMITTERS

The monoamine neurotransmitters and acetylcholine have been historically implicated in the pathophysiology and treatment of a wide variety of neuropsychiatric disorders. Each monoamine neurotransmitter system modulates many different neural pathways, which themselves subserve multiple behavioral and physiological processes. Conversely, each central nervous system (CNS) neurobehavioral process is likely modulated by multiple interacting neurotransmitter systems, including monoamines.

This complexity poses a major challenge to understanding the precise molecular, cellular, and systems level pathways through which various monoamine neurotransmitters affect neuropsychiatric disorders. However, recent advances in human genetics and genomics, as well as in experimental neuroscience, have shed light on this question. Molecular cloning has identified a large number of genes that regulate monoaminergic neurotransmission, such as the enzymes, receptors, and transporters that mediate the synthesis, cellular actions, and cellular reuptake of these neurotransmitters, respectively. Human genetics studies have provided evidence of tantalizing links between allelic variants in specific monoamine-

related genes and psychiatric disorders and trait abnormalities, whereas the ability to modify gene function and cellular activity in experimental animals has clarified the roles of specific genes and neural pathways in mediating behavioral processes.

Monoamines act on target cells by binding to specific cell-surface receptors. There are multiple receptor subtypes for each monoamine, which are expressed in diverse regions and subcellular locales and which engage a variety of intracellular signaling pathways. This panoply of receptors thus allows each monoamine neurotransmitter to modulate target cells in many ways; the same molecule may activate some cells while inhibiting others, depending on which receptor subtype is expressed by each cell. The various monoamines are discussed below.

Serotonin

Although only one in a million CNS neurons produces serotonin, these cells influence virtually all aspects of CNS function. The cell bodies of these serotonergic neurons are clustered in the midline raphe nuclei of the brainstem; the rostral raphe nuclei send ascending axonal projections throughout the brain, whereas the descending caudal raphe nuclei send projections into the medulla, cerebellum, and spinal cord (Fig. 1.4-1). The descending serotonergic fibers that innervate the dorsal horn of the spinal cord have been implicated in the suppression of nociceptive pathways, a finding that may relate to the pain-relieving effects of some antidepressants. The tonic firing of CNS serotonin neurons varies across the sleep-wake cycle, with an absence of activity during rapid eye movement (REM) sleep. Increased serotonergic firing is observed during rhythmic motor behaviors and suggests that serotonin modulates some forms of motor output.

FIGURE 1.4-1

Brain serotonergic pathways (in rats). Serotonergic neurons are located in brainstem midline raphe nuclei and project throughout the neuraxis. (There is an approximate similarity between monoamine pathways in rats and in humans.) AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CRN, caudal raphe nuclei; CTX, neocortex; DR, dorsal raphe nucleus; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; MR, median raphe nucleus; NAc, nucleus accumbens; OB, olfactory bulb; SN, substantia nigra; TE, tectum; TH, thalamus; TM, tuberomammillary nucleus of hypothalamus. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:65.)

Most serotonergic innervation of the cortex and limbic system arises from the dorsal and median raphe nuclei in the midbrain; the serotonergic neurons in these areas send projections through the medial forebrain bundle into target forebrain regions. The median raphe provides most of the serotonergic fibers that innervate the limbic system, whereas the dorsal raphe nucleus provides most of the serotonergic fibers that innervate the striatum and thalamus.

In addition to the different target fields of these serotonergic nuclei, there are also cellular differences between their constituent neurons. Dorsal raphe serotonergic fibers are fine, with small vesicle-coated swellings called varicosities, whereas median raphe fibers have large spherical or beaded varicosities. It is unclear to what extent serotonin acts as a true synaptic or "private" neurotransmitter versus action as a local endocrine hormone or "social transmitter," or whether its roles differ depending on the fiber type from which it is released. These fibers show differential sensitivity to the neurotoxic effects of the amphetamine analog 3,4-methylenedioxy-methamphetamine (MDMA, "ecstasy"), which lesions the fine axons of the dorsal raphe while sparing the thick beaded axons of the median raphe. The significance of these morphological differences is unclear, although recent work has identified functional differences between the serotonergic neurons of the dorsal and median raphe nuclei.

Dopamine

Dopamine neurons are more widely distributed than those of other monoamines, residing in the midbrain substantia nigra and ventral tegmental area and in the periaqueductal gray, hypothalamus, olfactory bulb, and retina. In the periphery, dopamine is found in the kidney where it functions to produce renal vasodilation, diuresis, and natriuresis. Three dopamine systems are highly relevant to psychiatry: The nigrostriatal, mesocorticolimbic, and tuberohypophyseal system (Fig. 1.4-2). Degeneration of the nigrostriatal system causes Parkinson's disease and has led to an intense research focus on the development and function of dopamine neurons in the midbrain substantia nigra nuclei. Dopamine cell bodies in the pars compacta division of this region send ascending projections to the dorsal striatum (especially to the caudate and putamen) and thereby modulate motor control. The extrapyramidal effects of antipsychotic drugs are thought to result from the blockade of these striatal dopamine receptors.

FIGURE 1.4-2

Brain dopaminergic pathways (in rats). The three principal dopaminergic pathways: (1) nigrostriatal pathway, (2) mesocorticolimbic pathway, and (3) tuberohypophyseal pathway. AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CTX, neocortex; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; NAc, nucleus accumbens; OB, olfactory bulb; PFC, prefrontal cortex; PI, pituitary; SNC, substantia nigra pars compacta; TE, tectum; TH, thalamus; VTA, ventral tegmental area. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:66.)

The midbrain ventral tegmental area (VTA) lies medial to the substantia nigra and contains dopaminergic neurons that give rise to the mesocorticolimbic dopamine system. These neurons send ascending projections that innervate limbic structures, such as the nucleus

accumbens and amygdala; the mesoaccumbens pathway is a central element in the neural representation of reward, and intense research has been devoted to this area in recent years. All known drugs of abuse activate the mesoaccumbens dopamine pathway, and plastic changes in this pathway are thought to underlie drug addiction. The mesolimbic projection is believed to be a major target for the antipsychotic properties of dopamine receptor antagonist drugs in controlling the positive symptoms of schizophrenia, such as hallucinations and delusions.

VTA dopamine neurons also project to cortical structures, such as the prefrontal cortex, and modulate working memory and attention; decreased activity in this pathway is proposed to underlie negative symptoms of schizophrenia. Thus antipsychotic drugs that decrease positive symptoms by blocking dopamine receptors in the mesolimbic pathway may simultaneously worsen these negative symptoms by blocking similar dopamine receptors in the mesocortical pathway. The decreased risk of extrapyramidal side effects seen with clozapine (Clozaril; versus other typical antipsychotic medications) is thought to be due to its relatively selective effects on this mesocortical projection. The tuberohypophyseal system consists of dopamine neurons in the hypothalamic arcuate and paraventricular nuclei that project to the pituitary gland and thereby inhibit prolactin release. Antipsychotic drugs that block dopamine receptors in the pituitary may thus disinhibit prolactin release and cause galactorrhea.

Norepinephrine and Epinephrine

The postganglionic sympathetic neurons of the autonomic nervous system release norepinephrine, resulting in widespread peripheral effects including tachycardia and elevated blood pressure. The adrenal medulla releases epinephrine, which produces similar effects; epinephrine-secreting pheochromocytoma tumors produce bursts of sympathetic activation, central arousal, and anxiety.

Norepinephrine-producing neurons are found within the brain in the pons and medulla in two major clusterings: The locus ceruleus (LC) and the lateral tegmental noradrenergic nuclei (Fig. 1.4-3). Noradrenergic projections from both of these regions ramify extensively as they project throughout the neuraxis. In humans, the LC is found in the dorsal portion of the caudal pons and contains approximately 12,000 tightly packed neurons on each side of the brain. These cells provide the major noradrenergic projections to the neocortex, hippocampus, thalamus, and midbrain tectum. The activity of LC neurons varies with the animal's level of wakefulness. Firing rates are responsive to novel and/or stressful stimuli, with largest responses to stimuli that disrupt ongoing behavior and reorient attention. Altogether, physiological studies indicate a role for this structure in the regulation of arousal state, vigilance, and stress response. The projections from lateral tegmental nucleus neurons, which are loosely scattered throughout the ventral pons and medulla, partially overlap those of the LC. Fibers from both cell groups innervate the amygdala, septum, and spinal cord. Other regions, such as the hypothalamus and lower brainstem, receive adrenergic inputs predominantly from the lateral tegmental nucleus. The relatively few neurons that utilize epinephrine as a neurotransmitter are located in the caudal pons and medulla, intermingled with noradrenergic neurons. Projections from these groups ascend to innervate the hypothalamus, LC, and visceral efferent and afferent nuclei of the midbrain.

Histamine

Histamine is perhaps best known for its role in allergies. It is an inflammatory mediator stored in mast cells and released upon cellular interaction with allergens. Once released, histamine causes vascular leakage and edema and other facial and topical allergy symptoms. In contrast, central histaminergic neural pathways have only more recently been characterized by immunocytochemistry using antibodies to the synthetic enzyme histidine decarboxylase and to histamine. Histaminergic cell bodies are located within a region of the posterior hypothalamus termed the tuberomammillary nucleus. The activity of tuberomammillary neurons is characterized by firing that varies across the sleep-wake cycle, with the highest activity during the waking state, slowed firing during slow-wave sleep, and absence of firing during REM sleep. Histaminergic fibers project diffusely throughout the brain and spinal cord (Fig. 1.4-4). Ventral ascending projections course through the medial forebrain bundle and then innervate the hypothalamus, diagonal band, septum, and olfactory bulb. Dorsal ascending projections innervate the thalamus, hippocampus, amygdala, and rostral forebrain. Descending projections travel through the midbrain central gray to the dorsal hindbrain and spinal cord. The fibers have varicosities that are seldom associated with classical synapses, and histamine has been proposed to act at a distance from its sites of release, like a local hormone. The hypothalamus receives the densest histaminergic innervation, consistent with a role for this transmitter in the regulation of autonomic and neuroendocrine processes. In addition, strong histaminergic innervation is seen in monoaminergic and cholinergic nuclei.

FIGURE 1.4-4

Brain histaminergic pathways (in rats). Histaminergic neurons are located in the tuberomammillary nucleus of the caudal hypothalamus (TM) and project to the hypothalamus (HY) and more distant brain regions. Acetylcholine

Within the brain, the axonal processes of cholinergic neurons may either project to distant brain regions (projection neurons) or contact local cells within the same structure (interneurons). Two large clusters of cholinergic projection neurons are found within the brain: The basal forebrain complex and the mesopontine complex (Fig. 1.4-5). The basal forebrain complex provides most of the cholinergic innervation to the nonstriatal telencephalon. It consists of cholinergic neurons within the nucleus basalis of Meynert, the horizontal and vertical diagonal bands of Broca, and the medial septal nucleus. These neurons project to widespread areas of the cortex and amygdala, to the anterior cingulate gyrus and olfactory bulb, and to the hippocampus, respectively. In Alzheimer's disease there is significant degeneration of neurons in the nucleus basalis, leading to substantial reduction in cortical cholinergic innervation. The extent of neuronal loss correlates with the degree of dementia, and the cholinergic deficit may contribute to the cognitive decline in this disease, consistent with the beneficial effects of drugs that promote acetylcholine signaling in this disorder.

FIGURE 1.4-5

Brain cholinergic projection pathways (in rats). The majority of cholinergic projection neurons are located in the basal forebrain complex (BFC) and the mesopontine complex (MPC). AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CTX, neocortex; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; NAc, nucleus accumbens; OB, olfactory bulb; SN, substantia nigra; TE, tectum; TH, thalamus. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:67.)

The mesopontine complex consists of cholinergic neurons within the pedunculopontine and laterodorsal tegmental nuclei of the midbrain and pons and provides cholinergic innervation to the thalamus and midbrain areas (including the dopaminergic neurons of the ventral tegmental area and substantia nigra) and descending innervation to other brainstem regions such as the LC, dorsal raphe, and cranial nerve nuclei. In contrast to central serotonergic, noradrenergic, and histaminergic neurons, cholinergic neurons may continue to fire during REM sleep and have been proposed to play a role in REM sleep induction. Acetylcholine is also found within interneurons of several brain regions, including the striatum. The modulation of striatal cholinergic transmission has been implicated in the antiparkinsonian actions of anticholinergic agents. Within the periphery, acetylcholine is a prominent neurotransmitter, located in motoneurons innervating skeletal muscle, preganglionic autonomic neurons, and postganglionic parasympathetic neurons. Peripheral acetylcholine mediates the characteristic postsynaptic effects of the parasympathetic system, including bradycardia and reduced blood pressure, and enhanced digestive function.

MONOAMINE SYNTHESIS, STORAGE, AND DEGRADATION

In addition to neuroanatomic similarities, monoamines are also synthesized, stored, and degraded in similar ways (Fig. 1.4-6). Monoamines are synthesized within neurons from common amino acid precursors (Fig. 1.4-6, step 1) and taken up into synaptic vesicles by way of a vesicular monoamine transporter (Fig. 1.4-6, step 2). On stimulation, vesicles within nerve terminals fuse with the presynaptic terminal and release the neurotransmitter into the synaptic cleft (Fig. 1.4-6, step 3). Once released, the monoamines interact with postsynaptic receptors to alter the function of postsynaptic cells (Fig. 1.4-6, step 4), and they may also act on presynaptic autoreceptors on the nerve terminal to suppress further release (Fig. 1.4-6, step 5). In addition, released monoamines may be taken back up from the synaptic cleft into the nerve terminal by plasma membrane transporter proteins (Fig. 1.4-6, step 6), a process known as reuptake. Reuptake plays an important role in limiting the total magnitude and temporal duration of monoamine signaling. Once monoamines are taken up, they may be subject to enzymatic degradation (Fig. 1.4-6, step 7), or they may be protected from degradation by uptake into vesicles. The processing of acetylcholine differs from this scheme and is described later in this section.

FIGURE 1.4-6

Schematic diagram of a monoaminergic synapse. Steps involved in synaptic transmission are described in the text. MAO, monoamine oxidase. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:68.)

SEROTONIN

The CNS contains less than 2 percent of the serotonin in the body; peripheral serotonin is located in platelets, mast cells, and

enterochromaffin cells. More than 80 percent of all the serotonin in the body is found in the gastrointestinal system, where it modulates motility and digestive functions. Platelet serotonin promotes aggregation and clotting through a most unusual mechanism: The covalent linkage of serotonin molecules to small GTP-binding proteins, which can then activate these proteins, is a process termed “serotonylation.” Peripheral serotonin cannot cross the blood–brain barrier, so serotonin is synthesized within the brain as well. Serotonin is synthesized from the amino acid tryptophan, which is derived from the diet. The rate-limiting step in serotonin synthesis is the hydroxylation of tryptophan by the enzyme tryptophan hydroxylase to form 5-hydroxytryptophan (4-HT) (Fig. 1.4-7). Two isoforms of tryptophan hydroxylase exist—one isoform is found mainly in the periphery, whereas the second isoform is restricted to the CNS.

FIGURE 1.4-7

Synthesis and catabolism of serotonin. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:68.)

Under normal circumstances, tryptophan concentration is rate limiting in serotonin synthesis. Therefore, much attention has focused on the factors that determine tryptophan availability. Unlike serotonin, tryptophan is taken up into the brain by way of a saturable active carrier mechanism. Because tryptophan competes with other large neutral amino acids for transport, brain uptake of this amino acid is determined both by the amount of circulating tryptophan and by the ratio of tryptophan to other large neutral amino acids. This ratio may be elevated by carbohydrate intake, which induces insulin release and the uptake of many large neutral amino acids into peripheral tissues. Conversely, high-protein foods tend to be relatively low in tryptophan, thus lowering this ratio. Moreover, the administration of specialized low tryptophan diets produces significant declines in brain serotonin levels. After tryptophan hydroxylation, 5-hydroxytryptophan is rapidly decarboxylated by aromatic amino acid decarboxylase (an enzyme also involved in dopamine synthesis) to form serotonin.

The first step in the degradation of serotonin is mediated by monoamine oxidase type A (MAO_A), which oxidizes the amino group to form an aldehyde. MAO_A is located in mitochondrial membranes and is nonspecific in its substrate specificity; in addition to serotonin, it oxidizes norepinephrine. The elevation of serotonin levels by MAO inhibitors (MAOIs) is believed to underlie the antidepressant efficacy of these drugs. After oxidation by MAO_A, the resulting aldehyde is further oxidized to 5-hydroxyindoleacetic acid (5-HIAA). Levels of 5-HIAA are often measured as a correlate of serotonergic system activity, although the relationship of these levels to serotonergic neuronal activity remains unclear.

Catecholamines

The catecholamines are synthesized from the amino acid tyrosine, which is taken up into the brain via an active transport mechanism (Fig. 1.4-8). Within catecholaminergic neurons, tyrosine hydroxylase catalyzes the addition of a hydroxyl group to the meta position of tyrosine, yielding L-dopa. This rate-limiting step in catecholamine synthesis is subject to inhibition by high levels of catecholamines (end-product inhibition). Because tyrosine hydroxylase is normally saturated with substrate, manipulation of tyrosine levels does not readily affect the rate of catecholamine synthesis. Once formed, L-dopa is rapidly converted to dopamine by dopa decarboxylase, which is located in the cytoplasm. It is now recognized that this enzyme acts not only on L-dopa but also on all naturally occurring aromatic L-amino acids, including tryptophan, and thus it is more properly termed aromatic amino acid decarboxylase. In noradrenergic and adrenergic neurons,

dopamine is actively transported into storage vesicles, where it is oxidized by dopamine β -hydroxylase to form norepinephrine. In adrenergic neurons and the adrenal medulla, norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT), which is located within the cytoplasmic compartment.

FIGURE 1.4-8

Synthesis of catecholamines. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:69.)

Two enzymes that play major roles in the degradation of catecholamines are monoamine oxidase and catechol-*O*-methyltransferase (COMT). MAO is located on the outer membrane of mitochondria, including those within the terminals of adrenergic fibers, and oxidatively deaminates catecholamines to their corresponding aldehydes. Two MAO isozymes with differing substrate specificities have been identified: MAO_A, which preferentially deaminates serotonin and norepinephrine, and MAO type B (MAO_B), which deaminates dopamine, histamine, and a broad spectrum of phenylethylamines. Neurons contain both MAO isoforms. The blockade of monoamine catabolism by MAO inhibitors produces elevations in brain monoamine levels. MAO is also found in peripheral tissues such as the gastrointestinal tract and liver, where it prevents the accumulation of toxic amines. For example, peripheral MAO degrades dietary tyramine, an amine that can displace norepinephrine from sympathetic postganglionic nerve endings, producing hypertension if tyramine is present in sufficient quantities. Thus patients treated with MAO inhibitors are cautioned to avoid pickled and fermented foods that typically have high levels of tyramine. Catechol-*O*-methyltransferase (COMT) is located in the cytoplasm and is widely distributed throughout the brain and peripheral tissues, although little to none is found in adrenergic neurons. It has a wide substrate specificity, catalyzing the transfer of methyl groups from *S*-adenosyl methionine to the *m*-hydroxyl group of most catechol compounds. The catecholamine metabolites produced by these and other enzymes are frequently measured as indicators of the activity of catecholaminergic systems. In humans, the predominant metabolites of dopamine and norepinephrine are homovanillic acid (HVA) and 3-methoxy-4-hydroxyphenylglycol (MHPG), respectively.

Histamine

As is the case for serotonin, the brain contains only a small portion of the histamine found in the body. Histamine is distributed throughout most tissues of the body, predominantly in mast cells. Because it does not readily cross the blood-brain barrier, it is believed that histamine is synthesized within the brain. In the brain, histamine is formed by the decarboxylation of the amino acid histidine by a specific L-histidine decarboxylase. This enzyme is not normally saturated with substrate, so synthesis is sensitive to histidine levels. This is consistent with the observation that the peripheral administration of histidine elevates brain histamine levels. Histamine is metabolized in the brain by histamine *N*-methyltransferase, producing methylhistamine. In turn, methylhistamine undergoes oxidative deamination by MAO_B.

Acetylcholine

Acetylcholine is synthesized by the transfer of an acetyl group from acetyl coenzyme A (ACoA) to choline in a reaction mediated by the enzyme choline acetyltransferase (ChAT). The majority of choline within the brain is transported from the blood rather than being synthesized de novo. Choline is taken up into cholinergic neurons by a high-affinity active transport mechanism, and this uptake is the rate-limiting step in acetylcholine synthesis. The rate of choline transport is regulated such that increased cholinergic neural activity is associated with enhanced choline uptake. After synthesis, acetylcholine is stored in synaptic vesicles through the action of a vesicular acetylcholine

transporter. After vesicular release, acetylcholine is rapidly broken down by hydrolysis by acetylcholinesterase, located in the synaptic cleft. Much of the choline produced by this hydrolysis is then taken back into the presynaptic terminal via the choline transporter. Of note, although acetylcholinesterase is localized primarily to cholinergic neurons and synapses, a second class of cholinesterase termed butyrylcholinesterase is found primarily in the liver and plasma as well as in glia. In the treatment of Alzheimer's disease, strategies aimed at enhancing cholinergic function, primarily through the use of cholinesterase inhibitors to prevent normal degradation of acetylcholine, have shown moderate efficacy in ameliorating cognitive dysfunction as well as behavioral disturbances. Cholinesterase inhibitors are also used in the treatment of myasthenia gravis, a disease characterized by weakness due to blockade of neuromuscular transmission by autoantibodies to acetylcholine receptors.

Transporters

A great deal of progress has been made in the molecular characterization of the monoamine plasma membrane transporter proteins. These membrane proteins mediate the reuptake of synaptically released monoamines into the presynaptic terminal. This process also involves cotransport of Na^+ and Cl^- ions and is driven by the ion concentration gradient generated by the plasma membrane Na^+/K^+ ATPase. Monoamine reuptake is an important mechanism for limiting the extent and duration of activation of monoaminergic receptors. Reuptake is also a primary mechanism for replenishing terminal monoamine neurotransmitter stores. Moreover, transporters serve as molecular targets for a number of antidepressant drugs, psychostimulants, and monoaminergic neurotoxins. Whereas transporter molecules for serotonin (SERT), dopamine (DAT), and norepinephrine (NET) have been well characterized, transporters selective for histamine and epinephrine have not been demonstrated.

Among drugs of abuse, cocaine binds with high affinity to all three known monoamine transporters, although the stimulant properties of the drug have been attributed primarily to its blockade of DAT. This view has been recently supported by the absence of cocaine-induced locomotor stimulation in a strain of mutant mice engineered to lack this molecule. In fact, psychostimulants produce a paradoxical locomotor suppression in these animals that has been attributed to their blockade of the serotonin transporter. The rewarding properties of cocaine have also been attributed primarily to dopamine transporter inhibition, although other targets mediate these effects as well, since cocaine still has rewarding effects in mice lacking the dopamine transporter. It appears that serotonergic as well as dopaminergic mechanisms may be involved. Transporters may also provide routes that allow neurotoxins to enter and damage monoaminergic neurons; examples include the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and the serotonergic neurotoxin MDMA.

Vesicular Monoamine Transporter

In addition to the reuptake of monoamines into the presynaptic nerve terminal, a second transport process serves to concentrate and store monoamines within synaptic vesicles. The transport and storage of monoamines in vesicles may serve several purposes: (1) to enable the regulated release of transmitter under appropriate physiological stimulation, (2) to protect monoamines from degradation by MAO, and (3) to protect neurons from the toxic effects of free radicals produced by the oxidation of cytoplasmic monoamines. In contrast with the plasma membrane transporters, a single type of vesicular monoamine transporter is believed to mediate the uptake of monoamines into synaptic vesicles within the brain. Consistent with this, blockade of this vesicular monoamine transporter by the antihypertensive drug reserpine (Serpasil) has been found to deplete brain levels of serotonin, norepinephrine, and dopamine and to increase the risk of suicide and affective dysfunction.

RECEPTORS

Ultimately, the effects of monoamines on CNS function and behavior depend on their interactions with receptor molecules. The binding of monoamines to these plasma membrane proteins initiates a series of intracellular events that modulate neuronal excitability. Unlike the transporters, multiple receptor subtypes exist for each monoamine neurotransmitter (Table 1.4-1).

Table 1.4-1
Monoamine Receptors: Overview

Transmitter	Subtype	Primary Effector	Proposed Clinical Relevance
Histamine	H ₁	↑ PI Turnover	Antagonists used as antiallergenic and anti-inflammatory agents, also promote sedation, weight gain
	H ₂	↑ AC	Antagonists used to treat peptic ulcers, GI reflux, and GI bleeding
	H ₃	↓ AC	Antagonists proposed to treat sleep disorders, obesity, dementia
	H ₄	↓ AC	Possible role for antagonists as anti-inflammatory agents
Epinephrine/ Norepinephrine	α _{1A,B,D}	↑ PI Turnover	Antagonists used in management of prostate disease
	α _{2A,B,C}	↓ AC	Agonists sedative and hypertensive
	β ₁	↑ AC	Regulation of cardiac function, antagonists may be anxiolytic
	β ₂ β ₃	↑ AC ↑ AC	Agonists used as bronchodilators Possible role for agonists to treat obesity
Serotonergic	5HT _{1A,1B,1D,1E,1F}	↓ AC, ↑ GIRK currents	Partial agonists (buspirone) anxiolytic, role in hippocampal neurogenesis; 5-HT _{1B/D} antagonists used as antimigraine agents (triptans)
	5-HT _{2A} , 5-HT _{2B} , 5-HT _{2C}	↑ PI Turnover	2A antagonists → antipsychotic effects, 2A agonists → hallucinogens; 2B agonism → cardiac valvulopathy 2C agonists → under development as anorexigens, antiepileptics?
	5-HT ₃	Na ⁺ channel, cell membrane depolarization	Agonists (ondansetron) are antiemetics.
	5-HT ₄	↑ AC	Partial agonists used in IBS (tegaserod)
	5-HT ₅ , 5-HT ₆ , 5-HT ₇	↑ AC	Unclear Unclear Antagonists may have antidepressant potential
Dopaminergic	D ₁ -like family (D ₁ , D ₅)	↑ AC	D ₁ agonists used in Parkinson's disease
	D ₂ -like family (D ₂ , D ₃ , D ₄)	↓ AC	D ₂ antagonists are antipsychotics (e.g., haloperidol) D ₃ agonists used in Parkinson's disease, restless legs syndrome (e.g., pramipexole)

Serotonin Receptors

The 5-hydroxytryptophan type 1 (5-HT₁) receptors comprise the largest serotonin receptor subfamily, with human subtypes designated 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}. All five 5-HT₁ receptor subtypes display intronless gene structures, high affinities for serotonin, and adenylate cyclase inhibition. The most intensively studied of these has been the 5-HT_{1A} receptor. This subtype is found on postsynaptic membranes of forebrain neurons, primarily in the hippocampus, cortex, and septum and on serotonergic neurons, where it functions as an inhibitory somatodendritic autoreceptor. There is significant interest in the 5-HT_{1A} receptor as a modulator of both anxiety and depression. The downregulation of 5-HT_{1A} autoreceptors by the chronic administration of serotonin reuptake inhibitors has been implicated in their antidepressant effects, and SSRIs may produce some behavioral effects via increases in hippocampal neurogenesis mediated by postsynaptic 5-HT_{1A} receptor activation. In addition, partial 5-HT_{1A} receptor agonists such as buspirone (BuSpar) display both anxiolytic and antidepressant properties.

Much recent attention has focused on the contributions of 5-HT_{2A/C} receptors to the actions of atypical antipsychotic drugs such as clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa). Analysis of the receptor-binding properties of these drugs has led to the hypothesis that 5-HT_{2A} receptor blockade correlates with the therapeutic effectiveness of atypical antipsychotics. Of interest, the 5-HT_{2A} receptor has also been implicated in the cognitive process of working memory, a function believed to be impaired in schizophrenia.

The 5-HT_{2C} receptor is expressed at high levels in many CNS regions, including the hippocampal formation, prefrontal cortex, amygdala, striatum, hypothalamus, and choroid plexus. Stimulation of 5-HT_{2C} receptors has been proposed to produce anxiogenic effects as well as anorectic effects, which may result from interactions with the hypothalamic melanocortin and leptin pathways. 5-HT_{2C} receptors may also play a role in the weight gain and development of type 2 diabetes mellitus associated with atypical antipsychotic treatment. Indeed, a line of mice lacking this receptor subtype exhibits an obesity syndrome associated with overeating and enhanced seizure susceptibility, suggesting that this receptor regulates neuronal network excitability. A variety of antidepressant and antipsychotic drugs antagonize 5-HT_{2C} receptors with high affinity. Conversely, hallucinogens such as lysergic acid diethylamide (LSD) display agonist activity at 5-HT₂ (and other) serotonin receptor subtypes. 5-HT_{2C} receptor transcripts also undergo RNA editing, producing isoforms of the receptor with significantly altered basal versus serotonin-induced activity. Alterations in 5-HT_{2C} receptor messenger ribonucleic acid (mRNA) editing have been found in the brains of suicide victims with a history of major depression, and SSRIs have been shown to alter these editing patterns.

Dopamine Receptors

In 1979, it was clearly recognized that the actions of dopamine are mediated by more than one receptor subtype. Two dopamine receptors, termed D₁ and D₂, were distinguished on the basis of differential binding affinities of a series of agonists and antagonists, distinct effector mechanisms, and distinct distribution patterns within the CNS. It was subsequently found that the therapeutic efficacy of antipsychotic drugs correlated strongly with their affinities for the D₂ receptor, implicating this subtype as an important site of antipsychotic drug action. Recent molecular cloning studies have identified three additional dopamine receptor genes encoding the D₃, D₄, and D₅ dopamine receptors. On the basis of their structure, pharmacology, and primary effector mechanisms, the D₃ and D₄ receptors are considered to be “D₂-like,” and the D₅ receptor “D₁-like.” The functional roles of the recently discovered subtypes remain to be definitively elucidated.

The D₁ receptor was initially distinguished from the D₂ subtype by its high affinity for the antagonist SCH 23390 and relatively low affinity for butyrophenones such as haloperidol (Haldol). Whereas D₁ receptor activation stimulates cyclic adenosine monophosphate (cAMP) formation, D₂ receptor stimulation produces the opposite effect.

Adrenergic Receptors

As for the α_1 receptors, the functions of α_2 receptor subtypes (designated α_{2A} , α_{2B} , and α_{2C}) have been difficult to determine due to a lack of selective agonists and antagonists; α_2 receptors display both presynaptic autoreceptor and postsynaptic actions, and all appear to inhibit cAMP formation and to activate potassium channels with resultant membrane hyperpolarization. These receptors regulate neurotransmitter release from peripheral sympathetic nerve endings. Within the brain the stimulation of α_2 autoreceptors (likely the α_{2A} subtype) inhibits firing of the noradrenergic neurons of the LC, which have been implicated in arousal states. This mechanism has been proposed to underlie the sedative effects of the α_2 receptor agonist clonidine (Catapres). In addition, the stimulation of brainstem α_2 receptors has been proposed to reduce sympathetic and to augment parasympathetic nervous system activity. This action may relate to the utility of clonidine in lowering blood pressure and in suppressing the sympathetic hyperactivity associated with opiate withdrawal. Activation of α_2 receptors inhibits the activity of serotonin neurons of the dorsal raphe nucleus, whereas activation of local α_1 receptors stimulates the activity of these neurons, and this is thought to be a major activating input to the serotonergic system.

Histamine Receptors

Histaminergic systems have been proposed to modulate arousal, wakefulness, feeding behavior, and neuroendocrine responsiveness. Four histaminergic receptor subtypes have been identified and termed H1, H2, H3, and H4. The H4 receptor was identified recently and is detected predominantly in the periphery, in regions such as the spleen, bone marrow, and leukocytes. The other three histamine receptors have prominent expression in the CNS. H1 receptors are expressed throughout the body, particularly in smooth muscle of the gastrointestinal tract and bronchial walls as well as on vascular endothelial cells. H1 receptors are widely distributed within the CNS, with particularly high levels in the thalamus, cortex, and cerebellum. H1 receptor activation is associated with G_q activation and stimulation of phosphoinositide turnover and tends to increase excitatory neuronal responses. These receptors are the targets of classical antihistaminergic agents used in the treatment of allergic rhinitis and conjunctivitis. The well-known sedative effects of these compounds have been attributed to their actions in the CNS and have implicated histamine in the regulation of arousal and the sleep-wake cycle. Accordingly, a line of mutant mice lacking histamine displays deficits in waking and attention. In addition, the sedation and weight gain produced by a number of antipsychotic and antidepressant drugs have been attributed to H1 receptor antagonism. Conversely, H1 receptor agonists stimulate arousal and suppress food intake in animal models.

Cholinergic Receptors

M1 receptors are the most abundantly expressed muscarinic receptors in the forebrain, including the cortex, hippocampus, and striatum.

Pharmacological evidence has suggested their involvement in memory and synaptic plasticity, and recent evaluation of mice lacking the M1 receptor gene revealed deficits in memory tasks believed to require interactions between the cortex and the hippocampus.

Nicotinic receptors have been implicated in cognitive function, especially working memory, attention, and processing speed. Cortical and hippocampal nicotinic acetylcholine receptors appear to be significantly decreased in Alzheimer's disease, and nicotine administration improves attention deficits in some patients. The acetylcholinesterase inhibitor galantamine used in the treatment of Alzheimer's disease also acts to positively modulate nicotinic receptor function. The α_7 nicotinic acetylcholine receptor subtype has been implicated as one of many possible susceptibility genes for schizophrenia, with lower levels of this receptor being associated with impaired sensory gating. Some rare forms of the familial epilepsy syndrome autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) are associated with mutations in the α_4 or β_2 subunits of the nicotinic acetylcholine receptor. Finally, the reinforcing properties of tobacco use are proposed to involve the stimulation of nicotinic acetylcholine receptors located in mesolimbic dopaminergic reward pathways.

AMINO ACID NEUROTRANSMITTERS

For more than 50 years, biogenic amines have dominated thinking about the role of neurotransmitters in the pathophysiology of psychiatric disorders. However, over the last decade, evidence has accumulated from postmortem, brain imaging, and genetic studies that the amino acid neurotransmitters, in particular glutamic acid and γ -aminobutyric acid (GABA), play an important, if not central, role in the pathophysiology of a broad range of psychiatric disorders including schizophrenia, bipolar disorder, major depression, Alzheimer's disease, and anxiety disorders.

Glutamic Acid

Glutamate mediates fast excitatory neurotransmission in the brain and is the transmitter for approximately 80 percent of brain synapses, particularly those associated with dendritic spines. The repolarization of neuronal membranes that have been depolarized by glutamatergic neurotransmission may account for as much as 80 percent of the energy expenditure in the brain. The concentration of glutamate in brain is 10 mM, the highest of all amino acids, of which approximately 20 percent represents the neurotransmitter pool of glutamate.

The postsynaptic effects of glutamate are mediated by two families of receptors. The first are the glutamate-gated cation channels that are responsible for fast neurotransmission. The second type of glutamate receptor are the metabotropic glutamate receptors (mGluR), which are G-protein-coupled receptors like α -adrenergic receptors and dopamine receptors. The mGluRs primarily modulate glutamatergic neurotransmission.

Major Glutamatergic Pathways in the Brain.

All primary sensory afferent systems appear to use glutamate as their neurotransmitter including retinal ganglion cells, cochlear cells, trigeminal nerve, and spinal afferents. The thalamocortical projections that distribute afferent information broadly to the cortex are glutamatergic. The pyramidal neurons of the corticolimbic regions, the major source of intrinsic, associational, and efferent excitatory projections from the cortex, are glutamatergic. A temporal lobe circuit that figures importantly in the development of new memories is a series of four glutamatergic synapses: The perforant path innervates the hippocampal granule cells that innervate CA3 pyramidal cells that innervate CA1 pyramidal cells. The climbing fibers innervating the cerebellar cortex are glutamatergic as well as the corticospinal tracks.

Ionotropic Glutamate Receptors.

Three families of ionotropic glutamate receptors have been identified on the basis of selective activation by conformationally restricted or synthetic analogs of glutamate. These include α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainic acid (KA), and *N*-methyl-D-aspartic acid (NMDA) receptors. Subsequent cloning revealed 16 mammalian genes that encode structurally related proteins, which represent subunits that assemble into functional receptors. Glutamate-gated ion channel receptors appear to be tetramers, and subunit composition affects both the pharmacologic and the biophysical features of the receptor.

Metabotropic Glutamate Receptors.

These receptors are so designated because their effects are mediated by G proteins. All mGluRs are activated by glutamate, although their sensitivities vary remarkably. To date, eight mGluRs have been cloned. These genes encode for seven membrane-spanning proteins that are members of the superfamily of G-protein-coupled receptors.

The Role of Astrocytes.

Specialized end-feet of the astrocyte surround glutamatergic synapses. The astrocyte expresses the two Na^+ -dependent glutamate transporters that play the primary role in removing glutamate from the synapse, thereby terminating its action: EAAT1 and EAAT2 (*excitatory amino acid transporter*). The neuronal glutamate transporter, EAAT3, is expressed in upper motor neurons, whereas EAAT4 is expressed primarily in cerebellar Purkinje cells and EAAT5 in retina. Mice homozygous for null mutations of either EAAT1 or EAAT2 exhibit elevated extracellular glutamate and excitotoxic neurodegeneration. Notably, several studies have described the loss of EAAT2 protein and transport activity in the ventral horn in amyotrophic lateral sclerosis.

The astrocytes express AMPA receptors so that they can monitor synaptic glutamate release. GlyT1, which maintains subsaturating concentrations of glycine in the synapse, is expressed on the astrocyte plasma membrane. GlyT1 transports three Na^+ out for each molecule of glycine transported into the astrocyte. This stoichiometry results in a robust reversal of the direction of transport when glutamate released in the synapse activates the AMPA receptors on the astrocyte, thus depolarizing the astrocyte. Thus glycine release in the synapse by GlyT1 is coordinated with glutamatergic neurotransmission. Similarly, activation of the astrocyte AMPA receptors causes GRIP to dissociate from the AMPA receptor and bind to serine racemase, activating it to synthesize D-serine. D-Serine levels are also determined by D-amino acid oxidase (DAAO) with low D-serine levels in the cerebellum and brainstem where DAAO expression is high, and high D-serine levels are found in corticolimbic brain regions where DAAO expression is quite low. In contrast, the expression of GlyT1 is highest in the cerebellum and brainstem. This distribution suggests that D-serine is the primary modulator of the NMDA receptor in the forebrain, whereas glycine is more prominent in the brainstem and cerebellum.

Plasticity in Glutamatergic Neurotransmission.

The extinction of conditioned fear has been shown to be an active process mediated by the activation of NMDA receptors in the amygdala. Treatment of rats with NMDA receptor antagonists prevents the extinction of conditioned fear, whereas treatment with the glycine modulatory site partial agonist D-cycloserine facilitates the extinction of conditioned fear. (D-Cycloserine is an antibiotic used to treat tuberculosis that has 50 percent of the efficacy of glycine at the NMDA receptor.) To determine whether the phenomenon generalizes to humans, patients with acrophobia were administered either placebo or a single dose of D-cycloserine along with cognitive behavioral therapy (CBT). D-Cycloserine plus CBT resulted in a highly significant reduction in acrophobic symptoms that persisted for at least 3 months as compared to placebo plus CBT. Other placebo-controlled clinical trials support the notion that D-cycloserine is a robust enhancer of CBT, suggesting that pharmacologically augmenting neural plasticity may be used to bolster psychological interventions.

Fragile X mental retardation protein (FMRP), which is deficient in individuals with fragile X syndrome, appears to be synthesized locally within the spine during times of NMDA receptor activation and also plays a role in transporting specific mRNAs to the spine for translation. Notably, mice in which the FMRP gene has been inactivated through a null mutation as well as patients with fragile X syndrome have fewer dendritic spines, the preponderance of which have an immature morphology. Loss of FMRP exaggerates responses of mGluR5, which stimulates dendritic protein synthesis, and treatment with an mGluR5 antagonist reverses the fragile-X-like phenotype in mice with the FMRP gene inactivated.

Excitotoxicity. In the early 1970s, it was shown that the systemic administration of large amounts of monosodium glutamate to immature animals resulted in the degeneration of neurons in brain regions where the blood-brain barrier was deficient.

Excitotoxicity has also been implicated in the proximate cause of neuronal degeneration in Alzheimer's disease. Most evidence points to the toxic consequences of aggregates of β -amyloid, especially β -amyloid₁₋₄₂. The β -amyloid fibrils depolarize neurons, resulting in loss of

the Mg^{2+} block and enhanced NMDA receptor sensitivity to glutamate. The fibrils also impair glutamate transport into astrocytes, thereby increasing the extracellular concentration of glutamate. β -Amyloid directly promotes oxidative stress through inflammation that further contributes to neuronal vulnerability to glutamate. Thus, several mechanisms contribute to neuronal vulnerability to NMDA-receptor-mediated excitotoxicity in Alzheimer's disease. Memantine, a recently approved treatment for mild to moderate Alzheimer's disease, is a weak noncompetitive inhibitor of NMDA receptors. It reduces tonic sensitivity of NMDA receptors to excitotoxicity but does not interfere with "phasic" neurotransmission, thereby attenuating neuronal degeneration in Alzheimer's disease.

Inhibitory Amino Acids: GABA

GABA is the major inhibitory neurotransmitter in the brain, where it is broadly distributed and occurs in millimolar concentrations. In view of its physiological effects and distributions, it is not surprising that the dysfunction of GABAergic neurotransmission has been implicated in a broad range of neuropsychiatric disorders including anxiety disorders, schizophrenia, alcohol dependence, and seizure disorders. Chemically, GABA differs from glutamic acid, the major excitatory neurotransmitter, simply by the removal of a single carboxyl group from the latter.

GABA is synthesized from glutamic acid by glutamic acid decarboxylase (GAD), which catalyzes the removal of the α -carboxyl group. In the CNS, the expression of GAD appears to be restricted to GABAergic neurons, although in the periphery it is expressed in pancreatic islet cells. Two distinct but related genes encode GAD. GAD65 is localized to nerve terminals, where it is responsible for synthesizing GABA that is concentrated in the synaptic vesicles. Consistent with its role in fast inhibitory neurotransmission, mice homozygous for a null mutation of GAD65 have an elevated risk for seizures. GAD67 appears to be the primary source for neuronal GABA because mice homozygous for a null mutation of GAD67 die at birth, have a cleft palate, and exhibit major reductions in brain GABA.

GABA is catabolized by GABA transaminase (GABA-T) to yield succinic semialdehyde. Transamination generally occurs when the parent compound, α -ketoglutarate, is present to receive the amino group, thereby regenerating glutamic acid. Succinic semialdehyde is oxidized by succinic semialdehyde dehydrogenase (SSADH) into succinic acid, which re-enters the Krebs cycle. GABA-T is a cell surface, membrane-bound enzyme expressed by neurons and glia, which is oriented toward the extracellular compartment. As would be anticipated, drugs that inhibit the catabolism of GABA have anticonvulsant properties. One of the mechanisms of action of valproic acid is the competitive inhibition of GABA-T. γ -Vinyl-GABA is a suicide substrate inhibitor of GABA-T that is used as an anticonvulsant in Europe (vigabatrin [Sabril]).

The synaptic action of GABA is also terminated by high-affinity transport back into the presynaptic terminal as well as into astrocytes. Four genetically distinct GABA high-affinity transporters have been identified with differing kinetic and pharmacological characteristics. They all share homology with other neurotransmitter transporters with the characteristic of 12 membrane-spanning domains. The active transport is driven by the sodium gradient so that upon depolarization, transportation of GABA out of the neuron is favored. GABA transported into astrocytes is catabolized by GABA-T and ultimately converted to glutamic acid and then to glutamine, which is transported back into the presynaptic terminal for GABA synthesis. Tiagabine (Gabitril) is a potent GABA transport inhibitor that is used to treat epilepsy. Preliminary results suggest that it also may be effective in panic disorder.

GABA_A Receptors. GABA_A receptors are distributed throughout the brain. The GABA_A complex, when activated, mediates an increase in membrane conductance with an equilibrium potential near the resting membrane potential of -70 mV (Fig. 1.4-9). In the mature neuron, this typically results with an influx of Cl^- , causing membrane hyperpolarization. Hyperpolarization is inhibitory because it increases the threshold for generating an action potential. In immature neurons, which have unusually high levels of intracellular Cl^- , activating the GABA_A receptor can counterintuitively cause depolarization. For this reason, anticonvulsants that act by enhancing GABA_A receptor activity may actually exacerbate seizures in the neonatal period.

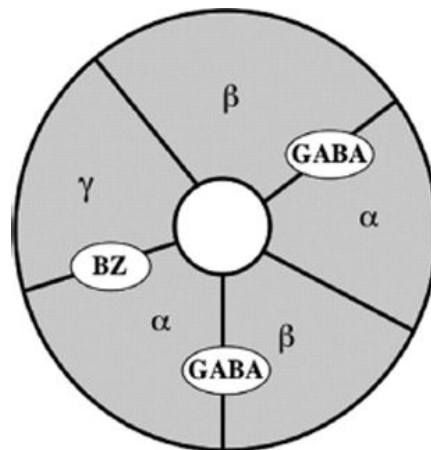

FIGURE 1.4-9

Schematic representation of the GABA_A receptor. The receptor-channel complex is a heteropentamer. The GABA binding site is at the interface of the α and β subunits. The benzodiazepine binding site is at the interface between the γ and α subunits. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:81.)

Barbiturates such as phenobarbital and pentobarbital are noted for their sedative and anticonvulsant activities. Barbiturates allosterically increase the affinities of the binding sites for GABA and benzodiazepines at concentrations that are pharmacologically relevant. Barbiturates also affect channel dynamics by markedly increasing the long open state and reducing the short open state, thereby increasing Cl^- inhibition. Chemically modified analogs of progesterone and corticosterone have been shown in behavioral studies to have sedative and anxiolytic effects through their interaction with the GABA_A receptor complex. They share features with barbiturates, although they act at a distinctly different site. Thus, they allosterically enhance agonist ligand binding to the receptor and increase the duration of chloride channel opening. A variety of behavioral effects associated with steroid administration or fluctuation of endogenous steroids and sex-specific effects of GABAergic drugs have been linked to the action of endogenous neurosteroids.

With regard to GABA_A receptor antagonists, picrotoxin, like the barbiturates, alters channel dynamics but in the opposite direction by reducing long open states and favoring the briefest open state. The proconvulsant pentylenetetrazol also acts by reducing chloride channel permeability. Penicillin, which at high concentrations is proconvulsant, binds to the positively charged residues in the channel, thereby occluding it. As a general class, anesthetics including barbiturates, steroids, and volatile anesthetics increase chloride conductance, thereby inhibiting neurotransmissions. Amino acids in the membrane-spanning domain of the GABA receptor subunits confer sensitivity to anesthetics. The precise mechanism whereby ethanol enhances GABA_A receptor function remains unclear due to inconsistent results,

suggesting that subunit composition may be important. However, recent studies suggest that ethanol increases the response of the tonic GABA-activated currents, which contain the δ subunit and exhibit remarkably high affinity to GABA.

Recently, recombinant DNA strategies exploiting site-directed mutagenesis have permitted the identification of sites on the specific subunits that mediate the pharmacological action of drugs such as the benzodiazepines. Removal of the binding ability for benzodiazepines has established that the α_1 subunit plays a major role in the sedative and amnesic effects of benzodiazepines, whereas inactivating the benzodiazepine site on the α_2 subunit eliminates the anxiolytic effect of benzodiazepines

GABA_B Receptors. The GABA_B receptors are distinguished pharmacologically from GABA_A receptors by the fact that they are insensitive to the canonical GABA_A receptor antagonist bicuculline and that they are potently activated by baclofen [β -(4-chlorophenyl)- γ -aminobutyric acid], which is inactive at GABA_A receptors. They are members of the G-protein-coupled superfamily of receptors but are highly unusual, as they are made of a dimer of two seven-transmembrane-spanning subunits. GABA_B receptors are widely distributed throughout the nervous system and are localized both presynaptically and postsynaptically. The postsynaptic GABA_B receptors cause a long-lasting hyperpolarization by activating potassium channels. Presynaptically, they act as autoreceptors and heteroreceptors to inhibit neurotransmitter release.

Glycine as a Neurotransmitter. Glycine is an inhibitory neurotransmitter primarily in the brainstem and spinal cord, although the expression of glycine receptor subunits in the thalamus, cortex, and hippocampus suggest a broader role. Glycine is a nonessential amino acid that is synthesized in the brain from L-serine by serine hydroxymethyltransferase. Glycine is concentrated within synaptic vesicles by H⁺-dependent vesicular inhibitory amino acid transporter (VIAAT or VGAT), which also transports GABA. Termination of the synaptic action of glycine is through reuptake into the presynaptic terminal by the glycine transporter II (GlyT2), which is quite distinct from GlyT1 that is expressed in astrocytes and modulates NMDA receptor function.

The inhibitory effects of glycine are mediated by a ligand-gated chloride channel, which can also respond to β -alanine, taurine, L-alanine, L-serine, and proline, but not to GABA. The canonical antagonist for the glycine receptor is the plant alkaloid strychnine. The receptor was first identified through the specific binding of [³H]strychnine. [³H]Glycine binds to two sites: One that is displaceable by strychnine and represents the glycine A receptor and a second that is insensitive to strychnine and is designated the glycine B receptor, representing the glycine modulatory site on the NMDA receptor.

Neuropsychiatric Implications of Amino Acid Transmitters

Schizophrenia. Evidence accumulating from postmortem, pharmacological, and genetic studies is shifting the focus of the pathophysiology of schizophrenia from dopamine to glutamate and GABA. Indeed, after the use of D₂ receptor antagonists as the sole treatment of schizophrenia for the last 50 years, more than two thirds of the treated patients remain substantially disabled. Early postmortem studies indicated a reduction in the activity of GAD in the cortex in patients with schizophrenia as compared to suitable controls. With the advent of immunocytochemistry and gene expression techniques, it has been possible to more precisely define the GABAergic deficit in schizophrenia. It appears that the parvalbumin-positive GABAergic interneurons in the intermediate layers of the cortex bear the brunt of the pathology, which includes reduced expression of GAD67, parvalbumin, and the GABA transporter (GAT). The finding that GABA_A receptors are upregulated, as measured by autoradiography or with antibodies, supports the theory that these changes reflect hypofunction of the presynaptic GABAergic neurons. These particular GABAergic interneurons, which include the chandelier cells, play an important role in negative feedback inhibition to the pyramidal cells in the cortex. Despite this highly reproducible neuropathology, genes related to GABAergic function have not figured prominently in genomewide searches, suggesting that GABAergic deficits may be a downstream consequence of some more proximal genetic defects.

The theory that hypofunction of NMDA receptors is an etiologic factor in schizophrenia initially arose from the observation that phencyclidine (PCP) and related dissociative anesthetics that block NMDA receptors produce a syndrome that can be indistinguishable from schizophrenia (Fig. 1.4-10). Dissociative anesthetics are so named because they prevent the acquisition of new memories while the patient is apparently conscious. In fact under laboratory conditions, low-dose infusion of ketamine can produce the positive symptoms, negative symptoms, and specific cognitive deficits associated with schizophrenia in clear consciousness. Subsequent studies indicated that low-dose ketamine can also cause enhanced amphetamine-induced subcortical dopamine release as is observed in schizophrenia as well as abnormal cortical event-related potentials (ERPs) and disruption of prepulse inhibition in experimental animals.

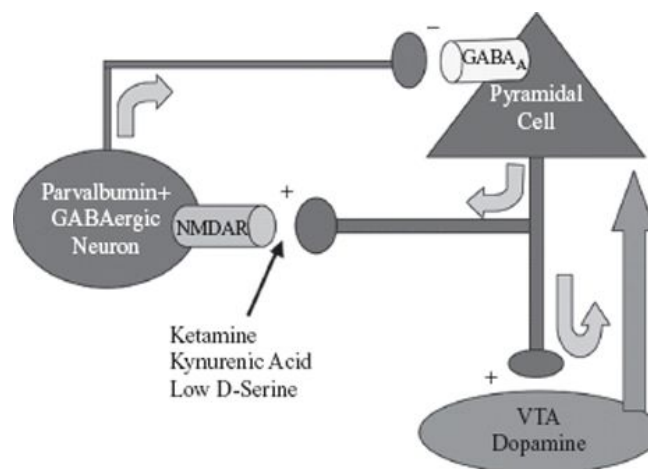

FIGURE 1.4-10

Pathological circuit in schizophrenia. The NMDA receptors on the rapidly firing parvalbumin (PV) expressing GABAergic interneurons in the intermediate levels of the cortex are disproportionately sensitive to antagonists or loss of the coagonist, D-serine. NMDA receptor hypofunction causes reduced expression of PV, GAD67, and the GABA transporter and upregulation of GABA_A receptors on pyramidal neurons. Disinhibition of the pyramidal neurons causes cognitive dysfunction and negative symptoms and drives excessive subcortical dopamine release resulting in psychosis. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:83.)

A number of putative risk genes for schizophrenia are closely associated with NMDA receptor function. DAAO, which encodes a protein that activates D-amino acid oxidase, has been repeatedly linked to the risk of schizophrenia. D-Amino acid oxidase itself has been associated with increased risk. Recently an allelic variant of serine racemase in the promoter region has also been associated with the risk for schizophrenia. Each of these gene variants could reduce the availability of D-serine in the cortex, thereby impairing NMDA receptor function. Notably, cerebrospinal fluid (CSF) and blood levels of D-serine are significantly reduced in patients with schizophrenia. Neuregulin 1 appears to be a convincing risk gene and interacts directly with NMDA receptors. Dysbindin, another risk gene, is expressed in glutamatergic terminals. mGluR3, which downregulates glutamate release, has also been associated with schizophrenia.

Recent findings have provided a link between the GABAergic neuropathology and NMDA receptor hypofunction. Chronic treatment of rats with NMDA receptor antagonists causes a downregulation of GAD67, parvalbumin, and GAT. The sensitive subpopulation of GABAergic neurons is the rapidly firing interneurons that provide the perisomatic innervation of the pyramidal cells. Their NMDA receptors appear to be much more sensitive to antagonists than those less active GABAergic neurons and pyramidal cells. The subtly reduced GABAergic inhibition results in a disinhibition of the glutamatergic pyramidal output. This degradation of the inhibitory feedback could account for the cognitive deficits and negative symptoms in schizophrenia, and the disinhibited output also results in elevated subcortical dopamine release and psychosis. Thus psychosis would be considered a downstream event resulting from a disruption in critical glutamatergic–GABAergic synaptic function in the cerebral cortex.

Anxiety and Depression. GABAergic dysfunction has been associated with anxiety disorders, especially panic disorder, as well as with major depressive disorder. Clinically, there is considerable comorbidity between anxiety and affective disorders. Decreased levels of the GABA_A receptor modulators, the three α -reduced neuroactive steroids, have been found both in plasma and in CSF in major depressive disorder. Effective treatment with selective serotonin reuptake inhibitors (SSRIs) increases the neurosteroid levels. In contrast, in patients with panic disorder, the plasma neurosteroid levels were significantly elevated, perhaps as a compensatory mechanism. Magnetic resonance spectroscopy (MRS) has disclosed significant reductions in GABA levels in the anterior cingulate and in the basal ganglia of medicated patients with panic disorder. Positron emission tomography (PET) scanning reveals a highly selective reduction in benzodiazepine receptor sites bilaterally in the insular cortex in panic disorder. A genomewide screen has shown significant linkage at 15q in a region containing GABA_A receptor subunit genes and panic disorder. MRS reveals significant reductions in both GABA and glutamate/glutamine (Glx) in the prefrontal cortex in major depressive disorder. Postmortem studies indicate upregulation of the GABA_A receptor α_1 and β_3 subunits in the cerebral cortices of depressed patients who committed suicide, consistent with a reduction in GABAergic neurotransmission. The reduced levels of GABA in the occipital cortex in episodes of major depressive disorder normalized with effective treatment with SSRI or with electroconvulsive therapy.

Glutamatergic dysfunction has also been implicated in depression. NMDA receptor antagonists have antidepressant effects in several animal models of depression including forced swim, tail suspension, and learned helplessness. A single injection of ketamine provides protection from the induction of behavioral despair in rats for up to 10 days. Chronic treatment with antidepressants alters the expression of NMDA receptor subunits and decreases glycine receptor B binding. Two placebo-controlled clinical trials have shown that a single dose of ketamine can produce a rapid, substantial, and persistent reduction in symptoms in patients with major depressive disorder.

Alcoholism. Ethanol at concentrations associated with intoxication has a dual action of enhancing GABAergic receptor function and attenuating NMDA receptor function. The GABA receptor effects may be associated with the anxiolytic effects of ethanol. Persistent abuse and dependency on ethanol result in a downregulation of GABA_A receptors and an upregulation of NMDA receptors such that acute discontinuation of ethanol results in a hyperexcitable state characterized by delirium tremens. Furthermore, supersensitive NMDA receptors in the context of thiamine deficiency may contribute to the excitotoxic neuron degeneration of Wernicke–Korsakoff's syndrome.

Acamprosate is a derivative of homotaurine that was developed as an agent to reduce alcohol consumption, craving, and relapse in alcoholic patients, for which it exhibits moderate efficacy in clinical trials. Because of taurine's resemblance to GABA, it was thought that acamprosate acted via GABA_A receptors, but electrophysiological studies found little evidence to support this hypothesis. Subsequent studies demonstrated that it inhibited NMDA receptor responses in cortical slices and recombinant NMDA receptors. The precise mechanism whereby acamprosate alters NMDA receptor function, however, remains unclear.

Fetal alcohol syndrome is the most common preventable cause of mental retardation. Convincing evidence has been developed that the microcephaly associated with fetal alcohol exposure results from inhibition of NMDA receptor function, resulting in widespread neuronal apoptosis in the immature cortex. NMDA receptor activation is essential for immature neuronal survival and differentiation.

NEUROPEPTIDES

Neuropeptides represent the most diverse class of signaling molecules in the CNS. Initially discovered for their role in the hypothalamic regulation of pituitary hormone secretion, the complex role of peptides in brain function has emerged over the last 30 years. Many neuropeptides and their receptors are widely distributed within the CNS where they have an extraordinary array of direct or neuromodulatory effects, ranging from modulating neurotransmitter release and neuronal firing patterns to the regulation of emotionality and complex behaviors. More than 100 unique biologically active neuropeptides have been identified in the brain, a subset of which is presented in [Table 1.4-2](#). Adding to the complexity of neuropeptide systems in the CNS, the actions of many peptides are mediated via multiple receptor subtypes localized in different brain regions. In fact, the discovery of new peptides and receptor subtypes has outpaced our understanding of the roles of these peptides in normal or aberrant CNS function. Pharmacological, molecular, and genetic approaches are now leading the way in our understanding of the contribution of neuropeptide systems in psychiatric disorders.

Table 1.4-2
Selected Neuropeptide Transmitters

Adrenocorticotrophic hormone (ACTH)
Angiotensin
Atrial natriuretic peptide
Bombesin
Calcitonin
Calcitonin gene-related peptide (CGRP)
Cocaine and amphetamine regulated transcript (CART)
Cholecystokinin (CCK)
Corticotropin-releasing factor (CRF)
Dynorphin
 β -Endorphin
Leu-enkephalin
Met-enkephalin
Galanin
Gastrin
Gonadotropin-releasing hormone (GnRH)
Growth hormone
Growth hormone-releasing hormone (GHRH; GRF)
Insulin
Motilin
Neuropeptide S
Neuropeptide Y (NPY)
Neurotensin
Neuromedin N
Orphanin FQ/Nociceptin
Orexin
Oxytocin
Pancreatic polypeptide
Prolactin
Secretin
Somatostatin (SS; SRIF)
Substance K
Substance P
Thyrotropin-releasing hormone (TRH)
Urocortin (1, 2, and 3)
Vasoactive intestinal polypeptide (VIP)
Vasopressin (AVP; ADH)

From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:84.

Neuropeptides have been implicated in the regulation of a variety of behavioral and physiological processes, including thermoregulation, food and water consumption, sex, sleep, locomotion, learning and memory, responses to stress and pain, emotion, and social cognition. Involvement in such behavioral processes suggests that neuropeptidergic systems may contribute to the symptoms and behaviors exhibited in major psychiatric illnesses such as psychoses, mood disorders, dementias, and autism spectrum disorders.

Investigating Neuropeptide Function

The roles of neuropeptides in CNS function and behavior have been examined using a multitude of experimental techniques. The levels of analysis include the following: Molecular structure and biosynthesis of the peptide and its receptor(s), the neuroanatomical localization of the peptide and its receptor(s), the regulation of the expression and release of the peptide, and the behavioral effects of the peptide. Most information on neuropeptide biology is derived from laboratory animal studies; however, there is a growing database on the localization, activity, and potential psychiatric relevance of several neuropeptide systems in humans.

Most neuropeptide structures have been identified based on the chemical analysis of purified biologically active peptides, leading ultimately to the cloning and characterization of the genes encoding them. Characterization of the gene structure of peptides and their receptors has provided insight into the molecular regulation of these systems, and their chromosomal localization is useful in genetic studies examining the potential roles of these genes in psychiatric disorders. Structural characterization permits the production of immunological and molecular probes that are useful in determining peptide distribution and regulation in the brain. Quantitative radioimmunoassays on microdissected brain regions or immunocytochemistry on brain sections are typically used to localize the distribution of peptide within the brain. Both techniques use specific antibodies generated against the neuropeptide to detect the presence of the peptide. Immunocytochemistry allows researchers to visualize the precise cellular localization of peptide-synthesizing cells as well as their projections throughout the brain, although the technique is generally not quantitative. With molecular probes homologous to the mRNA encoding the peptides or receptor, *in situ* hybridization can be used to localize and quantify gene expression in brain sections. This is a powerful technique for examining the molecular regulation of neuropeptide synthesis with precise neuroanatomical resolution, which is impossible for other classes of nonpeptide neurotransmitters that are not derived directly from the translation of mRNAs, such as dopamine, serotonin, and norepinephrine.

Generally, the behavioral effects of neuropeptides are initially investigated by infusions of the peptide directly into the brain. Unlike many nonpeptide neurotransmitters, most neuropeptides do not penetrate the blood-brain barrier in amounts sufficient enough to produce CNS effects. Furthermore, serum and tissue enzymes tend to degrade the peptides before they reach their target sites. The degradation is usually the result of the cleavage of specific amino acid sequences targeted by a specific peptidase designed for that purpose. Thus, intracerebroventricular (ICV) or site-specific infusions of peptide in animal models are generally required to probe for behavioral effects of peptides. However, there are some examples of delivery of neuropeptides via intranasal infusions in human subjects, which in some cases has been shown to permit access of the peptide to the brain.

One of the greatest impediments for exploring the roles and potential therapeutic values of neuropeptides is the inability of the peptides or their agonists/antagonists to penetrate the blood-brain barrier. Thus the behavioral effects of most peptides in humans are largely uninvestigated, with the exception of a few studies utilizing intranasal delivery. However, in some instances small-molecule, nonpeptide agonists/antagonists have been developed that can be administered peripherally and permeate the blood-brain barrier in sufficient quantities to affect receptor activation.

The use of pretreatment and posttreatment CSF samples or of samples obtained during the active disease state versus when the patient is in remission addresses some of the serious limitations in study design. For such progressive diseases as schizophrenia or Alzheimer's disease, serial CSF samples may be a valuable indicator of disease progression or response to treatment. Even with these constraints, significant

progress has been made in describing the effects of various psychiatric disease states on neuropeptide systems in the CNS.

Biosynthesis

Unlike other neurotransmitters, the biosynthesis of a neuropeptide involves the transcription of an mRNA from a specific gene, translation of a polypeptide preprohormone encoded by that mRNA, and then posttranslational processing involving proteolytic cleavage of the preprohormone to yield the active neuropeptide. Over the last 25 years the gene structures and biosynthetic pathways of many neuropeptides have been elucidated. The gene structure of selected neuropeptides is illustrated in Figure 1.4-11. Neuropeptide genes are generally composed of multiple exons that encode a protein preprohormone. The N-terminus of the preprohormone contains a signal peptide sequence, which guides the growing polypeptide to the rough endoplasmic reticulum (RER) membrane. The single preprohormone molecule often contains the sequences of multiple peptides that are subsequently separated by proteolytic cleavage by specific enzymes. For example, translation of the gene encoding NT yields a preprohormone, which upon enzymatic cleavage produces both NT and neuromedin N.

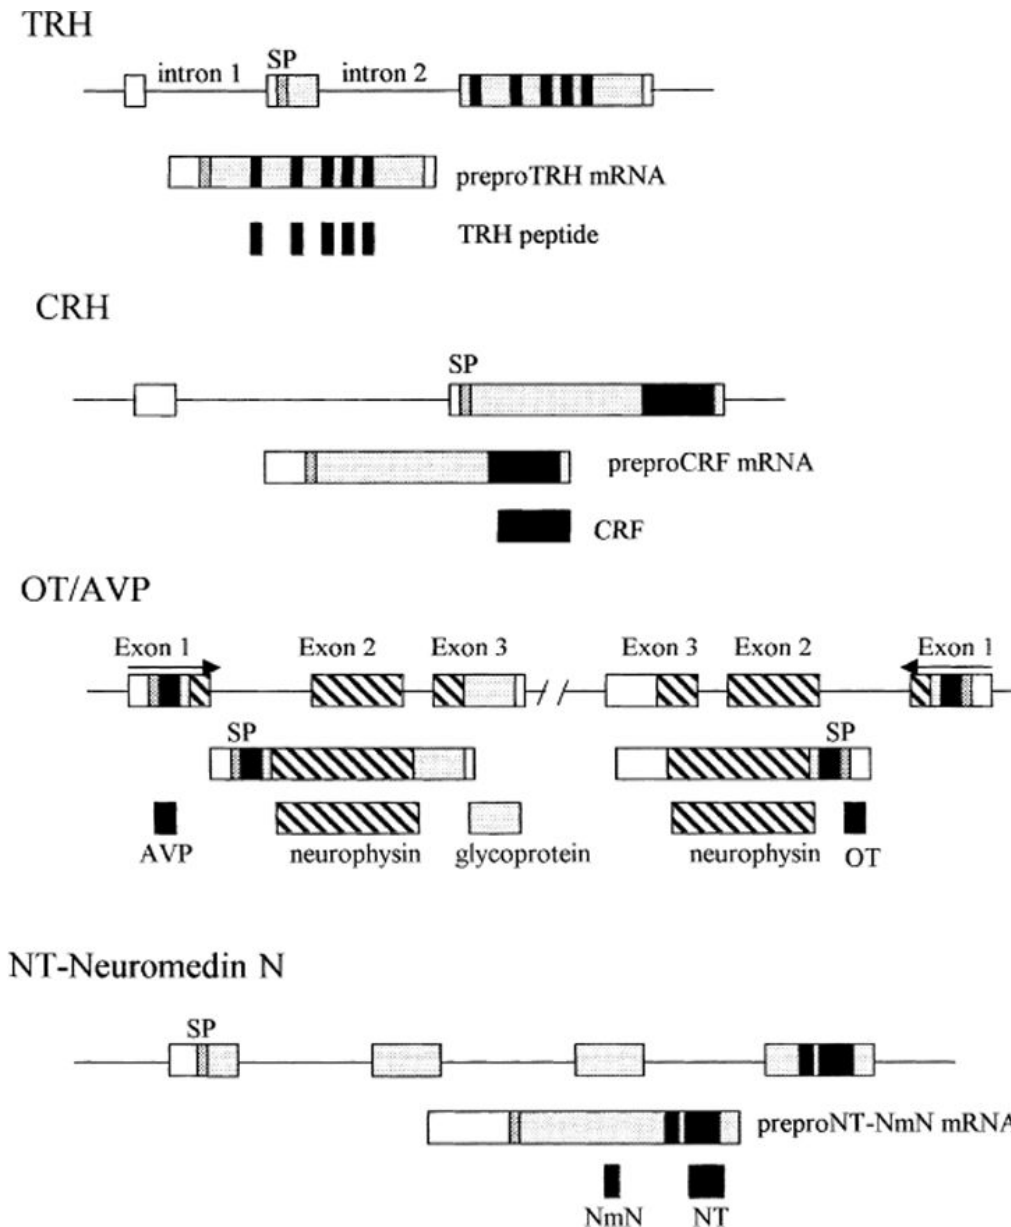

FIGURE 1.4-11

Schematics illustrating the gene structure, preprohormone messenger RNA (mRNA), and processed neuropeptides of thyrotropin-releasing hormone (TRH), corticotropin-releasing factor (CRF), oxytocin (OT), arginine vasopressin (AVP), and neurotensin (NT). *Boxed regions* indicate the locations of the exons in the respective genes. *Shaded or hatched regions* indicate coding regions. Each preprohormone begins with a signal peptide (SP) sequence. *Black boxes* indicate the locations of the sequences encoding the neuropeptide. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:87.)

Distribution and Regulation

Although many neuropeptides were originally isolated from pituitary and peripheral tissues, the majority of neuropeptides were subsequently found to be widely distributed throughout the brain. Those peptides involved in regulating pituitary secretion are concentrated in the hypothalamus. Hypothalamic releasing and inhibiting factors are produced in neurosecretory neurons adjacent to the third ventricle that send projections to the median eminence where they contact and release peptide into the hypothalamohypophysial portal circulatory system. Peptides produced in these neurons are often subject to regulation by the peripheral hormones that they regulate. For example, thyrotropin-releasing hormone (TRH) regulates the secretion of thyroid hormones, and thyroid hormones negatively feedback on TRH gene expression. However, neuropeptide-expressing neurons and their projections are found in many other brain regions, including limbic structures, midbrain, hindbrain, and spinal cord.

Neuropeptide Signaling

Neuropeptides may act as neurotransmitters, neuromodulators, or neurohormones. Neurotransmitters are typically released from axonal terminals into a synapse where they change the postsynaptic membrane potential, either depolarizing or hyperpolarizing the cell. For classical neurotransmitters, this often involves direct modulation of voltage-gated ion channels. In contrast, neuromodulators and neurohormones do not directly affect the firing of the target cell itself but may alter the response of the cell to other neurotransmitters through the modulation of second messenger pathways. Neuropeptide release is not restricted to synapses or axon terminals but may occur throughout the axon or even from dendrites.

The cellular signaling of neuropeptides is mediated by specific neuropeptide receptors. Thus understanding neuropeptide receptor function is essential for understanding neuropeptide biology. Neuropeptide receptors have undergone the same process of discovery and characterization that receptors for other neurotransmitters have enjoyed. Most neuropeptide receptors are G-protein-coupled, seven-transmembrane domain receptors belonging to the same family of proteins as the monoamine receptors.

Molecular technology has made it possible to clone and characterize neuropeptide receptor genes and complementary DNAs (cDNAs). This is most often accomplished in one of three ways. First, the neuropeptide receptor protein is biochemically purified and partially sequenced, which allows the development of oligonucleotide probes that can be used to isolate the cDNA encoding the protein from a cDNA library. A second approach involves producing expression libraries in which cells containing the receptor cDNA can be isolated based on their ability to bind to a radiolabeled peptide ligand. Finally, many neuropeptide receptors are now isolated based on their sequence homology with other known peptide receptors. Once the cDNA of the receptor has been isolated, it can be used to produce purified receptor protein for structural and functional studies. By mutation of specific amino acids in the receptor structure and determination of relative binding affinities of peptides with various amino acid substitutions, it is possible to elucidate the nature of the ligand-receptor interaction. This information facilitates the development of drugs that specifically modulate receptor function, including nonpeptide drugs, leading to the ability to manipulate peptide systems in ways that are currently enjoyed by the more classic neurotransmitters. The availability of cDNAs encoding the receptor also permits the neuroanatomical mapping of the receptor-producing cells in the brain, which is critical for understanding the neural circuits modulated by the peptide. Finally, with the cloned receptor in hand, it is possible to use transgenic techniques, such as targeted gene overexpression or gene knockouts, to further elucidate the functions of these receptors. siRNA techniques now allow the targeted synthesis disruption of specific receptor populations, allowing researchers to examine the roles of these receptor populations on physiology and behavior.

The following three factors determine the biological roles of a neuropeptide hormone: (1) the temporal-anatomical release of the peptide, (2) functional coupling of the neuropeptide receptor to intracellular signaling pathways, and (3) the cell type and circuits in which the receptor is expressed. Genetic studies have demonstrated that regulatory sequences flanking the receptor coding region determine the expression pattern of the receptor and thus the physiological and behavioral response to the neuropeptide.

Peptidases

Unlike monoamine neurotransmitters, peptides are not actively taken up by presynaptic nerve terminals. Rather, released peptides are degraded into smaller fragments, and eventually into single amino acids by specific enzymes termed peptidases. The enzymes may be found bound to presynaptic or postsynaptic neural membranes or in solution in the cytoplasm and extracellular fluid, and they are distributed widely in peripheral organs and serum as well as in the CNS. As a result, neuropeptides generally have half-lives on the order of minutes once released.

Specific Neuropeptides as Prototypes of Neuropeptide Biology

Thyrotropin-Releasing Hormone. In 1969, TRH, a pyroglutamylhistidylprolinamide tripeptide (Table 1.4-3), became the first of the hypothalamic releasing hormones to be isolated and characterized. The discovery of the structure of this hormone led to the conclusive demonstration that peptide hormones secreted from the hypothalamus regulate the secretion of hormones from the anterior pituitary. The gene for TRH in humans resides on chromosome 3q13.3-q21. In the rat it consists of three exons (coding regions) separated by two introns (noncoding sequences) (see Fig. 1.4-11). The first exon contains the 5' untranslated region of the mRNA encoding the TRH prohormone, the second exon contains the signal peptide (SP) sequence and much of the remaining N-terminal end of the precursor peptide, and the third contains the remainder of the sequence, including five copies of the TRH precursor sequence, the C-terminal region, and the 3' untranslated region. The 5' flanking of the gene, or promoter, contains sequences homologous to the glucocorticoid receptor and the thyroid hormone receptor DNA binding sites, providing a mechanism for the regulation of this gene by cortisol and negative feedback by thyroid hormone. Enzymatic processing of TRH begins with excision of the progenitor peptides by carboxypeptidases, amidation of the C-terminal proline, and cyclization of the N-terminal glutamine to yield five TRH molecules per prohormone molecule. TRH is widely distributed in the CNS with TRH immunoreactive neurons being located in the olfactory bulbs, entorhinal cortices, hippocampus, extended amygdala, hypothalamus, and midbrain structures. As is the case for most neuropeptides, the TRH receptor is also a member of the seven-transmembrane domain, G-protein-coupled receptor family.

Table 1.4-3
Selected Neuropeptide Structures

Name	Amino Acid Sequence
Thyrotropin-releasing hormone (TRH)	pE-H-P-NH ₂
Corticotropin-releasing factor (CRF)	S-E-E-P-P-I-S-L-D-L-T-F-H-L-L-R- E-V-L-E-M-A-R-A-E-Q-L-A-Q- Q-A-H-S-N-R-K-L-M-E-I-I-NH ₂
Arginine vasopressin (AVP)	C-Y-I-Q-N-C-P-L-G-NH ₂
Oxytocin (OT)	C-Y-F-Q-N-C-P-R-G-NH ₂
Neurotensin (NT)	pE-L-Y-E-N-K-P-R-R-P-Y-I-L-OH

Note the cyclized glutamines at the N-termini of TRH and NT indicated by pE-, the cysteine-cysteine disulfide bonds of AVP and OT, and the amidated C-termini of TRH, CRF, AVP, and OT.

From Sadock BJ, Sadock VA, Ruiz P. Kaplan & Sadock's Comprehensive Textbook of Psychiatry. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:85.

Hypothalamic TRH neurons project nerve terminals to the median eminence; there they release TRH into the hypothalamohypophyseal portal system where it is transported to the adenohypophysis, causing the release of thyroid-stimulating hormone (TSH) into systemic circulation. TSH subsequently stimulates the release of the thyroid hormones triiodothyronine (T₃) and thyroxine (T₄) from the thyroid gland. TRH neurons in the paraventricular nucleus (PVN) contain thyroid hormone receptors and respond to increases in thyroid hormone secretion with a decrease in TRH gene expression and synthesis. This negative feedback of thyroid hormones on the TRH-synthesizing

neurons was first demonstrated by a decrease in TRH content in the median eminence, but not in the PVN of the hypothalamus, after thyroidectomy. This effect can be reversed with exogenous thyroid hormone treatment. The treatment of normal rats with exogenous thyroid hormone decreases TRH concentration in the PVN and the posterior nucleus of the hypothalamus. With a probe against the TRH preprohormone mRNA, *in situ* hybridization studies have demonstrated that TRH mRNA is increased in the PVN 14 days after thyroidectomy. The ability of thyroid hormones to regulate TRH mRNA can be superseded by other stimuli that activate the hypothalamic–pituitary–thyroid (HPT) axis. In that regard, repeated exposure to cold (which releases TRH from the median eminence) induces increases in the levels of TRH mRNA in the PVN despite concomitantly elevated concentrations of thyroid hormones. Further evidence of the different levels of communication of the HPT axis are seen in the ability of TRH to regulate the production of mRNA for the pituitary TRH receptor and for TRH concentrations to regulate the mRNA coding for both the α and β subunits of the thyrotropin (TSH) molecule. In addition, TRH-containing synaptic boutons have been observed in contact with TRH-containing cell bodies in the medial and periventricular subdivisions of the paraventricular nucleus, thus providing anatomical evidence for ultrashort feedback regulation of TRH release. Negative feedback by thyroid hormones may be limited to the hypothalamic TRH neurons because negative feedback on TRH synthesis by thyroid hormones has not been found in extrahypothalamic TRH neurons.

The early availability of adequate tools to assess HPT axis function (i.e., radioimmunoassays and synthetic peptides), coupled with observations that primary hypothyroidism is associated with depressive symptomatology, ensured extensive investigation of the involvement of this axis in affective disorders. Early studies established the hypothalamic and extrahypothalamic distribution of TRH. This extrahypothalamic presence of TRH quickly led to speculation that TRH might function as a neurotransmitter or neuromodulator. Indeed, a large body of evidence supports such a role for TRH. Within the CNS, TRH is known to modulate several different neurotransmitters, including dopamine, serotonin, acetylcholine, and the opioids. TRH has been shown to arouse hibernating animals and counteracts the behavioral response and hypothermia produced by a variety of CNS depressants including barbiturates and ethanol.

The use of TRH as a provocative agent for the assessment of HPT axis function evolved rapidly after its isolation and synthesis. Clinical use of a standardized TRH stimulation test, which measures negative feedback responses, revealed blunting of the TSH response in approximately 25 percent of euthyroid patients with major depression. These data have been widely confirmed. The observed TSH blunting in depressed patients does not appear to be the result of excessive negative feedback due to hyperthyroidism because thyroid measures such as basal plasma concentrations of TSH and thyroid hormones are generally in the normal range in these patients. It is possible that TSH blunting is a reflection of pituitary TRH receptor downregulation as a result of median eminence hypersecretion of endogenous TRH. Indeed, the observation that CSF TRH concentrations are elevated in depressed patients as compared to those of controls supports the hypothesis of TRH hypersecretion but does not elucidate the regional CNS origin of this tripeptide. In fact, TRH mRNA expression in the PVN of the hypothalamus is decreased in patients with major depression. However, it is not clear whether the altered HPT axis represents a causal mechanism underlying the symptoms of depression or simply a secondary effect of depression-associated alterations in other neural systems.

Corticotropin-Releasing Factor (CRF) and Urocortins. There is convincing evidence to support the hypothesis that CRF and the urocortins play a complex role in integrating the endocrine, autonomic, immunological, and behavioral responses of an organism to stress.

Although it was originally isolated because of its functions in regulating the hypothalamic–pituitary–adrenal (HPA) axis, CRF is widely distributed throughout the brain. The PVN of the hypothalamus is the major site of CRF-containing cell bodies that influence anterior pituitary hormone secretion. These neurons originate in the parvocellular region of the PVN and send axon terminals to the median eminence, where CRF is released into the portal system in response to stressful stimuli. A small group of PVN neurons also projects to the brainstem and spinal cord where they regulate autonomic aspects of the stress response. CRF-containing neurons are also found in other hypothalamic nuclei, the neocortex, the extended amygdala, brainstem, and spinal cord. Central CRF infusion into laboratory animals produces physiological changes and behavioral effects similar to those observed following stress, including increased locomotor activity, increased responsiveness to an acoustic startle, and decreased exploratory behavior in an open field.

The physiological and behavioral roles of the urocortins are less understood, but several studies suggest that urocortins 2 and 3 are anxiolytic and may dampen the stress response. This has led to the hypothesis that CRF and the urocortins act in opposition, but this is likely an oversimplification. Urocortin 1 is primarily synthesized in the Edinger–Westphal nucleus, lateral olivary nucleus, and supraoptic hypothalamic nucleus. Urocortin 2 is synthesized primarily in the hypothalamus, while urocortin 3 cell bodies are found more broadly in the extended amygdala, perifornical area, and preoptic area.

Hyperactivity of the HPA axis in major depression remains one of the most consistent findings in biological psychiatry. The reported HPA axis alterations in major depression include hypercortisolemia, resistance to dexamethasone suppression of cortisol secretion (a measure of negative feedback), blunted adrenocorticotrophic hormone (ACTH) responses to intravenous CRF challenge, increased cortisol responses in the combined dexamethasone/CRF test, and elevated CSF CRF concentrations. The exact pathological mechanism(s) underlying HPA axis dysregulation in major depression and other affective disorders remains to be elucidated.

Mechanistically, two hypotheses have been advanced to account for the ACTH blunting following exogenous CRF administration. The first hypothesis suggests that pituitary CRF receptor downregulation occurs as a result of hypothalamic CRF hypersecretion. The second hypothesis postulates altered sensitivity of the pituitary to glucocorticoid negative feedback. Substantial support has accumulated favoring the first hypothesis. However, neuroendocrine studies represent a secondary measure of CNS activity; the pituitary ACTH responses principally reflect the activity of hypothalamic CRF rather than that of the corticolimbic CRF circuits. The latter of the two are more likely to be involved in the pathophysiology of depression.

Of particular interest is the demonstration that the elevated CSF CRF concentrations in drug-free depressed patients are significantly decreased after successful treatment with electroconvulsive therapy (ECT), indicating that CSF CRF concentrations, like hypercortisolemia, represent a state rather than a trait marker. Other recent studies have confirmed this normalization of CSF CRF concentrations following successful treatment with fluoxetine. One group demonstrated a significant reduction of elevated CSF CRF concentrations in 15 female patients with major depression who remained depression free for at least 6 months following antidepressant treatment, as compared to little significant treatment effect on CSF CRF concentrations in 9 patients who relapsed in this 6-month period. This suggests that elevated or increasing CSF CRF concentrations during antidepressant treatment may be the harbinger of a poor response in major depression despite early symptomatic improvement. Of interest, treatment of normal subjects with desipramine or, as noted above, of individuals with depression with fluoxetine is associated with a reduction in CSF CRF concentrations.

If CRF hypersecretion is a factor in the pathophysiology of depression, then reducing or interfering with CRF neurotransmission might be an effective strategy to alleviate depressive symptoms. Over the last several years, a number of pharmaceutical companies have committed considerable effort to the development of small-molecule CRF₁ receptor antagonists that can effectively penetrate the blood–brain barrier. Several compounds have been produced with reportedly promising characteristics.

Oxytocin (OT) and Vasopressin (AVP). The vasopressor effects of posterior pituitary extracts were first described in 1895, and the potent extracts were named AVP. OT and AVP mRNAs are among the most abundant messages in the hypothalamus, being heavily concentrated in the magnocellular neurons of the PVN and the supraoptic nucleus of the hypothalamus, which send axonal projections to the neurohypophysis. These neurons produce all of the OT and AVP that is released into the bloodstream where these peptides act as hormones on peripheral targets. OT and AVP are generally synthesized in separate neurons within the hypothalamus. OT released from the pituitary is most often associated with functions associated with female reproduction, such as regulating uterine contractions during parturition and the milk ejection reflex during lactation. AVP, also known as antidiuretic hormone, regulates water retention in the kidney and vasoconstriction through interactions with vasopressin V₂ and V_{1a} receptor subtypes, respectively. AVP is released into the bloodstream

from the neurohypophysis following a variety of stimuli including plasma osmolality, hypovolemia, hypertension, and hypoglycemia. The actions of OT are mediated via a single receptor subtype (oxytocin receptor, OTR), which is distributed in the periphery and within the limbic CNS. In contrast to the OTR there are three vasopressin receptor subtypes, V1a, V1b, and V2 receptors, each of which are G-protein-coupled, seven-transmembrane domain receptors. The V2 receptor is localized in the kidney and is not found in the brain. The V1a receptor is distributed widely in the CNS and is thought to mediate most of the behavioral effects of AVP. The V1b receptor is concentrated in the anterior pituitary, and some reports describe V1b receptor mRNA in the brain, although its function is unknown.

Neurotensin (NT)

Although NT is found in a number of brain regions, it has been most thoroughly investigated in terms of its association with other neurotransmitter systems, particularly the mesolimbic dopamine system, and has gained interest in research on the pathophysiology of schizophrenia. There are several lines of evidence suggesting that NT and its receptors should be considered as potential targets for pharmacological intervention in this disorder. First, the NT system is positioned anatomically to modulate the neural circuits implicated in schizophrenia. Second, peripheral administration of antipsychotic drugs has been shown to consistently modulate NT systems. Third, there is evidence that central NT systems are altered in patients with schizophrenia.

NT was first shown to interact with dopamine systems while undergoing characterization of its potent hypothermic-potentiating and sedative-potentiating activities. Subsequent work indicated that NT possessed many properties that were also shared by antipsychotic drugs, including the ability to inhibit avoidance, but not escape responding in a conditioned active avoidance task; the ability to block the effects of indirect dopamine agonists or endogenous dopamine in the production of locomotor behavior; and the ability to elicit increases in dopamine release and turnover. Perhaps most importantly, both antipsychotic drugs and NT neurotransmission enhance sensorimotor gating. Sensorimotor gating is the ability to screen or filter relevant sensory input, deficits in which may lead to an involuntary flooding of indifferent sensory data. Increasing evidence suggests that deficits in sensorimotor gating are a cardinal feature of schizophrenia. Both dopamine agonists and NT antagonists disrupt performance on tasks designed to gauge sensorimotor gating. Unlike antipsychotic drugs, NT is not able to displace dopamine from its receptor. As noted earlier, NT is colocalized in certain subsets of dopamine neurons and is co-released with dopamine in the mesolimbic and medial prefrontal cortex dopamine terminal regions that are implicated as the sites of dopamine dysregulation in schizophrenia. Antipsychotic drugs that act at D₂ and D₄ receptors increase the synthesis, concentration, and release of NT in those dopamine terminal regions but not in others. That effect of antipsychotic drugs in increasing NT concentrations persists after months of treatment and is accompanied by the expected increase in NT mRNA concentrations as well as expression of the "immediate early gene" c-fos within hours of initial drug treatment. The altered regulation of NT expression by antipsychotic drugs apparently extends to the peptidases that degrade the peptide, because recent reports have revealed decreased NT metabolism in rat brain slices 24 hours after the acute administration of haloperidol. When administered directly into the brain, NT preferentially opposes dopamine transmission in the nucleus accumbens but not the caudate putamen. In the nucleus accumbens, NT receptors are located predominantly on GABAergic neurons, which release GABA on dopamine terminals, thereby inhibiting release.

Decreased CSF NT concentrations have been reported in several populations of patients with schizophrenia when compared to those of controls or other psychiatric disorders. Although treatment with antipsychotic drugs has been observed to increase NT concentrations in the CSF, it is not known whether this increase is causal or merely accompanies the decrease in psychotic symptoms seen with successful treatment. Postmortem studies have shown an increase in NT concentrations in the dopamine-rich Brodmann's area 32 of the frontal cortex, but that result may have been confounded by premortem antipsychotic treatment. Other researchers have found no postmortem alterations in NT concentrations of a wide sampling of subcortical regions. Decreases in NT receptor densities in the entorhinal cortex have been reported in entorhinal cortices of schizophrenic postmortem samples. A critical test of the hypothesis that NT may act as an endogenous antipsychotic-like substance awaits the development of an NT receptor agonist that can penetrate the blood-brain barrier.

Other Neuropeptides

A number of other neuropeptides have been implicated in the pathophysiology of psychiatric disorders. These include, but are not limited to, cholecystokinin (CCK), substance P, and neuropeptide Y.

CCK, originally discovered in the gastrointestinal tract, and its receptor are found in areas of the brain associated with emotion, motivation, and sensory processing (e.g., cortex, striatum, hypothalamus, hippocampus, and amygdala). CCK is often colocalized with dopamine in the VTA neurons that comprise the mesolimbic and mesocortical dopamine circuits. Like NT, CCK decreases dopamine release. Infusions of a CCK fragment have been reported to induce panic in healthy individuals, and patients with panic disorder exhibit increased sensitivity to the CCK fragment compared to that of normal controls. Pentagastrin, a synthetic CCK agonist, dose-dependently produced increased blood pressure, pulse, HPA activation, and physical symptoms of panic. Recently, a CCK receptor gene polymorphism has been associated with panic disorder.

The undecapeptide substance P is localized in the amygdala, hypothalamus, periaqueductal gray, LC, and parabrachial nucleus and is colocalized with norepinephrine and serotonin. Substance P serves as a pain neurotransmitter, and administration to animals elicits behavioral and cardiovascular effects resembling the stress response. More recent data suggest a role for substance P in major depression and PTSD. Both depressed and PTSD patients had elevated CSF substance P concentrations. Furthermore, in PTSD patients, marked increases in CSF substance P concentrations were detected following precipitation of PTSD symptoms. One study has indicated that a substance P receptor (termed the neurokinin 1 [NK1] receptor) antagonist capable of passing the BBB is more effective than placebo and as effective as paroxetine in patients with major depression with moderate to severe symptom severity, although subsequent studies have been unable to confirm these findings.

Neuropeptide Y (NPY) is a 36 amino acid peptide found in the hypothalamus, brainstem, spinal cord, and several limbic structures and is involved in the regulation of appetite, reward, anxiety, and energy balance. NPY is colocalized with serotonergic and noradrenergic neurons and is thought to facilitate the containment of negative effects following exposure to stress. Suicide victims with a diagnosis of major depression are reported to have a pronounced reduction in NPY levels in the frontal cortex and caudate nucleus. Furthermore, CSF NPY levels are decreased in depressed patients. Chronic administration of antidepressant drugs increases neuropeptide Y concentrations in the neocortex and hippocampus in rats. Plasma NPY levels were found to be elevated in soldiers subjected to the "uncontrollable stress" of interrogation, and NPY levels were correlated with the feelings of dominance and confidence during the stress. In addition, low NPY response to stress has been associated with increased vulnerability to depression and PTSD.

NOVEL NEUROTRANSMITTERS

Nitric Oxide

The discovery that gases could function as neurotransmitters revealed that highly atypical modes of signaling existed between neurons. In the early 1990s, nitric oxide was the first gas to be ascribed a neurotransmitter function and proved to be an atypical neurotransmitter for several reasons. First, it was not stored in or released from synaptic vesicles, as it was a small gas it could freely diffuse into the target neuron. Second, its target was not a specific receptor on the surface of a target neuron, but intracellular proteins whose activity could directly be modulated by nitric oxide, leading to neurotransmission. Nitric oxide also lacks a reuptake mechanism to remove it from the synapse. Although enzymatic inactivation of it is postulated to exist, nitric oxide appears to have a very short half-life of a few seconds.

Nitric oxide was initially discovered as a bactericidal compound released from macrophages, and as an endothelial cell it derived relaxation factor allowing for the dilation of blood vessels. A role for nitric oxide in the brain followed, revealing a role for the gas in neurotransmission, learning and memory processes, neurogenesis, and neurodegenerative disease.

Nitric Oxide and Behavior

Nitric oxide neurotransmission can play a role in behavior, as neuronal nitric oxide synthase (nNOS)-deficient male mice display exaggerated aggressive tendencies and increased sexual activity. In female mice the contrary is true, as they have reduced aggression. As

manic bipolar patients may show both hypersexuality and aggression, the nitric oxide pathway may participate in the psychopathology of affective states.

In the periphery, nNOS localizes to neurons that innervate blood vessels of the penis, including the corpus cavernosa. Stimulation of these nerves releases nitric oxide, leading to cyclic guanosine monophosphate (cGMP) formation, blood vessel wall relaxation and vasodilation, penile engorgement, and initial erection. The sustained phase of erection also depends on nitric oxide; turbulent blood flow leads to phosphorylation of eNOS and sustained nitric oxide production. Drugs used in treatment of erectile dysfunction—sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra)—act to inhibit phosphodiesterase type 5 (PDE5), an enzyme that degrades cGMP in the penis (Fig. 1.4-12), thereby potentiating nitric oxide neurotransmission and penile erection.

FIGURE 1.4-12

Neurotransmitter and signaling functions of nitric oxide (NO) via production of cyclic guanosine monophosphate (cGMP). Gaseous nitric oxide is enzymatically generated and freely diffuses into an adjacent neuron (upper right). In comparison to traditional neurotransmitters (upper left), nitric oxide (NO) does not act via a specific neurotransmitter receptor on the surface membrane of a neuron. In contrast, NO freely diffuses across the neuronal membrane and activates the enzyme, guanylyl cyclase, which converts guanosine 5'-triphosphate (GTP) into the second messenger, cGMP. Nitric oxide effects are mediated, in part, by cGMP activation of neuronal protein kinases, new gene expression, and effects on neuronal long-term potentiation (LTP) and long-term depression (LTD). ATP, adenosine triphosphate. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:104.)

Numerous lines of evidence have suggested a role for nitric oxide in the regulation of sleep-wake cycles. nNOS expressing neurons occur in several areas that initiate REM sleep, including the pons, dorsal raphe nucleus, laterodorsal tegmentum, and pedunculopontine tegmentum. In animal models, microinjection of compounds that release nitric oxide result in decreased wakefulness and increased slow wave sleep. Consistent with this, NOS inhibitors show a trend toward decreasing slow wave and REM sleep. Studies of NOS-deficient mice suggest that nitric oxide may serve a more complex role than merely promoting sleep. nNOS-deficient animals also show reduced REM sleep; however, inducible nitric oxide synthase (iNOS)-deficient mice demonstrate the reverse, suggesting a complex interplay between NOS enzymatic isoforms.

Nitric Oxide and Mood Disorders. NOS-expressing neurons are well represented in areas implicated in depression, including the dorsal raphe nucleus and prefrontal cortex. A role for nitric oxide has been suggested in antidepressant response, as SSRI antidepressants can directly inhibit NOS activity. Moreover, in animal studies such as the forced swim test, NOS and soluble guanylyl cyclase inhibitors can achieve antidepressant-like effects. Plasma nitric oxide levels were elevated in patients with bipolar disorder compared to healthy controls. However, in depressed subjects, studies have found decreased nitric oxide levels and increased plasma nitrite, a byproduct of nitric oxide. Reduced NOS has also been described in the paraventricular nucleus of patients with schizophrenia and depression compared to controls.

Nitric oxide has been questioned as to its ability to regulate neurotransmission at serotonin, norepinephrine, and dopamine nerve termini. However, there has been no clear consensus, and nitric oxide appears to be able to increase or decrease activity at these neurons depending on the timing of its activation and the region of the brain studied.

Nitric Oxide and Schizophrenia. Nitric oxide has been investigated as a candidate molecule contributing to symptoms of schizophrenia. Two genetic studies have identified schizophrenia-associated single nucleotide polymorphisms (SNPs) in CAPON, a protein that associates with nNOS. SNPs in nNOS itself have been associated with schizophrenia, although others have not been able to reproduce such findings. Changes in NOS levels have been reported in postmortem brain samples of individuals with schizophrenia. Abnormalities have been noted in the cortex, cerebellum, hypothalamus, and brainstem, although no specific trend can be discerned. Elevated NOS activity has been noted in platelets from drug-naïve and drug-treated individuals with schizophrenia. Some investigators find increased nitric oxide activity and others the reverse. In autopsy samples, schizophrenic patients were found to have abnormally localized NOS expressing neurons in the prefrontal cortex, hippocampus, and lateral temporal lobe, consistent with abnormal migration of these neuronal types during development. In a rat model, prenatal stress led to reduced NOS expressing neurons in the fascia dentate and hippocampus.

Neuropathological Roles of Nitric Oxide. Abundant evidence exists that nitric oxide is a direct participant in a variety of neuropathic events. Superoxide, a byproduct of cellular metabolism, can react with nitric oxide to form peroxynitrite (chemical formula ONOO⁻). This labile and toxic compound forms chemical adducts with protein tyrosine residues, a process termed *protein nitration*, and deoxyribonucleic acid (DNA), leading to cellular dysfunction.

Cell loss resulting from ischemic stroke is mediated in part by overstimulation of the glutamate NMDA receptor, a process termed *excitotoxicity*. Nitric oxide produced by NMDA activation appears to mediate a significant portion of this excitotoxic neuronal death, and stroke damage is reduced in mice with a genetic deletion of nNOS.

S-Nitrosylation has also been implicated in pathologic processes in the brain. Mutations in the Parkin protein are associated with early onset Parkinson's disease. Parkin is an E3 ubiquitin ligase, adding ubiquitin molecules to proteins and targeting them for destruction in the cell proteasome. In sporadic Parkinson's disease (i.e., without the early onset mutation), nitric oxide can nitrosylate the Parkin protein and inhibit its protective E3 ubiquitin ligase function. An overabundance of nitric oxide signaling may thus predispose to the dysfunction and cell death of dopaminergic neurons in Parkinson's disease by interfering with proteins essential for cell functioning. In Alzheimer's disease excess oxidation of brain protein, lipids, and carbohydrates has long been appreciated, but nitrosative stress from excess nitric oxide also appears to participate in the disease. Protein disulfide isomerase (PDI) is a cellular protective protein that may help combat the accumulation of misfolded proteins such as the amyloid fibrils occurring in the disease. In both Alzheimer's and Parkinson's disease brains, PDI appears to be S-nitrosylated in a harmful way that impedes its cellular protective function.

The discovery that nitric oxide participates in neurodegenerative processes raises the possibility for improved diagnostic processes, such as detecting damage to cellular components produced by nitric oxide prior to the onset of full-blown symptoms. In addition, drugs may be designed to attenuate the damage to crucial neuronal proteins that protect against disease onset. However, completely and nonspecifically inhibiting or stimulating NOS is likely to produce significant side effects because of its wide-ranging activities throughout the body.

Carbon Monoxide

Although carbon monoxide (CO) is most well known as an air pollutant derived from combustion reactions, it is produced physiologically in a great variety of organisms ranging from human to bacterium. Once thought to be a toxic byproduct of metabolic reactions, carbon monoxide is increasingly recognized to play an important role in regulating a variety of physiological processes in the brain and other organs. These varied effects include regulation of olfactory neurotransmission, blood vessel relaxation, smooth muscle cell proliferation, and platelet aggregation.

Carbon monoxide is far better known for its toxic effects than its activities at physiologic concentrations. It binds tightly to heme molecules within hemoglobin, forming carboxyhemoglobin, which can no longer transport oxygen to tissues. One- to two-pack per day smokers typically have 3 to 8 percent of their hemoglobin as carboxyhemoglobin, with nonsmokers having less than 2 percent. Following acute carbon monoxide poisoning, 5 to 10 percent carboxyhemoglobin is associated with impaired alertness and cognition, and 30 to 50 percent carboxyhemoglobin leads to significant drops in oxygen transport to tissues.

Carbon Monoxide and Neurotransmission. Carbon monoxide appears to participate in the neurotransmission of odorant perception. Odorants lead to carbon monoxide production and subsequent cGMP synthesis that promotes long-term adaptation to odor stimuli. Carbon monoxide has the potential to regulate a variety of perceptual and cognitive processes that are yet untested. Similarly, in the rat retina, long periods of light exposure led to increased HO1 expression, carbon monoxide production, and cGMP signaling. Carbon monoxide may also participate in adaptation to chronic pain. HO2-deficient animals manifest reduced hyperalgesia and allodynia after exposure to chronic pain stimuli. Carbon monoxide may thus set the threshold for pain perception, although it is unclear whether the effect occurs in the central or peripheral nervous system. Aside from its role in promoting cGMP production, carbon monoxide may also directly bind to and open the calcium-activated big potassium (BK_{Ca}) channel, leading to as yet uncharacterized effects on neurotransmission.

In the gastrointestinal (GI) nervous system, carbon monoxide serves as a neurotransmitter to relax the internal anal sphincter in response to nonadrenergic noncholinergic (NANC) nerve stimulation and vasoactive intestinal peptide (VIP).

Carbon monoxide has been implicated in the development of hippocampal LTP, although lines of evidence are contradictory. Carbon monoxide and tetanic stimulation of nerves leads to increased excitatory postsynaptic potentials (EPSPs). HO inhibitors that block carbon monoxide production lead to impaired induction of LTP and reduced calcium-dependent release of glutamate neurotransmitter. However, HO2-deficient animals fail to manifest any differences in LTP. These disparate findings may be explained by a role for HO1 in LTP, or an ability of HO inhibitors to nonspecifically block some other processes important to LTP induction.

At toxic levels, carbon monoxide is well known to impair oxygen transport by binding to hemoglobin with a higher affinity than oxygen. Amazingly, carbon monoxide itself plays a physiological role in the mechanism by which the carotid body senses oxygen. HO, expressed in glomus cells of the carotid body, uses oxygen as a substrate in the production of carbon monoxide (Fig. 1.4-13). When oxygen levels drop, so does carbon monoxide production, leading to a resetting of the threshold in which the carotid body senses oxygen. The molecular mechanism may occur via carbon monoxide regulation of the carotid body BK ion channel.

FIGURE 1.4-13

Synthesis of carbon monoxide (CO), an unexpected neurotransmitter. Gaseous carbon monoxide is enzymatically synthesized in neurons by way of the enzyme heme oxygenase, also converting heme into the molecule biliverdin and liberating free iron (Fe). Similar to nitric oxide, CO is not stored in neuronal vesicles and can freely diffuse across neuronal membranes. CO also similarly activates soluble guanylyl cyclase, and leads to activation of multiple intracellular signaling molecules such as p38 MAP kinase. CO exerts its neurotransmitter and signaling functions at concentrations far below that at which classical CO toxicity occurs. The significance of this pathway in neurons is underlined by the existence of two distinct heme oxygenase enzymes, one of which is predominantly expressed in the brain. Biliverdin is converted to bilirubin via the enzyme biliverdin reductase. Similar to CO, bilirubin is no longer relegated to the status of toxic byproduct and may be an important antioxidant. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:107.)

Endocannabinoids: From Marijuana to Neurotransmission

Whether known as cannabis, hemp, hashish, ma-fen, or a variety of slang terms, marijuana has been cultivated and utilized by human populations for thousands of years. Despite long debate as to whether its risks and benefits are evenly matched, it has only been in recent decades that some of the mystery has been revealed by which marijuana exerts its effects on the brain. The “high” users experience, euphoria and tranquility, relates to cannabis acting on a neural pathway involving cannabinoids endogenous to the human brain, or endocannabinoids.

The first described medicinal use of cannabis dates to approximately 2700 BC in the pharmacopeia of Chinese Emperor Shen Nung, who recommended its use for a variety of ailments. At this time, adverse properties were also apparent, and large amounts of the fruits of hemp could lead to “seeing devils,” or a user might “communicate with spirits and lighten one’s body.” For centuries, cannabis was employed in India as an appetite stimulant; habitual marijuana users remain well acquainted with “the munchies.”

For many years the mechanisms by which the active components of marijuana, *cannabinoids*, exerted their psychoactive effects remained a mystery. Chemists sought to isolate the psychoactive components of cannabis from the many components of the plant oil (Table 1.4-4).

Table 1.4-4
Selected Discoveries in Cannabinoid Research

- 1899: Cannabinol isolated from cannabis resin
- 1940: Identification of cannabinol structure
- 1964: Discovery of the structure of δ -9-tetrahydrocannabinol (THC), the most psychoactive component of cannabis
- 1988: Specific THC binding sites identified in brain
- 1990: Identification of a brain cannabinoid receptor, CB1
- 1992: Discovery of the first endogenous brain endocannabinoid, anandamide
- 1993: Identification of a second cannabinoid receptor, CB2
- 1994: Rimonabant (Acomplia), a CB1 receptor blocker is developed
- 1995: Report of a second endocannabinoid, 2-AG
- 1996: Fatty acid amide hydrolase (FAAH), an endocannabinoid degrading enzyme, is discovered
- 2003: FAAH inhibitors reduce anxiety-like behaviors in animal studies
- 2003: Identification of enzymes that synthesize endocannabinoids
- 2006: Monoacylglycerol lipase (MAGL), a second endocannabinoid-degrading enzyme, is found
- 2006: Rimonabant approved for use in Europe for weight loss
- 2007: Rimonabant meta-analysis finds increased anxiety and depressive symptoms in humans without a history of psychiatric illness

From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:109.

Discovery of the Brain Endocannabinoid System. Estimates suggest that 20 to 80 μ g of tetrahydrocannabinol (THC) reaches the brain after one smokes a marijuana cigarette (i.e., “joint”). This is comparable to the 100 to 200 μ g of norepinephrine neurotransmitter present in the entire human brain. Thus the effects of THC might be explained by the effects on neurotransmitter systems. In the 1960s, there were at least two schools of thought on how THC exerted its psychoactive effects. One held that THC worked in a manner similar to that of the inhaled volatile anesthetics (i.e., no specific receptor existed), and it might have a generalized effect on neuronal membranes or widespread actions on neurotransmitter receptors. A competing school of thought speculated that specific receptors for cannabinoids existed in the brain, but they were difficult to identify due to the lipophilic nature of these chemicals. Novel cannabinoids were synthesized that were more water soluble, and in the late 1980s, this allowed for the discovery of a specific cannabinoid receptor, CB1.

Several additional endocannabinoids were soon discovered, 2-arachidonoylglycerol (2-AG), *N*-arachidonyldopamine (NADA), 2-arachidonoylglycerol ether (noladin ether), and virodhamine (Fig. 1.4-14). The reason for having several different endocannabinoids may lie with their differing affinities for the cannabinoid receptors, CB1 and CB2. Anandamide appears to have the greatest selectivity for the CB1 receptor, followed by NADA and noladin ether. In contrast, virodhamine prefers CB2 receptors and has only partial agonist activity at CB1. 2-AG appears not to discriminate between CB1 and CB2.

Endogenous Cannabinoids

FIGURE 1.4-14

Endogenous cannabinoids. At least five endocannabinoids exist in the mammalian brain, each differing in affinity for CB1 and CB2 cannabinoid receptors. All are derived from the essential omega-6 fatty acid, arachidonic acid, which is also a substrate in the formation of prostaglandins and leukotrienes. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:111.)

Biosynthesis of Endocannabinoids. Arachidonic acid is utilized as a building block for biosynthesis of endocannabinoids, prostaglandins, and leukotrienes and is found within cellular phospholipids of the plasma membrane and other intracellular membranes. Synthesis of anandamide requires the sequential action of two enzymes (Fig. 1.4-15). In the first reaction the enzyme *N*-acetyltransferase (NAT) transfers an arachidonic acid side chain from a phospholipid to phosphatidylethanolamine (PE), generating NAPE (*N*-arachidonoyl-phosphatidylethanolamine). In the second reaction the enzyme *N*-arachidonoyl-phosphatidylethanolamine phospholipase (NAPD-PLD) converts NAPE to anandamide. Because NAPE is already a natural component of mammalian membranes, it is the second step that generates anandamide, which is most crucial to neurotransmission.

FIGURE 1.4-15

Retrograde neurotransmission of the endocannabinoids, anandamide, and 2-arachidonylglycerol (2-AG). Anandamide is synthesized on demand for neurotransmission via a two-step process. The enzyme NAT transfers the arachidonic acid chain from a phospholipid (APL) to phosphatidylethanolamine (PE), thereby producing NAPE. A second enzyme, NAPE-PLD, generates anandamide. 2-AG is similarly synthesized in two steps by the enzymes PLC and DAGL. The endocannabinoids made in a postsynaptic neuron cross the synapse and activate presynaptic CB1 receptors, and suppress neurotransmission of the presynaptic neuron (although activation of the presynaptic neuron occurs in some cases). Enzymes involved in endocannabinoid synthesis are *yellow*, those that break them down in *red*. 2-AG is predominantly inactivated in the presynaptic neuron by MAGL, whereas anandamide is destroyed in the postsynaptic neuron by FAAH. PE, phosphatidylethanolamine; APL, arachidonyl phospholipids; NAT, *N*-acyltransferase; NAPE, *N*-arachidonyl-phosphatidylethanolamine; NAPE-PLD, *N*-arachidonyl-phosphatidylethanolamine phospholipase D; FAAH, fatty acid amide hydrolase; MAGL, monoacylglycerol lipase; PLC, phospholipase C; DAG, diacylglycerol; DAGL, diacylglycerol lipase; R₁-R₃, various acyl or alkyl side chains of phospholipids; R', side chain of phospholipid head group. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:112.)

Endocannabinoids are not stored in synaptic vesicles for later use, but are synthesized on demand as is done for the gaseous neurotransmitters. An important criterion for a signaling molecule to be considered a neurotransmitter is that neuronal depolarization should lead to its release. Depolarization leads to increases in cellular calcium, which in turn promotes synthesis of the endocannabinoids and their release. The mechanism is explained in part by calcium activation of NAPE-PLD and DAGL, leading to augmented biosynthesis of anandamide and 2-AG, respectively.

Endocannabinoids generated in a neuron must cross the synaptic cleft to act on cannabinoid receptors. Similar to THC, endocannabinoids are highly lipophilic and thus poorly soluble in CSF. It is hypothesized that a specific endocannabinoid transporter exists to allow endocannabinoids to cross the synaptic cleft and allow entry into the target neuron.

Inactivation of Endocannabinoids. Neurotransmitters are typically inactivated either by reuptake from the neurons that release them or by degradation by highly specific enzymes, such as the example of acetylcholine being hydrolyzed by acetylcholinesterase. At least two enzymes exist to target the destruction of endocannabinoids and attenuate their neurotransmission. Fatty acid amide hydrolase (FAAH) converts anandamide to arachidonic acid and ethanolamine (Fig. 1.4-15). FAAH is found in regions of the brain where CB1 receptors are predominant and localizes to postsynaptic neurons where anandamide is made. Rapid degradation of anandamide in part explains its relatively low potency compared to THC. Confirming a role of FAAH in anandamide inactivation, knockout mice without FAAH exhibit a 15-fold increase of anandamide, but not 2-AG. These mice have greater behavioral responses to exogenous anandamide, owing to its

decreased degradation. The endocannabinoid 2-AG is inactivated by FAAH, but also by a monoacylglycerol lipase (MAGL) located in presynaptic neurons.

Pharmacologic inhibitors of FAAH have analgesic effects and reduce anxiety in animal models, but do not have the undesirable effects of THC such as immobility, lowered body temperature, or greater appetite. Such a pharmacological strategy would be analogous to MAOIs and COMT inhibitors (COMTIs). MAOIs, used to treat depression, slow the breakdown of serotonin and other monoamines, thereby increasing serotonin, whereas COMTIs serve an analogous role in blocking destruction of dopamine and other catecholamines.

Cannabinoid Receptors. Underscoring their importance in neural functions, CB1 receptors are possibly the most abundant G-protein-coupled receptors in the brain. They occur at highest density in the basal ganglia, cerebellum, hippocampus, hypothalamus, anterior cingulate cortex, and cerebral cortex, particularly the frontal cortex. Humans or animals that receive large doses of THC develop catalepsy, a reduction of spontaneous movement, and freeze in bizarre and unnatural postures. The action of cannabinoids in the basal ganglia and cerebellum may be associated with these behaviors, which may prove relevant in understanding catatonic symptoms in schizophrenia.

CB1 receptors are predominantly found on axons and nerve termini, with little present on neuronal dendrites and the cell body. CB1 receptors tend to be localized to the presynaptic rather than postsynaptic side of the neuronal cleft, suggesting a role in regulation of neurotransmission. A second cannabinoid receptor, CB2, is predominantly expressed on the surface of white blood cells of the immune system, but small amounts appear to be present in the brainstem.

EFFECTS ON NEUROTRANSMISSION. The cannabinoid CB1 receptor is associated with G proteins that mediate its intracellular signaling, in part, through inhibition of adenylyl cyclase. This leads to a decrease in levels of the important second messenger, cyclic adenosine monophosphate. Activation of the CB1 receptor also leads to activation of potassium channels and inhibition of N-type calcium channels. Because calcium is integral to neurotransmitter release, cannabinoids can block neurotransmission through this mechanism. Cannabinoid receptors also activate mitogen-activated protein kinases.

With the use of cell culture models and slices of brain, cannabinoids have been shown to block the release of a variety of neurotransmitters, including GABA, norepinephrine, and acetylcholine. Norepinephrine and acetylcholine tend to be excitatory neurotransmitters, and cannabinoid inhibition of their release would be expected to have an overall inhibitory effect. However, GABA is an inhibitory neurotransmitter, and cannabinoid inhibition of it would lead to overall excitatory effects, demonstrating that cannabinoids can have complex effects on neurotransmission depending on the specific context. Cannabinoids also appear to increase the release of brain endorphin neurotransmitters and increase dopamine release in the nucleus accumbens, a "reward center" relevant to addiction and learning. The endocannabinoids have been implicated in a variety of forms of synaptic plasticity, including LTP and long-term depression (LTD).

Endocannabinoids in Anxiety and Mood. Endocannabinoid neurotransmission may be an important regulator of anxiety, and cannabis users regularly describe a tranquilizing effect of THC. Loss of signaling by the endocannabinoid system appears to promote anxiety-like states in animal studies. CB1 receptor-deficient animals exhibit more pronounced anxiety behavior when exposed to stress or new environs.

The endocannabinoid pathway may represent an attractive target in understanding posttraumatic stress responses and phobias. Although one cannot yet safely measure endocannabinoid levels in human subjects, this model is supported by clinical trials of the cannabinoid receptor blocker, rimonabant (Acomplia), which may offer promise as a strategy for weight loss (see below). A frequent adverse reaction to the drug is increased anxiety and depression.

ADDICTION. The endocannabinoid system may be an attractive target for understanding addiction. Mice deficient in CB1 receptors are unsurprisingly resistant to the behavioral effects of cannabinoids; they also appear to have reduced addiction to and withdrawal from opiates. Further interaction has also been found between the opioid and cannabinoid systems, as cannabinoids appear to increase the release of dopamine in the nucleus accumbens, a key reward area of the brain implicated in addiction. This dopamine release appears to require μ -opioid receptors, as pharmacological inhibition of these receptors blocks the ability of cannabinoids to increase dopamine release. Rats with a preference for alcohol have decreased FAAH activity, suggestive of greater cannabinoid signaling. CB1 receptor antagonists dampen their alcohol consumption, whereas inhibiting FAAH increases their alcohol consumption. Furthermore, CB1-deficient animals also appear to have reduced alcohol intake. A single amino acid mutation in human FAAH has been found to be associated with drug abuse, and this abnormal enzyme appears to be less stable than its wild-type counterpart.

Endocannabinoids in Psychosis. Heavy use of cannabis can produce psychotic symptoms in individuals with no prior history of psychiatric disorder, although it is unclear whether this is solely due to the drug or to an underlying vulnerability to psychosis in such persons. Cannabis use often worsens psychosis in schizophrenia, and heavy use has been associated with developing schizophrenia, although some suggest that this association is an accelerated development of symptoms in those who would eventually manifest schizophrenia. Nonetheless, the endocannabinoid system has implications for the pathophysiology of schizophrenia, as cannabinoid signaling appears to increase the release of dopamine. Medications that act as antagonists of D_2 receptors will likely remain a component of schizophrenia treatment for some time.

FEEDING. Following drug ingestion, THC users develop an increased appetite ("the munchies"), and cannabis has been utilized as an appetite stimulant for centuries. This effect may depend on CB1 receptors present in the hypothalamus. Endocannabinoid levels increase in the hypothalamus and limbic system when animals are deprived of food. Mice genetically deficient in CB1 receptors become resistant to developing obesity after being given a high-fat diet. Similarly, the CB1 receptor antagonist, rimonabant, appears to facilitate weight loss by blocking cannabinoid signaling. In a clinical trial of more than 3,000 obese patients, those treated with 20 mg per day of rimonabant lost 6.3 kg at 1 year, compared to 1.6 kg in the placebo group. Nausea was the most common side effect reported. A 2007 meta-analysis of clinical trials reported an overall 4.7 kg weight loss with rimonabant treatment, besting the weight-loss drugs orlistat (Xenical; 2.9 kg) and sibutramine (Meridia; 4.2 kg).

Effects on Brain Injury and Pain. In mouse models of traumatic brain injury, 2-AG appears neuroprotective, reducing brain edema, infarct size, and cell death, while improving functional outcomes. Anandamide also protected against brain injury in a model of multiple sclerosis (MS), and human patients with the disease have increased production of anandamide. A study of cannabinoid agonist, HU-211, led to more rapid clinical improvement following head trauma. FAAH inhibitors improved motor symptoms in a mouse model of Parkinson's disease, likely via cannabinoids increasing dopamine neurotransmission.

There is increasing evidence that neurotransmission via the endocannabinoid pathway regulates pain perception. THC and cannabinoid agonists have proven effective in animal models of acute and chronic pain, ranging from burn injury to nerve damage and inflammation. The CB1 receptor plays an important role in these effects, as the analgesic effects of cannabinoid drugs are lost when CB1 antagonist rimonabant is given. Similarly, the analgesic effect of THC is lost in mice that are genetically deficient in the CB1 receptor.

Stress has long been associated with diminished pain perception, such as in cases of injured military personnel who demonstrate remarkable pain tolerance, a phenomenon known as *stress-induced analgesia*. The endocannabinoid system may mediate these effects. Animal models reveal anandamide and 2-AG production after stress, and stress-induced analgesia is blocked by the CB1 blocker, rimonabant, in these animals.

Endocannabinoid regulation of pain perception appears to be distinct from that of the endogenous opiate system, but the two pathways

may share overlapping neural pathways. Evidence for this has been provided using CB1 blocker, rimonabant, and naloxone (Narcan), which blocks opiate receptors. Rimonabant attenuates analgesia provided by THC and cannabinoids, but only partly blocks the response to morphine. However, the opposite is true for opiates: Naloxone blocks morphine-induced analgesia but also partially blocks the analgesia of THC and cannabinoid drugs. Combinations of cannabinoid and opiate drugs evince synergistic analgesic effects in animal models.

Although it was initially assumed that cannabinoids exert their analgesic effects via the CNS, in animal models it has been shown that localized administration of cannabinoids may also be effective, including drugs selective for the CB2 receptor, whose expression is minimal in the CNS.

Endocannabinoids may also influence pain sensitivity by mechanisms that do not involve the CB1 and CB2 receptors. Both anandamide and NADA can also activate a calcium channel known as the vanilloid receptor (also known as transient receptor potential vanilloid type 1 [TRPV-1]) that is found on sensory nerves. This same receptor is also famous for being activated by capsaicin, which causes the hot sensation after eating chili peppers. Thus endocannabinoids can exert opposing functions: Promoting analgesia through the CB1 and CB2 receptors, but potentially increasing pain via TRP channels. Although CB2 receptors are largely expressed in the periphery, postmortem analyses reveal an upregulation in brain from those with Alzheimer's disease.

The rapid development of novel cannabinoid drugs may allow for targeting of specific symptoms, rather than elicit all of the typical effects of THC. For instance, ajulemic acid demonstrates analgesic and anti-inflammatory properties, but may offer a benefit of limited psychoactive side effects. In a randomized clinical trial of this compound, Mathias Karst and colleagues found efficacy in reducing chronic neuropathic pain.

Effects in the Periphery. Cannabinoids lead to direct relaxation of vascular smooth muscle by local CB1 receptors. This vasodilation extends to the conjunctiva, leading to a "bloodshot" appearance in some cannabis users. Relaxation of ocular arteries by cannabinoids may offer utility as a treatment for glaucoma, a condition of high intraocular pressure, and activation of CB1 receptors in the kidney can improve renal blood flow. A role in generalized blood pressure regulation is unproven, and blood pressure is unaltered in persons treated with rimonabant or animals deficient in CB1 receptors. Cannabinoid signaling may also be relevant to ectopic pregnancy, as CB1-deficient mice retain many embryos in the oviduct.

Nonpsychoactive Cannabinoids

Although THC is the principal psychoactive component of cannabis, the many nonpsychoactive cannabinoids also have intriguing properties and may regulate neurotransmission.

Cannabidiol may offer potential therapeutic effects and appears to stimulate TRPV-1 receptors and influence endocannabinoid degradation. In addition, cannabidiol demonstrated a protective effect in a mouse model of inflammatory arthritis. Although results have been mixed, purified cannabidiol may also exert antipsychotic activity, although the net effect of plant cannabis use typically exacerbates schizophrenia symptoms owing to THC. Tetrahydrocannabinol is a plant cannabinoid that antagonizes CB1 receptors. It is a candidate marker to distinguish whether a patient has been using plant-derived cannabis or prescription THC, which contains no tetrahydrocannabinol.

Eicosanoids

Overview. Clinical findings suggest that the dietary supplements omega-3 fatty acids, eicosapentaenoic acid (EPA), its ester ethyl-eicosapentaenoic (E-EPA), and docosahexaenoic acid (DHA), help relieve symptoms of depression, bipolar illness, schizophrenia, and cognitive impairment. DHA and EPA may help reduce behavioral outbursts and improve attention in children.

Chemistry. Essential fatty acids are a group of polyunsaturated fats that contain a carbon-carbon double bond in the third position from the methyl end group in the fatty acid chain. They are essential because unlike monosaturated and saturated fatty acids, polyunsaturated fatty acids cannot be synthesized *de novo* and can be acquired only through diet from natural fats and oils. Linoleic acid (LA) is the parent compound of omega-6 fatty acids, and α -linolenic acid (ALA) is the parent compound of omega-3 fatty acids. Both omega-3 and omega-6 groups use the same enzymes for desaturation and chain elongation. Omega-3 fatty acids are synthesized by algae and plankton. Fish such as herring, salmon, mackerel, and anchovy feed on these aquatic species and become a rich dietary source of omega-3. EPA and DHA are highly unsaturated omega-3 fatty acids that contain 6 and 5 double bonds on their long structural chain, respectively. They are positioned in the cell membrane by phospholipids and play a crucial role in cell membrane signaling.

Effects on Specific Organs and Systems. The strongest scientific evidence for treatment with fatty acid supplements comes from the cardiovascular literature. Several human trials have demonstrated that omega-3 fatty acids lower blood pressure, reduce the rate of recurrent myocardial infarction, and lower triglyceride levels. In the nervous system, fatty acids are essential components of neurons, immune cells, and glial phospholipid membrane structures. They increase cerebral blood flow, decrease platelet aggregation, and delay progression of atherosclerosis in the cardiovascular system. Omega-6 fatty acids appear to reduce inflammation and neuronal apoptosis and decrease phosphatidylinositol second messenger activity. Omega-3 fatty acids have been suggested to alter gene expression.

In the CNS, fatty acids are selectively concentrated in neuronal membranes and involved in cell membrane structure. Omega-6 arachidonic acid has been shown to enhance glutamate neurotransmission, stimulate stress hormone secretion, and trigger glial cell activation in the setting of oxidative toxicity and neurodegeneration. The omega-3 fatty acids DHA and EPA appear to protect neurons from inflammatory and oxidative toxicities. Increases in serotonin, enhancement of dopamine, and regulation of CRF have been demonstrated in cell culture models.

In rodent models of depression, chronic EPA treatment normalized behavior in open field tests. Serotonin and norepinephrine were also increased in the limbic regions. Mice fed omega-3 poor diets had reduced memory, altered learning patterns, and more behavioral problems.

Therapeutic Indications. Clinical research with the use of fish oil for mood disorders was based on epidemiology studies where there appears to be negative correlation between fish consumption and depressive symptoms. Countries with lower per capita fish consumption had up to 60 times increased rates of major depression, bipolar disorder, and postpartum depression. Observational studies concluded that the lower incidence of seasonal affective disorder in Iceland and Japan, rather than latitude predicted, is related to the amount of fatty acid these populations consume in their diet. A study in Norway showed that use of cod liver oil decreased depressive symptoms. Depression after a myocardial infarction shows higher arachidonic acid to EPA ratio. Postmortem studies in brains of patients diagnosed with major depressive disorder show reduced DHA in the orbitofrontal cortex.

The first randomized, controlled pilot study of omega-3 fatty acids focused on adjunctive treatment in both bipolar and unipolar patients with depression in addition to their standard lithium (Eskalith) or valproic acid (Depakene) treatment. The omega-3 fatty acid group had significant improvement on the Hamilton Depression scale and a longer period of remission than the placebo group. A subsequent larger study supported a benefit from treatment with E-EPA for bipolar illness. However, a study of a group of patients with either bipolar disorder or rapid cycling treated with E-EPA showed no significant difference on any outcome measure between the EPA and placebo groups. Bleeding time was also increased in the treatment group. There are no current data on monotherapy in bipolar illness or depression.

The most convincing evidence comes from early brain development and learning studies. Pregnant mothers who consumed foods rich in DHA gave birth to infants who had improved problem-solving skills, but not necessarily improved memory. Visual acuity and eye development are also associated with DHA supplementation during pregnancy.

Reports of behavioral studies of prisoners in England who consumed higher amounts of seafood containing omega-3 fatty acids showed a decrease in assault rates. A Finnish study of violent criminals identified lower levels of omega-3 fatty acids in their system compared to the nonviolent offenders.

The negative and psychotic symptoms of schizophrenia may be improved with supplementation with omega-3 fatty acids. Antipsychotic medications like haloperidol (Haldol) appear to have fewer extrapyramidal side effects when combined with antioxidants and omega-3 fatty acids.

EPA and DHA have been associated with decreased dementia incidence. After reviewing the Rotterdam study of a longitudinal cohort of more than 5,300 patients, fish consumption appeared to be inversely related to development of new cases of dementia. A later analysis of the study after 6 years demonstrated that low intake of omega-3 fatty acids was not associated with increased risk of dementia. In contrast, the Zutphen study, also in the Netherlands, concluded that high fish consumption was inversely related with cognitive decline at 3-year follow-up and after 5 years. Well-designed clinical trials are needed before omega-3 fatty acids can be recommended for prevention of cognitive impairment.

Precautions and Adverse Reactions. The most adverse complication of eicosanoid use is increased risk for bleeding. Dietary sources can contain heavy metals, and there is no standard preparation for capsule formulations. Treatment studies have yielded a variety of different doses, but evidence for the therapeutic dose and clinical guidelines are almost nonexistent. The length of treatment still needs to be determined.

Neurosteroids

Background. Although steroids are critical for the maintenance of body homeostasis, neurosteroids are synthesized from cholesterol in the brain and independent of peripheral formation in the adrenals and gonads. Neurosteroids are produced by a sequence of enzymatic processes governed by cytochrome P450 (CYP) and non-CYP enzymes, either within or outside the mitochondria of several types of CNS and peripheral nervous system (PNS) cells.

Recent work has shown that neurosteroids can operate through a nongenomic pathway to regulate neuronal excitability through their effects on neurotransmitter-gated ion channels. Receptors are generally located in the nucleus, membrane, or microtubules of the CNS and PNS. Although steroids and neurosteroids can act on the same nuclear receptors, neurosteroids differ from steroids in their topological distribution and regional synthesis. The most well-known effect of neurosteroids is on the GABA receptor, particularly the GABA_A receptor.

Neurosteroids acting primarily at this site include allopregnanolone (3 α ,5 α -tetrahydroprogesterone), pregnanolone (PREG), and tetrahydrodeoxycorticosterone (THDOC). Dehydroepiandrosterone sulfate (DHEA-S), the most prevalent neurosteroid, acts as a noncompetitive modulator of GABA, and its precursor dehydroepiandrosterone (DHEA) has also been shown to exert inhibitory effects at the GABA receptor. Some neurosteroids may also act at the NMDA, α -amino-3-hydroxy-5-methyl-4-isoxazole-propanoic acid (AMPA), kainate, glycine, serotonin, sigma type-1, and nicotinic acetylcholine receptors. Progesterone is also considered a neurosteroid and has the ability to regulate gene expression at progesterone receptors.

Neurosteroids in Neurodevelopment and Neuroprotection. In general, neurosteroids stimulate axonal growth and promote synaptic transmission. Specific neuroprotective effects are unique to each neurosteroid. DHEA acts to regulate brain serotonin and dopamine levels, suppress cortisol, increase hippocampal primed burst potentiation and cholinergic function, decrease amyloid- β protein, inhibit the production of proinflammatory cytokines, and prevent free radical scavenging. DHEA and DHEA-S have both been shown to have a role in glial development and neuronal growth and to promote their survival in animals; the injection of these substances into the brains of mice promoted long-term memory while reversing amnesia. Progesterone is linked to myelinating processes like aiding in the repair of damaged neural myelination (Color Plate 1.4-16). Allopregnanolone contributes to the reduction of contacts during axonal regression.

Role of Neurosteroids in Mental Illness. Neurosteroids have distinct implications for the maintenance of normal neurologic function and also may contribute to neuropathology. Neurosteroids are differentially regulated in males and females and may affect the manifestation of psychological disorders in these two populations. Specifically, they play a distinct role in depression and anxiety disorders and may be targeted by psychiatric medications in the near future.

DEPRESSION. When compared with nondepressed controls, studies show that depressed patients have lower plasma and CSF concentrations of allopregnanolone. In addition, this research has elucidated an inverse relationship between allopregnanolone concentrations and severity of depressive illness. However, there are no allopregnanolone-based therapies available for humans, so its direct efficacy is unsubstantiated. Antidepressant drugs, specifically fluoxetine (Prozac), have been shown in multiple studies to increase the levels of certain neurosteroids. Nonetheless, there is debate over the therapeutic properties of neurosteroids, prompting the investigation of neurosteroid concentrations in patients undergoing nonpharmacological therapies. Preliminary results indicate that the lack of modifications in neurosteroid levels during nonpharmacological treatments supports the validity of the pharmacological properties of antidepressants, not their therapeutic action, in the elevation of neurosteroid levels in medicated populations.

ANXIETY DISORDERS. In patients with anxiety disorders, the major mechanism of action is on the GABA receptor. Homeostasis characterized by normal GABAergic activity is restored after panic attacks as neurosteroids are released in response to stress. Allopregnanolone stimulates GABAergic activity with 20 times the strength of benzodiazepines and 200 times the potency of barbiturates. Both positive and negative regulation of the GABA_A receptor are correlated with anxiolytic and anxiogenic action, respectively.

PSYCHOTIC DISORDERS. In addition to their primary relevance to the pharmacological treatment of mood and anxiety disorders, neurosteroids contribute to psychotic, childhood, substance abuse, eating, and postpartum disorders. The effect of neurosteroids on psychotic disorders such as schizophrenia is mediated by DHEA and DHEA-S. DHEA has been dispensed to decrease anxiety in patients with schizophrenia, as DHEA and DHEA-S suppress GABA inhibition and heighten the neuronal response at the NMDA and sigma receptors. DHEA and DHEA-S levels are typically elevated in the initial episode of a patient with schizophrenia, indicating neurosteroids are upregulated by the onset of psychosis. Because neurosteroid levels are studied across various illness stages, some questions still exist regarding the role of neurosteroids in psychosis.

CHILDHOOD MENTAL ILLNESS. In children, the clinical symptomology of ADHD is inversely correlated with DHEA and pregnanolone levels.

SUBSTANCE ABUSE. Alcohol is theorized to regulate the GABA receptor and induce de novo steroid synthesis in the brain; specifically, pregnanolone, allopregnanolone, and allotetrahydrodeoxycorticosterone levels are increased in the brain and periphery in response to increases in peripheral alcohol levels. It is hypothesized that sharp increases in ethanol concentration may mimic the acute stress response and elevate neurosteroid concentrations by the HPA axis. To prevent ethanol dependence, researchers are investigating fluctuations in neurosteroid levels and in vivo neurosteroid responsiveness. Neurosteroids (increased allopregnanolone levels in particular) are associated with drug abuse. However, DHEA-S may actually check the acquisition of morphine tolerance. Past research has shown that DHEA-S levels were also increased in patients who abstained from cocaine use in a treatment program, and as patients relapsed DHEA-S concentrations decreased accordingly.

EATING DISORDERS. With regard to eating disorders, DHEA has been shown to diminish food intake, temper obesity, moderate insulin resistance, and lower lipids in rats with a model of youth-onset, hyperphagic, and genetic obesity. By regulating the serotonergic system, DHEA is hypothesized to promote a reduced caloric load. Although hypothetical, low levels of DHEA and DHEA-S are recorded in young women with anorexia nervosa, and 3 months of oral DHEA supplementation increased bone density and tempered the emotional problems associated with the disorder.

POSTPARTUM AND GYNECOLOGICAL DISORDERS. Because estrogen and progesterone levels fluctuate during the course of pregnancy and drop markedly after delivery, neurosteroids are thought to contribute to postpartum disorders. Low postpartum DHEA concentrations have been linked to mood instability. In addition, allopregnanolone levels correlated with mood disorders during pregnancy and in premenstrual syndrome (PMS). It has been noted that women with premenstrual dysphoric disorder have higher allopregnanolone/progesterone ratios than normal controls; women treated for this disorder reported improvement as allopregnanolone levels decreased.

NEUROSTEROIDS, MEMORY DISORDERS, AND AGING. Neurosteroid levels may be irregular in neurodegenerative disorders and aging conditions such as Alzheimer's disease and Parkinson's disease. DHEA levels at age 70 are only about 20 percent of their maximum value recorded in the late 20s, and some researchers believe DHEA supplementation can prevent or slow the cognitive declines associated with the aging process. However, conflicting studies have indicated that DHEA administration does not improve cognitive measures in patients. In addition, in patients with Alzheimer's disease, DHEA concentrations have been found to be markedly decreased.

1.5 Psychoneuroendocrinology

The term *psychoneuroendocrinology* encompasses the structural and functional relationships between hormonal systems and the central nervous system (CNS) and behaviors that modulate and are derived from both. Classically, *hormones* have been defined as the products of endocrine glands transported by the blood to exert their action at sites distant from their release. Advances in neuroscience have shown, however, that in the CNS the brain not only serves as a target site for regulatory control of hormonal release but also has secretory functions of its own and serves as an end organ for some hormonal actions. These complex interrelationships make classic distinctions between the origin, structure, and function of neurons and those of endocrine cells dependent of physiological context.

HORMONE SECRETION

Hormone secretion is stimulated by the action of a neuronal secretory product of neuroendocrine transducer cells of the hypothalamus. Examples of hormone regulators (Table 1.5-1) include corticotropin-releasing hormone (CRH), which stimulates adrenocorticotropin (adrenocorticotrophic hormone [ACTH]); thyrotropin-releasing hormone (TRH), which stimulates release of thyroid-stimulating hormone (TSH); gonadotropin-releasing hormone (GnRH), which stimulates release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH); and somatostatin (somatotropin release-inhibiting factor [SRIF]) and growth-hormone-releasing hormone (GHRH), which influence growth hormone (GH) release. Chemical signals cause the release of these neurohormones from the median eminence of the hypothalamus into the portal hypophyseal bloodstream and subsequent transport to the pituitary to regulate the release of target hormones. Pituitary hormones in turn act directly on target cells (e.g., ACTH on the adrenal gland) or stimulate the release of other hormones from peripheral endocrine organs. In addition, these hormones have feedback actions that regulate secretion and exert neuromodulatory effects in the CNS.

 **Table 1.5-1**
Examples of Regulating Hormones

Regulating Hormone	Hormone Stimulated (or Inhibited)
Corticotropin-releasing hormone	Adrenocorticotrophic hormone
Thyrotropin-releasing hormone	Thyroid-stimulated hormone
Luteinizing-hormone-releasing hormone	Luteinizing hormone
Gonadotropin-releasing hormone	Follicle-stimulating hormone
Somatostatin	Growth hormone (inhibited)
Growth-hormone-releasing hormone	Growth hormone
Progesterone, oxytocin	Prolactin
Arginine vasopressin	Adrenocorticotrophic hormone

From Sadock BJ, Sadock VA, Ruiz P, Kaplan & Sadock's *Comprehensive Textbook of Psychiatry*, 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:162.

Hormones are divided into two general classes: (1) proteins, polypeptides, and glycoproteins, and (2) steroids and steroid-like compounds (Table 1.5-2); these are secreted by an endocrine gland into the bloodstream and are transported to their sites of action.

Table 1.5-2
Classifications of Hormones

Structure	Examples	Storage	Lipid Soluble
Proteins, polypeptides, glycoproteins	ACTH, β -endorphin, TRH, LH, FSH	Vesicles	No
Steroids, steroid-like compounds	Cortisol, estrogen, thyroxine	Diffusion after synthesis	Yes
Functions			
Autocrine	Self-regulatory effects		
Paracrine	Local or adjacent cellular action		
Endocrine	Distant target site		

ACTH, adrenocorticotrophic hormone; TRH, thyrotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone. (Courtesy of Victor I Reus, M.D., and Sydney Frederick-Osborne, Ph.D.)

DEVELOPMENTAL PSYCHONEUROENDOCRINOLOGY

Hormones can have both organizational and activational effects. Exposure to gonadal hormones during critical stages of neural development directs changes in brain morphology and function (e.g., sex-specific behavior in adulthood). Similarly, thyroid hormones are essential for the normal development of the CNS, and thyroid deficiency during critical stages of postnatal life will severely impair growth and development of the brain, resulting in behavioral disturbances that may be permanent if replacement therapy is not instituted.

ENDOCRINE ASSESSMENT

Neuroendocrine function can be studied by assessing baseline measures and by measuring the response of the axis to some neurochemical or hormonal challenge. The first method has two approaches. One approach is to measure a single time point—for example, morning levels of growth hormone; this approach is subject to significant error because of the pulsatile nature of the release of most hormones. The second approach is to collect blood samples at multiple points or to collect 24-hour urine samples; these measurements are less susceptible to major errors. The best approach, however, is to perform a neuroendocrine challenge test, in which the person is given a drug or a hormone that perturbs the endocrine axis in some standard way. Persons with no disease show much less variation in their responses to such challenge studies than in their baseline measurements.

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Since the earliest conceptions of the stress response, by Hans Selye and others, investigation of hypothalamic-pituitary-adrenal (HPA) function has occupied a central position in psychoendocrine research. CRH, ACTH, and cortisol levels all rise in response to a variety of physical and psychic stresses and serve as prime factors in maintaining homeostasis and developing adaptive responses to novel or challenging stimuli. The hormonal response depends both on the characteristics of the stressor itself and on how the individual assesses and is able to cope with it. Aside from generalized effects on arousal, distinct effects on sensory processing, stimulus habituation and sensitization, pain, sleep, and memory storage and retrieval have been documented. In primates, social status can influence adrenocortical profiles and, in turn, be affected by exogenously induced changes in hormone concentration.

Pathological alterations in HPA function have been associated primarily with mood disorders, posttraumatic stress disorder (PTSD), and dementia of the Alzheimer's type, although recent animal evidence points toward a role of this system in substance use disorders as well. Disturbances of mood are found in more than 50 percent of patients with Cushing's syndrome (characterized by elevated cortisol concentrations), with psychosis or suicidal thought apparent in more than 10 percent of patients studied. Cognitive impairments similar to those seen in major depressive disorder (principally in visual memory and higher cortical functions) are common and relate to the severity of the hypercortisolemia and possible reduction in hippocampal size. In general, reduced cortisol levels normalize mood and mental status. Conversely, in Addison's disease (characterized by adrenal insufficiency), apathy, social withdrawal, impaired sleep, and decreased concentration frequently accompany prominent fatigue. Replacement of glucocorticoid (but not of electrolyte) resolves behavioral symptomatology. Similarly, HPA abnormalities are reversed in persons who are treated successfully with antidepressant medications. Failure

to normalize HPA abnormalities is a poor prognostic sign. Alterations in HPA function associated with depression include elevated cortisol concentrations, failure to suppress cortisol in response to dexamethasone, increased adrenal size and sensitivity to ACTH, a blunted ACTH response to CRH, and, possibly, elevated CRH concentrations in the brain.

HYPOTHALAMIC-PITUITARY-GONADAL AXIS

The gonadal hormones (progesterone, androstenedione, testosterone, estradiol, and others) are steroids that are secreted principally by the ovary and testes, but significant amounts of androgens arise from the adrenal cortex as well. The prostate gland and adipose tissue, also involved in the synthesis and storage of dihydrotestosterone, contribute to individual variance in sexual function and behavior.

The timing and presence of gonadal hormones play a critical role in the development of sexual dimorphisms in the brain. Developmentally, these hormones direct the organization of many sexually dimorphic CNS structures and functions, such as the size of the hypothalamic nuclei and corpus callosum, neuronal density in the temporal cortex, the organization of language ability, and responsiveness in Broca's motor speech area. Women with congenital adrenal hyperplasia—a deficiency of the enzyme 21-hydroxylase, which leads to high exposure to adrenal androgens in prenatal and postnatal life, in some studies—have been found to be more aggressive and assertive and less interested in traditional female roles than control female subjects. Sexual dimorphisms may also reflect acute and reversible actions of relative steroid concentrations (e.g., higher estrogen levels transiently increase CNS sensitivity to serotonin).

Testosterone

Testosterone is the primary androgenic steroid, with both androgenic (i.e., facilitating linear body growth) and somatic growth functions. Testosterone is associated with increased violence and aggression in animals and in correlation studies in humans, but anecdotal reports of increased aggression with testosterone treatment have not been substantiated in investigations in humans. In hypogonadal men, testosterone improves mood and decreases irritability. Varying effects of anabolic-androgenic steroids on mood have been noted anecdotally. A prospective, placebo-controlled study of anabolic-androgenic steroid administration in normal subjects reported positive mood symptoms, including euphoria, increased energy, and sexual arousal, in addition to increases in the negative mood symptoms of irritability, mood swings, violent feelings, anger, and hostility.

Testosterone is important for sexual desire in both men and women. In males, muscle mass and strength, sexual activity, desire, thoughts, and intensity of sexual feelings depend on normal testosterone levels, but these functions are not clearly augmented by supplemental testosterone in those with normal androgen levels. Adding small amounts of testosterone to normal hormonal replacement in postmenopausal women has proved, however, to be as beneficial as its use in hypogonadal men.

Dehydroepiandrosterone

DHEA and DHEA sulfate (DHEA-S) are adrenal androgens secreted in response to ACTH and represent the most abundant circulating steroids. DHEA is also a neurosteroid that is synthesized in situ in the brain. DHEA has many physiological effects, including reduction in neuronal damage from glucocorticoid excess and oxidative stress. Behavioral interest has centered on its possible involvement in memory, mood, and a number of psychiatric disorders. *Adrenarche* is the prepubertal onset of adrenal production of DHEA-S and may play a role in human maturation through increasing the activity of the amygdala and hippocampus and promoting synaptogenesis in the cerebral cortex. DHEA has been shown to act as an excitatory neurosteroid and to enhance memory retention in mice, but studies of DHEA administration to humans have not consistently shown any improvement in cognition. Several trials of DHEA administration point to an improvement in well-being, mood, energy, libido, and functional status in depressed individuals. Administration of DHEA to women with adrenal insufficiency (e.g., Addison's disease) has repeatedly been demonstrated to enhance mood, energy, and sexual function; effects in men remain to be assessed. Mood, fatigue, and libido improved in human immunodeficiency virus (HIV)-positive patients treated with DHEA in one study, and DHEA and DHEA-S have been found to be inversely correlated with severity in attention-deficit/hyperactivity disorder (ADHD). Women diagnosed with fibromyalgia have significantly decreased DHEA-S levels, but supplementation does not improve outcome. Several cases of possible DHEA-induced mania have been reported, and DHEA has been reported to be inversely related to extrapyramidal symptoms (EPS) in patients with schizophrenia who are treated with antipsychotics. DHEA administration in these cases improves EPS.

Double-blind treatment studies have shown antidepressant effects of DHEA in patients with major depression, midlife-onset dysthymia, and schizophrenia, although beneficial effects on memory have not been reliably demonstrated. A small, double-blind trial of DHEA treatment of Alzheimer's disease failed to reveal significant benefit, although a near-significant improvement in cognitive function was seen after 3 months of treatment.

Animal studies suggest that DHEA may be involved in eating behavior, aggressiveness, and anxiety as well, with its effects resulting from its transformation into estrogen, testosterone, or androsterone from its antiglucocorticoid activity, or from direct effects on GABA_A, N-methyl-D-aspartate (NMDA), and σ receptors. Because of the putative antiglucocorticoid effects, the ratio of cortisol to DHEA levels may be particularly important in understanding adaptive responses to stress. Both cortisol and DHEA appear to be involved in fear conditioning, with the cortisol/DHEA ratio hypothesized to be an index of the degree to which an individual is buffered against the negative effects of stress. This ratio has been found to be related to some measures of psychopathology and response to treatment, predicting the persistence of the first episode major depression and being related to degree of depression, anxiety, and hostility in patients with schizophrenia and response to antipsychotic treatment. Patients with PTSD have higher DHEA levels and lower cortisol/DHEA ratios related to symptom severity, suggesting a role in PTSD recovery. Fear-potentiated startle is larger in individuals with high as compared to low cortisol/DHEA-S ratios and is positively associated with cortisol and negatively with DHEA-S. Greater DHEA response to ACTH is related to lower PTSD ratings, and the cortisol/DHEA ratio to negative mood symptoms. A genetic variation in an ACTH receptor promoter has been found to influence DHEA secretion in response to dexamethasone and may underlie some individual differences in stress response.

Estrogen and Progesterone

Estrogens can influence neural activity in the hypothalamus and limbic system directly through modulation of neuronal excitability, and they have complex multiphasic effects on nigrostriatal dopamine receptor sensitivity. Accordingly, evidence indicates that the antipsychotic effect of psychiatric drugs can change over the menstrual cycle and that the risk of tardive dyskinesia depends partly on estrogen concentrations. Several studies have suggested that gonadal steroids modulate spatial cognition and verbal memory and are involved in impeding age-related neuronal degeneration. Increasing evidence also suggests that estrogen administration decreases the risk and severity of dementia of the Alzheimer's type in postmenopausal women. Estrogen has mood-enhancing properties and can also increase sensitivity to serotonin, possibly by inhibiting monoamine oxidase. In animal studies, long-term estrogen treatment results in a decrease in serotonin 5-HT₁ receptors and an increase in 5-HT₂ receptors. In oophorectomized women, significant reductions in tritiated imipramine binding sites (which indirectly measures presynaptic serotonin uptake) were restored with estrogen treatment.

The association of these hormones with serotonin is hypothetically relevant to mood change in premenstrual and postpartum mood disturbances. In premenstrual dysphoric disorder, a constellation of symptoms resembling major depressive disorder occurs in most menstrual cycles, appearing in the luteal phase and disappearing within a few days of the onset of menses. No definitive abnormalities in estrogen or progesterone levels have been demonstrated in women with premenstrual dysphoric disorder, but decreased serotonin uptake with premenstrual reductions in steroid levels has been correlated with the severity of some symptoms.

Most psychological symptoms associated with the menopause are actually reported during perimenopause rather than after complete cessation of menses. Although studies suggest no increased incidence of major depressive disorder, reported symptoms include worry, fatigue, crying spells, mood swings, diminished ability to cope, and diminished libido or intensity of orgasm. Hormone replacement therapy (HRT) is effective in preventing osteoporosis and reinstating energy, a sense of well-being, and libido; however, its use is extremely controversial. Studies have shown that combined estrogen–progestin drugs (e.g., Premarin) cause small increases in breast cancer, heart attack, stroke, and blood clots among menopausal women. Studies of the effects of estrogen alone in women who have had hysterectomies (because estrogen alone increases the risk for uterine cancer) are ongoing.

HYPOTHALAMIC–PITUITARY–THYROID AXIS

Thyroid hormones are involved in the regulation of nearly every organ system, particularly those integral to the metabolism of food and the regulation of temperature, and are responsible for optimal development and function of all body tissues. In addition to its prime endocrine function, TRH has direct effects on neuronal excitability, behavior, and neurotransmitter regulation.

Thyroid disorders can induce virtually any psychiatric symptom or syndrome, although no consistent associations of specific syndromes and thyroid conditions are found. Hyperthyroidism is commonly associated with fatigue, irritability, insomnia, anxiety, restlessness, weight loss, and emotional lability; marked impairment in concentration and memory may also be evident. Such states can progress into delirium or mania or they can be episodic. On occasion, a true psychosis develops, with paranoia as a particularly common presenting feature. In some cases, psychomotor retardation, apathy, and withdrawal are the presenting features rather than agitation and anxiety. Symptoms of mania have also been reported following rapid normalization of thyroid status in hypothyroid individuals and may covary with thyroid level in individuals with episodic endocrine dysfunction. In general, behavioral abnormalities resolve with normalization of thyroid function and respond symptomatically to traditional psychopharmacological regimens.

The psychiatric symptoms of chronic hypothyroidism are generally well recognized (Fig. 1.5-1). Classically, fatigue, decreased libido, memory impairment, and irritability are noted, but a true secondary psychotic disorder or dementia-like state can also develop. Suicidal ideation is common, and the lethality of actual attempts is profound. In milder, subclinical states of hypothyroidism, the absence of gross signs accompanying endocrine dysfunction can result in its being overlooked as a possible cause of a mental disorder.

GROWTH HORMONE

Growth hormone deficiencies interfere with growth and delay the onset of puberty. Low GH levels can result from a stressful experience. Administration of GH to individuals with GH deficiency benefits cognitive function in addition to its more obvious somatic effects, but evidence indicates poor psychosocial adaptation in adulthood for children who were treated for GH deficiency. A significant percentage of patients with major depressive disorder and dysthymic disorder may have a GH deficiency. Some prepubertal and adult patients with diagnoses of major depressive disorder exhibit hyposecretion of GHRH during an insulin tolerance test, a deficit that has been interpreted as reflecting alterations in both cholinergic and serotonergic mechanisms. A number of GH abnormalities have been noted in patients with anorexia nervosa. Secondary factors, such as weight loss, however, in both major depressive disorder and eating disorders, may be responsible for alterations in endocrine release. Nonetheless, at least one study has reported that GHRH stimulates food consumption in patients with anorexia nervosa and lowers food consumption in patients with bulimia. Administration of GH to elderly men increases lean body mass and improves vigor. GH is released in pulses throughout the day, but the pulses are closer together during the first hours of sleep than at other times.

PROLACTIN

Since its identification in 1970, the anterior pituitary hormone prolactin has been examined as a potential index of dopamine activity, dopamine receptor sensitivity, and antipsychotic drug concentration in studies of CNS function in psychiatric patients and as a correlate of stress responsivity. The secretion of prolactin is under direct inhibitory regulation by dopamine neurons located in the tuberoinfundibular section of the hypothalamus and is, therefore, increased by classical antipsychotic medications. Prolactin also inhibits its own secretion by means of a short-loop feedback circuit to the hypothalamus. In addition, a great number of prolactin-releasing or prolactin-modifying factors have been identified, including estrogen, serotonin (particularly through the 5-HT₂ and 5-HT₃ receptors), norepinephrine, opioids, TRH, T₄, histamine, glutamate, cortisol, CRH, and oxytocin, with interaction effects possible. For example, estrogen may promote the serotonin-stimulated release of prolactin.

Prolactin is primarily involved in reproductive functions. During maturation, prolactin secretion participates in gonadal development, whereas, in adults, prolactin contributes to the regulation of the behavioral aspects of reproduction and infant care, including estrogen-dependent sexual receptivity and breast-feeding. In female rats, prolactin secretion is strongly stimulated with exposure to pups. In women, basal prolactin levels are elevated in the postpartum period before weaning, and prolactin release is stimulated by suckling. Hyperprolactinemia is associated with low testosterone in men and reduced libido in men and women. In rodents, prolactin level is increased along with corticosterone in response to such stressful stimuli as immobilization, hypoglycemia, surgery, and cold exposure and may be specifically associated with the use of passive coping in the face of a stressor. Prolactin promotes various stress-related behaviors in rats, depending on the condition, such as increasing object-directed exploration while decreasing other exploration.

Patients with hyperprolactinemia often complain of depression, decreased libido, stress intolerance, anxiety, and increased irritability. These behavioral symptoms usually resolve in parallel with decrements in serum prolactin when surgical or pharmacological treatments are used. In psychotic patients, prolactin concentrations and prolactin-related sexual disturbances have been positively correlated with the severity of tardive dyskinesia. Prolactin levels are also positively correlated with negative symptoms in schizophrenia.

MELATONIN

Melatonin, a pineal hormone, is derived from the serotonin molecule and it controls photoperiodically mediated endocrine events (particularly those of the hypothalamic–pituitary–gonadal axis). It also modulates immune function, mood, and reproductive performance and is a potent antioxidant and free-radical scavenger. Melatonin has a depressive effect on CNS excitability, is an analgesic, and has seizure-inhibiting effects in animal studies. Melatonin can be a useful therapeutic agent in the treatment of circadian phase disorders such as jet lag. Intake of melatonin increases the speed of falling asleep, as well as its duration and quality.

OXYTOCIN

Oxytocin, also a posterior pituitary hormone, is involved in osmoregulation, the milk ejection reflex, food intake, and female maternal and sexual behaviors. Oxytocin is theorized to be released during orgasm, more so in women than in men, and is presumed to promote bonding between the sexes. It has been used in autistic children experimentally in an attempt to increase socialization.

INSULIN

Increasing evidence indicates that insulin may be integrally involved in learning and memory. Insulin receptors occur in high density in the hippocampus and are thought to help neurons metabolize glucose. Patients with Alzheimer's disease have lower insulin concentrations in the cerebrospinal fluid (CSF) than controls, and both insulin and glucose dramatically improve verbal memory. Depression is frequent in patients with diabetes, as are indexes of impaired hormonal response to stress. It is not known whether these findings represent direct effects of the disease or are secondary, nonspecific effects. Some antipsychotics are known to dysregulate insulin metabolism.

ENDOCRINE VARIABLES IN PSYCHIATRIC DISORDERS

Although it is clear that alterations in endocrine regulation are involved in the pathophysiology and treatment responses of many psychiatric disorders, incorporating these findings into clinical diagnostic assessment and decision-making remains problematic. Large-scale longitudinal or cost-effectiveness studies are rare, despite indications that baseline alterations in glucocorticoid regulation and thyroid status (two of the best studied abnormalities) may actually be useful in subtyping psychiatric disorders and in prediction of outcome. Alterations in HPA/stress regulation underlie a number of psychiatric diagnoses and may serve as complementary independent variables in assigning treatment response and course of illness to the classical behavioral categories that have thus far defined psychiatric practice. Studying genetic polymorphisms in factors regulating hormonal response may help us better understand the influence of hormonal variability on the illness and also possible underlying differences in the nature of the illness reflected in these genetic subtypes.

1.6 Immune System and Central Nervous System Interactions

Interactions between the immune system and the central nervous system (CNS) play a critical role in the maintenance of bodily homeostasis and the development of diseases, including psychiatric disease. Alterations in CNS function brought about by a variety of stressors have been shown to influence both the immune system as well as diseases that involve the immune system. Moreover, many of the relevant hormonal and neurotransmitter pathways that mediate these effects have been elucidated. Of considerable interest is accumulating data that cytokines, which derive from immune cells and microglia, have profound effects on the CNS. The relative role of cytokines and their signaling pathways in the various psychiatric diseases is an area of active investigation, as is the role of infectious and autoimmune diseases in the pathophysiology of psychiatric disorders. Taken together, these findings highlight the importance of interdisciplinary efforts involving the neurosciences and immunology for gaining new insights into the etiology of psychiatric disorders.

OVERVIEW OF THE IMMUNE SYSTEM

The immune system has the capacity to protect the body from the invasion of foreign pathogens, such as viruses, bacteria, fungi, and parasites. In addition, the immune system can detect and eliminate cells that have become neoplastically transformed. These functions are accomplished through highly specific receptors on immune cells for molecules derived from invading organisms and a rich intercellular communication network that involves direct cell-to-cell interactions and signaling between cells of the immune system by soluble factors called *cytokines*. The body's absolute dependence on the efficient functioning of the immune system is illustrated by the less than 1-year survival rate of untreated infants born with severe combined immunodeficiency disease and the devastating opportunistic infections and cancers that arise during untreated acquired immunodeficiency syndrome (AIDS).

BEHAVIORAL CONDITIONING

The fact that learning processes are capable of influencing immunological function is an example of interactions between the immune system and the nervous system. Several classical conditioning paradigms have been associated with suppression or enhancement of the immune response in various experimental designs. The conditioning of immunological reactivity provides further evidence that the CNS can have significant immunomodulatory effects.

Some of the first evidence for immunological conditioning was derived from the serendipitous observation that animals undergoing extinction in a taste-aversion paradigm with cyclophosphamide, an immunosuppressive agent, had unexpected mortality. In that taste-aversion paradigm, animals were simultaneously exposed to an oral saccharin solution (the conditioned stimulus) and an intraperitoneal injection of cyclophosphamide (unconditioned stimulus). Because the animals experienced considerable physical discomfort from the

cyclophosphamide injection, through the process of conditioning they began to associate the ill effects of cyclophosphamide with the taste of the oral saccharin solution. If given a choice, the animals avoided the saccharin solution (taste aversion). Conditioned avoidance can be eliminated or extinguished if the saccharin is repeatedly presented in the absence of cyclophosphamide. However, it was observed that animals undergoing extinction of cyclophosphamide-induced taste aversion unexpectedly died, leading to the speculation that the oral saccharin solution had a specific conditioned association with the immunosuppressive effects of cyclophosphamide. Repeated exposure to the saccharin-associated conditioned immunosuppression during extinction might explain the unexpected death of animals. To test that hypothesis researchers conditioned the animals with saccharin (conditioned stimulus) and intraperitoneal cyclophosphamide (unconditioned stimulus) and then immunized them with sheep red blood cells. At different times after immunization the conditioned animals were re-exposed to saccharin (conditioned stimulus) and examined. The conditioned animals exhibited a significant decrease in mean antibody titers to sheep red blood cells when compared to the control animals. Thus, the evidence demonstrated that immunosuppression of humoral immunity was occurring in response to the conditioned stimulus of saccharin alone.

STRESS AND THE IMMUNE RESPONSE

Interest in the effects of stress on the immune system grew out of a series of animal and human studies suggesting that stressful stimuli can influence the development of immune-related disorders, including infectious diseases, cancer, and autoimmune disorders. Although stress has been historically associated with suppression of immune function, recent data indicate that such a conclusion oversimplifies the complexities of the mammalian immune response to environmental perturbation and that stress may also activate certain aspects of the immune system, particularly the innate immune response.

Stress and Illness

Experiments conducted on laboratory animals in the late 1950s and the early 1960s indicated that a wide variety of stressors—including isolation, rotation, crowding, exposure to a predator, and electric shock—increased morbidity and mortality in response to several types of tumors and infectious diseases caused by viruses and parasites. However, as research progressed it became increasingly clear that “stress” is too variegated a concept to have singular effects on immunity and that, in fact, the effects of stress on immunity depend on a number of factors. Chief among these factors is whether a stressor is acute or chronic. Other critical variables include stressor severity and type, as well as the timing of stressor application and the type of tumor or infectious agent investigated. For example, mice subjected to electric grid shock 1 to 3 days before the infection of Maloney murine sarcoma virus-induced tumor cells exhibited decreased tumor size and incidence. In contrast, mice exposed to grid shock 2 days after tumor cell injection exhibited an increase in tumor size and number.

The relevance of the effects of stress on immune-related health outcomes in humans has been demonstrated in studies that have shown an association between chronic stress and increased susceptibility to the common cold, reduced antibody responses to vaccination, and delayed wound healing. In addition, stress, as well as depression, through their effects on inflammation have been linked to increased morbidity and mortality in infectious diseases, such as HIV infection, autoimmune disorders, neoplastic diseases, as well as diabetes and cardiovascular disorders, which are increasingly being recognized as diseases in which the immune system, inflammation in particular, plays a pivotal role (Fig. 1.6-1).

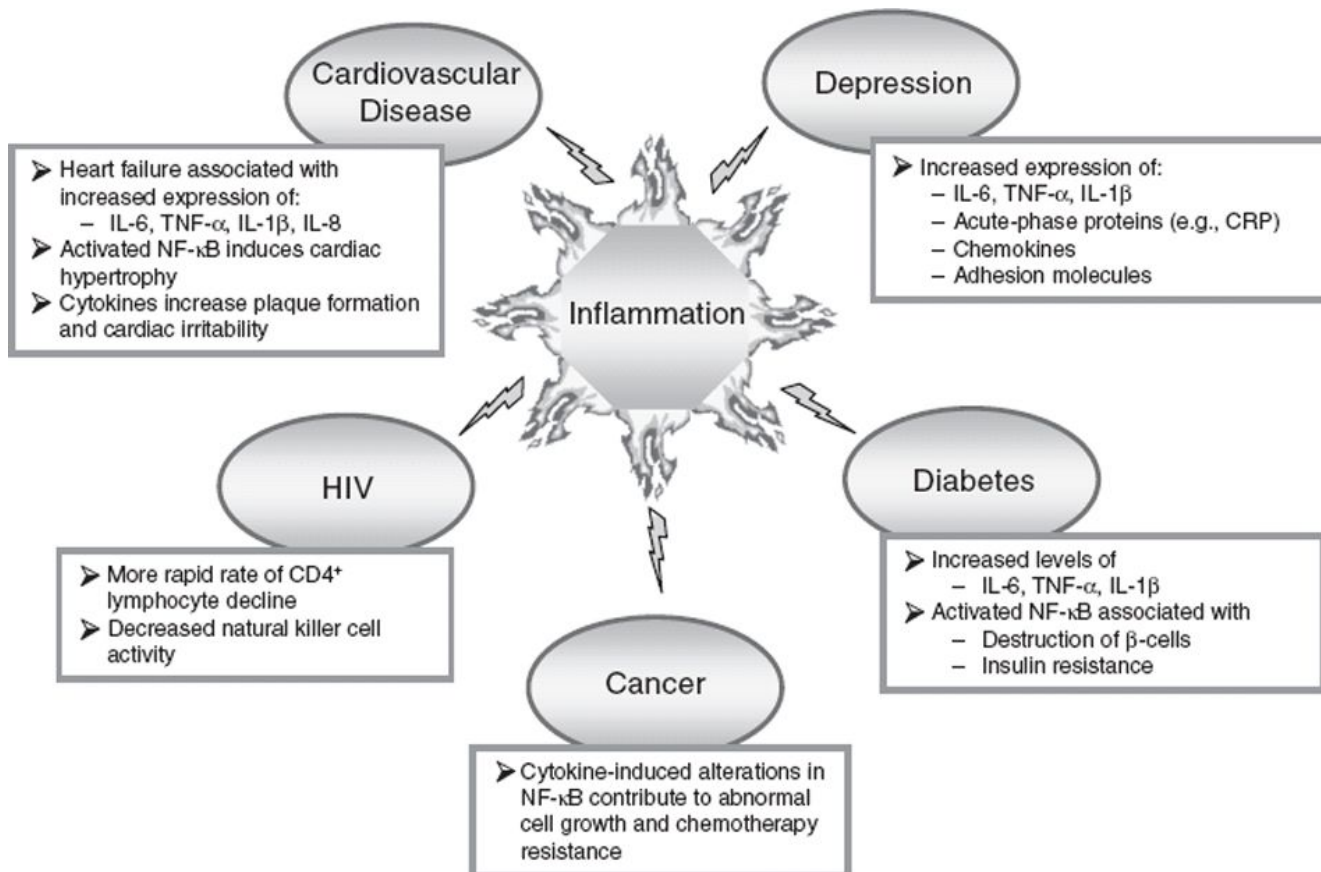

FIGURE 1.6-1

Effects of Chronic Stress

When challenged with a medical illness or chronic psychological stressor, complex interactions between the immune and nervous systems promote a constellation of immune-induced behavioral changes, alternatively referred to as “sickness syndrome” or “sickness behavior.” These behavioral changes include dysphoria, anhedonia, fatigue, social withdrawal, hyperalgesia, anorexia, altered sleep-wake patterns, and cognitive dysfunction. Although seen in response to infection, the full syndrome can be reproduced in humans and laboratory animals by administration of innate immune cytokines. Blocking cytokine activity diminishes or prevents the development of sickness behavior in

laboratory animals, even when such behavior develops as a result of psychological stress. Evidence that cytokine-induced behavioral toxicity is related to major depression comes in part from studies showing that in humans and laboratory animals, antidepressants are able to abolish or attenuate the development of sickness behavior in response to cytokine administration.

RELEVANCE OF IMMUNE SYSTEM–CNS INTERACTIONS TO PSYCHIATRIC DISORDERS

Major Depression

The neuropsychiatric disorder that has been best characterized in terms of the influence of the brain on the immune system and vice versa is major depression. For many years major depression was seen as the quintessential example of how stress-related disorders may decrease immunocompetence. More recently, however, it has become evident that stress also activates inflammatory pathways, even while suppressing measures of acquired immunity. Not surprisingly, studies now indicate that, in addition to immunosuppression, major depression is also frequently associated with inflammatory activation. Recent research showing that proinflammatory cytokines are capable of suppressing many of the immune measures examined in major depression may provide a mechanism to account for how chronic stress-induced inflammatory activity may give rise to depression-related suppression of *in vitro* functional assays, such as lymphocyte proliferation.

Bipolar Disorder

Patients with bipolar disorder evince many of the immune alterations frequently observed in the context of unipolar depression. Several studies have observed that bipolar patients, especially when manic, demonstrate increased plasma concentrations of inflammatory cytokines. Other studies indicate that treatments for mania, such as lithium, lower plasma concentrations of a number of cytokines. Of interest, the available literature seems to suggest that patients in the manic phase of the disorder may be more likely than depressed patients to demonstrate increased inflammatory markers. It should not be surprising that mania—which seems the phenomenological opposite of depression—should be associated with increased inflammation, given that mania and depression have also been reported to show identical neuroendocrine and autonomic abnormalities, such as dexamethasone nonsuppression and increased sympathetic activity, both of which would be expected to promote inflammatory activity.

Schizophrenia

There has been growing interest in the idea that infectious agents, particularly viruses, may underlie at least some cases of schizophrenia. Although it is well established that viral encephalitis can present clinically as psychosis, the primary focus of the “viral hypothesis” for schizophrenia has been on infections during neurodevelopment given its congruence with the emerging consensus that prenatal or early postnatal insult is implicated in the causality of schizophrenia. Several lines of indirect evidence suggest that viral infection during CNS development may be involved in the pathogenesis of schizophrenia. The data include: (1) an excess number of patient births in the late winter and early spring, suggesting possible exposure to viral infection *in utero* during the fall and winter peak of viral illnesses, (2) an association between exposure to viral epidemics *in utero* and the later development of schizophrenia, (3) a higher prevalence of schizophrenia in crowded urban areas, which have conditions that are particularly conducive to the transmission of viral pathogens, and (4) seroepidemiological studies indicating a higher infection rate for certain viruses in schizophrenia patients or their mothers.

In addition, schizophrenia has been associated with indices of immune activation, including elevations in cytokines. Although these immune findings in patients with schizophrenia may indicate evidence of immune system activation secondary to infection, it should be noted that they might also indicate that an autoimmune process is involved in the disorder. Despite the plethora of studies pointing to abnormalities in cellular and humoral immunity in schizophrenia, the data have not been uniform or conclusive, and there is a need for more studies that account for confounding variables such as medication status and tobacco use. Moreover, attempts to isolate infectious agents from schizophrenic brain tissue or to detect viral nucleic acids in the CNS or peripheral blood of patients with schizophrenia have generally yielded negative results.

Because the initial neuronal abnormalities in schizophrenia have been proposed to arise during neurodevelopment, a perinatal viral infection could insidiously disrupt development and then be cleared by the immune system prior to clinical diagnosis. In such a scenario, host factors such as cytokines could be responsible for causing the developmental abnormality by interacting with growth factors or adhesion molecules. Recent animal models have identified that maternal immune activation with resultant production of interleukin 6 (IL-6) critically affects behavioral and transcriptional changes in offspring. Behavioral changes, including deficits in prepulse inhibition and latent inhibition, are consistent with behavioral abnormalities in animal models of both schizophrenia and autism. Various animal models using influenza virus, Borna disease virus, or lymphocytic choriomeningitis virus in rodents have demonstrated that prenatal or postnatal viral infections can lead to neuroanatomical or behavioral alterations that are somewhat reminiscent of schizophrenia in humans. As mentioned earlier, epidemiological studies also support the link between infection with a teratogenic virus and the development of psychotic disorders later in life. Associations have been observed between maternal infection with rubella or influenza during gestation and the development of a schizophrenia spectrum disorder in the offspring. Similarly, maternal antibodies to herpes simplex virus that develop during pregnancy are correlated with increased rates of psychosis during adulthood in the offspring.

Non-HIV retroviruses might also play a role in the pathogenesis of schizophrenia. Retroviruses integrate into host deoxyribonucleic acid (DNA) and can disrupt the function of adjacent genes. Moreover, the genomes of all humans contain sequences of “endogenous retroviruses” that hold the capacity to alter the transcriptional regulation of host genes. If genes controlling the development or function of the brain undergo transcriptional disruption by retroviral effects, then this might lead to a cascade of biochemical abnormalities eventually giving rise to schizophrenia.

Autism

Although a convincing case can be made for a significant immune component in autism, the relationship of immune abnormalities to the neurobehavioral symptoms of the disease remains controversial. The claim that autism is triggered by childhood vaccines has not been substantiated by recent epidemiological studies, and immune-based therapies for autism have not been reliably effective. Thus, although it is tempting to speculate that the immune system holds a clue to a cure for autism, there is currently not enough data to determine whether immune anomalies cause autism, are *caused by* autism, or are just adventitiously associated with the disease.

Alzheimer's Disease

Although Alzheimer's disease is not considered primarily an inflammatory disease, emerging evidence indicates that the immune system may contribute to its pathogenesis. The discovery that amyloid plaques are associated with acute-phase proteins, such as complement proteins and C-reactive protein, suggests the possibility of an ongoing immune response. The idea that inflammatory processes are involved in Alzheimer's disease has been bolstered by recent studies showing that long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs) is negatively correlated with the development of Alzheimer's disease.

HIV AIDS

AIDS is an immunological disease associated with a variety of neurological manifestations, including dementia. HIV encephalitis results in

synaptic abnormalities and loss of neurons in the limbic system, basal ganglia, and neocortex.

Multiple Sclerosis

Multiple sclerosis (MS) is a demyelinating disease characterized by disseminated inflammatory lesions of white matter. Considerable progress has been made in elucidating the immunopathology of myelin destruction that occurs in MS and in the animal model for the disease, experimental allergic encephalomyelitis. Although the initial step in lesion formation has not been determined, disruption of the blood–brain barrier and infiltration of T cells, B cells, plasma cells, and macrophages appear to be associated with lesion formation.

Other Disorders

Finally, several disorders are seen in which neural-immune interactions are suspected but not well documented. *Chronic fatigue syndrome* is an illness with a controversial etiology and pathogenesis. In addition to persistent fatigue, symptoms frequently include depression and sleep disturbances. Tests of immune function have found indications of both immune activation and immunosuppression. Neuroendocrine assessments indicate that patients with chronic fatigue syndrome may be hypocortisolemic because of impaired activation of the hypothalamic–pituitary–adrenal axis. Although an acute viral infection frequently precedes the onset of chronic fatigue syndrome, no infectious agent has been causally associated with it. In contrast, *Lyme disease*, in which sleep disturbances and depression are also common, is clearly caused by infection with the tick-borne spirochete *Borrelia burgdorferi*, which can invade the CNS and cause encephalitis and neurological symptoms. Lyme disease is remarkable because it appears to produce a spectrum of neuropsychiatric disorders, including anxiety, irritability, obsessions, compulsions, hallucinations, and cognitive deficits. Immunopathology of the CNS may be involved, because symptoms can persist or reappear even after a lengthy course of antibiotic treatment, and the spirochete is frequently difficult to isolate from the brain. *Gulf War syndrome* is a controversial condition with inflammatory and neuropsychiatric features. The condition has been attributed variously to combat stress, chemical weapons (e.g., cholinesterase inhibitors), infections, and vaccines. Given the impact of stress on neurochemistry and immune responses, these pathogenic mechanisms are not mutually exclusive.

THERAPEUTIC IMPLICATIONS

The bidirectional nature of CNS–immune system interactions implies the therapeutic possibility that agents known to positively alter stress system activity might benefit immune functioning and, conversely, that agents that modulate immune functioning may be of potential benefit in the treatment of neuropsychiatric disturbance, especially in the context of medical illness. Increasing evidence supports both hypotheses.

Antidepressants and the Immune System

Emerging data indicate that in animals and humans, antidepressants attenuate or abolish behavioral symptoms induced by inflammatory cytokine exposure. For example, pretreatment of rats with either imipramine or fluoxetine (a tricyclic antidepressant and selective serotonin reuptake inhibitor, respectively) for 5 weeks prior to endotoxin administration significantly attenuated endotoxin-induced decrements in saccharine preference (commonly accepted as a measure for anhedonia), as well as weight loss, anorexia, and reduced exploratory, locomotor, and social behavior. Similarly, several studies in humans suggest that antidepressants can ameliorate mood disturbances in the context of chronic cytokine therapies, especially if given prophylactically before cytokine exposure. For example, the selective serotonin reuptake inhibitor paroxetine significantly decreased the development of major depression in patients receiving high doses of interferon- α (IFN- α) for malignant melanoma.

Behavioral Interventions and Immunity

It has been known for years that psychosocial factors can mitigate or worsen the effects of stress, not only on immune functioning but also on the long-term outcomes of medical conditions in which the immune system is known to play a role. Therefore, behavioral interventions aimed at maximizing protective psychosocial factors might be predicted to have a beneficial effect, not only in terms of mitigating the effect of stress on immune functioning but perhaps also on diminishing emotional disturbances that arise in the context of immune system dysregulation.

Two factors that have been repeatedly identified as protective against stress-induced immune alterations are social support and the ability to see stressors as being to some degree under the individual's control. In this regard, a recent study that conducted a genome-wide scan to assess gene expression activity in socially isolated versus nonisolated individuals found that social isolation was associated with increased activation of a number of proinflammatory, cytokine-related pathways and reduced activity in anti-inflammatory cytokine pathways, as well as in the glucocorticoid receptor, which plays an important role in neuroendocrine control of inflammatory processes. Of interest, the two types of psychotherapy most often examined in illnesses associated with immune dysregulation are group therapy, which provides social support, and cognitive behavioral therapy, which provides cognitive reframing techniques aimed at enhancing one's sense of agency (and hence control).

1.7 Neurogenetics

Starting from the rediscovery of Gregor Mendel's basic concepts at the turn of the 20th century, the field of genetics has matured into an

essential cornerstone not only of the biological sciences but of all of medicine. The discovery of the basic structure and properties of deoxyribonucleic acid (DNA) in the middle of the century led to an exponential acceleration in our understanding of all aspects of the life sciences, including deciphering the complete sequence of the human genome, and those of myriad other species. Massive databases of such sequences now provide 21st-century biologists with the task of decoding the functional significance of all this information. In particular, attention has turned to determining how sequence variations contribute to the phenotypic variation between species and between individuals within a species; in humans it is hoped that discoveries about the relationship between genotypes and phenotypes will revolutionize our understanding of why and how some individuals but not others develop common diseases. This hope is particularly strong for psychiatry, as our knowledge of the pathogenic mechanisms of psychiatric disease remains sparse.

Genetic mapping studies aim to identify the genes implicated in heritable diseases, based on their chromosomal location. These studies are carried out by investigating affected individuals and their families through two approaches, linkage and association (Fig. 1.7-1). It is now straightforward to genetically map Mendelian traits (traits for which a specific genotype at one particular locus is both necessary and sufficient to cause the trait). Psychiatric diseases, however, do not follow simple Mendelian inheritance patterns but rather are examples of etiologically complex traits. Etiological complexity may be due to many factors, including incomplete penetrance (expression of the phenotype in only some of the individuals carrying the disease-related genotype), the presence of phenocopies (forms of the disease that are not caused by genetic factors), locus heterogeneity (different genes associated with the same disease in different families or populations), or polygenic inheritance (risk for disease increases only if susceptibility variants at multiple genes act in concert). Mapping a complex disorder involves several component steps, including definition of the phenotype to be studied, epidemiological studies to determine the evidence for genetic transmission of that phenotype, choice of an informative study population, and determination of the appropriate experimental and statistical approaches.

Gene Mapping Strategies				
	Linkage Analysis		Genome Wide Association	
	Pedigree Analysis	Affected Sib Pair Analysis	Case-Control	Family-Trios
Study Subjects	Multi-generational families with multiple affected individuals	Two or more affected siblings	Affected individuals and matched unaffected controls sampled from population	Affected individual and parents
Basic Idea	Identify genetic markers that cosegregate with disease phenotype	Identify chromosomal regions shared by siblings concordant for disease.	Tests for statistical association of alleles and disease in cases versus controls.	Tests for association using non-transmitted parental chromosome as control.

Limitations	<ol style="list-style-type: none"> 1) Limited power to identify common variants of small effect. 2) Cost intensive. 	<ol style="list-style-type: none"> 1) Limited power to identify common variants of small effect. 	<ol style="list-style-type: none"> 1) Increased false positive rate in the presence of population stratification. 2) Requires large sample sizes. 	<ol style="list-style-type: none"> 1) About two-thirds as powerful as case-control designs. 2) Difficult to collect samples for late onset diseases.

FIGURE 1.7-1 Comparison of gene-mapping strategies. Genetic mapping approaches can be divided into those that rely on linkage analysis and those that rely on association analysis. Linkage studies can be further categorized as either focused on investigation of pedigrees or focused on investigation of sib pairs. Association studies can be categorized as either case-control or family-based. Some of the key features as well as advantages and disadvantages of these different approaches are shown. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:321.)

GENETIC EPIDEMIOLOGICAL APPROACHES

Genetic epidemiological investigations provide quantitative evidence regarding the degree to which a given trait aggregates in families and, furthermore, can suggest to what degree such aggregation reflects a genetic contribution to the etiology of the trait. Family studies compare the aggregation of disease among the relatives of affected individuals compared to control samples. Because these studies do not differentiate between genetic and environmental contributions to such familial aggregation, they provide only indirect evidence regarding the heritability of a trait. Often these studies measure the relative risk (λ), defined as the rate of occurrence of a disease among specified categories of relatives of an affected individual divided by the rate of occurrence of the disease for the general population. A relative risk of > 1 suggests a genetic etiology, and the magnitude of the measure gives an estimate of the genetic contribution to the disease. Relative risks can be calculated for sibling pairs, parent-offspring pairs, and various other types of family relationships. Likely modes of transmission can be assessed by comparing the degree of relative risk for each type of relationship. Multiple family studies have been carried out for many of the major psychiatric disorders, including major depression, bipolar disorder, schizophrenia, and obsessive-compulsive disorder (OCD). Although these studies have consistently reported familial aggregation for all of these disorders, the degree of such aggregation has varied substantially across studies, largely reflecting differences in phenotype definition and how study samples were ascertained and assessed.

Twin studies examine the concordance rates of a particular disorder (the percentage of twin pairs where both twins have the disorder) in monozygotic (MZ) and dizygotic (DZ)

twins. For a disorder that is strictly determined by genetic factors, the concordance rate should be 100 percent in MZ twin pairs (who share 100 percent of their genetic material) and 25 or 50 percent in DZ twin pairs (who are no more closely related than any siblings), depending on whether the disease is recessive or dominant, respectively. For a disorder where genetic factors play a role in disease causation but are not the exclusive cause of disease, the concordance rates should be greater for MZ twins than those for DZ twins. The higher the degree of concordance of MZ twins, the higher the trait heritability or the evidence for a genetic contribution to disease risk. When genetic factors do not play a role, the concordance rates should not differ between the twin pairs, under the simplifying assumption that the environment for MZ twin pairs is no more similar than that for DZ twin pairs. The several twin studies that have been conducted for traits such as autism, bipolar disorder, and schizophrenia have consistently suggested high heritability and have therefore spurred efforts to genetically map loci for each of these conditions. Different twin studies may however generate varying point estimates for the heritability of any given disorder. When evaluating the results of twin studies, it is therefore important to scrutinize how the phenotype was ascertained because, as with family studies, the different heritability estimates are likely due to differences in the mode of assessing and defining phenotypes. For example, early twin studies of psychiatric disorders often relied for their phenotypes on unstructured interviews by a single clinician. In contrast, modern studies generally utilize standardized assessments and review of diagnostic material by a panel of expert clinicians. Similarly, part of the apparent variation in heritability between different twin studies can be attributed to the fact that some studies employ narrow definitions of affectedness for a given phenotype, while other studies employ broader phenotype definitions (e.g., considering a twin with major depressive disorder to be phenotypically concordant with a co-twin diagnosed with bipolar disorder). Because of such differences in approach across studies it is usually prudent to view such investigations as providing a rough estimate of the genetic contribution to trait variability. Nevertheless, even such estimates are useful in deciding which traits are likely to be mappable.

BASIC CONCEPTS OF GENE MAPPING

Recombination and Linkage

Once genetic epidemiological studies of particular phenotypes have suggested that these phenotypes are heritable, genetic mapping studies are conducted to identify the specific genetic variants that contribute to the risk of the disorder. All genetic mapping methods aim to identify disease-associated variants based on their chromosomal position and the principle of genetic linkage. All cells contain two copies of each chromosome (called homologs), one inherited from the mother and one inherited from the father. During meiosis, the parental homologs cross over, or recombine, creating unique new chromosomes that are then passed on to the progeny. Genes that are physically close to one another on a chromosome are genetically linked, and those that are farther apart or are on different chromosomes are genetically unlinked. Genes that are unlinked will recombine at random (i.e., there is a 50 percent chance of recombination with each meiosis). Genetic loci that are linked will recombine less frequently than expected by random segregation, with the degree of recombination proportional to the physical distance between them. The principle of linkage underlies the use of genetic markers, segments of DNA of known chromosomal location that contain variations or polymorphisms (described in more detail later). Strategies to map disease genes are based on identifying genetic marker alleles that are shared—to a greater extent than expected by chance—by affected individuals. It is presumed that such sharing reflects linkage between a disease locus and a marker locus, that is, the alleles at both loci are inherited “identical by descent” (IBD), from a common ancestor, and, furthermore, that this linkage pinpoints the chromosomal site of the disease locus.

The evidence for linkage between two loci depends on the recombination frequency between them. Recombination frequency is measured by the recombination fraction (Θ) and is equal to the genetic distance between the two loci (1 percent recombination equals 1 centimorgan [cM] in genetic distance and, on average, covers a physical distance of about 1 megabase [mB] of DNA). A recombination fraction of 0.5 or 50 percent indicates that two loci are not linked but rather that they are segregating independently. A LOD (logarithm of the odds) score is calculated to determine the likelihood that two loci are linked at any particular genetic distance. The LOD score is calculated by dividing the likelihood of acquiring the data if the loci are linked at a given recombination fraction by the likelihood of acquiring the data if the loci are unlinked ($\Theta = 0.5$). This step gives an odds ratio, and the log (base 10) of this odds ratio is the LOD score. A LOD score can be obtained for various values of the recombination fraction, from $\Theta = 0$ (completely linked) to $\Theta = 0.5$ (unlinked). The value of Θ that gives the largest LOD score is considered to be the best estimate of the recombination fraction between the disease locus and the marker locus. This recombination fraction can then be converted into a genetic map distance between the two loci.

Linkage Disequilibrium

Linkage disequilibrium (LD) is a phenomenon that is used to evaluate the genetic distance between loci in populations rather than in families. When alleles at two loci occur together in the population more often than would be expected given the allele frequencies at the two loci, those alleles are said to be in LD. When strong LD is observed between two loci it usually indicates that the two loci are sited in very close physical proximity to one another on a given chromosome, and is useful in mapping disease susceptibility loci because one locus can be used to predict the presence of another locus. This predictability is important because current gene-mapping strategies are able to sample only a subset of the estimated 10 million common human polymorphisms. Because of the existence of LD, one can use data from a subset of genotyped polymorphisms to infer genotypes at nearby loci. Clusters of alleles that are in LD and inherited as a single unit are termed haplotypes. Thus LD mapping “consolidates” genomic information by identifying haplotypes in populations that can then be used to infer IBD sharing among unrelated individuals.

There are several methods to measure the extent of LD. One of the most commonly used measures of LD is r^2 , a measure of the difference between observed and expected haplotype probabilities. Unlike D' , another widely used measure of LD, r^2 values do not depend on the allele frequencies of the loci being assessed. A large r^2 value indicates that the observed frequency of association between two alleles is greater than that expected by chance; that is, the alleles are in LD. LD studies have traditionally been used to complement traditional pedigree analyses, for example, to hone in on a locus that has been mapped by linkage analysis. However, LD-based association analysis has become the method of choice for whole genome screens, particularly for diseases where traditional linkage studies have been unsuccessful. These studies have one great advantage over a traditional family analysis: because affected individuals are chosen from an entire population rather than from one or a few pedigrees, the number of potential subjects is limited only by the size of the population and the frequency of the disease. Maximizing the potential number of affected individuals that can be included in the analysis is extremely important for disorders where genetic heterogeneity or incomplete penetrance is likely to be a factor.

Genetic Markers

Mapping studies, regardless of their type, depend on the availability of genetic markers. The most widely used markers are microsatellite markers (also called simple tandem repeats [STRs], or simple sequence length polymorphisms [SSLPs]) and single nucleotide polymorphisms (SNPs). SSLPs are stretches of variable numbers of repeated nucleotides two to four base pairs in length. These markers are highly polymorphic, as the number of repeat units at any given STR locus varies substantially between individuals. SNPs, as the name implies, are single base pair changes at a specific nucleotide; they are the most common form of sequence variation in the genome. SNPs are widely used for genetic mapping studies because they are distributed so widely across the genome and because they can be assessed in a high-throughput, automated fashion. Other forms of genetic variation that have been investigated for use as genetic markers include small insertion or deletion polymorphisms, termed indels, that generally range between 1 and 30 base pairs and copy number variations (CNVs), which can refer to either deletions or duplications. Recent genomewide surveys have revealed that CNVs are common and can range in length from several base pairs to several million base pairs. CNVs may contribute to chromosomal recombination and rearrangements, thereby playing an important role in generating genetic diversity, and also, as many of these variants are sizable, it is hypothesized that they may significantly influence the expression of genes that encompass or are adjacent to the variant.

MAPPING STRATEGIES

The genetic variants that contribute to disease susceptibility can be roughly categorized into those that are highly penetrant and those that

are of low penetrance. High-penetrance variants by definition have a large effect on phenotype, and therefore identifying these variants usually provides fundamental insights into pathobiology. Because individuals carrying high-penetrance variants have a high probability of expressing a disease phenotype, such variants tend to be rare and to segregate in families and are generally most powerfully mapped using pedigree-based approaches (see Fig. 1.7-1). In contrast, low-penetrance variants have a relatively weak effect on phenotype, and therefore identification of individual low-penetrance variants may, at least initially, provide relatively little new biological knowledge. However, because of their small effects, such variants are typically common in the population, and therefore identifying them may add to our understanding of disease risk in the population as a whole. Because we do not expect these variants to segregate strongly with the disease phenotype in pedigrees, efforts to identify them focus on population samples.

Pedigree Analysis

A pedigree analysis, which is conducted in multigenerational families, consists of scanning the genome or a portion of the genome with a series of markers in one or more affected pedigrees, calculating a LOD score at each marker position, and identifying the chromosomal regions that show a significant deviation from what would be expected under independent assortment. The primary goal of pedigree analysis is to determine if two or more genetic loci (i.e., a genetic marker of known location and the unknown disease loci) are cosegregating within a pedigree.

Following the successful application of pedigree analysis to map Mendelian disorders such as Huntington's disease, many investigators adopted this strategy for mapping psychiatric disease genes with, at best, mixed success. In the late 1980s and mid-1990s, several pedigree-based studies reported the mapping of susceptibility loci for Alzheimer's disease, bipolar disorder, and schizophrenia. Although the linkage findings for three Alzheimer's disease loci were relatively quickly replicated, the findings reported for bipolar disorder and schizophrenia were ultimately determined to have been false positives. A number of different explanations have been proposed for the failure of pedigree-based approaches to map psychiatric loci; however, most investigators now recognize that these studies were generally drastically underpowered considering the apparent etiological complexity of psychiatric disorders.

Pedigree analysis in psychiatry has increasingly turned toward an application that is more appropriately powered, namely, the mapping of quantitative trait loci (QTLs). QTLs are defined as genetic loci that contribute to the variation in continuously varying traits (as opposed to categorical traits such as disease diagnoses). QTLs are typically loci of small effect that only contribute to a portion of the observed variance of a trait in the population. It is now generally accepted that, using analytical methods developed in the late 1990s, it may be possible to use pedigree studies to map a wide range of quantitative traits that are relevant for understanding psychiatric disorders. Several such studies are now being undertaken, typically with multiple phenotypes being assessed in each individual in the pedigree.

Sib Pair Analysis

Affected sib pair (ASP) analysis became widely used during the 1990s for the genetic mapping of complex traits, including many psychiatric disorders. Sib pair analysis examines the frequency with which sibling pairs concordant for a trait share a particular region of the genome compared with the frequency that is expected under random segregation.

Sib pair analysis is based on the fact that siblings share approximately 50 percent of their genomes IBD. Therefore, if a set of unrelated sib pairs affected with a given trait shares a particular area of the genome at a frequency significantly greater than 50 percent (the proportion of sharing expected under conditions of random segregation), then that area of the genome is likely to be linked to the trait in question. In this method, siblings are genotyped, and population frequencies and parental genotypes are used to estimate the proportion of genes shared IBD at each site for each sib pair. The linkage analysis then compares those pairs concordant and discordant for each locus.

Like pedigree studies, ASP studies have more power to locate genes of large effect than genes of small effect. This limitation can be partially addressed by a two-tiered design that incorporates additional markers or family members after an initial linkage study in affected siblings or by increased sample size. It generally requires less effort to identify and assess even large sets of affected sibs than to identify and assess all members of extended pedigrees, particularly when investigators can take advantage of data repositories that include samples and phenotype data from sib pairs ascertained from multiple sites. For example, the U.S. National Institute of Mental Health (NIMH) maintains such repositories for sizable collections of sib pairs affected with schizophrenia, bipolar disorder, autism, and Alzheimer's disease. An additional benefit of the ASP design is that it allows for the incorporation of epidemiological information, permitting the simultaneous examination of environmental and gene-environment interactions.

Association Studies

In the last few years, there has been increasing acceptance of the notion that association studies are more powerful than linkage approaches for mapping the loci of relatively small effect that are thought to underlie much of the risk for complex disorders. Whereas linkage studies attempt to find cosegregation of a genetic marker and a disease locus within a family or families, association studies examine whether a particular allele occurs more frequently than expected in affected individuals within a population. As noted previously in this chapter, mapping of genes using association studies is based on the idea that certain alleles at markers closely surrounding a disease gene will be in LD with the gene; that is, these alleles will be carried in affected individuals more often than expected by random segregation, because they are inherited IBD.

There are two common approaches to association studies (see Fig. 1.7-1), case-control designs and family-based designs, which typically investigate trios (mother, father, and an affected offspring). In a case-control study, allele frequencies are compared between a group of unrelated affected individuals and a matched control sample. This design is generally more powerful than a family-based design, because large samples of cases and controls are easier to collect than trios and are less expensive, since they require the genotyping of fewer individuals. Case-control samples may be the only practical design for traits with a late age of onset (such as Alzheimer's disease) for which parents of affected individuals are typically unavailable. The main drawback of the case-control approach is the potential problem of population stratification; if the cases and controls are not carefully matched demographically, then they may display substantial differences in allele frequency that reflect population differences rather than associations with the disease.

Family-based association studies are designed to ameliorate the problem of population stratification. In this design, the nontransmitted chromosomes (the copy of each chromosome that is not passed from parent to child) are used as control chromosomes, and differences between allele frequencies in the transmitted and nontransmitted chromosomes are examined, eliminating the problem of stratification, as the comparison group is by definition genetically similar to the case group. Although more robust to population stratification than a case-control study, family-based studies are only about two-thirds as powerful using the same number of affected individuals, as noted previously.

Until recently, it was not practical to conduct association studies on a genome-wide basis, as relatively few SNPs were available. Therefore, association studies focused on testing one or a few markers in candidate genes chosen on the basis of their hypothesized function in relation to a given disease. Recently, however, as a result of international efforts that have identified millions of SNPs distributed relatively evenly across the genome and that have developed technology for genotyping them relatively inexpensively, genome-wide association (GWA) studies are now a reality. Such studies hold much promise for the identification of common variants contributing to common diseases. While few GWA studies of psychiatric disorders have been completed, such studies have already reported remarkable findings for complex traits such as rheumatoid arthritis, inflammatory bowel disease, and type 2 diabetes. The successful studies of these diseases have made use of very large samples (in some cases up to several thousand cases and controls), providing further support for the hypothesis that underpowered study designs bear much of the responsibility for the disappointing results to date of psychiatric genetic investigations.

Statistical Considerations

Scientists in other biomedical research fields are often surprised by the apparently high level of statistical evidence that geneticists require to

consider a linkage or association result to be significant. Most simply, this requirement can be thought of in terms of the very low expectation that any two loci selected from the genome are either linked or associated with one another. The likelihood that any two given loci are linked (i.e., the prior probability of linkage) is expected to be approximately 1:50, based on the genetic length of the genome. To compensate for this low prior probability of linkage and bring the posterior (or overall) probability of linkage to about 1:20, which corresponds to the commonly accepted significance level of $P = .05$, a conditional probability of 1,000:1 odds in favor of linkage is required, corresponding to the traditionally accepted LOD score threshold of 3. This generally provides an acceptable false-positive rate (Fig. 1.7-2), but some false-positive findings have exceeded even this threshold.

FIGURE 1.7-2

Number of false positives expected in a whole genome scan for a given threshold of logarithm of odds (LOD) score. *Solid line* represents the expectation for a perfect genetic map. *Symbols* represent the results for 100 sib pairs using genetic maps with markers spaced every .1 cM (*circles*), every 1 cM (*squares*), and every 10 cM (*triangles*). The *dotted line* indicates the 5 percent genomewide significance level. (Courtesy of Dr. Eric Lander).

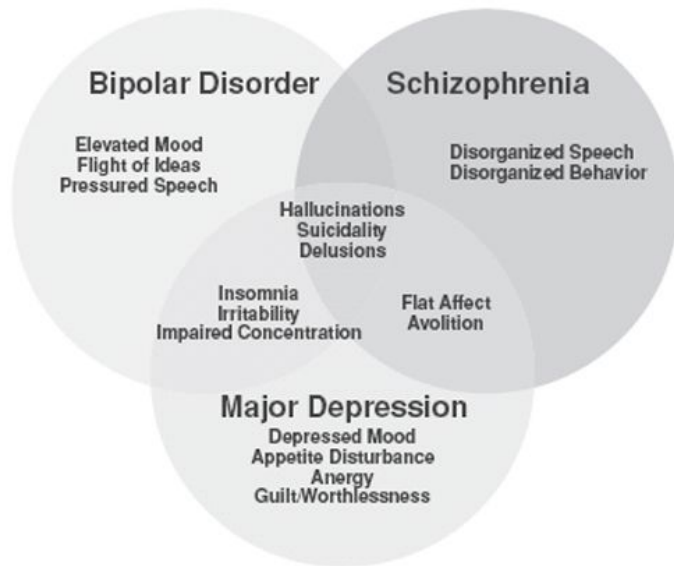

Geneticists generally assume that the expectation that any two loci in the genome are associated with one another is even lower than that of their being in linkage, and typically a P value of less than about 10^{-7} is considered to indicate “genomewide significance.” This standard essentially discounts the prior probability that some investigators assign to variants in candidate genes chosen on the basis of their hypothesized functional relevance to a given disorder or trait. GWA studies are now replicating associations with very low P values for a wide range of complex traits, whereas most candidate gene associations (which usually report as significant much higher P values) remain unreplicated. It is therefore increasingly apparent that genomewide levels of significance are appropriately applied to all initial association studies for a given trait.

DEFINING PHENOTYPES FOR MAPPING STUDIES

The generally disappointing results of psychiatric genetic mapping studies have focused increasing attention on the problem of defining and assessing phenotypes for such studies. Most psychiatric mapping studies to date have relied on categorical disease diagnoses, as exemplified by the *Diagnostic and Statistical Manual* (DSM-5) classification scheme. Criticisms of this approach rest on two arguments. First, diagnosis of psychiatric disease depends on subjective clinical evaluation, a fact that underscores the difficulty in ascertaining individuals who can be considered definitely affected with a given disease. Second, even when a psychiatric diagnosis can be established unambiguously, the menu-based system used for psychiatric classification provides the possibility that any two individuals affected with a given disorder may display largely nonoverlapping sets of symptoms, likely reflecting distinct etiologies. Concern that the diagnosis-based approach to phenotyping may represent one of the chief obstacles to the genetic mapping of psychiatric phenotypes has generated considerable interest in mapping heritable traits known to demonstrate continuous variation in the population. Continuous measures that are hypothesized to be related to psychiatric disorders include biochemical measures (e.g., serum or CSF levels of neurotransmitter metabolites or hormones), cognitive measures, personality assessments, structural or functional brain images, biophysical markers such as responses to evoked potentials, or molecular assays such as gene expression profiles. Key features of categorical and continuous phenotyping strategies are shown in [Figure 1.7-3](#), and each is discussed in more detail below.

Phenotyping Strategies

A. Categorical Traits

B. Continuous Traits

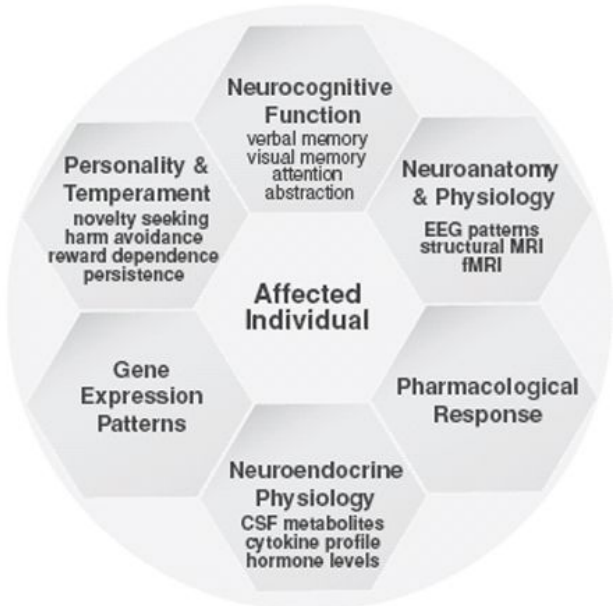

FIGURE 1.7-3

Two alternate schemes for conceptualizing psychiatric phenotypes. **A.** Categorical Traits as conceptualized by the *Diagnostic and Statistical Manual* (DSM-5) represent a “menu-based” approach to psychiatric disorders. Individuals are assessed for a checklist of signs and symptoms that are then used to categorize the individual as “affected” according to a specific diagnosis. Not all symptoms are present in samples of individuals who carry a particular DSM diagnosis, and many of these symptoms occur across diagnostic boundaries, as illustrated in this Venn diagram. DSM phenotypes therefore probably represent etiologically heterogeneous categories, and this fact may help to explain the limited progress thus far of genetic mapping investigations focused on these phenotypes. **B.** Alternatively, in the Continuous Traits model, “affectedness” can be conceptualized in terms of an expectation that an individual will demonstrate extreme values on a set of continuous measures that correlate with psychopathology and thus are hypothesized to underlie the disorder (as illustrated by examples of six different types of measures shown in the hexagon). Such measures may also be associated with particular components of categorical phenotypes, such as those depicted in the Venn diagram in Figure 19-3A. The justification for using continuous measures as the phenotypes for genetic mapping studies is that they are considered etiologically simpler and more reliably assessed compared to categorical phenotypes. In addition, mapping such traits combines information from all members of the study population (affected and unaffected individuals alike), which adds considerably to power. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock’s Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:325.)

Categorical Phenotypes

The most commonly used categorical phenotypes in psychiatry are DSM diagnoses. Some studies focus on a single DSM diagnosis, whereas other studies include individuals with a range of different diagnoses. The latter approach is typically used for disorders that are hypothesized to represent a single disease spectrum, such as mood disorders. Using the categorical approach, it is important to be able to classify subjects as unambiguously as possible. Several strategies are used to accomplish this goal. The first strategy involves deciding on the appropriate diagnostic criteria for the study in question and deciding how these criteria will be applied to individuals in the study. One way of standardizing the procedures used to identify and assess potential study subjects is to use only experienced clinicians in the diagnostic process and to train them in the administration of the instruments and the diagnostic criteria to be employed. In addition, a “best estimate” procedure and/or a consensus diagnosis is frequently used. The best estimate process involves making use of every piece of available information, including medical records, interviews, and videotapes, to arrive at a diagnosis. For a consensus diagnosis, two or more diagnosticians independently review the material and make a diagnosis for each individual. The diagnoses are then compared, and individuals for whom an agreement in diagnosis cannot be reached are not entered as “affected” into the study.

A well-designed study makes use of all available information about the genetic epidemiology of the disorder to choose a sample of affected individuals to study. It is often the case that a subset of families carries the disorder in what appears to be a simple Mendelian pattern, whereas the inheritance pattern is less clear for other families or groups. In a disorder where there are likely to be multiple genes contributing to the phenotype, it makes sense to begin with a study sample where there may be major loci. Redefining the disease phenotype can often simplify the mapping process by identifying such groups or families. For example, in the search for a genetic defect for Alzheimer’s disease, the process was advanced enormously by limiting the study population to those individuals who had early age of onset (before age 65); the early onset trait segregated in an autosomal dominant fashion. Other ways of redefining the phenotype include focusing on factors such as ethnic background, age of onset, treatment response, symptom severity, or the presence of comorbid disorders.

Narrowing the phenotype using the approaches discussed earlier may increase the chances of finding a genetic defect in complex diseases, but it can also greatly reduce the power of the study by limiting the number of available affected individuals. For this reason, it has been argued that for some disorders broadening the phenotype is an appropriate strategy. The suggestion is that for some complex diseases the phenotype of interest may represent the extreme end of a spectrum and that to have enough power to map genes other phenotypes within the spectrum must also be included. For example, mapping studies of bipolar disorder might include as affected individuals with major depressive disorder as well as those individuals diagnosed with bipolar disorder.

Although the two approaches of narrowing the disease phenotype and broadening the disease phenotype may seem to be mutually exclusive, many groups studying complex disorders have incorporated both approaches into their study designs. One way to do this is to create stratified diagnostic categories, ranging from a narrow diagnostic category to a broad diagnostic category, and test for genetic linkage under each of these schemas. Some investigators argue that for complex diseases that are part of a spectrum, this strategy decreases the rate of false negatives, that is, of missing an existing linkage because of misspecification. Others argue that using several models and picking the one that gives the highest scores greatly increases the rates of false positives, that is, of identifying an area of linkage where none exists. One problem that clearly exists with the use of multiple diagnostic categories is that as more models are used (and therefore more statistical tests are performed), increasingly stringent levels of evidence are required to consider a result significant.

While categorical phenotypes remain the mainstay of psychiatric genetic studies, the limitations of DSM nosology as the basis of phenotyping for genetic studies are becoming

clear. Genetic investigations are focusing increasingly on traits that may be components of one or more DSM diagnostic categories. For example, there is growing evidence that genetic susceptibility to psychosis, broadly defined, contributes to both severe bipolar disorder and schizophrenia, and a number of investigative approaches are being employed to attempt to identify genes that underlie such susceptibility and even to explore possible etiological relationships between psychiatric and nonpsychiatric disorders. For example, bioinformatics models have been employed to investigate medical records databases and have uncovered extensive pairwise correlations among a diverse list of psychiatric disorders, neurological disorders, autoimmune disorders, and infectious diseases. Eventually, the results of such model-fitting experiments may provide a framework to design more powerful linkage and association studies that can search for alleles that contribute to susceptibility to multiple disorders.

Continuous Phenotypes

Because of the difficulties experienced in genetic mapping of categorical diagnoses, neurobehavioral geneticists are increasingly focused on investigating quantitative traits that are hypothesized to underlie a particular psychiatric diagnosis and that may be simpler to genetically map. The rationale for efforts to map such alternative phenotypes, or endophenotypes, is that the genes identified through such efforts may provide clues regarding the biological pathways that are relevant to understanding a particular disorder. Several features characterize useful endophenotypes. First, they should be state-independent; that is, they should not fluctuate as a function of the disease course or medication treatment and should show adequate test-retest stability. Second, they should be heritable; that is, there should be evidence that genetic factors are responsible for a substantial proportion of the variability of the trait within the population. Third, the endophenotype should be correlated with the disease under investigation; that is, different values of the trait measure are observed in patients compared to unrelated control subjects.

Measures of brain structure and function provide most of the traits now under investigation as endophenotypes for psychiatric disorders. For example, several features of brain morphometry (as assessed by magnetic resonance imaging [MRI]) are highly heritable (in the range of 60 to 95 percent) including total brain volume, cerebellar volume, gray and white matter density, amygdala and hippocampal volume, and regional cortical volume. Several studies show that brain structural features that are correlated in clinical samples with disorders such as schizophrenia or bipolar disorder are also abnormal in relatives of affected individuals. Physiological measures of brain activity that have been employed as candidate endophenotypes for psychiatric disorders include electroencephalography (EEG) patterns. Several "pencil and paper" assessments have been employed to measure endophenotypes relating to neurocognitive function and temperament.

Animal Models

In contrast to categorical phenotypes, endophenotypes can be more straightforwardly related to phenotypes that can be assessed in animal models. Studies of genetic variations that affect circadian rhythms provide a good example. Variations in circadian rhythms have long been recognized as important features of mood disorders, and quantitative assessments of activity patterns have been proposed as endophenotypes for such disorders. Numerous studies in animal models have demonstrated that genetically controlled biological clocks determine circadian activity and that variations in clock genes are associated with variations in such activity from bacteria to humans. Genetic mapping efforts in fruit flies starting in the early 1970s resulted in the identification of at least seven "clock genes," beginning with *period*. Subsequent studies showed that the homologs of several of these genes play essential roles in regulating mammalian circadian rhythms. Genetic mapping studies in mice also have identified previously unknown circadian rhythm genes, beginning with the discovery and characterization in the early 1990s of *clock*. These genetic discoveries have not only explicated the cellular networks and neurophysiological circuits responsible for the control of mammalian circadian rhythms but have also generated animal models that may shed light on the pathobiology of psychiatric syndromes such as bipolar disorder. For example, mice carrying a targeted mutation in *clock* demonstrate abnormal activity patterns, such as hyperactivity and decreased sleep, which are apparently modified by administration of lithium.

PROGRESS IN THE GENETICS OF SPECIFIC DISORDERS

Taken as a whole, the progress in identifying susceptibility genes for psychiatric disorders has been disappointing compared to that observed for nonpsychiatric disorders. Alzheimer's disease represents the most successful application of gene-mapping strategies to complex neurobehavioral disorders, and the section on this disease provides an example of how genetic linkage studies add to understanding of the pathogenesis of a complex trait. An overview section on autism describes genetic investigations of syndromes that have features of autism but have relatively simple inheritance patterns and discusses how these studies have provided starting points for investigations of more complex autism spectrum disorders. Finally, the frustrating search for unequivocal gene findings for bipolar disorder and schizophrenia is used to illustrate the challenges that are motivating new approaches in the field of neurobehavioral genetics.

ALZHEIMER'S DISEASE

Alzheimer's disease provides an excellent example of the power of genetics to elucidate the complex biology of a neuropsychiatric disorder. Alzheimer's disease is a well-defined form of dementia characterized by progressive impairment of memory and intellectual functioning. The clinical signs and symptoms, although characteristic, are not limited to Alzheimer's disease; they are also found in several other types of dementia. For this reason, the diagnosis of Alzheimer's disease can only be confirmed histopathologically at autopsy. The presence of senile plaques (made up of a core of β -amyloid fibrils surrounded by dystrophic neurites), tau-rich neurofibrillary tangles, and congophilic angiopathy in the brain parenchyma and associated blood vessels are pathognomonic for Alzheimer's disease.

A variable age of onset has been noted for Alzheimer's disease, ranging from as early as age 35 to as late as age 95. The concordance rate for Alzheimer's disease in MZ twin pairs is about 50 percent, indicating a moderately strong genetic contribution to disease risk. It is now evident from a wide range of genetic studies that Alzheimer's disease can be divided into two broad categories: familial forms, which account for a tiny minority of Alzheimer's disease cases and are characterized by early onset and autosomal dominant inheritance with high penetrance; and sporadic forms, in which the genetic contribution is hypothesized to be similar to that characterizing other common neuropsychiatric diseases.

The search for the genetic basis of familial Alzheimer's disease began with traditional linkage studies. First, an investigation of a candidate locus on chromosome 21 in humans identified mutations in the *amyloid precursor protein (APP)* gene in a small number of families in which significant linkage had previously been observed to markers from this region. Transgenic mice with different *APP* mutations were created and have been shown to produce β -amyloid deposits and senile plaques as well as to show synapse loss, astrogliosis, and microgliosis, all part of the pathology of Alzheimer's disease. Mutations in the genes that encode β -APP all lead to an increase in the extracellular concentration of longer fragments of β -amyloid (A β 42). Most of the strains of transgenic mice with mutations in *APP* exhibit increased rates of behavioral changes and impairment in several memory tasks, indicating dysfunction in object-recognition memory and working memory among others. These findings represent striking evidence that mutations in the β -amyloid gene are indeed responsible for at least some of the histopathological elements of Alzheimer's disease.

Even as the preceding findings were being reported, it was clear that mutations in the β -amyloid gene could not completely explain the etiology and pathology of Alzheimer's disease, not least because it was shown that linkage to chromosome 21 was excluded in most early onset Alzheimer's disease families. In addition, no neurofibrillary tangles are observed in most of the different β -amyloid transgenic mice. The subsequent search for the genetic underpinnings of Alzheimer's disease using genomewide linkage analysis of early onset Alzheimer's disease families resulted in the identification of two additional Alzheimer's disease susceptibility genes: *presenilin-1 (PS-1)* on chromosome 14q24.3 and *presenilin-2 (PS-2)* on chromosome 1q. PS-1 and PS-2 are integral transmembrane proteins with at least seven transmembrane domains. Although their function has not yet been completely elucidated, they are clearly involved in the pathogenesis of Alzheimer's disease. Inactivation of *presenilins* in mice leads to neurodegeneration and behavioral manifestations of memory loss. Biochemical and cellular studies have implicated presenilins in several important pathways, including apoptosis (programmed cell death) and protein processing in the

endoplasmic reticulum.

These findings emphasize one of the strengths of using family-based linkage analysis. Pedigree-based studies are especially suited to identify highly penetrant disease genes that serve important roles in important biological processes. Although mutations in *APP* and *presenilin* are rare, research into the biology of the expressed proteins has provided key insights into the pathophysiology of dementia. Because these highly penetrant mutations elucidate important biological functions, they also provide a firm ground to design therapeutic interventions. For example, amyloid- β “vaccines” designed to induce an immunogenic response to pathogenic amyloid are now in advanced clinical trials. Unlike the current psychopharmacological treatments for Alzheimer’s disease that nonspecifically target cholinergic and glutamergic neuronal systems, the amyloid- β vaccines specifically treat the causes of Alzheimer’s disease by generating an immune response that may actually reverse the deposition of senile plaques.

Sporadic and Late-Onset Alzheimer’s Disease

Mutations in *APP*, *PS-1*, or *PS-2* are present in a majority of familial cases of early-onset Alzheimer’s disease but do not account for sporadic or familial late-onset Alzheimer’s disease. For this reason, investigators turned to other approaches to search for evidence of linkage in a large number of small families with late-onset Alzheimer’s disease. In 1991, the results of a nonparametric linkage study using 36 markers in late-onset Alzheimer’s disease families provided evidence for a susceptibility gene on the long arm of chromosome 19. In 1993, association studies revealed that the e4 allele of the *apolipoprotein E* gene was strongly associated with late-onset Alzheimer’s disease and that this association almost certainly was responsible for the previously observed linkage signal on chromosome 19. There are three known alleles of this gene—e2, e3, and e4. In most populations, the e3 allele is the most common. However, in familial late-onset Alzheimer’s disease the incidence of e4 is approximately 50 percent, and in sporadic late-onset Alzheimer’s disease it is 40 percent, compared with about 16 percent in normal controls. Epidemiological studies suggest that between 30 and 60 percent of late-onset Alzheimer’s disease cases have at least one *apoE-e4* allele. The e4 genotype appears to be a more important risk factor for Alzheimer’s disease in populations of European and Asian origin when compared with populations of African origin. Overall, the association of *apoE-e4* with Alzheimer’s disease remains probably the strongest association yet identified for a common human disease.

The establishment of *apoE-e4* as a susceptibility allele for late-onset Alzheimer’s disease has led to the search for additional alleles that might interact with *apoE-e4* to modify disease risk. In 2007, investigators used genomewide association strategies (in histologically confirmed cases and controls) to identify *GAB2* (GRB-associated binding protein 2) as an additional risk allele in *apoE-e4* carriers (but not in Alzheimer’s disease patients who were not e4 carriers). Initial studies suggest that carriers of both *apoE-e4* and *GAB2* risk alleles have an almost 25-fold greater risk for Alzheimer’s disease than individuals who do not carry either risk allele. Larger-scale GWA studies of Alzheimer’s disease are in progress and will likely yield further associations; however, it is unlikely that any will have as strong an effect as *apoE*.

AUTISM

Autism is a severe neurodevelopmental disorder that is characterized by three primary features: impaired language and communication; abnormal or impaired social interaction; and restricted, repetitive, and stereotyped patterns of behavior. Understanding of the etiology of autism has proceeded slowly, but there is now convincing evidence that alterations in specific cellular and molecular neurodevelopmental pathways are important in its etiology. In comparison with other neuropsychiatric disorders, there is particularly strong evidence for a genetic contribution to the risk of autism and autism spectrum disorders (ASDs). The sibling recurrence risk for autism and/or ASD is between 2 and 6 percent. Given a population prevalence of about 1 in 2,000 (.04 percent), this means that the siblings of autistic individuals are approximately 50 to 100 times more likely to develop autism than a person in the general population. Twin studies of autism show an extraordinarily high heritability (as demonstrated by MZ twin concordance of 80 to 92 percent) but also demonstrate the genetic complexity of these disorders, with the DZ twin concordance rate of 1 to 10 percent suggesting a highly multigenic mode of inheritance.

Increasing interest is now focused on the possibility that individuals affected with autism may display larger numbers of large-scale chromosomal aberrations (5 to 10 percent in some studies) than unaffected individuals. In addition to such gross abnormalities, several recent studies have suggested that autism is associated with an unusually high prevalence of submicroscopic CNVs. For example, in 2007, the Autism Genome Project Consortium applied microarray strategies to almost 8,000 individuals from about 1,500 families, each with at least two affected family members, and found that about 10 percent of the ASD families carried CNVs, with an average size of more than 3 million base pairs, mostly consisting of duplications rather than deletions. Although the design of this study did not permit assessment of whether the frequency of CNVs is greater in patients with autism than that in controls, another study found a de novo CNV incidence of 10 percent in sporadic (no family history) cases of autism compared to an incidence of 1 percent in controls. These results, while exciting, are still considered preliminary. Even before the demonstration of high rates of de novo mutations in autism, epidemiological studies had strongly suggested that the genetic basis of this disorder is likely complex. For example, although the risk of autism in first-degree relatives of autistic probands is high, there is a substantial falloff for second-degree and third-degree relatives of such probands, suggesting that multiple genetic variants must interact to increase susceptibility to this syndrome. Segregation analyses of autism also support the hypothesis that it is a heterogeneous disorder that reflects the actions of multiple genetic variants of small effect. A latent class analysis performed to study possible modes of transmission suggested an epistatic model with up to about 10 interacting loci, whereas other studies have estimated that as many as 15 such loci may be involved. Genetic studies of autism have included whole genome screens, candidate gene studies, chromosome rearrangement studies, mutation analyses, and, most recently, comparative genomic hybridization studies. Taken together and recognizing that most findings still await adequate replication, these studies have contributed to an emerging picture of autism susceptibility that includes genes involved in three major systems: those involving synapse formation and maintenance, those involving cell migration, and those involving the excitatory/inhibitory neurotransmitter networks. [Figure 1.7-4](#) shows a schematic of the currently known potential candidate genes for autism and their molecular relationships with one another.

FIGURE 1.7-4

Schematic of the cell biology of proteins expressed from genes identified through mapping studies of autism spectrum disorders. The function of each gene product falls into three broad functional categories. Proteins involved in synapse formation and maintenance include FMR1, TSC1, TSC2, MeCP2, NLGN 3 and 4, and SHANK3. Another set of proteins is involved in neuronal migration and cell fate including REELIN, WNT2, LAMB1, and NrCAM. Proteins involved in neurotransmitter systems are also altered in some individuals with autism and include 5-HTT (serotonin transporter encoded by SLC6A4), GABAR, and the NMDA subunit encoded by GRIN2A. See text for details. (From Persico AM, Bourgeron T. Searching for ways out of the autism maze: Genetic, epigenetic and environmental clues. *Trends Neurosci.* 2006;29:349, with permission.)

Synapse Formation and Maintenance

Perhaps the biggest breakthroughs in identifying susceptibility genes for autism have come from studies of disorders that display clinical features associated with autism or ASDs but with simpler inheritance patterns, including fragile X syndrome, tuberous sclerosis, and Rett syndrome. In general, the genetic defects associated with these disorders affect synapse formation and maintenance. Fragile X, which accounts for 3 to 4 percent of autism cases, is caused by an unstable trinucleotide repeat in the 5' region of the fragile X mental retardation 1 (*FMR1*) gene at Xq27.3. This repeat expands as it is transmitted to succeeding generations, resulting in abnormal methylation and inhibition of expression of *FMR1*. *FMR1* produces a ribonucleic acid (RNA)-binding protein that acts as a chaperone for the transport of RNA from the nucleus to the cytoplasm and is involved in messenger RNA (mRNA) translation at the synapse. Abnormalities in dendritic spine density (increased over normal) and anatomy (longer and thinner than normal) have been reported in individuals with fragile X as well as in mouse models of this disorder. Tuberous sclerosis, which accounts for perhaps 2 to 10 percent of autism cases (the rate of tuberous sclerosis is higher among autistic individuals with seizure disorders), results from mutations in one of two tumor suppressor genes, *TSC1* on 9q34, and *TSC2* on 16p13, both of which are involved in guanosine triphosphatase (GTPase) inactivation. Loss of a single copy of *TSC1* in mice has been shown to disrupt cytoskeletal dynamics and dendritic spine structure. Although somewhat less well understood, the genetics of Rett syndrome, an X-linked pervasive developmental disorder (the first with a known genetic etiology) that occurs only in girls and is associated with normal early development followed by loss of skills—particularly social engagement and purposeful hand skills by age 4—also point to abnormalities in synapse formation and maintenance in ASD and ASD-like disorders. Rett syndrome is caused by mutations in *MeCP2*, which makes a methylated-DNA-binding protein that regulates gene expression and chromatin structure. Although little is known about the exact role of *MeCP2* in the development of Rett syndrome, the pattern of normal early development and later regression suggests that this gene is more likely to be involved in synapse maintenance and remodeling than in synapse development.

Neuroigin (NLGN) 3 and 4 and SHANK3, additional genes that appear to play a role in synapse formation, may be affected by chromosomal rearrangements observed in some individuals affected with autism. The neuroigin genes, sited on the X chromosome, produce cell adhesion molecules that are located on postsynaptic glutamatergic neurons. When mutated in rodents, these genes show defective trafficking and synapse induction. In nonmutated form, their expression induces the formation of normal, presynaptic terminals in axons. *SHANK3* is a binding partner of the neuroligins and regulates the structural organization of dendritic spines. Mutations in *SHANK3* have been identified in ASD-affected members of at least three families to date, and a comparative genomic hybridization study of autistic individuals, their family members, and controls recently identified a large deletion in chromosome 22q13, the region containing *SHANK3*, in at least one individual with autism.

Cell Migration

Of the regions highlighted by a genome screen in autism families, chromosome 7q has provided the most consistent evidence for linkage, albeit over a very broad region. Known chromosomal rearrangements in this region in individuals affected with autism add to its interest. The linkage region on chromosome 7q contains several genes that are strong candidates for autism, most notably *RELN*, which maps to chromosome 7q22. *RELN* codes for reelin, a signaling protein secreted by Cajal-Retzius cells located in the marginal zone of the developing brain. It plays an important role in neuronal migration as well as in the development of neural connections. Reeler mice, which have spontaneous deletions of *RELN*, have cytoarchitectonic alterations in their brains during development that are similar to those that have been described in autistic brains. The complete absence of *RELN* in humans leads to a more severe phenotype with lissencephaly and severe mental retardation but not autism. Individuals with autism show reduced levels of reelin mRNA and protein in brain and blood serum, suggesting that mutations leading to reduced expression of *RELN* rather than its absence may be important in ASD. Genetic association studies with *RELN* have been equivocal, suggesting that if *RELN* does contribute to the development of autism, then it may play such a role in a small subset of affected individuals. *WNT2* (wingless-type MMTV integration site family member 2) is another gene identified as a potential candidate for autism based on linkage studies. *WNT2* is located on 7q31 and is part of a family of genes that encode secreted

signaling proteins implicated in several developmental processes, including the regulation of cell fate and patterning during embryogenesis. At least two families have been identified in which nonconservative coding sequence variants in *WNT2* segregate with autism. LD between a SNP in the 3' untranslated region of *WNT2* and autism is also present in families with severe language abnormalities that accounted for most of the evidence for linkage on chromosome 7q in one of the original genome screens.

Excitatory/Inhibitory Neurotransmitter Systems

Although there is little current evidence that mutations in genes encoding neurotransmitter transporters and/or receptors are directly responsible for the development of autism, there is some evidence that such genes might act as modifiers or susceptibility factors for an autism spectrum phenotype. The evidence is perhaps strongest for the role of the γ -aminobutyric acid (GABA) receptors in the development and expression of autistic disorders. These receptors occur in a cluster on chromosome 15q11–13, and duplications of this region are the most common cytogenetic abnormalities seen in autism cases (up to 6 percent of cases). GABA is an important inhibitory neurotransmitter in the central nervous system and is responsible for controlling excitability in mature brains. Chromosome 15q11–13 is one of the most complex regions of the genome. It has a high rate of genomic instability, including frequent duplication and deletion events, and imprinting plays an important role in the expression of genes in this region. The 15q11–13 region is the critical region for Angelman and Prader-Willi syndromes, neurological disorders due to deletions or mutations in this region that occur on maternally and paternally inherited chromosomes, respectively.

Despite the high rate of duplications of 15q11–13 among autistic individuals, genome screens have not shown strong support for linkage or association to this region. Candidate gene studies continue, however, in part because a rate of 6 percent of autistic individuals with duplications in this region is hard to ignore.

BIPOLAR DISORDER

The search for the genetic basis of bipolar affective disorder has been fraught with missteps and partial answers. The history of genetic mapping attempts for bipolar disorder illustrates not only the extreme complexity of psychiatric disorders but also the evolution of genetic approaches to such diseases. Bipolar disorder is an episodic illness characterized by recurrent periods of both mania and depression. Psychotic symptoms are often a part of the clinical picture, particularly in more severely affected individuals.

Numerous genetic epidemiological investigations conducted over several decades have strongly supported a genetic contribution to risk for bipolar disorder. As with other psychiatric disorders, however, the definition of the bipolar disorder phenotype in these studies has varied substantially, and this in turn has resulted in a wide range in estimates of its heritability. For example, many early studies into the genetic basis of mood disorders did not distinguish between unipolar and bipolar mood disorders. Furthermore, the diagnostic methodology used in such early studies differs substantially from that employed in current-day genetic studies. For example, a Danish twin study that suggested a very high heritability for bipolar disorder and thereby had a heavy influence on the design of initial genetic mapping studies of mood disorders employed only unstructured diagnostic interviews by a single clinician rather than the structured assessments used in current studies, which have suggested somewhat lower heritabilities.

Current estimates of concordance for bipolar disorder range between 65 and 100 percent in MZ twins and between 10 and 30 percent in DZ twins, indicating that the disorder is highly heritable (between about 60 and 80 percent). Several studies have shown that bipolar disorder is substantially more heritable than unipolar major depression, which has an estimated heritability between 30 and 40 percent.

Early family studies suggested that bipolar disorder segregation patterns were compatible with single gene inheritance of a locus of major effect. However, although it is possible that some bipolar disorder pedigrees segregate such a locus, mounting evidence indicates that if such pedigrees exist they must be quite rare. Furthermore, the fact that genetic linkage studies have failed to uncover such a locus with unequivocal evidence in any pedigrees argues against this possibility. The observed rapid decrease in recurrence risk for bipolar disorder from monozygotic co-twins to first-degree relatives is also not consistent with single gene inheritance models but rather suggests models of multiple interacting genes.

Early Linkage Studies

Tremendous excitement followed the first reports of linkage to bipolar disorder on chromosomes X and 11 in 1987. Investigators noted that in several families, bipolar disorder and other affective disorders appeared to be inherited in an X-linked fashion. Likewise, these disorders appeared to cosegregate in several Israeli families with color blindness and G6PD deficiency, which map to the X chromosome. Linkage studies in these pedigrees, using color blindness or G6PD deficiency as marker loci, gave LOD scores between 4 and 9. Early studies of chromosome 11 were similar to those for chromosome X in that they reported significant linkage after testing only a few markers in a single region, in this case in an extended Old Order Amish pedigree heavily loaded for bipolar disorder.

Not surprisingly, these findings generated a great deal of interest. Both studies showed high LOD scores and seemed to provide clear evidence for linkage. However, replication studies in other populations failed to produce positive results for either the X chromosome or chromosome 11, and evidence for linkage essentially disappeared in both chromosomal regions in the samples in which linkage was originally reported when the pedigrees were extended to include additional affected individuals and when additional markers were typed in the putative linkage regions. The most likely explanation in each case is that the original linkage results were false-positive findings and may have reflected overoptimistic interpretation of evidence that, in retrospect, was relatively scanty.

Genomewide Screens

The early linkage studies of bipolar disorder evaluated only a few markers because they were all that were available. With the construction of genetic linkage maps of the genome in the 1990s, linkage studies of most complex traits, including bipolar disorder, began to search genomewide. The advantage of genomewide mapping studies is that they do not require *a priori* knowledge of the biological underpinnings of a particular phenotype. Complete genome screens provide an opportunity to evaluate the evidence of linkage at all points in the genome without bias (see [Color Plate 1.7-5](#)). Although genomewide studies clearly had greater power to detect true linkage than studies focused on only a few markers in arbitrary locations or around a few candidate genes, these investigations have also generally had disappointing results. The challenge of achieving replicated significant linkage results for bipolar disorder and other complex traits is apparent when one reviews the many gene-mapping studies that have suggested—but not demonstrated unequivocally—bipolar disorder susceptibility loci on chromosome 18.

Chromosome 18

The first report of linkage came from a partial genome screen that examined 11 markers on chromosome 18 and identified suggestive linkage near the centromere. Because the inheritance patterns for bipolar disorder are unknown, the results were analyzed using both recessive and dominant models. Some of the markers were positive under a recessive model in some families, some were positive under a dominant model in other families, and some markers gave positive LOD scores in a subset of families under both models. Attempts to replicate this finding in other populations have been mixed. So far at least two groups have found no evidence for linkage to the pericentromeric region of chromosome 18 in their samples, although one other group has found evidence to support linkage to this region. Other studies have found suggestive evidence for linkage on chromosome 18, including a complete genome screen in two large Costa Rican

pedigrees that gave evidence for linkage on chromosome 18q22–23 as well as in an area on 18p. The combined evidence of these several studies, although somewhat contradictory and confusing, points to at least two different susceptibility loci on chromosome 18: one on 18p and one on 18q.

Improving Study Power

The equivocal findings represented by the attempts to pinpoint susceptibility loci on chromosome 18 have led investigators to implement several new strategies to map bipolar disorder genes. One such strategy is meta-analysis, which involves combining data across multiple individual investigations to increase statistical power, and in some cases the combined analysis points to loci not originally found in the individual studies. Several meta-analytical techniques have been used to explore gene-mapping studies for bipolar disorder. The multiple scan probability (MSP) and genome scan meta-analysis (GSMA) methods require only linkage statistics and *P*-values from each study to examine combined data. MSP was used to combine chromosomal regions with *P*-values less than .01 from 11 independent bipolar disorder studies and provided evidence for susceptibility loci on chromosomes 13q and 22q. Although the MSP and GSMA methods have the advantage of requiring only linkage significance data, they are not able to account for study-specific issues that will limit the extent to which multiple studies can be compared. Combining original genotype data from multiple studies can circumvent this problem. With this method, the largest meta-analysis to date combined 11 bipolar disorder genomewide linkage scans consisting of 5,179 individuals from 1,067 families. Access to the original genotype data allowed the construction of a standardized genetic map in which the markers of each respective study were mapped onto one common gender-averaged map. The results of this meta-analysis identified two susceptibility loci with genomewide significance on 6q and 8q.

Another strategy that has been used to increase the power of gene-mapping studies is the formation of consortia that combine data across multiple clinical sites. A consortium combining data from the UK and Ireland led to support for linkage at 9p21 and 10p14–21. Likewise, combining data from Spanish, Romanian, and Bulgarian families provided additional support for findings on chromosomes 4q31 and 6q24. Investigators can also increase power by standardizing marker sets and clinical evaluation protocols between independent studies to permit direct comparisons between such studies. This approach was used to identify a bipolar disorder susceptibility locus on chromosome 5q31–33. The region showed suggestive nonparametric linkage results in pedigrees from the Central Valley of Costa Rica. With identical genetic markers and diagnostic criteria, the same region was highlighted in an independent analysis of a set of Colombian families who have a genetic background similar to that of the Costa Rican families. A follow-up study using additional markers in an expanded set of Colombian and Costa Rican families confirmed genomewide significant evidence to a candidate region of 10 cM in 5q31–33. This finding is especially interesting given that the linkage peak in the bipolar studies overlaps with linkage regions for schizophrenia and psychosis, identified in a previous study of 40 families from the Portuguese Islands. These results contribute to a growing opinion that there may be substantial genetic overlap between different DSM disorders.

SCHIZOPHRENIA

As with bipolar disorder, investigations of the genetic basis of schizophrenia exemplify the frustrations still characteristic of psychiatric genetics, and the field still struggles to interpret the significance of initially promising linkage and association results that began to emerge over a decade ago. Unlike with bipolar disorder, however, candidate genes have emerged from each of the regions highlighted from these studies. Thus, although none of these findings have been validated unequivocally, they have spawned a diverse range of basic and clinical investigations aiming to elucidate their functional significance, for example, using mouse gene targeting and functional MRI. Here we discuss some of the more extensively investigated loci for purposes of illustration; it could be argued that roughly equivalent evidence supports schizophrenia candidate loci that we do not discuss in detail, for example, *AKT1* on chromosome 14 or *COMT* on chromosome 22.

Chromosome 6p24–22 was among the first regions to be implicated by a complete genome screen for schizophrenia, in this case from a study of Irish families heavily loaded for schizophrenia. The linkage results were strongest under a broad diagnostic definition that included schizophrenia spectrum disorders, such as schizotypal personality disorder. Six additional linkage studies have shown positive results over approximately the same region, but at least three studies have found no linkage to the region. Fine-scale mapping of this region using association analysis in the original Irish kindreds led to the proposal of *Dysbindin* (*DTNBI*) as a candidate gene for schizophrenia. Additional association studies of *Dysbindin* have been equivocal. Although multiple association studies in a variety of populations have shown positive results, interpretation of the results has been difficult. Different association studies have not used the same SNP marker sets. Meta-analysis of five “positive” association studies using a high-resolution haplotype map designed to compare the five studies showed significant inconsistencies with regard to the identified disease-associated *Dysbindin* allele. Although it is possible that several different variants in the same gene could each contribute to disease susceptibility in different families or populations, this possibility does not explain the inconsistencies between the several *Dysbindin* association studies.

Linkage studies subsequently pointed to a region on chromosome 1 containing the candidate genes *DISC 1* and *DISC 2* (*disrupted in schizophrenia 1 and 2*) located on chromosome 1q21–22 and 1q32–42. These genes were initially identified in a large Scottish pedigree in the early 1990s. A balanced translocation between chromosomes 1 and 11 segregated in this pedigree and was possibly associated with serious mental illness. *DISC 1* and 2 were identified in the original Scottish family because of their location near the chromosomal translocation breakpoint. As with *Dysbindin*, follow-up studies of *DISC 1* and 2 have been equivocal.

Genome screens, including a screen focused on extended Icelandic kindreds, have identified a schizophrenia candidate region on chromosome 8p21–22. Fine mapping of the region narrowed the search and eventually led to the proposal of *neuregulin 1* (*NRG1*) as a schizophrenia candidate gene. Association studies again provided equivocal and difficult-to-interpret results. Meta-analysis of 14 separate studies using the SNP marker that demonstrated an association in the original study showed significant heterogeneity between the follow-up studies. It also showed that there is no consistent association between the specific risk allele “tagged” by the marker SNP and schizophrenia in different populations. However, after taking account of the statistical power of each association study, the meta-analysis showed a positive association between *NRG1* at the level of the gene (as opposed to the SNP or haplotype level).

Despite the equivocal genetic studies, significant resources have been channeled into molecular and neurophysiological investigations of the functional products of *dysbindin*, *DISC 1* and 2, and *neuregulin*. Mutant mice for each of the three genes are now available and have been used to demonstrate interesting biological findings. For example, *dysbindin* is expressed in the hippocampus and dorsolateral prefrontal cortex. The dysbindin protein binds to B-dystrobrevin and has been implicated in synaptic structure and signaling. *DISC 1* has been shown to influence neurite formation in cellular studies, and mutant mice for *DISC 1* show impairments in a wide variety of tests including learning, memory, and sociability. Neuregulin belongs to a family of growth factors that mediate numerous functions including synapse formation, neuronal migration, and neurotransmission. Targeted disruption of *erbB4*, the postsynaptic target of neuregulin, leads to synaptic glutamatergic hypofunction. Despite the interesting biology uncovered, it remains unclear whether and to what extent any of these genes contribute to the etiology of schizophrenia in humans, and many geneticists have been cautious in their endorsement of the legitimacy of the mutant mice generated from the current list of candidate genes as models of psychiatric disorders.

As with bipolar disorder, the genetic mapping findings for schizophrenia are promising but equivocal. Unlike for bipolar disorder, these mapping studies have generated a set of candidate genes that have stimulated a wide range of functional investigations, many of which have biologically interesting findings. As with bipolar disorder and other psychiatric disorders, the primary challenge in elucidating the genetic basis of schizophrenia is assembling adequate richly phenotyped samples for well-powered genomewide mapping studies.

1.8 Applied Electrophysiology

Electroencephalography (EEG) is the recording of the electrical activity of the brain. It is used in clinical psychiatry principally to evaluate the presence of seizures, particularly temporal lobe, frontal lobe, and petit mal seizures (absence seizures), which can produce complex behaviors. EEG is also used during electroconvulsive therapy (ECT) to monitor the success of the stimulus in producing seizure activity, and as a key component of polysomnography used in the evaluation of sleep disorders. Quantitative electroencephalography (QEEG) and cerebral evoked potentials (EPs) represent newer EEG-based methods that provide improved research and clinical insights into brain functioning.

ELECTROENCEPHALOGRAPHY

A brain wave is the transient difference in electrical potential (greatly amplified) between any two points on the scalp or between some electrode placed on the scalp and a reference electrode located elsewhere on the head (i.e., ear lobe or nose). The difference in electrical potential measured between any two EEG electrodes fluctuates or oscillates rapidly, usually many times per second. It is this oscillation that produces the characteristic “squiggly line” that is recognized as the appearance of “brain waves.”

Brain waves reflect change by becoming faster or slower in frequency or lower or higher in voltage, or perhaps some combination of these two responses. A normal EEG can never constitute positive proof of absence of brain dysfunction. Even in diseases with established brain pathophysiology, such as multiple sclerosis, deep subcortical neoplasm, some seizure disorders, and Parkinson's disease and other movement disorders, a substantial incidence of patients with normal EEG studies may be encountered. Nonetheless, a normal EEG can often provide convincing evidence for excluding certain types of brain pathology that may present with behavioral or psychiatric symptoms. More often, information from the patient's symptoms, clinical course and history, and other laboratory results identifies a probable cause for the EEG findings. EEG studies are often ordered when a pathophysiological process is already suspected or a patient experiences a sudden, unexplained change in mental status.

Electrode Placement

The electrodes normally used to record the EEG are attached to the scalp with a conductive paste. A standard array consists of 21 electrodes. Placement of the electrodes is based on the 10/20 International System of Electrode Placement (Fig. 1.8-1). This system measures the distance between readily identifiable landmarks on the head and then locates electrode positions at 10 percent or 20 percent of that distance in an anterior-posterior or transverse direction. Electrodes are then designated by an uppercase letter denoting the brain region beneath that electrode and a number, with odd numbers used for the left hemisphere and with even numbers signifying the right hemisphere (the subscript Z denotes midline electrodes). Thus, the O₂ electrode is placed over the right occipital region, and the P₃ lead is found over the left parietal area (Fig. 1.8-2).

FIGURE 1.8-2

A left-lateral diagram of the head showing the locations of the routine 10–20 electrodes (left-side electrode locations F7 and T3 and the new electrode placement [T1]) in relation to the temporal pole. (Modification of figure reprinted courtesy of Grass, Astro-Med, Inc. Product Group.)

In special circumstances, other electrodes may be used. Nasopharyngeal (NP) electrodes can be inserted into the NP space through the nostrils and can be closer to the temporal lobe than scalp electrodes. No actual penetration of tissue occurs. These electrodes may be contraindicated with many psychiatric patients displaying behaviors, such as confusion, agitation, or belligerence, which could pull the leads out, possibly lacerating the nasal passage. Sphenoidal electrodes use a hollow needle through which a fine electrode that is insulated, except at the tip, is inserted between the zygoma and the sigmoid notch in the mandible, until it is in contact with the base of the skull lateral to the foramen ovale.

Activated EEG

Certain activating procedures are used to increase the probability that abnormal discharges, particularly spike or spike-wave seizure discharges, will occur. Strenuous hyperventilation is one of the most frequently used activation procedures. While remaining reclined with the eyes closed, the patient is asked to overbreathe through the open mouth with deep breaths for 1 to 4 minutes, depending on the laboratory (3 minutes is common). In general, hyperventilation is one of the safest EEG-activating procedures, and, for most of the population, it presents no physical risk. It can pose a risk for patients with cardiopulmonary disease or risk factors for cerebral vascular pathophysiology, however. Photic stimulation (PS) generally involves placing an intense strobe light approximately 12 inches in front of the subject's closed eyes and flashing at frequencies that can range from 1 to 50 Hz, depending on how the procedure is carried out. Retinal damage does not occur, because each strobe flash, although intense, is extremely brief in duration. When the resting EEG is normal, and a seizure disorder or behavior that is suspected to be a manifestation of a paroxysmal EEG dysrhythmia is suspected, PS can be a valuable activation method to use. EEG recording during sleep, natural, or sedated, is now widely accepted as an essential technique for eliciting a variety of paroxysmal discharges, when the wake tracing is normal, or for increasing the number of abnormal discharges to permit a more definitive interpretation. It has been shown that the central nervous system (CNS) stress produced by 24 hours of sleep deprivation alone can lead to the activation of paroxysmal EEG discharges in some cases.

NORMAL EEG TRACING

The normal EEG tracing (Fig. 1.8-3) is composed of a complex mixture of many different frequencies. Discrete frequency bands within the broad EEG frequency spectrum are designated with Greek letters.

FIGURE 1.8-3

Normal electroencephalogram (EEG) tracings in an awake 28-year-old man. (Reprinted from Emerson RG, Walesak TS, Turner CA. EEG and evoked potentials. In: Rowland LP, ed. *Merritt's Textbook of Neurology*. 9th ed. Baltimore: Lippincott Williams & Wilkins; 1995:68, with permission.)

Awake EEG

The four basic wave forms are alpha, beta, delta, and theta. Highly rhythmic *alpha waves* with a frequency range of 8 to 13 Hz constitute the dominant brain wave frequency of the normal eyes-closed awake EEG. Alpha frequency can be increased or decreased by a wide variety of pharmacological, metabolic, or endocrine variables. Frequencies that are faster than the upper 13 Hz limit of the alpha rhythm are termed *beta waves*, and they are not uncommon in normal adult waking EEG studies, particularly over the frontal-central regions. *Delta waves* (≤ 3.5 Hz) are not present in the normal waking EEG, but are a prominent feature of deeper stages of sleep. The presence of significant generalized or focal delta waves in the awake EEG is strongly indicative of a pathophysiological process. Waves with a frequency of 4.0 to 7.5 Hz are collectively referred to as *theta waves*. A small amount of sporadic, arrhythmic, and isolated theta activity can be seen in many normal waking EEG studies, particularly in frontal-temporal regions. Although theta activity is limited in the waking EEG, it is a prominent feature of the drowsy and sleep tracing. Excessive theta in awake EEG, generalized or focal in nature, suggests the operation of a pathological process.

With maturation, EEG activity gradually goes from a preponderance of irregular medium- to high-voltage delta activity in the tracing of the infant, to greater frequency and more rhythmic pattern. Rhythmic activity in the upper theta-lower alpha range (7 to 8 Hz) can be seen in posterior areas by early childhood, and, by mid-adolescence, the EEG essentially has the appearance of an adult tracing.

Sleep EEG

The EEG patterns that characterize drowsy and sleep states are different from the patterns seen during the awake state. The rhythmic posterior alpha activity of the waking state subsides during drowsiness and is replaced by irregular low-voltage theta activity. As drowsiness deepens, slower frequencies emerge, and sporadic vertex sharp waves may appear at central electrode sites, particularly among younger persons. Finally, the progression into sleep is marked by the appearance of 14-Hz sleep spindles (also called *sigma waves*), which, in turn, gradually become replaced by high-voltage delta waves as deep sleep stages are reached.

EEG ABNORMALITIES

Apart from some of the obvious indications for an EEG study (i.e., suspected seizures), EEG studies are not routinely performed as part of a diagnostic work-up in psychiatry. EEG, however, is a valuable assessment tool in clinical situations in which the initial presentation or the clinical course appear to be unusual or atypical (Table 1.8-1). Table 1.8-2 summarizes some common types of EEG abnormalities.

 **Table 1.8-1**
Warning Signs of the Presence of Covert Medical or Organic Factors Causing or Contributing to Psychiatric Presentation

Atypical age of onset (i.e., anorexia nervosa beginning at mid-adulthood)
Complete lack of positive family history of the disorder when a positive family history is expected
Any focal or localized symptoms (i.e., unilateral hallucinations)
Focal neurological abnormalities
Catatonia
Presence of any difficulty with orientation or memory (in general, Mini Mental State Examination should be normal)
Atypical response to treatment
Atypical clinical course

Note: Clinicians should have a high index of suspicion for underlying medical conditions and a low threshold for initiating appropriate workups.

 **Table 1.8-2**
Common Electroencephalography (EEG) Abnormalities

Diffuse slowing of background rhythms	Most common EEG abnormality; nonspecific and is present in patients with diffuse encephalopathies of diverse causes
Focal slowing	Suggests localized parenchymal dysfunction and focal seizure disorder; seen with focal fluid collection, such as hematomas
Triphasic waves	Typically consist of generalized synchronous waves occurring in brief runs; approximately one half of patients with triphasic waves have hepatic encephalopathy, and the remainder have other toxic–metabolic encephalopathies
Epileptiform discharges	Interictal hallmark of epilepsy; strongly associated with seizure disorders
Periodic lateralizing epileptiform discharges	Suggest the presence of an acute destructive cerebral lesion; associated with seizures, obtundation, and focal neurological signs
Generalized periodic sharp waves	Most commonly seen following cerebral anoxia; recorded in about 90% of patients with Creutzfeldt-Jakob disease

Some psychotropic medications and recreational or abused drugs produce EEG changes, yet, with the exception of the benzodiazepines and some compounds with a propensity to induce paroxysmal EEG discharges, little, if any, clinically relevant effect is noted when the medication is not causing toxicity. Benzodiazepines, which always generate a significant amount of diffuse beta activity, have EEG-protective effects, so that they can mask alterations caused by concomitant medications (Table 1.8-3).

Table 1.8-3
Electroencephalography (EEG) Alterations Associated with Medication and Drugs

Drug	Alterations
Benzodiazepines	Increased beta activity
Clozapine (Clozaril)	Nonspecific change
Olanzapine (Zyprexa)	Nonspecific change
Risperidone (Risperdal)	Nonspecific change
Quetiapine (Seroquel)	No significant changes
Aripiprazole (Abilify)	No significant changes
Lithium	Slowing or paroxysmal activity
Alcohol	Decreased alpha activity; increased theta activity
Opioids	Decreased alpha activity; increased voltage of theta and delta waves; in overdose, slow waves
Barbiturates	Increased beta activity; in withdrawal states, generalized paroxysmal activity and spike discharges
Marijuana	Increased alpha activity in frontal area of brain; overall slow alpha activity
Cocaine	Similar to marijuana
Inhalants	Diffuse slowing of delta and theta waves
Nicotine	Increased alpha activity; in withdrawal, marked decrease in alpha activity
Caffeine	In withdrawal, increase in amplitude or voltage of theta activity

Medical and neurological conditions produce a wide range of abnormal EEG findings. EEG studies, thus, can contribute to the detection of unsuspected organic pathophysiology influencing a psychiatric presentation (Fig. 1.8-4). Table 1.8-4 lists EEG alterations in medical disorders and Table 1.8-5 lists EEG alterations associated with psychiatric disorders.

FIGURE 1.8-4

Diffuse slowing in a 67-year-old patient with dementia. Six- to seven cycles per second (cps) activity predominates over the parieto-occipital regions. Although reactive to eye closure, the frequency of this rhythm is abnormally slow. (Reprinted from Emerson RG, Walesak TS, Turner CA. EEG and evoked potentials. In: Rowland LP, ed. *Merritt's Textbook of Neurology*. 9th ed. Baltimore: Lippincott Williams & Wilkins; 1995:68, with permission.)

Table 1.8-4
Electroencephalography (EEG) Alterations Associated with Medical Disorders

Seizures	Generalized, hemispheric, or focal spike, spike-wave discharge, or both
Structural lesions	Focal slowing, with possible focal spike activity
Closed head injuries	Focal slowing (sharply focal head trauma) Focal delta slowing or more widespread slowing (subdural hematomas)
Infectious disorders	Diffuse, often synchronous, high voltage slowing (acute phase of encephalitis)
Metabolic and endocrine disorders	Diffuse generalized slowing of wake frequencies Triphasic waves: 1.5 to 3.0 per second high-voltage slow waves, with each slow wave initiated by a blunt or rounded spike-like transient (hepatic encephalopathy)
Vascular pathophysiology	Slowed alpha frequency and increased generalized theta slowing (diffuse atherosclerosis) Focal or regional delta activity (cerebrovascular accidents)

Table 1.8-5
Electroencephalography (EEG) Alterations Associated with Psychiatric Disorders

Panic disorder	Paroxysmal EEG changes consistent with partial seizure activity during attack in one third of patients; focal slowing in about 25% of patients
Catatonia	Usually normal, but EEG indicated in new patient presenting with catatonia to rule out other causes
Attention-deficit/hyperactivity disorder (ADHD)	High prevalence (up to 60%) of EEG abnormalities versus normal controls; spike or spike-wave discharges
Antisocial personality disorder	Increased incidence of EEG abnormalities in those with aggressive behavior
Borderline personality disorder	Positive spikes: 14 and 6 per second seen in 25% of patients
Chronic alcoholism	Prominent slowing and periodic lateralized paroxysmal discharges
Alcohol withdrawal	May be normal in patients who are not delirious; excessive fast activity in patients with delirium
Dementia	Rarely normal in advanced dementia; may be helpful in differentiating pseudodementia from dementia

TOPOGRAPHIC QUANTITATIVE ELECTROENCEPHALOGRAPHY (QEEG)

Unlike standard EEG interpretation, which relies on waveform recognition, QEEG involves a computer analysis of data extracted from the EEG. Findings are compared with a large population database of subjects without any known neurological or psychiatric disorder as well as QEEG profiles that may be characteristic of some defined diagnostic group. In QEEG, the analog-based electrical signals are processed digitally and converted to graphic, colored topographical displays. These images are sometimes called “brain maps.” Color Plate 1.8-5 illustrates topographic QEEG images of a patient with a closed head injury.

QEEG remains primarily a research method, but it holds considerable clinical potential for psychiatry, mainly in establishing neurophysiological subtypes of specific disorders and for identifying electrophysiological predictors of response. Examples of some of the more promising results of QEEG research include the identification of subtypes of cocaine dependence and the subtype most likely to be associated with sustained abstinence; identification of subtypes of obsessive-compulsive disorder (OCD) that predict clinical responsiveness or lack of responsiveness to selective serotonin reuptake inhibitors (SSRIs); and the differentiation between normals, attention-deficit disorder and attention-deficit/hyperactivity disorder (ADHD), and learning disability subpopulations. QEEG findings in ADHD show that increased theta abnormality frontally may be a strong predictor of response to methylphenidate and other psychostimulants and that favorable clinical responses may be associated with a normalization of the EEG abnormality.

CEREBRAL EVOKED POTENTIALS

Cerebral EPs are a series of surface (scalp) recordable waves that result from brain visual, auditory, somatosensory, and cognitive stimulation. They have been shown to be abnormal in many psychiatric conditions, including schizophrenia and Alzheimer’s disease, thus creating difficulty in using cerebral EPs for differential diagnosis purposes.

1.9 Chronobiology

Chronobiology is the study of biological time. The rotation of the Earth about its axis imposes a 24-hour cyclicity on the biosphere. Although it is widely accepted that organisms have evolved to occupy geographical niches that can be defined by the three spatial dimensions, it is less appreciated that organisms have also evolved to occupy temporal niches that are defined by the fourth dimension—time. Much like light represents a small portion of the electromagnetic spectrum, the 24-hour periodicity represents a small time domain within the spectrum of temporal biology. A broad range of frequencies exist throughout biology, ranging from millisecond oscillations in ocular field potentials to the 17-year cycle of emergence seen in the periodic cicada (*Magicicada* spp.). Although these different periodicities all fall within the realm of chronobiology, *circadian* (Latin: *circa*, about; *dies*, day) rhythms that have a period of about one day are among the most extensively studied and best understood biological rhythms.

A defining feature of circadian rhythms is that they persist in the absence of time cues and are not simply driven by the 24-hour environmental cycle. Experimental animals housed for several months under constant darkness, temperature, and humidity continue to exhibit robust circadian rhythms. Maintenance of rhythmicity in a “timeless” environment points to the existence of an internal biological timing system that is responsible for generating these endogenous rhythms.

The site of the primary circadian oscillator in mammals, including humans, is the suprachiasmatic nucleus (SCN), located in the anterior hypothalamus. The mean circadian period generated by the human SCN is approximately 24.18 hours. Like a watch that ticks 10 minutes and 48 seconds too slowly per day, an individual with such a period gradually comes out of synchrony with the astronomical day. In slightly

more than 3 months, a normally diurnal human would be in antiphase to the day–night cycle and thus would become transiently nocturnal. Therefore, a circadian clock must be reset on a regular basis to be effective at maintaining the proper phase relationships of behavioral and physiological processes within the context of the 24-hour day.

Although factors such as temperature and humidity exhibit daily fluctuations, the environmental parameter that most reliably corresponds to the period of Earth’s rotation around its axis is the change in illuminance associated with the day–night cycle. Accordingly, organisms have evolved to use this daily change in light levels as a time cue or *zeitgeber* (German: *zeit*, time; *geber*, giver) to reset the endogenous circadian clock. Regulation of the circadian pacemaker through the detection of changes in illuminance requires a photoreceptive apparatus that communicates with the central oscillator. This apparatus is known to reside in the eyes, because surgical removal of the eyes renders an animal incapable of resetting its clock in response to light.

The circadian clock drives many rhythms, including rhythms in behavior, core body temperature, sleep, feeding, drinking, and hormonal levels. One such circadian-regulated hormone is the indoleamine, melatonin. Melatonin synthesis is controlled through a multisynaptic pathway from the SCN to the pineal gland. Serum levels of melatonin become elevated at night and return to baseline during the day. The nocturnal rise in melatonin is a convenient marker of circadian phase. Exposure to light elicits two distinct effects on the daily melatonin profile. First, light acutely suppresses elevated melatonin levels, immediately decreasing them to baseline levels. Second, light shifts the phase of the circadian rhythm of melatonin synthesis. Because melatonin can be assayed easily, it provides a convenient window into the state of the circadian pacemaker. Any perturbation of the clock is reflected in the melatonin profile; thus melatonin offers an output that can be used to study the regulation of the central circadian pacemaker.

SLEEP AND CIRCADIAN RHYTHMS

Sleep Regulation

Restful consolidated sleep is most appreciated when sleep disturbances are experienced. Sleep is the integrated product of two oscillatory processes. The first process, frequently referred to as the *sleep homeostat*, is an oscillation that stems from the accumulation and dissipation of sleep debt. The biological substrates encoding sleep debt are not known, although adenosine is emerging as a primary candidate neuromodulator of the sleep homeostat. The second oscillatory process is governed by the circadian clock and controls a daily rhythm in sleep propensity or, conversely, arousal. These interacting oscillations can be dissociated by housing subjects in a timeless environment for several weeks.

The circadian cycle in arousal (wakefulness) steadily increases throughout the day, reaching a maximum immediately before the circadian increase in plasma melatonin (Fig. 1.9-1). Arousal subsequently decreases to coincide with the circadian trough in core body temperature. Experiments imposing forced sleep schedules throughout the circadian day have shown that an uninterrupted 8-hour bout of sleep can only be obtained if sleep is initiated approximately 6 hours before the temperature nadir. This nadir typically occurs at approximately 5:00 AM to 6:00 AM. In healthy individuals, initiating sleep between 11:00 PM and 12:00 AM affords the highest probability of getting 8 solid hours of sleep.

FIGURE 1.9-1

Relative phase relationship of sleep in young adults to other circadian phase markers. (From Dijk D-J, Lockley SW. Invited review: Integration of human sleep-wake regulation and circadian rhythmicity. *J Appl Physiol*. 2002;92:852, with permission.)

It should be stressed that diurnal preference varies among individuals as a function of age, endogenous circadian periods, and other factors. This variability is paralleled by physiology. Clinically, diurnal preference can be quantified using the Horne–Östberg (HO) Morningness-Eveningness Questionnaire (MEQ). In qualitative terms, *morning people* or *morning larks* tend to awaken earlier and experience the core body temperature minimum at an earlier clock time relative to *night people* or *night owls*. Sleep deprivation studies have shown that the homeostatic component of sleep is remarkably similar among individuals of similar age. (It should be noted that there is a well-established age-dependent decline in sleep need.) Therefore, diurnal preference is dictated almost exclusively by the circadian component of sleep regulation.

Circadian Sleep Disorders

Advanced sleep phase syndrome (ASPS) is a pathological extreme of the morning lark phenotype. An autosomal-dominant familial form of ASPS (FASPS) recently has been genetically characterized. Afflicted family members exhibit a striking 4-hour advance of the daily sleep-wake rhythm. They typically fall asleep at approximately 7:30 PM and spontaneously awaken at approximately 4:30 AM. Affected individuals have a single nucleotide polymorphism in the gene encoding hPER2, the human homolog of the mouse *Per2* clock gene. This adenine-to-guanine nucleotide polymorphism results in serine-to-glycine amino acid substitution that causes the mutant protein to be inefficiently phosphorylated by casein kinase I ϵ , an established component of the circadian molecular clockwork. Similarly, delayed sleep phase syndrome (DSPS) has been shown to be influenced by genetics. A length polymorphism in a repeat region of the *hPER3* gene appears to be associated with diurnal preference in patients with DSPS, the shorter allele being associated with evening preference.

The advent of the light bulb has extended the human day into the natural night. This encroachment on the night, although increasing productivity, has affected human sleep patterns (Fig. 1.9-2). Typical use of artificial lights results in a single, consolidated bout of sleep lasting approximately 8 hours. This pattern of sleep is uncommon among most other mammals, which typically experience more fractured sleep. Human sleep under more natural photoperiods, where the duration of the night is longer, becomes decompressed. Specifically, a bimodal distribution of sleep is observed; bouts of sleep occur in early and late night. Periods of *quiet wakefulness* are interspersed between the two primary bouts of sleep. This natural sleep pattern is more similar to the sleep patterns of other mammals.

FIGURE 1.9-2

Change in sleep structure in response to artificial lighting. Total sleep time is reduced, and periods of quiet wakefulness are abolished by extending daytime into nighttime through artificial lighting. (From Wehr TA, Moul DE, Barbato G, et al. Conservation of photoperiod-responsive mechanisms in humans. *Am J Physiol.* 1993;265:R846, with permission.)

SEASONALITY

The 24-hour period of the Earth's rotation around its axis is unchanging. However, the Earth's axis is tilted 23.45 degrees from the plane of its own orbit around the sun (the ecliptic). As a result, the relative proportion of daytime to nighttime within the 24-hour astronomical day varies as the Earth proceeds through its orbit of the sun. Many organisms are capable of synchronizing physiology to the seasonal cycle to maximize survival. For example, precise seasonal cycles in reproduction are seen throughout the plant and animal kingdoms. Large mammals that typically have long gestation periods, such as sheep, conceive in the fall when the nights are long and the days are short, so birth occurs during the relatively mild season of spring. These animals are referred to as *short-day breeders*. Conversely, mammals with gestation periods of only a few weeks, such as hamsters, conceive and give birth during spring and summer, when the days are long and the nights are short. Hence, these animals are referred to as *long-day breeders*. Like circadian rhythms, many of these yearly (circannual) rhythms tend to persist in the absence of seasonal cues with endogenous periods of approximately 1 year.

Melatonin and Seasonality

The most reliable environmental parameter providing a faithful representation of the solar day is the day-night cycle. Similarly, the most reliable environmental parameter reflecting the progression through the seasons is the change in day length, the fraction of the 24-hour day between sunrise and sunset. In seasonally breeding animals, day length is physiologically encoded through the melatonin profile. As described previously, melatonin levels are elevated during the night. A long night, such as that experienced during the short day lengths of

winter, results in an elevated melatonin profile of a relatively long duration. A short summer night, by contrast, results in a short duration of elevated melatonin. This seasonal signal is interpreted by the reproductive axis, resulting in an appropriate reproductive response. Melatonin's role in transducing day length was elucidated by pinealectomizing seasonally breeding animals, thereby removing the primary endogenous source of melatonin. Melatonin was then infused in profiles mimicking long days or short days. The duration of elevated melatonin was the primary determinant of seasonal reproductive status, even when the infused profile was administered under a conflicting day length. Variations in other parameters, such as the amplitude of the melatonin profile, the amount of total melatonin synthesized, or the phase relationship of the profile to the light-dark cycle, are of limited importance in producing a humoral signal that transduces day length.

Reproductive responses to changing day length can be dramatic. A male Siberian hamster (*Phodopus sungorus*) maintained in long days is reproductively competent and typically has a testicular weight of approximately 250 mg per testis. Under short days, however, the testes regress to approximately 15 mg per testis, representing a 94 percent decrease in testicular mass. The same degree of regression is observed in response to melatonin infusions that mimic short days. Communication of the hormonally transduced day length to the reproductive axis is likely to be mediated, at least partially, through melatonin receptors in the *pars tuberalis* of the pituitary gland. The exact mechanism remains unknown, but activation of these receptors is hypothesized to indirectly regulate an unidentified factor putatively named *tuberalin*. Tuberalin, in turn, controls gene expression and prolactin release from lactotrophs in the adenohypophysis of the pituitary.

Seasonality in Humans

Whether humans are truly seasonal is still a point of considerable debate. Several lines of evidence exist that suggest the presence of a residual tendency toward seasonality. A peak in the rate of suicide occurs in the summer; this peak is cross-cultural. Birth rates also tend to show a seasonal variation; a small but distinguishable peak in the rate of births occurs in spring and summer. This pattern, however, is itself variable and is heavily influenced by unknown cultural and geographic factors. Of interest, the amplitude of the spring-summer birth rate peak has diminished as societies have become industrialized.

The decompressed bimodal structure of human sleep during long nights indicates that the length of natural sleep is related to the length of the night. Potentially, a two-oscillator system could function to maintain proper sleep patterns during changing photoperiods. Such a proposed system would consist of an evening oscillator that tracks the transition from day to night (dusk) and a morning oscillator that tracks the transition from night to day (dawn). The relative phase differences between these oscillators may encode the changing day lengths associated with the passing of the seasons. Biological evidence for a two-oscillator system exists in rodents and humans.

The melatonin profile of many vertebrates, including some humans, is bimodal, with evening and morning peaks. In rodents, metabolic and electrophysiological studies of the SCN typically have been done in brain slices cut in the coronal plane. Results of electrophysiological studies conducted in brain slices cut in the horizontal plane have provided new insights. The action potential frequency in SCN neurons from horizontally cut preparations is bimodal, with peaks in the early and late subjective day. Furthermore, the interpeak interval varies as a function of the photoperiod in which the animal was housed. These studies lend credence to long-standing suspicions that the SCN of seasonally breeding mammals and, perhaps, nonseasonal mammals harbor a morning and evening oscillator that interact to convey day-length information.

Effect of Aging

In general, as humans age, the circadian period shortens, the circadian phase advances resulting in earlier waking times and bedtimes, the amplitudes of most circadian rhythms decrease, and dramatic phase shifts such as those caused by jet-lag are less tolerated. Again, a mouse model has provided interesting insight into the interaction of the aging process and the circadian clock. The effect of chronic jet-lag on aged mice has dramatic consequences on mortality. About half of aged mice forced to phase advance 6 hours once per week survive this treatment compared with an 83 percent survival rate in unshifted age-matched mice. Aged mice subjected to weekly 6-hour phase delays show an intermediate survival of 68 percent. These profound effects of phase shifting are not observed in younger mice. The pathogenesis of chronic jet-lag remains to be determined. Of interest, these mice did not have an increased rate of tumorigenesis. It is likely that in humans, as in mice, the internal desynchrony of oscillators that result from a rotating light schedule may have dire consequences that may be exacerbated by aging.

CIRCADIAN RHYTHMS AND PHARMACOTHERAPY

Circadian rhythmicity can be affected by drugs, and conversely, the circadian clock can modulate the efficacy of drugs throughout the course of the day. A better understanding of these interactions will lead to more effective pharmacotherapies. Some of the best-studied interactions between medications and the circadian clock have included the circadian effects of antidepressants. Elevated nocturnal body temperature is a common feature among depressed patients. This effect may be due to a reduced amplitude of the master circadian oscillator in the hypothalamus that drives body temperature. Tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) reduce elevated nocturnal body temperature while simultaneously enhancing circadian amplitude. Similarly, many depressed patients exhibit a dampened amplitude in daily activity rhythms. Like body temperature, the amplitude in daily activity cycles of depressed individuals may be augmented by TCA or SSRI therapy.

The use of lithium to treat bipolar disorder has been long established. However, lithium also affects the circadian system, resulting in a lengthening of circadian period. The molecular mechanism by which this occurs remains unknown. Glycogen synthase kinase 3 β (GSK3 β) has been implicated in participating within the molecular clock mechanism. Of interest, GSK3 β is inhibited by lithium. In cell culture, GSK3 β has been shown to stabilize the negative clockwork regulator REV-ERB α via phosphorylation. REV-ERB α typically represses the transcription of the *BMAL1* gene. In the presence of lithium, however, GSK3 β is inhibited, thereby preventing the phosphorylation and stabilization of REV-ERB α , which as a consequence is targeted for proteasomal degradation. The degradation of REV-ERB α results in the de-repression of *BMAL1* transcription. Whether lithium's influence on circadian behavior is attributable to its inhibitory effect on GSK3 β -mediated stabilization of REV-ERB α remains to be determined.

Short-acting benzodiazepines (e.g., triazolam [Halcion] and brotizolam [Lendormin]) also exert chronobiological effects. In hamsters, triazolam or brotizolam administered during the middle of the subjective day induces circadian phase advances in activity. Brotizolam has been shown to reduce the light-induced expression of clock genes *Per1* and *Per2* in the SCN. Although benzodiazepines are allosteric modulators of γ -aminobutyric acid A receptors (GABA $_A$), several lines of evidence indicate that the circadian effects of short-acting benzodiazepines require an intact serotonergic system. When the 5-HT $_{1A/7}$ receptor agonist 8-hydroxy-2-(di-*n*-propylamino)-tetralin (8-OH-DPAT) is injected into hamsters at subjective midday, phase advances in locomotor behavior and SCN neuronal activity are observed in addition to a reduction in *Per1* and *Per2* gene expression in the SCN. Recreational drugs of abuse also affect the circadian system. 3,4-Methylenedioxymethamphetamine (MDMA), or "ecstasy," can act as a serotonin neurotoxin. Hamsters treated with MDMA showed reduced triazolam-induced phase shifts in circadian locomotor activity and a diminished ability to reentrain rhythms posttreatment. MDMA-treated animals exhibited a reduction of serotonergic axonal terminals in the SCN, again emphasizing the importance of an intact serotonergic system in the regulation of the circadian axis. Recreational use of methamphetamine has increased dramatically. Chronic administration of methamphetamine disorganizes rodent activity rhythms. However, administration of methamphetamine to rodents rendered arrhythmic through ablation of the SCN results in a reemergence of rhythmicity. The mechanism involved in the rescue of rhythmicity or site of action remains unknown.

The efficacy and toxicity of many pharmacotherapeutics vary as a function of circadian phase. Daily variations in fixed-dose lethal toxicity have been appreciated in rodents for years. Many anticancer drugs, ranging in mechanism from antimetabolites to deoxyribonucleic acid (DNA) intercalators to mitotic inhibitors, have been shown to have 2- to 10-fold changes in tolerability in rodents over the course of the day. Much of this difference is attributed to circadian variations in the body's ability to absorb, distribute, metabolize, and eliminate toxic compounds. These four processes are affected by underlying circadian rhythms in physiological processes such as daily variations in gastric pH, gastrointestinal mobility, glomerular filtration rate, and membrane viscosity. The rhythmic intake of food during traditionally timed meals also influences how therapeutic drugs are handled by the body. It is becoming clear that to maximize efficacy and minimize toxicity of drugs, the circadian phase of administration must be considered. Appropriate circadian timing of the administration of multiple drugs can be a daunting challenge to infirmed individuals or their caretakers. The development of small implanted programmable pumps that can be directed to administer anticancer drugs or other therapeutics at particular times of day may provide a limited solution to this challenge. The emergence of the field of chronotherapy is a reflection of our increased understanding of the impact of the circadian system on the effectiveness of pharmacological treatments.

Contributions of the Psychosocial Sciences

2.1 Jean Piaget and Cognitive Development

Jean Piaget (1896–1980) is considered one of the greatest thinkers of the 20th century. His contributions to the understanding of cognitive development had paradigmatic influence in developmental psychology and had major implications for interventions with children, both educational and clinical.

Piaget was born in Neuchatel, Switzerland, where he studied at the university and received a doctorate in biology at the age of 22 (Fig. 2.1-1). Interested in psychology, he studied and carried out research at several centers, including the Sorbonne in Paris, and he worked with Eugen Bleuler at the Burghölzli Psychiatric Hospital.

FIGURE 2.1-1 Jean Piaget (1896–1980). (Reprinted from the Jean Piaget Society, Temple University, Philadelphia, PA, with permission.)

Piaget created a broad theoretical system for the development of cognitive abilities; in this sense, his work was similar to that of Sigmund Freud, but Piaget emphasized the ways that children think and acquire knowledge.

Widely renowned as a child (or developmental) psychologist, Piaget referred to himself primarily as a *genetic epistemologist*; he defined genetic epistemology as the study of the development of abstract thought on the basis of a biological or innate substrate. That self-designation reveals that Piaget's central project was more than the articulation of a *developmental child psychology*, as this term is generally understood; it was an account of the progressive development of human knowledge.

COGNITIVE DEVELOPMENT STAGES

According to Piaget, the following four major stages lead to the capacity for adult thought (Table 2.1-1): (1) sensorimotor, (2) preoperational thought, (3) concrete operations, and (4) formal operations. Each stage is a prerequisite for the following one, but the rate at which different children move through different stages varies with their native endowment and environmental circumstances.

Table 2.1-1
Stages of Intellectual Development Postulated by Piaget

Age (yr)	Period	Cognitive Developmental Characteristics
0–1.5 (to 2)	Sensorimotor	Divided into six stages, characterized by: 1. Inborn motor and sensory reflexes 2. Primary circular reaction 3. Secondary circular reaction 4. Use of familiar means to obtain ends 5. Tertiary circular reaction and discovery through active experimentation 6. Insight and object permanence
2–7	Preoperations subperiod ^a	Deferred imitation, symbolic play, graphic imagery (drawing), mental imagery, and language
7–11	Concrete operations	Conservation of quantity, weight, volume, length, and time based on reversibility by inversion or reciprocity; operations; class inclusion and seriation
11–end of adolescence	Formal operations	Combinatorial system, whereby variables are isolated and all possible combinations are examined; hypotheticodeductive thinking

^aThis subperiod is considered by some authors to be a separate developmental period.

Sensorimotor Stage (Birth to 2 Years)

Piaget used the term *sensorimotor* to describe the first stage: Infants begin to learn through sensory observation, and they gain control of their motor functions through activity, exploration, and manipulation of the environment. Piaget divided this stage into six substages, listed in

Table 2.1-2.

Age	Characteristics
Birth–2 mos	Uses inborn motor and sensory reflexes (sucking, grasping, looking) to interact and accommodate to the external world
2–5 mos	Primary circular reaction: Coordinates activities of own body and five senses (e.g., sucking thumb); reality remains subjective—does not seek stimuli outside of its visual field; displays curiosity
5–9 mos	Secondary circular reaction: Seeks out new stimuli in the environment; starts both to anticipate consequences of own behavior and to act purposefully to change the environment; beginning of intentional behavior
9 mos–1 yr	Shows preliminary signs of object permanence; has a vague concept that objects exist apart from itself; plays peek-a-boo; imitates novel behaviors
1 yr–18 mos	Tertiary circular reaction: Seeks out new experiences; produces novel behaviors
18 mos–2 yrs	Symbolic thought: Uses symbolic representations of events and objects; shows signs of reasoning (e.g., uses one toy to reach for and get another); attains object permanence

From the outset, biology and experience blend to produce learned behavior. For example, infants are born with a sucking reflex, but a type of learning occurs when infants discover the location of the nipple and alter the shape of their mouths. A stimulus is received, and a response results, accompanied by a sense of awareness that is the first schema, or elementary concept. As infants become more mobile, one schema is built on another, and new and more complex schemata are developed. Infants' spatial, visual, and tactile worlds expand during this period; children interact actively with the environment and use previously learned behavior patterns. For example, having learned to use a rattle, infants shake a new toy as they did the rattle they had already learned to use. Infants also use the rattle in new ways.

The critical achievement of this period is the development of *object permanence* or the *schema of the permanent object*. This phrase relates to a child's ability to understand that objects have an existence independent of the child's involvement with them. Infants learn to differentiate themselves from the world and are able to maintain a mental image of an object, even when it is not present and visible. When an object is dropped in front of infants, they look down to the ground to search for the object; that is, they behave for the first time as though the object has a reality outside themselves.

At about 18 months, infants begin to develop mental symbols and to use words, a process known as *symbolization*. Infants are able to create a visual image of a ball or a mental symbol of the word *ball* to stand for, or signify, the real object. Such mental representations allow children to operate on new conceptual levels. The attainment of object permanence marks the transition from the sensorimotor stage to the preoperational stage of development.

Stage of Preoperational Thought (2 to 7 Years)

During the stage of preoperational thought, children use symbols and language more extensively than in the sensorimotor stage. Thinking and reasoning are intuitive; children learn without the use of reasoning. They are unable to think logically or deductively, and their concepts are primitive; they can name objects but not classes of objects. Preoperational thought is midway between socialized adult thought and the completely autistic Freudian unconscious. Events are not linked by logic. Early in this stage, if children drop a glass that then breaks, they have no sense of cause and effect. They believe that the glass was ready to break, not that they broke the glass. Children in this stage also cannot grasp the sameness of an object in different circumstances: The same doll in a carriage, a crib, or a chair is perceived to be three different objects. During this time, things are represented in terms of their function. For example, a child defines a bike as "to ride" and a hole as "to dig."

In this stage, children begin to use language and drawings in more elaborate ways. From one-word utterances, two-word phrases develop, made up of either a noun and a verb or a noun and an objective. A child may say, "Bobby eat," or "Bobby up."

Children in the preoperational stage cannot deal with moral dilemmas, although they have a sense of what is good and bad. For example, when asked, "Who is more guilty, the person who breaks one dish on purpose or the person who breaks 10 dishes by accident?" a young child usually answers that the person who breaks 10 dishes by accident is more guilty because more dishes are broken. Children in this stage have a sense of *immanent justice*, the belief that punishment for bad deeds is inevitable.

Children in this developmental stage are *egocentric*: They see themselves as the center of the universe; they have a limited point of view; and they are unable to take the role of another person. Children are unable to modify their behavior for someone else; for example, children are not being negativistic when they do not listen to a command to be quiet because their brother has to study. Instead, egocentric thinking prevents an understanding of their brother's point of view.

During this stage, children also use a type of magical thinking, called *phenomenalistic causality*, in which events that occur together are thought to cause one another (e.g., thunder causes lightning, and bad thoughts cause accidents). In addition, children use *animistic thinking*, which is the tendency to endow physical events and objects with life-like psychological attributes, such as feelings and intentions.

Semiotic Function. The semiotic function emerges during the preoperational period. With this new ability, children can represent something—such as an object, an event, or a conceptual scheme—with a signifier, which serves a representative function (e.g., language, mental image, symbolic gesture). That is, children use a symbol or sign to stand for something else. Drawing is a semiotic function initially done as a playful exercise but eventually signifying something else in the real world.

Stage of Concrete Operations (7 to 11 Years)

The stage of concrete operations is so named because in this period children operate and act on the concrete, real, and perceivable world of objects and events. Egocentric thought is replaced by *operational thought*, which involves dealing with a wide array of information outside

the child. Therefore, children can now see things from someone else's perspective.

Children in this stage begin to use limited logical thought processes and can serialize, order, and group things into classes on the basis of common characteristics. *Syllogistic reasoning*, in which a logical conclusion is formed from two premises, appears during this stage; for example, all horses are mammals (premise); all mammals are warm blooded (premise); therefore, all horses are warm blooded (conclusion). Children are able to reason and to follow rules and regulations. They can regulate themselves, and they begin to develop a moral sense and a code of values.

Children who become overly invested in rules may show obsessive-compulsive behavior; children who resist a code of values often seem willful and reactive. The most desirable developmental outcome in this stage is that a child attains a healthy respect for rules and understands that there are legitimate exceptions to rules.

Conservation is the ability to recognize that, although the shape of objects may change, the objects still maintain or conserve other characteristics that enable them to be recognized as the same. For example, if a ball of clay is rolled into a long, thin sausage shape, children recognize that each form contains the same amount of clay. An inability to conserve (which is characteristic of the preoperational stage) is observed when a child declares that there is more clay in the sausage-shaped piece because it is longer. *Reversibility* is the capacity to understand the relation between things, to realize that one thing can turn into another and back again—for example, ice and water.

The most important sign that children are still in the preoperational stage is that they have not achieved conservation or reversibility. The ability of children to understand concepts of quantity is one of Piaget's most important cognitive developmental theories. Measures of quantity include measures of substance, length, number, liquids, and area (Fig. 2.1-2).

FIGURE 2.1-2

Some simple tests for conservation, with approximate ages of attainment. When the sense of conservation is achieved, the child answers that **B** contains the same quantity as **A**. (Modified from Lefrancois GR. *Of Children: An Introduction to Child Development*. Wadsworth: Belmont, CA; 1973:305, with permission.)

The 7- to 11-year-old child must organize and order occurrences in the real world. Dealing with the future and its possibilities occurs in the formal operational stage.

Stage of Formal Operations (11 through the End of Adolescence)

The stage of formal operations is so named because young persons' thinking operates in a formal, highly logical, systematic, and symbolic manner. This stage is characterized by the ability to think abstractly, to reason deductively, and to define concepts, and also by the emergence of skills for dealing with permutations and combinations; young persons can grasp the concept of probabilities. Adolescents attempt to deal with all possible relations and hypotheses to explain data and events during this stage. Language use is complex; it follows formal rules of logic and is grammatically correct. Abstract thinking is shown by adolescents' interest in a variety of issues—philosophy, religion, ethics, and politics.

Hypothetico-deductive Thinking. Hypothetico-deductive thinking, the highest organization of cognition, enables persons to make a hypothesis or proposition and to test it against reality. *Deductive reasoning* moves from the general to the particular and is a more complicated process than *inductive reasoning*, which moves from the particular to the general.

Because young persons can reflect on their own and other persons' thinking, they are susceptible to self-conscious behavior. As adolescents attempt to master new cognitive tasks, they may return to egocentric thought, but on a higher level than in the past. For example, adolescents may think that they can accomplish everything or can change events by thought alone. Not all adolescents enter the stage of formal operations at the same time or to the same degree. Depending on individual capacity and intervening experience, some may not reach the stage of formal operational thought at all and may remain in the concrete operational mode throughout life.

PSYCHIATRIC APPLICATIONS

Piaget's theories have many psychiatric implications. Hospitalized children who are in the sensorimotor stage have not achieved object

permanence and, therefore, have separation anxiety. They do best if their mothers are allowed to stay with them overnight. Children at the preoperational stage, who are unable to deal with concepts and abstractions, benefit more from role-playing proposed medical procedures and situations than by having them verbally described in detail. For example, a child who is to receive intravenous therapy is helped by acting out the procedure with a toy intravenous set and dolls.

Because children at the preoperational stage do not understand cause and effect, they may interpret physical illness as punishment for bad thoughts or deeds; and because they have not yet mastered the capacity to conserve and do not understand the concept of reversibility (which normally occurs during the concrete operational stage), they cannot understand that a broken bone mends or that blood lost in an accident is replaced.

Adolescents' thinking, during the stage of formal operations, may appear overly abstract when it is, in fact, a normal developmental stage. Adolescent turmoil may not herald a psychotic process but may well result from a normal adolescent's coming to grips with newly acquired abilities to deal with the unlimited possibilities of the surrounding world.

Adults under stress may regress cognitively as well as emotionally. Their thinking can become preoperational, egocentric, and sometimes animistic.

Implications for Psychotherapy

Piaget was not an applied psychologist and did not develop the implications of his cognitive model for psychotherapeutic intervention. Nevertheless, his work formed one of the foundations of the *cognitive revolution* in psychology. One aspect of this revolution was an increasing emphasis on the cognitive components of the therapeutic endeavor. In contrast to classical psychodynamic therapy, which focused primarily on drives and affects, and in contrast to behavior therapy, which focused on overt actions, cognitive approaches to therapy focused on thoughts, including automatic assumptions, beliefs, plans, and intentions. By including "theory theory" and "script theory" we can see additional applications to psychotherapy.

Cognitive development theory has influenced psychotherapeutic approaches in multiple ways. Some therapists have taken developmental notions from Piaget's work and developed intervention techniques. Others have developed cognitive models of treatment independent of Piaget but with heavy reliance on the role of cognition. Others have included Piaget's concepts in a broader set of constructs to undergird new developmental approaches to psychotherapy.

First, some psychotherapists applied Piagetian notions directly to child interventions. Susan Harter, for example, discussed techniques for helping young children become aware of divergent or contradictory emotions and to integrate these complex emotions within a more abstract or higher class of emotions. One of Harter's techniques is to ask the young child to make a drawing that shows different and conflicting feelings in one person. This technique represents an application of the concrete operation of class inclusion to the realm of the emotions. Harter's work applied Piagetian findings to the common therapeutic problem of helping children to recognize, tolerate, and integrate mixed or ambivalent affects within stable object relations.

As such, it drew on cognitive theory and psychodynamic theory. Similar techniques are important in work with children who have been exposed to trauma or to sexual abuse. It is an essential component of such work to assist them in labeling, differentiating, and accepting the full range of emotions stemming from these experiences.

Second, other psychotherapists developed treatment models that, although not directly dependent on Piagetian psychology, emphasized core ideas quite similar to those Piaget discovered in his naturalistic observations of cognitive development. These models are even more closely aligned with recent developments in "theory theory." Aaron Beck, for example, developed an entire school of cognitive therapy that focuses on the role of cognitions in causing or maintaining psychopathology. Cognitive therapy has been shown to be an effective treatment for problems as diverse as depression, anxiety disorders, and substance abuse.

A core idea in cognitive therapy is that the patient has developed certain core beliefs, aspects of the self-schema, and conditional probability beliefs as a result of developmental experiences, and these contribute to emotional or behavioral problems. For example, depressed persons may have the core belief "I am unlovable." Addicted persons may have the belief "Unless I drink I cannot feel happy." In cognitive therapy, the person can be assisted to identify the negative automatic thoughts and underlying dysfunctional attitudes or beliefs that contribute to emotional distress or addictive behavior. The key therapeutic process after identification of the maladaptive thoughts is to help the patient view these thoughts more objectively, not take them in an unquestioning manner as veridical. Here, cognitive therapy emphasizes evidence, consistent both with Piagetian theory and "theory theory." The patient is assisted to seek out evidence to test negative thinking; active involvement, rather than passive listening, is required.

What the cognitive therapist accomplishes through such techniques as Socratic questioning and asking if there are other ways to look at the same event is similar to what the talented teacher does in guiding children to more adequate, more intelligent understanding of operational tasks. The notion of equilibration is relevant in both instances. By helping the individual see that previous cognitive structures are in some ways inadequate, the therapist or teacher disturbs the old cognitive structure, and the patient or student experiences a disruption that leads to the search for more-adequate structures. The compensation for external disturbance is what Piaget termed *equilibration*. New structures can be constructed only through a process of accommodation, enabling the subject to assimilate a wider array of data, a new perspective, or more complex information.

Because it requires *thinking about thinking*, cognitive therapy seems to require formal operational thinking, although this has not been empirically tested. At the least, it requires the ability to recognize and articulate affects, to recognize and label events that give rise to affects, and to translate into a thought the mediating process that occurs rapidly between the event and the affect. Cognitive-behavioral models of psychotherapy include cognitive techniques and more behavioral, interactive techniques, such as increasing pleasant activities and improving communication and problem-solving skills. It is possible that the less-cognitive, more-behavioral techniques, although requiring a lower level of cognitive development, can also lead to garnering of evidence and modification of specific expectancies, attributions, and self-schemata.

Because "script theory" or narrative approaches to cognition in psychotherapy are empirically based, generated by repetitive experiences rather than by reflective abstraction, and domain specific, they may have even more general application to psychotherapy than classic Piagetian theories or "theory theory." For example, in dialectical behavior therapy, patients provide a "chain analysis" of events, feelings, thoughts, situational stimuli, and interpersonal factors that led up to a negative or self-damaging behavior. This narrative provides guidance to the patient and the therapist about where and how to intervene to prevent subsequent similar behavior.

Developmentally Based Psychotherapy

Developmentally based psychotherapy, developed by Stanley Greenspan, M.D., integrates cognitive, affective, drive, and relationship-based approaches with new understanding of the stages of human development. The clinician first determines the level of the patient's ego or personality development and the presence or absence of deficits or constrictions. For example, can the person regulate activity and sensations, relate to others, read nonverbal affective symbols, represent experience, build bridges between representations, integrate emotional polarities, abstract feelings, and reflect on internal wishes and feelings?

From a developmental point of view, the integral parts of the therapeutic process include learning how to regulate experience; to engage more fully and deeply in relationships; to perceive, comprehend, and respond to complex behaviors, and interactive patterns; and to be able to engage in the ever-changing opportunities, tasks, and challenges during the course of life (e.g., adulthood and aging) and, throughout, to observe and reflect on one's own and others' experiences. These processes are the foundation of the ego, and more broadly, the personality.

Their presence constitutes emotional health and their absence, emotional disorder. The developmental approach describes how to harness these core processes and so assist the patients in mobilizing their own growth.

2.2 Attachment Theory

ATTACHMENT AND DEVELOPMENT

Attachment can be defined as the emotional tone between children and their caregivers and is evidenced by an infant's seeking and clinging to the caregiving person, usually the mother. By their first month, infants usually have begun to show such behavior, which is designed to promote proximity to the desired person.

Attachment theory originated in the work of John Bowlby, a British psychoanalyst (1907–1990) (Fig. 2.2-1). In his studies of infant attachment and separation, Bowlby pointed out that attachment constituted a central motivational force and that mother–child attachment was an essential medium of human interaction that had important consequences for later development and personality functioning. Being monotropic, infants tend to attach to one person; but they can form attachments to several persons, such as the father or a surrogate. Attachment develops gradually; it results in an infant's wanting to be with a preferred person, who is perceived as stronger, wiser, and able to reduce anxiety or distress. Attachment thus gives infants feelings of security. The process is facilitated by interaction between mother and infant; the amount of time together is less important than the amount of activity between the two.

FIGURE 2.2-1
John Bowlby (1907–1990).

The term *bonding* is sometimes used synonymously with attachment, but the two are different phenomena. Bonding concerns the mother's feelings for her infant and differs from attachment. Mothers do not normally rely on their infants as a source of security, as is the case in attachment behavior. Much research reveals that the bonding of mother to infant occurs when there is skin-to-skin contact between the two or when other types of contact, such as voice and eye contact, are made. Some workers have concluded that a mother who has skin-to-skin contact with her baby immediately after birth shows a stronger bonding pattern and may provide more attentive care than a mother who does not have this experience. Some researchers have even proposed a critical period immediately after birth, during which such skin-to-skin contact must occur if bonding is to take place. This concept is much disputed: Many mothers are clearly bonded to their infants and display excellent maternal care even though they did not have skin-to-skin contact immediately postpartum. Because human beings can develop representational models of their babies in utero and even before conception, this representational thinking may be as important to the bonding process as skin, voice, or eye contact.

Ethological Studies

Bowlby suggested a Darwinian evolutionary basis for attachment behavior; namely, such behavior ensures that adults protect their young.

Ethological studies show that nonhuman primates and other animals exhibit attachment behavior patterns that are presumably instinctual and are governed by inborn tendencies. An example of an instinctual attachment system is *imprinting*, in which certain stimuli can elicit innate behavior patterns during the first few hours of an animal's behavioral development; thus, the animal offspring becomes attached to its mother at a critical period early in its development. A similar sensitive or critical period during which attachment occurs has been postulated for human infants. The presence of imprinting behavior in humans is highly controversial, but bonding and attachment behavior during the first year of life closely approximate the critical period; in humans, however, this period occurs over a span of years rather than hours.

Harry Harlow. Harry Harlow's work with monkeys is relevant to attachment theory. Harlow demonstrated the emotional and behavioral effects of isolating monkeys from birth and keeping them from forming attachments. The isolates were withdrawn, unable to relate to peers, unable to mate, and incapable of caring for their offspring.

PHASES OF ATTACHMENT

In the first attachment phase, sometimes called the *preattachment stage* (birth to 8 or 12 weeks), babies orient to their mothers, follow them with their eyes over a 180-degree range, and turn toward and move rhythmically with their mother's voice. In the second phase, sometimes called *attachment in the making* (8 to 12 weeks to 6 months), infants become attached to one or more persons in the environment. In the third phase, sometimes called *clear-cut attachment* (6 through 24 months), infants cry and show other signs of distress when separated from the caretaker or mother; this phase can occur as early as 3 months in some infants. On being returned to the mother, the infant stops crying and clings, as if to gain further assurance of the mother's return. Sometimes, seeing the mother after a separation is sufficient for crying to stop. In the fourth phase (25 months and beyond), the mother figure is seen as independent, and a more complex relationship between the mother and the child develops. [Table 2.2-1](#) summarizes the development of normal attachment from birth through 3 years.

Table 2.2-1
Normal Attachment

Birth to 30 days
Reflexes at birth
Rooting
Head turning
Sucking
Swallowing
Hand-mouth
Grasp
Digital extension
Crying—signal for particular kind of distress
Responsiveness and orientation to mother's face, eyes, and voice
4 days—anticipatory approach behavior at feeding
3 to 4 wks—infant smiles preferentially to mother's voice
Age 30 days through 3 mos
Vocalization and gaze reciprocity further elaborated from 1 to 3 mos; babbling at 2 mos, more with the mother than with a stranger
Social smile
In strange situation, increased clinging response to mother
Age 4 through 6 mos
Briefly soothed and comforted by sound of mother's voice
Spontaneous, voluntary reaching for mother
Anticipatory posturing to be picked up
Differential preference for mother intensifies
Subtle integration of responses to mother
Age 7 through 9 mos
Attachment behaviors further differentiated and focused specifically on mother
Separation distress, stranger distress, strange-place distress
Age 10 through 15 mos

- Crawls or walks toward mother
- Subtle facial expressions (coyness, attentiveness)
- Responsive dialogue with mother clearly established
- Early imitation of mother (vocal inflections, facial expression)
- More fully developed separation distress and mother preference
- Pointing gesture
- Walking to and from mother
- Affectively positive reunion responses to mother after separation or, paradoxically, short-lived, active avoidance or delayed protest
- Age 16 mos through 2 yrs
 - Involvement in imitative jargon with mother (12 to 14 mos)
 - Head-shaking “no” (15 to 16 mos)
 - Transitional object used during the absence of mother
 - Separation anxiety diminishes
 - Mastery of strange situations and persons when mother is near
 - Evidence of delayed imitation
 - Object permanence
 - Microcosmic symbolic play
- Age 25 mos through 3 yrs
 - Able to tolerate separations from mother without distress when familiar with surroundings and given reassurances about mother’s return
 - Two- and three-word speech
 - Stranger anxiety much reduced
 - Object consistency achieved—maintains composure and psychosocial functioning without regression in absence of mother
 - Microcosmic play and social play; cooperation with others begins

Based on material by Justin Call, M.D.

Mary Ainsworth

Mary Ainsworth (1913–1999) was a Canadian developmental psychologist from the University of Toronto. She described three main types of insecure attachment: insecure–avoidant, insecure–ambivalent, and insecure–disorganized. The insecure–avoidant child, having experienced brusque or aggressive parenting, tends to avoid close contact with people and lingers near caregivers rather than approaching them directly when faced with a threat. The insecure–ambivalent child finds exploratory play difficult, even in the absence of danger, and clings to his or her inconsistent parents. Insecure–disorganized children have parents who are emotionally absent with a parental history of abuse in their childhood. These children tend to behave in bizarre ways when threatened. According to Ainsworth, disorganization is a severe form of insecure attachment and a possible precursor of severe personality disorder and dissociative phenomena in adolescence and early adulthood.

Mary Ainsworth expanded on Bowlby’s observations and found that the interaction between the mother and her baby during the attachment period significantly influences the baby’s current and future behavior. Patterns of attachments vary among babies; for example, some babies signal or cry less than others. Sensitive responsiveness to infant signals, such as cuddling a crying baby, causes infants to cry less in later months, rather than reinforcing crying behavior. Close bodily contact with the mother when the baby signals for her is also associated with the growth of self-reliance, rather than a clinging dependence, as the baby grows older. Unresponsive mothers produce anxious babies; these mothers often have lower intelligence quotients (IQs) and are emotionally more immature and younger than responsive mothers.

Ainsworth also confirmed that attachment serves to reduce anxiety. What she called the *secure base effect* enables children to move away from attachment figures and to explore the environment. Inanimate objects, such as a teddy bear and a blanket (called the transitional object by Donald Winnicott), also serve as a secure base, one that often accompanies them as they investigate the world.

Strange Situation. Ainsworth developed strange situation, the research protocol for assessing the quality and security of an infant’s attachment. In this procedure, the infant is exposed to escalating amounts of stress; for example, the infant and the parent enter an unfamiliar room, an unfamiliar adult then enters the room, and the parent leaves the room. The protocol has seven steps (Table 2.2-2). According to Ainsworth’s studies, about 65 percent of infants are securely attached by the age of 24 months.

 **Table 2.2-2**
The Strange Situation

Episode ^a	Persons Present	Change
1	Parent, infant	Enter room
2	Parent, infant, stranger	Unfamiliar adult joins the dyad
3	Infant, stranger	Parent leaves
4	Parent, infant	Parent returns, stranger leaves
5	Infant	Parent leaves
6	Infant, stranger	Stranger returns
7	Parent, infant	Parent returns, stranger leaves

^aAll episodes are usually 3 minutes long, but episodes 3, 5, and 6 can be curtailed if the infant becomes too distressed, and episodes 4 and 7 are sometimes extended. (Reprinted from Lamb ME, Nash A, Teti DM, Bornstein MH. *Infancy*. In: Lewis M, ed. *Child and Adolescent Psychiatry: A Comprehensive Textbook*. 2nd ed. Philadelphia: Williams & Wilkins; 1996:256, with permission.)

ANXIETY

Bowlby's theory of anxiety holds that a child's sense of distress during separation is perceived and experienced as anxiety and is the prototype of anxiety. Any stimuli that alarm children and cause fear (e.g., loud noises, falling, and cold blasts of air) mobilize signal indicators (e.g., crying) that cause the mother to respond in a caring way by cuddling and reassuring the child. The mother's ability to relieve the infant's anxiety or fear is fundamental to the growth of attachment in the infant. When the mother is close to the child and the child experiences no fear, the child gains a sense of security, the opposite of anxiety. When the mother is unavailable to the infant because of physical absence (e.g., if the mother is in prison) or because of psychological impairment (e.g., severe depression), anxiety develops in the infant.

Expressed as tearfulness or irritability, separation anxiety is the response of a child who is isolated or separated from its mother or caretaker. It is most common at 10 to 18 months of age and disappears generally by the end of the third year. Somewhat earlier (at about 8 months) stranger anxiety, an anxiety response to someone other than the caregiver, appears.

Signal Indicators

Signal indicators are infants' signs of distress that prompt or elicit a behavioral response in the mother. The primary signal is crying. The three types of signal indicators are hunger (the most common), anger, and pain. Some mothers can distinguish between them, but most mothers generalize the hunger cry to represent distress from pain, frustration, or anger. Other signal indicators that reinforce attachment are smiling, cooing, and looking. The sound of an adult human voice can prompt these indicators.

Losing Attachments

Persons' reactions to the death of a parent or a spouse can be traced to the nature of their past and present attachment to the lost figure. An absence of demonstrable grief may be owing to real experiences of rejection and to the lack of closeness in the relationship. The person may even consciously offer an idealized picture of the deceased. Persons who show no grief usually try to present themselves as independent and as disinterested in closeness and attachment.

Sometimes, however, the severing of attachments is traumatic. The death of a parent or a spouse can precipitate a depressive disorder, and even suicide, in some persons. The death of a spouse increases the chance that the surviving spouse will experience a physical or mental disorder during the next year. The onset of depression and other dysphoric states often involves having been rejected by a significant figure in a person's life.

DISORDERS OF ATTACHMENT

Attachment disorders are characterized by biopsychosocial pathology that results from maternal deprivation, a lack of care by, and interaction with, the mother or caregiver. Failure-to-thrive syndromes, psychosocial dwarfism, separation anxiety disorder, avoidant personality disorder, depressive disorders, delinquency, academic problems, and borderline intelligence have been traced to negative attachment experiences. When maternal care is deficient because (1) a mother is mentally ill, (2) a child is institutionalized for a long time, or (3) the primary object of attachment dies, children sustain emotional damage. Bowlby originally thought that the damage was permanent and invariable, but he revised his theories to take into account the time at which the separation occurred, the type and degree of separation, and the level of security that the child experienced before the separation.

Bowlby described a predictable set and sequence of behavior patterns in children who are separated from their mothers for long periods (more than 3 months): protest, in which the child protests the separation by crying, calling out, and searching for the lost person; despair, in which the child appears to lose hope that the mother will return; and detachment, in which the child emotionally separates himself or herself from the mother. Bowlby believed that this sequence involves ambivalent feelings toward the mother; the child both wants her and is angry with her for her desertion.

Children in the detachment stage respond in an indifferent manner when the mother returns; the mother has not been forgotten, but the child is angry at her for having gone away in the first place and fears that she will go away again. Some children have affectionless personalities characterized by emotional withdrawal, little or no feeling, and a limited ability to form affectionate relationships.

Anaclitic Depression

Anaclitic depression, also known as hospitalism, was first described by René Spitz in infants who had made normal attachments but were then suddenly separated from their mothers for varying times and placed in institutions or hospitals. The children became depressed, withdrawn, nonresponsive, and vulnerable to physical illness, but they recovered when their mothers returned or when surrogate mothering was available.

CHILD MALTREATMENT

Abused children often maintain their attachments to abusive parents. Studies of dogs have shown that severe punishment and maltreatment increase attachment behavior. When children are hungry, sick, or in pain, they too show clinging attachment behavior. Similarly, when children are rejected by their parents or are afraid of them, their attachment may increase; some children want to remain with an abusive parent. Nevertheless, when a choice must be made between a punishing and a nonpunishing figure, the nonpunishing person is the preferable choice, especially if the person is sensitive to the child's needs.

PSYCHIATRIC APPLICATIONS

The applications of attachment theory in psychotherapy are numerous. When a patient is able to attach to a therapist, a secure base effect is seen. The patient may then be able to take risks, mask anxiety, and practice new patterns of behavior that otherwise might not have been attempted. Patients whose impairments can be traced to never having made an attachment in early life may do so for the first time in therapy, with salutary effects.

Patients whose pathology stems from exaggerated early attachments may attempt to replicate them in therapy. Therapists must enable such patients to recognize the ways their early experiences have interfered with their ability to achieve independence.

For patients who are children and whose attachment difficulties may be more apparent than those of adults, therapists represent consistent and trusted figures who can engender a sense of warmth and self-esteem in children, often for the first time.

Relationship Disorders

A person's psychological health and sense of well-being depend significantly on the quality of his or her relationships and attachment to others, and a core issue in all close personal relationships is establishing and regulating that connection. In a typical attachment interaction, one person seeks more proximity and affection, and the other either reciprocates, rejects, or disqualifies the request. A pattern is shaped through repeated exchanges. Distinct attachment styles have been observed. Adults with an anxious-ambivalent attachment style tend to be obsessed with romantic partners, suffer from extreme jealousy, and have a high divorce rate. Persons with an avoidant attachment style are

relatively uninvested in close relationships, although they often feel lonely. They seem afraid of intimacy and tend to withdraw when there is stress or conflict in the relationship. Break-up rates are high. Persons with a secure attachment style are highly invested in relationships and tend to behave without much possessiveness or fear of rejection.

2.3 Learning Theory

Learning is defined as a change in behavior resulting from repeated practice. The principles of learning are always operating and always influencing human activity. Learning principles are often deeply involved in the etiology and maintenance of psychiatric disorders because so much of human behavior (including overt behavior, thought patterns, and emotion) is acquired through learning. Learning processes also strongly influence psychotherapy because human behavior changes. Thus, learning principles can influence the effectiveness of therapy. In fact, no method of therapy can be said to be immune to the effects of learning. Even the simple prescription of a medication can bring learning processes into play because the patient will have opportunities to learn about the drug’s effects and side effects, will need to learn to comply with the instructions and directions for taking it, and will need to learn to overcome any resistance to compliance.

BASIC CONCEPTS AND CONSIDERATIONS

A great deal of modern research on learning still focuses on Pavlovian (classical) and operant learning. Pavlovian conditioning, developed by Ivan Petrovich Pavlov (1849–1936), occurs when neutral stimuli are associated with a psychologically significant event. The main result is that the stimuli come to evoke a set of responses or emotions that may contribute to many clinical disorders, including (but not limited to) anxiety disorders and drug dependence. The events in Pavlov’s experiment are often described using terms designed to make the experiment applicable to any situation. The food is the unconditional stimulus (*US*) because it unconditionally elicits salivation before the experiment begins. The bell is known as the conditional stimulus (*CS*) because it only elicits the salivary response conditional on the bell–food pairings. The new response to the bell is correspondingly called the conditional response (*CR*), and the natural response to the food itself is the unconditional response (*UR*). Modern laboratory studies of conditioning use a very wide range of CSs and USs and measure a wide range of conditioned responses.

Operant conditioning, developed by B.F. Skinner (1904–1990), occurs when a behavior (instead of a stimulus) is associated with a psychologically significant event. In the laboratory, the most famous experimental arrangement is the one in which a rat presses a lever to earn food pellets. In this case, as opposed to Pavlov’s, the behavior is said to be an operant because it operates on the environment. The food pellet is a reinforcer—an event that increases the strength of the behavior of which it is made a consequence. A major idea behind this method is that the rat’s behavior is “voluntary” in the sense that the animal is not compelled to make the response (it can perform it whenever it “wants” to). In this sense, it is similar to the thousands of operant behaviors that humans choose to commit—freely—in any day. Of course, the even larger idea is that even though the rat’s behavior appears as though it is voluntary, it is lawfully controlled by its consequences: If the experimenter were to stop delivering the food pellet, the rat would stop pressing the lever, and if the experimenter were to allow the lever press to produce larger pellets, or perhaps pellets at a higher probability or rate, then the rate of the behavior might increase. The point of operant conditioning experiments, then, is largely to understand the relation of behavior to its payoff.

Pavlovian and operant conditioning differ in several ways. One of the most fundamental differences is that the responses observed in Pavlov’s experiment are *elicited* and thus controlled by the presentation of an antecedent stimulus. In contrast, the “response” observed in Skinner’s experiment is not elicited or compelled by an antecedent stimulus in any obvious way—it is instead controlled by its consequences. This distinction between *operants* and *respondents* is important in clinical settings. If a young patient is referred to the clinic for acting out in the classroom, an initial goal of the clinician will be to determine whether the behavior is a respondent or an operant, and then the clinician will go about changing either its antecedents or its consequences, respectively, to reduce its probability of occurrence.

Despite the academic separation of operant and respondent conditioning, they have an important common function: Both learning processes are designed by evolution to allow organisms to adapt to the environment. The idea is illustrated by considering the *law of effect* (Fig. 2.3-1), which says that whether an operant behavior increases or decreases in strength depends on the effect it has on the environment. When the action leads to a positive outcome, the action is strengthened; conversely, when the action leads to a negative outcome, we have *punishment*, and the action is weakened. In a similar manner, when an action decreases the probability of a positive event, behavior also declines. (Such a procedure is now widely known as *time-out* from reinforcement.) When an action terminates or prevents the occurrence of a negative event, the behavior will strengthen. By thus enabling the organism to maximize its interaction with positive events and minimize its interaction with negative ones, operant conditioning allows the organism to optimize its interaction with the environment. Of course, events that were once positive in the human’s earlier evolutionary history are so prevalent in modern society that they do not always seem adaptive today. Thus, reward learning also provides a framework for understanding the development of rather maladaptive behaviors like overeating (in which behavior is reinforced by food) and drug taking (in which behaviors are reinforced by the pharmacological effects of drugs)—cases in which reward principles lead to psychopathology.

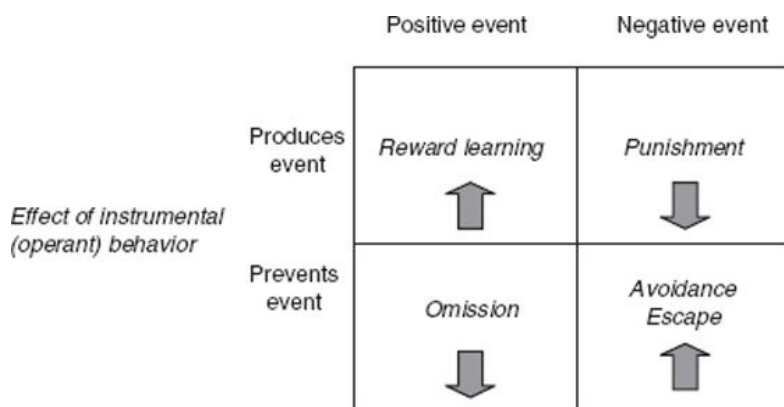

FIGURE 2.3-1

The law of effect in instrumental/operant learning. Actions either produce or prevent good or bad events, and the strength of the action changes accordingly (*arrow*). “Reinforcement” refers to a strengthening of behavior. *Positive reinforcement* occurs when an action produces a positive event, whereas *negative reinforcement* occurs when an action prevents or eliminates a negative event. (Courtesy of Mark E. Bouton, PhD.)

A parallel to **Figure 2.3-1** exists in Pavlovian conditioning, in which one can likewise think of whether the CS is associated with positive or negative events (**Fig. 2.3-2**). Although such learning can lead to a wide constellation or system of behaviors, in a very general way, it also leads to behavioral tendencies of approach or withdrawal. Thus, when a CS signals a positive US, the CS will tend to evoke approach behaviors—called *sign tracking*. For example, an organism will approach a signal for food. Analogously, when a CS signals a negative US, it will evoke behaviors that tend to move the organism away from the CS. Conversely, CSs associated with a decrease in the probability of a good thing will elicit withdrawal behaviors, whereas CSs associated with the decrease in the probability of a bad thing can elicit approach. An example of the latter case might be a stimulus that signals safety or the decrease in probability of an aversive event, which evokes approach in a frightened organism. In the end, these very basic behavioral effects of both operant (see **Fig. 2.3-1**) and Pavlovian (see **Fig. 2.3-2**) learning serve to maximize the organism’s contact with good things and minimize contact with bad things.

	Positive event	Negative event
Increase in Probability of event	Approach CS	Withdraw from CS
Decrease in Probability of event	Withdraw from CS	Approach CS

FIGURE 2.3-2

Sign tracking in Pavlovian learning. Conditional stimuli (CSs) signal either an increase or a decrease in the probability of good or bad events, and the CS generally engages approach or withdrawal behaviors accordingly. (Courtesy of Mark E. Bouton, PhD.)

Perhaps because they have such similar functions, Pavlovian learning and operant learning are both influenced by similar variables. For example, in either case, behavior is especially strong if the magnitude of the US or reinforcer is large, or if the US or reinforcer occurs relatively close to the CS or operant response in time. In either case, the learned behavior decreases if the US or reinforcer that was once paired with the CS or the response is eliminated from the situation. This phenomenon, called *extinction*, provides a means of eliminating unwanted behaviors that were learned through either form of conditioning and has led to a number of very effective cognitive-behavioral therapies.

PAVLOVIAN CONDITIONING

Effects of Conditioning on Behavior

Many lay people have the mistaken impression that Pavlovian learning is a rigid affair in which a fixed stimulus comes to elicit a fixed response. In fact, conditioning is considerably more complex and dynamic than that. For example, signals for food may evoke a large set of responses that function to prepare the organism to digest food: They can elicit the secretion of gastric acid, pancreatic enzymes, and insulin in addition to Pavlov’s famous salivary response. The CS can also elicit approach behavior (as described earlier), an increase in body temperature, and a state of arousal and excitement. When a signal for food is presented to a satiated animal or human, he or she may eat more food. Some of these effects may be motivational; for example, an additional effect of presenting a CS for food is that it can invigorate ongoing operant behaviors that have been reinforced with food. CSs thus have powerful behavioral potential. Signals for food evoke a whole *behavior system* that is functionally organized to find, procure, and consume food.

Pavlovian conditioning is also involved in other aspects of eating. Through conditioning, humans and other animals may learn to like or dislike certain foods. In animals like rats, flavors associated with nutrients (sugars, starches, calories, proteins, or fats) come to be preferred. Flavors associated with sweet tastes are also preferred, whereas flavors associated with bitter tastes are avoided. At least as important, flavors associated with illness become disliked, as illustrated by the person who gets sick drinking an alcoholic beverage and consequently learns to hate the flavor. The fact that flavor CSs can be associated with such a range of biological consequences (USs) is important for omnivorous animals that need to learn about new foods. It also has some clinical implications. For example, chemotherapy can make cancer patients sick, and it can therefore cause the conditioning of an aversion to a food that was eaten recently (or to the clinic itself). Other evidence suggests that animals may learn to dislike food that is associated with becoming sick with cancer. On the flip side, conditioning can enable external cues to trigger food consumption and craving, a potential influence on overeating and obesity.

Pavlovian conditioning also occurs when organisms ingest drugs. Whenever a drug is taken, in addition to reinforcing the behaviors that lead to its ingestion, the drug constitutes a US and may be associated with potential CSs that are present at the time (e.g., rooms, odors, injection paraphernalia). CSs that are associated with drug USs can sometimes have an interesting property: They often elicit a conditioned response that seems opposite to the unconditional effect of the drug. For example, although morphine causes a rat to feel less pain, a CS associated with morphine elicits an opposite increase, not a decrease in pain sensitivity. Similarly, although alcohol can cause a drop in body temperature, a conditioned response to a CS associated with alcohol is typically an increase in body temperature. In these cases, the conditioned response is said to be *compensatory* because it counteracts the drug effect. Compensatory responses are another example of how classical (Pavlovian) conditioning helps organisms prepare for a biologically significant US.

Compensatory conditioned responses have implications for drug abuse. First, they can cause drug tolerance, in which repeated administration of a drug reduces its effectiveness. As a drug and a CS are repeatedly paired, the compensatory response to the CS becomes stronger and more effective at counteracting the effect of the drug. The drug therefore has less impact. One implication is that tolerance will be lost if the drug is taken without being signaled by the usual CS. Consistent with this idea, administering a drug in a new environment can cause a loss of drug tolerance and make drug overdose more likely. A second implication stems from the fact that compensatory responses may be unpleasant or aversive. A CS associated with an opiate may elicit several compensatory responses—it may cause the drug user to be more sensitive to pain, undergo a change in body temperature, and perhaps become hyperactive (the opposite of another unconditional opiate effect). The unpleasantness of these responses may motivate the user to take the drug again to get rid of them, an example of escape learning, or negative reinforcement, and a classic example of how Pavlovian and operant learning processes might readily interact. The idea is that the urge to take drugs may be strongest in the presence of CSs that have been associated with the drug. The hypothesis is consistent with self-reports of abusers, who, after a period of

abstinence, are tempted to take the drug again when they are reexposed to drug-associated cues.

Pavlovian learning may potentially be involved in anxiety disorders. CSs associated with frightening USs can elicit a whole system of conditioned fear responses, broadly designed to help the organism cope. In animals, cues associated with frightening events (such as a brief foot shock) elicit changes in respiration, heart rate, and blood pressure, and even a (compensatory) decrease in sensitivity to pain. Brief CSs that occur close to the US in time can also elicit adaptively timed protective reflexes. For example, the rabbit blinks in response to a brief signal that predicts a mild electric shock near the eye. The same CS, when lengthened in duration and paired with the same US, elicits mainly fear responses, and fear elicited by a CS may potentiate the conditioned eyeblink response elicited by another CS or a startle response to a sudden noise. Once again, CSs do not merely elicit a simple reflex, but also evoke a complex and interactive set of responses.

Classical fear conditioning can contribute to phobias (in which specific objects may be associated with a traumatic US), as well as other anxiety disorders, such as panic disorder and posttraumatic stress disorder (PTSD). In panic disorder, people who have unexpected panic attacks can become anxious about having another one. In this case, the panic attack (the US or UR) may condition anxiety to the external situation in which it occurs (e.g., a crowded bus) and also internal (“interoceptive”) CSs created by early symptoms of the attack (e.g., dizziness or a sudden pounding of the heart). These CSs may then evoke anxiety or panic responses. Panic disorder may begin because external cues associated with panic can arouse anxiety, which may then exacerbate the next unconditional panic attack and/or panic response elicited by an interoceptive CS. It is possible that the emotional reactions elicited by CSs may not require conscious awareness for their occurrence or development. Indeed, fear conditioning may be independent of conscious awareness.

In addition to eliciting conditioned responses, CSs also motivate ongoing operant behavior. For example, presenting a CS that elicits anxiety can increase the vigor of operant behaviors that have been learned to avoid or escape the frightening US. Thus, an individual with an anxiety disorder will be more likely to express avoidance in the presence of anxiety or fear cues. Similar effects may occur with CSs that predict other USs (such as drugs or food)—as already mentioned, a drug-associated CS may motivate the drug abuser to take more drugs. The motivating effects of CSs may stem from the fact that CSs may be associated with both the sensory and emotional properties of USs. For example, the survivor of a traumatic train derailment might associate stimuli that occur immediately before derailment (such as the blue flash that occurs when the train separates from its overhead power supply) with both the emotional and the sensory aspects of the crash. Consequently, when the survivor later encounters another flashing blue light (e.g., the lights on a police car), the CS might evoke both emotional responses (mediated by association with the trauma’s emotional qualities) and sensory associations (mediated by association with the trauma’s sensory qualities). Both might play a role in the nightmares and “re-experiencing” phenomena that are characteristic of PTSD.

The Nature of the Learning Process

Research beginning in the late 1960s began to uncover some important details about the learning process behind Pavlovian conditioning. Several findings proved especially important. It was shown, for example, that conditioning is not an inevitable consequence of pairing a CS with a US. Such pairings will not cause conditioning if there is a second CS present that already predicts the US. This finding (known as *blocking*) suggests that a CS must provide new information about the US if learning is to occur. The importance of the CS’s information value is also suggested by the fact that a CS will not be treated as a signal for the US if the US occurs equally often (or is equally probable) in the presence and the absence of the CS. Instead, the organism treats the CS as a signal for the US if the probability of the US is greater in the presence of the CS than in its absence. In addition, the organism will treat the CS as a signal for “no US” if the probability of the US is less in the presence of the CS than in its absence. In the latter case, the signal is called a *conditioned inhibitor* because it will inhibit performance elicited by other CSs. The conditioned inhibition phenomenon is clinically relevant because inhibitory CSs may hold pathological CRs like fear or anxiety at bay. A loss of the inhibition would allow the anxiety response to emerge.

There are also important variants of classical conditioning. In *sensory preconditioning*, two stimuli (A and B) are first paired, and then one of them (A) is later paired with the US. Stimulus A evokes conditioned responding, of course, but so does stimulus B—indirectly, through its association with A. One implication is that exposure to a potent US like a panic attack may influence reactions to stimuli that have never been paired with the US directly; the sudden anxiety to stimulus B might seem spontaneous and mysterious. A related finding is *second-order conditioning*. Here, A is paired with a US first and then subsequently paired with stimulus B. Once again, both A and B will evoke responding. Sensory preconditioning and second-order conditioning increase the range of stimuli that can control the conditioned response. A third variant worth mentioning occurs, as indicated previously, when the onset of a stimulus becomes associated with the rest of that stimulus, as when a sudden increase in heart rate caused by the onset of a panic attack comes to predict the rest of the panic or feeling, or when the onset of a drug may predict the rest of the drug effect. Such intraevent associations may play a role in many of the body’s regulatory functions, such that an initial change in some variable (e.g., blood pressure or blood glucose level) may come to signal a further increase in that variable and therefore initiate a conditioned compensatory response.

Emotional responses can also be conditioned through observation. For example, a monkey that merely observes another monkey being frightened by a snake can learn to be afraid of the snake. The observer learns to associate the snake (CS) with its emotional reaction (US/UR) to the other monkey being afraid. Although monkeys readily learn to fear snakes, they are less likely to associate other salient cues (such as colorful flowers) with fear in the same way. This is an example of *preparedness* in classical conditioning—some stimuli are especially effective signals for some USs because evolution has made them that way. Another example is the fact that tastes are easily associated with illness but not shock, whereas auditory and visual cues are easily associated with shock but not illness. Preparedness may explain why human phobias tend to be for certain objects (snakes or spiders) and not others (knives or electric sockets) that may as often be paired with pain or trauma.

Erasing Pavlovian Learning

If Pavlovian learning plays a role in the etiology of behavioral and emotional disorders, a natural question concerns how to eliminate it or undo it. Pavlov studied *extinction*: Conditioned responding decreases if the CS is presented repeatedly without the US after conditioning. Extinction is the basis of many behavioral or cognitive-behavioral therapies designed to reduce pathological conditioned responding through repeated exposure to the CS (exposure therapy), and it is presumably a consequence of any form of therapy in the course of which the patient learns that previous harmful cues are no longer harmful. Another elimination procedure is *counterconditioning*, in which the CS is paired with a very different US/UR. Counterconditioning was the inspiration for *systematic desensitization*, a behavior therapy technique in which frightening CSs are deliberately associated with relaxation during therapy.

Although extinction and counterconditioning reduce unwanted conditioned responses, they do not destroy the original learning, which remains in the brain, ready to return to behavior under the right circumstances. For example, conditioned responses that have been eliminated by extinction or counterconditioning can recover if time passes before the CS is presented again (spontaneous recovery). Conditioned responses can also return if the patient returns to the context of conditioning after extinction in another context, or if the CS is encountered in a context that differs from the one in which extinction has occurred (all are examples of the renewal effect). The renewal effect is important because it illustrates the principle that extinction performance depends on the organism being in the context in which extinction was learned. If the CS is encountered in a different context, the extinguished behavior may relapse or return. Recovery and relapse can also occur if the current context is associated again with the US (“reinstatement”) or if the CS is paired with the US again (“rapid reacquisition”). One theoretical approach assumes that extinction and counterconditioning do not destroy the original learning but instead entail new learning that gives the CS a second meaning (e.g., “the CS is safe” in addition to “the CS is dangerous”). As with an ambiguous word, which has more than one meaning, responding evoked by an extinguished or counterconditioned CS depends fundamentally on the current context.

Research on context effects in both animal and human learning and memory suggests that a wide variety of stimuli can play the role of context (Table 2.3-1). Drugs, for example, can be very salient in this regard. When rats are given fear extinction while under the influence of a benzodiazepine tranquilizer or alcohol, fear is renewed when the CS is tested in

the absence of the context provided by the drug. This is an example of *state-dependent learning*, in which the retention of information is best when tested in the same state in which it was originally learned. State-dependent fear extinction has obvious implications for combining therapy with drugs. It also has implications for the administration of drugs more generally. For example, if a person were to take a drug to reduce anxiety, the anxiety reduction would reinforce drug taking. State-dependent extinction might further preserve any anxiety that might otherwise be extinguished during natural exposure to the anxiety-eliciting cues. Thus, drug use could paradoxically preserve the original anxiety, creating a self-perpetuating cycle that could provide a possible explanation for the link between anxiety disorders and substance abuse. One point of this discussion is that drugs can play multiple roles in learning: They can be USs or reinforcers on one hand, and CSs or contexts on the other. The possible complex behavioral effects of drugs are worth bearing in mind.

 **Table 2.3-1**
Effective Contextual Stimuli Studied In Animal and Human Research Laboratories

Exteroceptive context:
Room, place, environment, other external background stimuli

Interoceptive context:
Drug state
Hormonal state
Mood state
Deprivation state
Recent events
Expectation of events
Passage of time

From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*, 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:652.

Another general message is that contemporary theory emphasizes the fact that extinction (and other processes, such as counterconditioning) entails new learning rather than a destruction of the old. Recent psychopharmacological research has built on this idea: If extinction and therapy constitute new learning, then drugs that might facilitate new learning might also facilitate the therapy process. For example, there has been considerable recent interest in *D*-cycloserine, a partial agonist of the *N*-methyl-*D*-aspartate (NMDA) glutamate receptor. The NMDA receptor is involved in long-term potentiation, a synaptic facilitation phenomenon that has been implicated in several examples of learning. Of interest, there is evidence that the administration of *D*-cycloserine can facilitate extinction learning in rats and possibly in humans undergoing exposure therapy for anxiety disorders. In the studies supporting this conclusion, the administration of the drug increased the amount of extinction that was apparent after a small (and incomplete) number of extinction trials. Although such findings are promising, it is important to remember that the context dependence of extinction, and thus the possibility of relapse with a change of context, may easily remain. Consistent with this possibility, although *D*-cycloserine allows fear extinction to be learned in fewer trials, it does not appear to prevent or reduce the strength of the renewal effect. Such results further underscore the importance of behavioral research—and behavioral theory—in understanding the effects of drugs on therapy. Nonetheless, the search for drugs that might enhance the learning that occurs in therapy situations will continue to be an important area of research.

Another process that might theoretically modify or erase a memory is illustrated by a phenomenon called *reconsolidation*. Newly learned memories are temporarily labile and easy to disrupt before they are consolidated into a more stable form in the brain. The consolidation of memory requires the synthesis of new proteins and can be blocked by the administration of protein synthesis inhibitors (e.g., anisomycin). Animal research suggests that consolidated memories that have recently been reactivated might also return briefly to a similarly vulnerable state; their “reconsolidation” can likewise be blocked by protein synthesis inhibitors. For example, several studies have shown that the reactivation of a conditioned fear by one or two presentations of the CS after a brief fear conditioning experience can allow it to be disrupted by anisomycin. When the CS is tested later, there is little evidence of fear—as if reactivation and then drug administration diminished the strength of the original memory. However, like the effects of extinction, these fear-diminishing effects do not necessarily mean that the original learning has been destroyed or erased. There is some evidence that fear of the CS that has been diminished in this way can still return over time (i.e., spontaneously recover) or with reminder treatments. This sort of result suggests that the effect of the drug is somehow able to interfere with retrieval or access to the memory rather than to be an actual “reconsolidation.”

Generally speaking, the elimination of a behavior after therapy should not be interpreted as erasure of the underlying knowledge. For the time being, it may be safest to assume that after any therapeutic treatment, a part of the original learning may remain in the brain, ready to produce relapse if retrieved. Instead of trying to find treatments that destroy the original memory, another therapeutic strategy might be to accept the possible retention of the original learning and build therapies that allow the organism to prevent or cope with its retrieval. One possibility is to conduct extinction exposure in the contexts in which relapse might be most problematic to the patient and to encourage retrieval strategies (such as the use of retrieval cues like reminder cards) that might help to remind the patient of the therapy experience.

OPERANT/INSTRUMENTAL LEARNING

The Relation Between Behavior and Payoff

Operant learning has many parallels with Pavlovian learning. As one example, extinction also occurs in operant learning if the reinforcer is omitted following training. Although extinction is once again a useful technique for eliminating unwanted behaviors, just as we saw with Pavlovian learning, it does not destroy the original learning—spontaneous recovery, renewal, reinstatement, and rapid reacquisition effects still obtain. Although early accounts of instrumental learning, beginning with Edward Thorndike, emphasized the role of the reinforcer as “stamping in” the instrumental action, more-modern approaches tend to view the reinforcer as a sort of guide or motivator of behavior. A modern, “synthetic” view of operant conditioning (see later discussion) holds that the organism associates the action with the outcome in much the way that stimulus–outcome learning is believed to be involved in Pavlovian learning.

Human behavior is influenced by a wide variety of reinforcers, including social ones. For example, simple attention from teachers or hospital staff members has been shown to reinforce disruptive or problematic behavior in students or patients. In either case, when the attention is withdrawn and redirected toward other activities, the problematic behaviors can decrease (i.e., undergo extinction). Human behavior is also influenced by verbal reinforcers, like praise, and, more generally, by *conditioned reinforcers*, such as money, that have no intrinsic value except for the value derived through association with more basic, “primary” rewards. Conditioned reinforcers have been used in schools and institutional settings in so-called *token economies* in which positive behaviors are reinforced with tokens that can be used to purchase valued items. In more natural settings, reinforcers are always delivered in social relationships, in which their effects are dynamic and reciprocal. For example, the relationship between a parent and a child is full of interacting and reciprocating operant contingencies in which the delivery (and withholding) of reinforcers and punishers shapes the behavior of each. Like Pavlovian learning, operant learning is always operating and always influencing behavior.

Research on operant conditioning in the laboratory has offered many insights into how action relates to its payoff. In the natural world, few actions are reinforced every time they are performed; instead, most actions are reinforced only intermittently. In a *ratio reinforcement schedule*, the reinforcer is directly related to the amount of work or responding that the organism emits. That is, there is some work requirement that determines when the next reinforcer will be presented. In a “fixed ratio schedule,” every *x*th action is reinforced; in a “variable ratio schedule,” there is an average ratio requirement, but the number of responses required for each successive reinforcer varies. Ratio schedules, especially variable ratio schedules, can generate high rates of behavior, as seen in the behavior directed at a casino slot machine. In an *interval reinforcement schedule*, the presentation of each reinforcer

depends on the organism emitting the response after some period of time has also elapsed. In a “fixed interval schedule,” the first response after x seconds have elapsed is reinforced. In a “variable interval schedule,” there is an interval requirement for each reinforcer, but the length of that interval varies. A person checking e-mail throughout the day is being reinforced on a variable interval schedule—a new message is not present to reinforce each checking response, but the presence of a new message becomes available after variable time points throughout the day. Of interest, on interval schedules, the response rate can vary substantially without influencing the overall rate of reinforcement. (On ratio schedules, there is a more direct relationship between behavior rate and reinforcement rate.) In part because of this, interval schedules tend to generate slower response rates than ratio schedules.

Classic research on operant behavior underscores the fact that the performance of any action always involves *choice*. That is, whenever the individual performs a particular behavior, he or she chooses to engage in that action over many other possible alternatives. When choice has been studied by allowing the organism to perform either of two different operant behaviors (paying off with their own separate schedules of reinforcement), the rate of operant behavior depends not only on the behavior’s rate of reinforcement, but also on the rate of reinforcement of all other behaviors in the situation. Put most generally, the strength of Behavior 1 (e.g., the rate at which Behavior 1 is performed) is given by

$$B_1 = KR_1/(R_1 + R_0)$$

where B_1 can be seen as the strength of Behavior 1, R_1 is the rate at which B_1 has been reinforced, and R_0 is the rate at which all alternative (or “other”) behaviors in the environment have been reinforced; K is a constant that corresponds to all behavior in the situation and may have a different value for different individuals. This principle, known as the *quantitative law of effect*, captures several ideas that are relevant to psychiatrists and clinical psychologists. It indicates that an action can be strengthened either by increasing its rate of reinforcement (R_1) or by decreasing the rate of reinforcement for alternative behaviors (R_0). Conversely, an action can be weakened either by reducing its rate of reinforcement (R_1) or by increasing the rate of reinforcement for alternative behaviors (R_0). The latter point has an especially important implication: In principle, one can slow the strengthening of new, undesirable behavior by providing an environment that is otherwise rich in reinforcement (high R_0). Thus, an adolescent who experiments with drugs or alcohol would be less likely to engage in this behavior at a high rate (high B_1) if his or her environment were otherwise rich with reinforcers (e.g., provided by extracurricular activities, outside interests, and so forth).

Choice among actions is also influenced by the size of their corresponding reinforcers and how soon the reinforcers will occur. For example, individuals sometimes have to choose between an action that yields a small but immediate reward (e.g., taking a hit of a drug) versus another that yields a larger but delayed reward (e.g., going to a class and earning credit toward a general educational development certificate). Individuals who choose the more immediate reward are often said to be “impulsive,” whereas those who choose the delayed reward are said to exercise “self-control.” Of interest, organisms often choose immediate small rewards over delayed larger ones, even though it may be maladaptive to do so in the long run. Such “impulsive” choices are especially difficult to resist when the reward is imminent. Choice is believed to be determined by the relative value of the two rewards, with that value being influenced by both the reinforcer’s size and its delay. The bigger the reinforcer, the better is the value, and the more immediate the reinforcer, the better too: When a reward is delayed, its value decreases or is “discounted” over time. When offered a choice, the organism will always choose the action that leads to the reward whose value is currently higher.

Theories of Reinforcement

It is possible to use the foregoing principles of operant conditioning without knowing in advance what kind of event or stimulus will be reinforcing for the individual patient. None of the reinforcement rules say much about what sorts of events in an organism’s world will play the role of reinforcer. Skinner defined a reinforcer empirically, by considering the effect it had on an operant behavior. A reinforcer was defined as any event that could be shown to increase the strength of an operant if it was made a consequence of the operant. This empirical (some would say “atheoretical”) view can be valuable because it allows idiosyncratic reinforcers for idiosyncratic individuals. For instance, if a therapist works with a child who is injuring himself, the approach advises the therapist merely to search for the consequences of the behavior and then manipulate them to bring the behavior under control. So if, for example, the child’s self-injurious behavior decreases when the parent stops scolding the child for doing it, then the scold is the reinforcer, which might seem counterintuitive to everyone (including the parent who thinks that the scold should function as a punisher). On the other hand, it would also be useful to know what kind of event will reinforce an individual before the therapist has to try everything.

This void is filled by several approaches to reinforcement that allow predictions ahead of time. Perhaps the most useful is the *Premack principle* (named for researcher David Premack), which claims that, for any individual, reinforcers can be identified by giving the individual a preference test in which she or he is free to engage in any number of activities. The individual might spend the most time engaging in activity A, the second-most time engaged in activity B, and the third-most time engaged in activity C. Behavior A can thus be said to be preferred to B and C, and B is preferred to C. The Premack principle asserts that access to a preferred action will reinforce any action that is less preferred. In the present example, if doing activity C allowed access to doing A or B, activity C will be reinforced—it will increase in strength or probability. Similarly, activity B will be reinforced by activity A (but not C). The principle accepts large individual differences. For example, in an early study, some children given a choice spent more time eating candy than playing pinball, whereas others spent more time playing pinball than eating candy. Candy eating reinforced pinball playing in the former group. In contrast, pinball playing reinforced candy eating in the latter group. There is nothing particularly special about food (eating) or any particular kind of activity as a possible reinforcer. Any behavior that is preferred to a second behavior will theoretically reinforce the second behavior.

The principle has been refined over the years. It is now recognized that even a less-preferred behavior can reinforce a more-preferred behavior if the organism has been deprived of doing the low-preferred behavior below its ordinary level. In the foregoing example, even the low-preference activity C could reinforce A or B if it were suppressed for a while below its baseline level of preference. However, the main implication is that in the long run, a person’s reinforcers can be discovered by simply looking at how he or she allocates his or her activities when access to them is free and unconstrained.

Motivational Factors

Instrumental action is often said to be goal oriented. As Edward Tolman illustrated in many experiments conducted in the 1930s and 1940s, organisms may flexibly perform any of several actions to get to a goal; instrumental learning thus provides a variable means to a fixed end. Tolman’s perspective on the effects of reinforcers has returned to favor. He argued that reinforcers are not necessary for learning, but instead are important for motivating instrumental behavior. The classic illustration of this point is the *latent learning* experiment. Rats received several trials in a complex maze in which they were removed from the maze without reward once they got to a particular goal location. When arriving at the goal was suddenly rewarded, the rats suddenly began working through the maze with very few errors. Thus, they had learned about the maze without the benefit of the food reinforcer, but the reinforcer was nonetheless important for motivating them to get through the maze efficiently. The reinforcer was not necessary for learning, but it gave the organism a reason to translate its knowledge into action.

Subsequent research has identified many motivating effects of reward. For example, organisms that have had experience receiving a small reward may show *positive contrast* when they are suddenly reinforced with a larger reward. That is, their instrumental behavior may become more vigorous than that in control subjects who have received the larger reward all along. Conversely, organisms show *negative contrast* when they are switched from a high reward to a lower reward—their behavior becomes weaker than control subjects who have received the same smaller reward all along. Negative contrast involves frustration and emotionality. Both types of contrast are consistent with the idea

that the current effectiveness of a reinforcer depends on what the organism has learned to expect; an increase from expectation causes elation, whereas a decrease from expectation causes frustration. There is a sense in which receiving a reward that is smaller than expected might actually seem punishing.

Negative contrast is an example of a *paradoxical reward effect*—a set of behavioral phenomena given the name because they show that reward can sometimes weaken behavior and that nonreward can sometimes strengthen it. The best known is the *partial reinforcement extinction effect*, in which actions that have been intermittently (or “partially”) reinforced persist longer when reinforcers are completely withdrawn than actions that have been continuously reinforced. The finding is considered paradoxical because an action that has been reinforced (say) half as often as another action may nonetheless be more persistent. One explanation is that the action that has been partially reinforced has been reinforced in the presence of some frustration—and is thus persistent in new adversity or sources of frustration. Other evidence suggests that effortfulness is a dimension of behavior that can be reinforced. That is, human and animal participants that have been reinforced for performing effortful responses learn a sort of “industriousness” that transfers to new behaviors. One implication is that new behaviors learned in therapy will be more persistent over time if high effort has been deliberately reinforced.

The effectiveness of a reinforcer is also influenced by the organism’s current motivational state. For example, food is more reinforcing for a hungry organism, and water is more reinforcing for a thirsty one. Such results are consistent with many theories of reinforcement (e.g., the Premack principle) because the presence of hunger or thirst would undoubtedly increase the organism’s preference ranking for food or water. Recent research, however, indicates that the effects of motivational states on instrumental actions are not this automatic. Specifically, if a motivational state is going to influence an instrumental action, the individual needs first to learn how the action’s reinforcer will influence the motivational state. The process of learning about the effects the reinforcer has on the motivational state is called *incentive learning*.

Incentive learning is best illustrated by an experimental example. In 1992, Bernard Balleine reported a study that taught trained rats that were not hungry to lever press to earn a novel food pellet. The animals were then food deprived and tested for their lever pressing under conditions in which the lever press no longer produced the pellet. The hunger state had no effect on lever-press rate; that is, hungry rats did not lever press any more than rats that were not food deprived. On the other hand, if the rat had been given separate experience eating the pellets while it was food deprived, during the test it lever pressed at a high rate. Thus, hunger invigorated the instrumental action only if the animal had previously experienced the reinforcer in that state—which allowed it to learn that the specific substance influenced the state (incentive learning). The interpretation of this result, and others like it, will be developed further later in this section. The main idea is that individuals will perform an instrumental action when they know that it produces an outcome that is desirable in the current motivational state. The clinical implications are underexplored but could be significant. For example, persons who abuse drugs will need to learn that the drug makes them feel better in the withdrawal state before withdrawal will motivate drug seeking. Persons with anxiety might not be motivated to take a beneficial medication while anxious until they have actually had the opportunity to learn how the medication makes them feel when they are in the anxious state, and a person with depression may need to learn what natural reinforcers really make them feel better while they are depressed. According to theory, direct experience with a reinforcer’s effect on depressed mood might be necessary before the person will be interested in performing actions that help to ameliorate the depressed state.

PAVLOVIAN AND OPERANT LEARNING TOGETHER

Avoidance Learning

Theories of the motivating effects of reinforcers have usually emphasized that Pavlovian CSs in the background are also associated with the reinforcer, and that the expectancy of the reinforcer (or conditioned motivational state) the CSs arouse increases the vigor of the operant response. This is *two-factor* or *two-process theory*: Pavlovian learning occurs simultaneously and motivates behavior during operant learning.

The interaction of Pavlovian and instrumental factors is especially important in understanding avoidance learning (see Fig. 2.3-1). In avoidance situations, organisms learn to perform actions that prevent the delivery or presentation of an aversive event. The explanation of avoidance learning is subtle because it is difficult to identify an obvious reinforcer. Although preventing the occurrence of the aversive event is obviously important, how can the nonoccurrence of that event reinforce? The answer is that cues in the environment (Pavlovian CSs) come to predict the occurrence of the aversive event, and consequently they arouse anxiety or fear. The avoidance response can therefore be reinforced if it escapes from or reduces that fear. Pavlovian and operant factors are thus both important: Pavlovian fear conditioning motivates and allows reinforcement of an instrumental action through its reduction. Escape from fear or anxiety is believed to play a significant role in many human behavior disorders, including the anxiety disorders. Thus, the obsessive-compulsive patient checks or washes his or her hands repeatedly to reduce anxiety, the agoraphobic stays home to escape fear of places associated with panic attacks, and the bulimic learns to vomit after a meal to reduce the learned anxiety evoked by eating the meal.

Although two-factor theory remains an important view of avoidance learning, excellent avoidance can be obtained in the laboratory without reinforcement: for example, if an animal is required to perform an action that resembles one of its natural and prepared fear responses—so-called *species-specific defensive reactions* (SSDRs). Rats will readily learn to freeze (remain motionless) or flee (run to another environment) to avoid shock, two behaviors that have evolved to escape or avoid predation. Freezing and fleeing are also respondents rather than operants; they are controlled by their antecedents (Pavlovian CSs that predict shock) rather than being reinforced by their consequences (escape from fear). Thus, when the rat can use an SSDR for avoidance, the only necessary learning is Pavlovian—the rat learns about environmental cues associated with danger, and these arouse fear and evoke natural defensive behaviors including withdrawal (negative sign tracking; Fig. 2.3-2). To learn to perform an action that is not similar to a natural SSDR requires more feedback or reinforcement through fear reduction. A good example is lever pressing, which is easy for the rat to learn when the reinforcer is a food pellet but difficult to learn when the same action avoids shock. More recent work with avoidance in humans suggests an important role for CS-aversive event and response—no aversive event expectancies. The larger point is that Pavlovian learning is important in avoidance learning; when the animal can avoid with an SSDR, it is the only learning necessary; when the required action is not an SSDR, Pavlovian learning permits the expectation of something bad.

A cognitive perspective on aversive learning is also encouraged by studies of *learned helplessness*. In this phenomenon, organisms exposed to either controllable or uncontrollable aversive events differ in their reactivity to later aversive events. For example, the typical finding is that a subject exposed to inescapable shock in one phase of an experiment is less successful at learning to escape shock with an altogether new behavior in a second phase, whereas subjects exposed to escapable shock are normal. Both types of subject are exposed to the same shock, but its psychological dimension (its controllability) creates a difference, perhaps because subjects exposed to inescapable shock learn the independence of their actions and the outcome. Although this finding (and interpretation) was once seen as a model of depression, the current view is that the controllability of stressors mainly modulates their stressfulness and negative impact. At a theoretical level, the result also implies that organisms receiving instrumental contingencies in which their actions lead to outcomes might learn something about the controllability of those outcomes.

One of the main conclusions of work on aversive learning is that there are both biological (i.e., evolutionary) and cognitive dimensions to instrumental learning. The possibility that much instrumental learning can be controlled by Pavlovian contingencies is also consistent with research in which animals have learned to respond to positive reinforcers. For example, pigeons have been widely used in operant learning experiments since the 1940s. In the typical experiment, the bird learns to peck at a plastic disk on a wall of the chamber (a response “key”) to earn food. Although pecking seems to be an operant response, it turns out that the pigeon’s peck can be entrained by merely illuminating the key for a few seconds before presenting the reinforcer on a number of trials. Although there is no requirement for the bird to peck the key, the bird will begin to peck at the illuminated key—a Pavlovian predictor of food—anyway. The pecking response is only weakly controlled by its consequences; if the experimenter arranges things so that pecks actually prevent the delivery of food (which is otherwise delivered on trials without pecks), the birds will continue to peck almost indefinitely on many trials. (Although the peck has a negative correlation with food, key illumination remains a weakly positive predictor of food.) Thus, this classic “operant” behavior is at least partly a Pavlovian one. Pavlovian contingencies

cannot be ignored. When rats are punished with mild foot shock for pressing a lever that otherwise produces food, they stop lever pressing at least partly (and perhaps predominantly) because they learn that the lever now predicts shock and they withdraw from it. A child might likewise learn to stay away from the parent who delivers punishment rather than refrain from performing the punished behavior. A great deal of behavior in operant learning settings may actually be controlled by Pavlovian learning and sign tracking rather than true operant learning.

A Synthetic View of Instrumental Action

The idea, then, is that behavior in any instrumental learning situation is controlled by several hypothetical associations, as illustrated in Figure 2.3-3. Much behavior in an instrumental learning arrangement can be controlled by a Pavlovian factor in which the organism associates background cues (CSs) with the reinforcer (S^* , denoting a biologically significant event). As discussed earlier, this type of learning can allow the CS to evoke a variety of behaviors and emotional reactions (and motivational states) that can additionally motivate instrumental action.

FIGURE 2.3-3

Any instrumental/operant learning situation permits a number of types of learning, which are always occurring all the time. R, operant behavior or instrumental action; S, stimulus in the background; S^* , biologically significant event (e.g., reinforcer, US). (Courtesy of Mark E. Bouton, PhD.)

In modern terms, the instrumental factor is represented by the organism learning a direct, and similar, association between the instrumental action (R) and the reinforcer (S^*). Evidence for this sort of learning comes from experiments on *reinforcer devaluation* (Fig. 2.3-4). In such experiments, the organism can first be trained to perform two instrumental actions (e.g., pressing a lever and pulling a chain), each paired with a different reinforcer (e.g., food pellet versus a liquid sucrose solution). In a separate second phase, one of the reinforcers (e.g., pellet) is paired with illness, which creates the conditioning of a powerful taste aversion to the reinforcer. In a final test, the organism is returned to the instrumental situation and is allowed to perform either instrumental action. No reinforcers are presented during the test. The result is that the organism no longer performs the action that produced the reinforcer that is now aversive. To perform in this way, the organism must have (1) learned which action produced which reinforcer and (2) combined this knowledge with the knowledge that it no longer likes or values that reinforcer. The result cannot be explained by the simpler, more traditional view that reinforcers merely stamp in or strengthen instrumental actions.

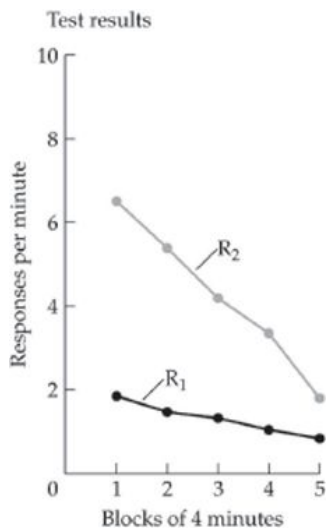

FIGURE 2.3-4

The reinforcer devaluation effect. Results of the test session. The result indicates the importance of the response–reinforcer association in operant learning. For the organism to perform in the way that it does during testing, it must learn which action leads to which reinforcer and then choose to perform the action that leads to the outcome it currently liked or valued. R1, R2, operant behaviors or instrumental actions. (Data from Colwill and Rescorla [1986]. From Bouton ME: *Learning and Behavior: A Contemporary Synthesis*. Sunderland, MA: Sinauer; 2007.)

Organisms also need to learn how reinforcers influence a particular motivational state—the process called “incentive learning.” Incentive learning is crucially involved in instrumental learning as a process through which the animal learns the value of the reinforcer. Thus, in the reinforcer devaluation experiment shown in Figure 2.3-4, an important thing that occurs in the second phase is that the organism must actually contact the reinforcer and learn that it does not like it. As described earlier, incentive learning is probably always involved in making outcomes (and the associated actions that produce them) more or less desirable.

Other experiments have illustrated the other associations to the stimulus that are represented in Figure 2.3-3. In addition to being directly associated with the reinforcer, a stimulus can signal a relation between an action and an outcome. This is called *occasion setting*: Instead of eliciting a response directly, stimuli in operant situations can set the occasion for the operant response. There is good evidence that they do

so by signaling a specific response-reinforcer relationship. For example, in one experiment, rats learned to lever press and chain pull in the presence of a background noise and a background light. When the noise was present, lever pressing yielded a pellet reinforcer, and chain pulling yielded sucrose. In contrast, when the light was present, the relations were reversed: Lever pressing yielded sucrose, and chain pulling yielded pellet. There was evidence that the rats learned corresponding relationships. In a second phase, pellets were associated with illness, so the rat no longer valued the pellet. In a final test, rats were allowed to lever press or chain pull in extinction in the presence of noise or light present during separate tests. In the presence of the noise, the animals chain pulled rather than lever pressed. When the light was present, the animals lever pressed rather than chain pulled. Thus, the noise informed the rat that lever press yielded pellet, and the light informed the rat that the chain pull did. This is the occasion-setting function illustrated in [Figure 2.3-3](#).

It is worth noting that other stimuli besides lights and noises set the occasion for operant behavior. Modern research on learning in animals has underscored the importance of other stimuli, such as temporal and spatial cues, and of certain perception and memory processes. A particularly interesting example of research on the *stimulus control* of operant behavior is categorization. Pigeons can be shown images of cars, chairs, flowers, and cats on a computer screen positioned on the wall of a Skinner box. Pecking one of four keys in the presence of these images is reinforced in the presence of any picture containing a car, a chair, a flower, or a cat. Of interest, as the number of exemplars in each category increases, the pigeon makes more errors as it learns the discrimination. However, more exemplars create better learning in the sense that it is more ready to transfer to new test images—after many examples of each category, the pigeon is more accurate at categorizing (and responding accurately to) new stimuli. One implication is that training new behaviors in a variety of settings or ways will enhance generalization to new situations.

The final association in [Fig. 2.3-3](#) is simple *habit learning*, or a direct association between the stimulus and the response. Through this association, the background may elicit the instrumental action directly, without the intervening cognition of $R-S^*$ and the valuation of S^* . Although $S-R$ learning was once believed to dominate learning, the current view sees it as developing only after extensive and consistent instrumental training. In effect, actions that have been performed repeatedly (and repeatedly associated with the reinforcer) become automatic and routine. One source of evidence is the fact that the reinforcer devaluation effect—which implies a kind of cognitive mediation of operant behavior—no longer occurs after extensive instrumental training, as if the animal reflexively engages in the response without remembering the actual outcome it produces. It seems reasonable to expect that many pathological behaviors that come into the clinic might also be automatic and blind through repetition. Of interest, the evidence suggests that the eventual dominance of the $S-R$ habit in behavior does not replace or destroy more cognitive mediation by learned $S-S^*$, $R-S^*$, and/or $S-(R-S^*)$ relations. Under some conditions, even a habitual response might be brought back under the control of the action-reinforcer association. The conversion of actions to habits and the relation of habit to cognition are active areas of research.

2.4 Biology of Memory

The topic of memory is fundamental to the discipline of psychiatry. Memory is the glue that binds our mental life, the scaffolding for our personal history. Personality is in part an accumulation of habits that have been acquired, many very early in life, which create dispositions and influence how we behave. In the same sense, the neuroses are often products of learning—anxieties, phobias, and maladaptive behaviors that result from particular experiences. Psychotherapy itself is a process by which new habits and skills are acquired through the accumulation of new experiences. In this sense, memory is at the theoretical heart of psychiatry's concern with personality, the consequences of early experience, and the possibility of growth and change.

Memory is also of clinical interest because disorders of memory and complaints about memory are common in neurological and psychiatric illness. Memory impairment is also a side effect of certain treatments, such as electroconvulsive therapy. Accordingly, the effective clinician needs to understand something of the biology of memory, the varieties of memory dysfunction, and how memory can be evaluated.

FROM SYNAPSES TO MEMORY

Memory is a special case of the general biological phenomenon of *neural plasticity*. Neurons can show history-dependent activity by responding differently as a function of prior input, and this plasticity of nerve cells and synapses is the basis of memory. In the last decade of the 19th century, researchers proposed that the persistence of memory could be accounted for by nerve cell growth. This idea has been restated many times, and current understanding of the synapse as the critical site of change is founded on extensive experimental studies in animals with simple nervous systems. Experience can lead to structural change at the synapse, including alterations in the strength of existing synapses and alterations in the number of synaptic contacts along specific pathways.

Plasticity

Neurobiological evidence supports two basic conclusions: First, short-lasting plasticity, which may last for seconds or minutes depending on specific synaptic events, including an increase in neurotransmitter release; and second, long-lasting memory depends on new protein synthesis, the physical growth of neural processes, and an increase in the number of synaptic connections.

A major source of information about memory has come from extended study of the marine mollusk *Aplysia californica*. Individual neurons and connections between neurons have been identified, and the wiring diagram of some simple behaviors has been described. *Aplysia* is capable of associative learning (including classic conditioning and operant conditioning) and nonassociative learning (habituation and sensitization). *Sensitization* had been studied using the gill-withdrawal reflex, a defensive reaction in which tactile stimulation causes the gill and siphon to retract. When tactile stimulation is preceded by sensory stimulation to the head or tail, gill withdrawal is facilitated. The cellular changes underlying this sensitization begin when a sensory neuron activates a modulatory interneuron, which enhances the strength of synapses within the circuitry responsible for the reflex. This modulation depends on a second-messenger system in which intracellular molecules (including cyclic adenosine monophosphate [cAMP] and cAMP-dependent protein kinase) lead to enhanced transmitter release that lasts for minutes in the reflex pathway. Both short- and long-lasting plasticity within this circuitry are based on enhanced transmitter

release. The long-lasting change uniquely requires the expression of genes and the synthesis of new proteins. Synaptic tagging mechanisms allow gene products that are delivered throughout a neuron to increase synaptic strength selectively at recently active synapses. In addition, the long-term change, but not the short-term change, is accompanied by the growth of neural processes of neurons within the reflex circuit.

In vertebrates, memory cannot be studied as directly as in the simple nervous system of *Aplysia*. Nevertheless, it is known that behavioral manipulations can also result in measurable changes in the brain's architecture. For example, rats reared in enriched as opposed to ordinary environments show an increase in the number of synapses ending on individual neurons in the neocortex. These changes are accompanied by small increases in cortical thickness, in the diameter of neuronal cell bodies, and in the number and length of dendritic branches. Behavioral experience thus exerts powerful effects on the wiring of the brain.

Many of these same structural changes have been found in adult rats exposed to an enriched environment, as well as in adult rats given extensive maze training. In the case of maze training, vision was restricted to one eye, and the corpus callosum was transected to prevent information received by one hemisphere from reaching the other hemisphere. The result was that structural changes in neuronal shape and connectivity were observed only in the trained hemisphere. This rules out a number of nonspecific influences, including motor activity, indirect effects of hormones, and overall level of arousal. Long-term memory in vertebrates is believed to be based on morphological growth and change, including increases in synaptic strength along particular pathways.

Long-Term Potentiation

The phenomenon of *long-term potentiation* (LTP) is a candidate mechanism for mammalian long-term memory. LTP is observed when a postsynaptic neuron is persistently depolarized after a high-frequency burst of presynaptic neural firing. LTP has a number of properties that make it suitable as a physiological substrate of memory. It is established quickly and then lasts for a long time. It is associative, in that it depends on the co-occurrence of presynaptic activity and postsynaptic depolarization. It occurs only at potentiated synapses, not all synapses terminating on the postsynaptic cell. Finally, LTP occurs prominently in the hippocampus, a structure that is important for memory.

The induction of LTP is known to be mediated postsynaptically and to involve activation of the *N*-methyl-D-aspartate (NMDA) receptor, which permits the influx of calcium into the postsynaptic cell. LTP is maintained by an increase in the number of α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA; non-NMDA) receptors in the postsynaptic cell and also possibly by increased transmitter release.

A promising method for elucidating molecular mechanisms of memory relies on introducing specific mutations into the genome. By deleting a single gene, one can produce mice with specific receptors or cell signaling molecules inactivated or altered. For example, in mice with a selective deletion of NMDA receptors in the CA1 field of the hippocampus, many aspects of CA1 physiology remain intact, but the CA1 neurons do not exhibit LTP, and memory impairment is observed in behavioral tasks. Genetic manipulations introduced reversibly in the adult are particularly advantageous, in that specific molecular changes can be induced in developmentally normal animals.

Associative Learning

The study of *classical conditioning* has provided many insights into the biology of memory. Classical conditioning has been especially well studied in rabbits, using a tone as the conditioned stimulus and an air puff to the eye (which automatically elicits a blink response) as the unconditioned stimulus. Repeated pairings of the tone and the air puff lead to a conditioned response, in that the tone alone elicits an eye blink. Reversible lesions of the deep nuclei of the cerebellum eliminate the conditioned response without affecting the unconditioned response. These lesions also prevent initial learning from occurring, and, when the lesion is reversed, rabbits learn normally. Thus, the cerebellum contains essential circuitry for the learned association. The relevant plasticity appears to be distributed between the cerebellar cortex and the deep nuclei.

An analogous pattern of cerebellar plasticity is believed to underlie motor learning in the vestibuloocular reflex and, perhaps, associative learning of motor responses in general. Based on the idea that learned motor responses depend on the coordinated control of changes in timing and strength of response, it has been suggested that synaptic changes in the cerebellar cortex are critical for learned timing, whereas synaptic changes in the deep nuclei are critical for forming an association between a conditioned stimulus and an unconditioned stimulus.

Fear conditioning and fear-potentiated startle are types of learning that serve as useful models for anxiety disorders and related psychiatric conditions. For example, mice exhibit freezing behavior when returned to the same context in which aversive shock was delivered on an earlier occasion. This type of learning depends on the encoding of contextual features of the learning environment. Acquiring and expressing this type of learning requires neural circuits that include both the amygdala and the hippocampus. The amygdala may be important for associating negative affect with new stimuli. The hippocampus may be important for representing the context. With extinction training, when the context is no longer associated with an aversive stimulus, the conditioned fear response fades. Frontal cortex is believed to play a key role in extinction.

CORTICAL ORGANIZATION OF MEMORY

One fundamental question concerns the locus of memory storage in the brain. In the 1920s, Karl Lashley searched for the site of memory storage by studying the behavior of rats after removing different amounts of their cerebral cortex. He recorded the number of trials needed to relearn a maze problem that rats learned prior to surgery, and he found that the deficit was proportional to the amount of cortex removed. The deficit did not seem to depend on the particular location of cortical damage. Lashley concluded that the memory resulting from maze learning was not localized in any one part of the brain but instead was distributed equivalently over the entire cortex.

Subsequent research has led to reinterpretations of these results. Maze learning in rats depends on different types of information, including visual, tactile, spatial, and olfactory information. Neurons that process these various types of information are segregated into different areas of the rat cerebral cortex, and memory storage is segregated in a parallel manner. Thus, the correlation between maze-learning abilities and lesion size that Lashley observed is a result of progressive encroachment of larger lesions on specialized cortical areas serving the many components of information processing relevant for maze learning.

The functional organization of the mammalian cerebral cortex has been revealed through neuropsychological analyses of deficits following brain damage and through physiological studies of intact brains. The cortical areas responsible for processing and storing visual information have been studied most extensively in nonhuman primates. Nearly one half of the primate neocortex is specialized for visual functions.

The cortical pathways for visual information processing begin in primary visual cortex (V1) and proceed from there along parallel pathways or streams. One stream projects ventrally to inferotemporal cortex and is specialized for processing information concerning the identification of visual objects. Another stream projects dorsally to parietal cortex and is specialized for processing information about spatial location.

Specific visual processing areas in the dorsal and ventral streams, together with areas in prefrontal cortex, register the immediate experience of perceptual processing. The results of perceptual processing are first available as *immediate memory*. Immediate memory refers to the amount of information that can be held in mind (like a telephone number) so that it is available for immediate use. Immediate memory can be extended in time by rehearsing or otherwise manipulating the information, in which case what is stored is said to be in *working memory*.

Regions of visual cortex in forward portions of the dorsal and ventral streams serve as the ultimate repositories of visual memories. Inferotemporal cortex, for example, lies at the end of the ventral stream, and inferotemporal lesions lead to selective impairments in both visual object perception and visual memory. Nonetheless, such lesions do not disrupt elementary visual functions, such as acuity. Electrophysiological studies in the monkey show that neurons in area TE, which is one part of inferotemporal cortex, register specific and complex features of visual stimuli, such as shape, and respond selectively to patterns and objects. Inferotemporal cortex can thus be thought of as both a higher-order visual processing system and a storehouse of the visual memories that result from that processing.

In sum, memory is distributed and localized in the cerebral cortex. Memory is distributed in the sense that, as Lashley concluded, there is

no cortical center dedicated solely to the storage of memories. Nonetheless, memory is localized in the sense that different aspects or dimensions of events are stored at specific cortical sites—namely, in the same regions that are specialized to analyze and process what is to be stored.

MEMORY AND AMNESIA

The principle that the functional specialization of cortical regions determines both the locus of information processing and the locus of information storage does not provide a complete account of the organization of memory in the brain. If it did, then brain injury would always include a difficulty in memory for a restricted type of information along with a loss of ability to process information of that same type. This kind of impairment occurs, for example, in the aphasias and the agnosias. However, there is another kind of impairment that can occur as well, called amnesia.

The hallmark of amnesia is a loss of new learning ability that extends across all sensory modalities and stimulus domains. This *anterograde amnesia* can be explained by understanding the role of brain structures critical for acquiring information about facts and events. Typically, anterograde amnesia occurs together with *retrograde amnesia*, a loss of knowledge that was acquired before the onset of amnesia. Retrograde deficits often have a temporal gradient, following a principle known as Ribot's law; deficits are most severe for information that was most recently learned.

A patient with a presentation of amnesia exhibits severe memory deficits in the context of preservation of other cognitive functions, including language comprehension and production, reasoning, attention, immediate memory, personality, and social skills. The selectivity of the memory deficit in these cases implies that intellectual and perceptual functions of the brain are separated from the capacity to lay down in memory the records that ordinarily result from engaging in intellectual and perceptual work.

Specialized Memory Function

Amnesia can result from damage to the medial portion of the temporal lobe or from damage to regions of the midline diencephalon. Studies of a severely amnesic patient known as HM stimulated intensive investigation of the role of the medial temporal lobe in memory.

HM became amnesic in 1953, at 27 years of age, when he sustained a bilateral resection of the medial temporal lobe to relieve severe epilepsy. The removal included approximately one half of the hippocampus, the amygdala, and most of the neighboring entorhinal and perirhinal cortices (Fig. 2.4-1). After the surgery, HM's seizure condition was much improved, but he experienced profound forgetfulness. His intellectual functions were generally preserved. For example, HM exhibited normal immediate memory, and he could maintain his attention during conversations. After an interruption, however, HM could not remember what had recently occurred. HM's dense amnesia was permanent and debilitating. In HM's words, he felt as if he were just waking from a dream, because he had no recollection of what had just taken place.

FIGURE 2.4-1

Structural magnetic resonance images of the brains of patients HM and EP through the level of the temporal lobe. Damaged tissue is indicated by bright signal in these T2-weighted axial images. Both patients sustained extensive damage to medial temporal structures, as the result of surgery for epilepsy in HM, and as the result of viral encephalitis in EP. Scale bar: 2 cm. L, left side of the brain. (Reprinted from Corkin S, Amaral EG, González RG, Johnson KA, Hyman BT. H.M.'s medial temporal lobe lesion: Findings from magnetic resonance imaging. *J Neurosci.* 1997;17:3964; and Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: A neuroanatomical and neuropsychological profile of patient E.P. *J Neurosci.* 2000;20:7024, with permission.)

In monkeys, many parallels to human amnesia have been demonstrated after surgical damage to anatomical components of the medial temporal lobe. Cumulative study of the resulting memory impairment eventually identified the medial temporal structures and connections that are crucial for memory. These include the hippocampus—which includes the dentate gyrus; hippocampal fields CA1, CA2, and CA3; and the subiculum—and the adjacent cortical regions, including the entorhinal, perirhinal, and parahippocampal cortices.

Another important medial temporal lobe structure is the amygdala. The amygdala is involved in the regulation of much of emotional behavior. In particular, the storage of emotional events engages the amygdala. Modulatory effects of projections from the amygdala to the neocortex are responsible for producing enhanced memory for emotional or arousing events compared to neutral events.

Detailed study of amnesic patients offers unique insights into the nature of memory and its organization in the brain. An extensive series of informative studies, for example, described the memory impairment of patient EP.

EP was diagnosed with herpes simplex encephalitis at 72 years of age. Damage to the medial temporal lobe region (see Fig. 2.4-1) produced a persistent and profound amnesia. During testing sessions, EP was cordial and talked freely about his life experiences, but he relied exclusively on stories from his childhood and early adulthood. He would repeat the same story many times. Strikingly, his performance on tests of recognition memory was no better than would result from guessing (Fig. 2.4-2A). Tests involving facts about his life and autobiographical experiences revealed poor memory for the time leading up to his illness but normal memory for his childhood (Fig. 2.4-2B). EP also has good spatial knowledge about the town in which he lived as a child, but he was unable to learn the layout of the neighborhood where he lived only after he became amnesic (Fig. 2.4-2C).

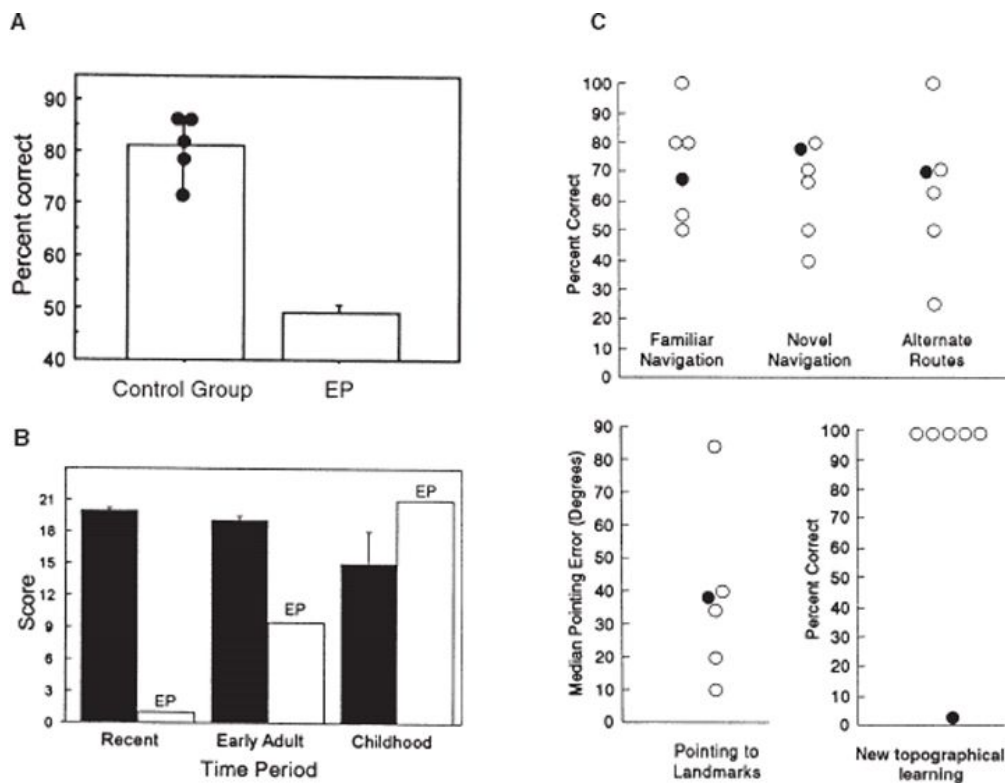

FIGURE 2.4-2

Formal test results for patient EP, showing severe anterograde and retrograde deficits, with intact remote memory. **A.** Scores were combined from 42 different tests of recognition memory for words given to patient EP and a group of five healthy control subjects. The testing format was either two-alternative forced choice or yes–no recognition. Brackets for EP indicate the standard error of the mean. Data points for the control group indicate each participant’s mean score across all 42 recognition memory tests. EP’s average performance (49.3 percent correct) was not different from chance and was approximately five standard deviations (SDs) below the average performance of control subjects (81.1 percent correct; SD, 6.3). **B.** Autobiographical remembering was quantified by using a structured interview known as the Autobiographical Memory Interview. Items assessed personal semantic knowledge (maximum score 21 for each time period). Performance for the recent time period reflects poor memory for information that could have been acquired only subsequent to the onset of his amnesia. For EP, performance for the early adult period reflects retrograde memory deficits. Performance for the childhood period reflects good remote memory. Similar results for semantic and episodic remembering were obtained from these time periods. (Data from Kopelman MD, Wilson BA, Baddeley AD. The autobiographical memory interview: A new assessment of autobiographical and personal semantic memory in amnesic patients. *J Clin Exp Neuropsychol.* 1989;5:724; and Reed JM, Squire LR. Retrograde amnesia for facts and events: Findings from four new cases. *J Neurosci.* 1998;18:3943). **C.** Assessments of spatial memory demonstrated EP’s good memory for spatial knowledge for that time period, along with extremely poor new learning of spatial information. Performance was compared to that of five individuals (*open circles*) who attended EP’s high school at the same time as he did, lived in the region over approximately the same time period, and, like EP (*filled circles*), moved away as young adults. Normal performance was found for navigating from home to different locations in the area (familiar navigation), between different locations in the area (novel navigation), and between these same locations when a main street was blocked (alternate routes). Subjects were also asked to point to particular locations while imagining themselves in a particular location (pointing to landmarks), or they were asked about locations in the neighborhoods in which they currently lived (new topographical learning). EP showed difficulty only in this last test, because he moved to his current residence after he became amnesic. (Data from Teng E, Squire LR. Memory for places learned long ago is intact after hippocampal damage. *Nature.* 1999;400:675.) (Adapted from Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: A neuroanatomical and neuropsychological profile of patient E.P. *J Neurosci.* 2000;20:7024. Printed with permission.)

Given the severity of the memory problems experienced by EP and other amnesic patients, it is noteworthy that these patients nonetheless perform normally on certain kinds of memory tests. The impairment selectively concerns memory for factual knowledge and autobiographical events, collectively termed *declarative memory*. Amnesia presents as a global deficit, in that it involves memory for information presented in any sensory modality, but the deficit is limited, in that it covers only memory for facts and events.

Hippocampal pathology in patients with amnesia can also be revealed using high-resolution magnetic resonance imaging (MRI). Such studies indicate that damage limited to the hippocampus results in clinically significant memory impairment. In addition to the hippocampus, other medial temporal lobe regions also make critical contributions to memory. Thus, a moderately severe memory impairment results from CA1 damage, whereas a more profound and disabling amnesia results from medial temporal lobe damage that includes the hippocampus and adjacent cortex. Memory impairment due to medial temporal lobe damage is also typical in patients with early Alzheimer’s disease or amnesic mild cognitive impairment. As Alzheimer’s disease progresses, the pathology affects many cortical regions and produces substantial cognitive deficits in addition to memory dysfunction.

Amnesia can also result from damage to structures of the medial diencephalon. The critical regions damaged in diencephalic amnesia include the mammillary nuclei in the hypothalamus, the dorsomedial nucleus of the thalamus, the anterior nucleus, the internal medullary lamina, and the mammillothalamic tract. However, uncertainty remains regarding which specific lesions are required to produce diencephalic amnesia. *Alcoholic Korsakoff’s syndrome* is the most prevalent and best-studied example of diencephalic amnesia, and in these cases damage is found in brain regions that may be especially sensitive to prolonged bouts of thiamine deficiency and alcohol abuse. Patients with alcoholic Korsakoff’s syndrome typically exhibit memory impairment due to a combination of diencephalic damage and frontal lobe pathology. Frontal damage alone produces characteristic cognitive deficits along with certain memory problems (e.g., in effortful retrieval and evaluation); in Korsakoff’s syndrome the pattern of deficits thus extends beyond what is commonly found in other cases of amnesia (see [Table 2.4-1](#)).

Table 2.4-1
Memory and Cognitive Deficits Associated with Frontal Damage

Test	Amnesia	Korsakoff's Syndrome	Frontal Lobe Damage
Delayed recall	+	+	-
Dementia Rating Scale: Memory index	+	+	-
Dementia Rating Scale: Initiation and perseveration index	-	+	+
Wisconsin Card Sorting Test	-	+	+
Temporal order memory	+	++	++
Metamemory	-	+	+
Release from proactive interference	-	+	-

+, deficit; -, no deficit; ++, disproportionate impairment relative to item memory.

From Squire LR, Zola-Morgan S, Cave CB, Haist F, Musen G, Suzuki WA. Memory, organization of brain systems and cognition. *Cold Spring Harb Symp Quant Biol.* 1990;55:1007.

The ability to remember factual and autobiographical events depends on the integrity of both the cortical regions responsible for representing the information in question and several brain regions that are responsible for memory formation. Thus, medial temporal and diencephalic brain areas work in concert with widespread areas of neocortex to form and to store declarative memories (Fig. 2.4-3).

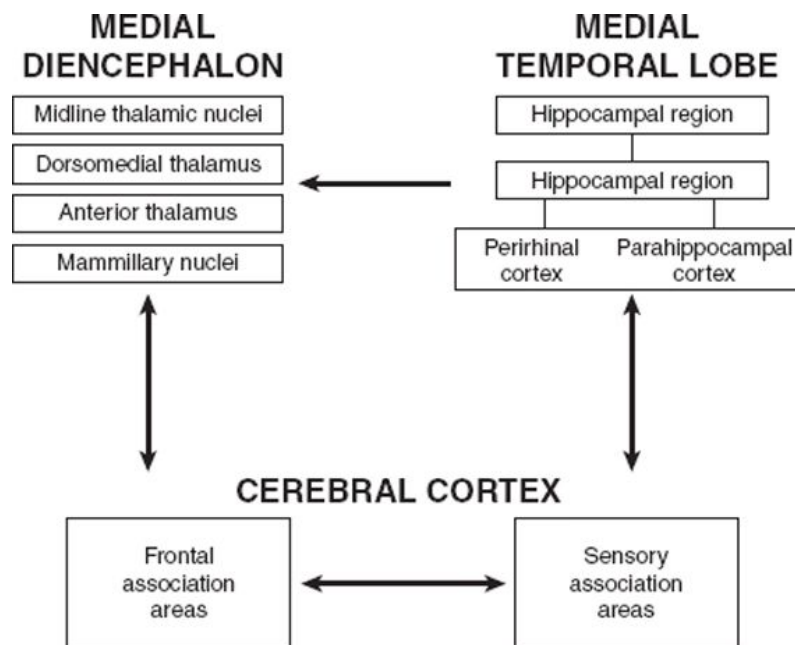

FIGURE 2.4-3

Brain regions believed to be critical for the formation and storage of declarative memory. Medial diencephalon and medial temporal regions are critical for declarative memory storage. The entorhinal cortex is the major source of projections for the neocortex to the hippocampus, and nearly two thirds of the cortical input to the entorhinal cortex originates in the perirhinal and parahippocampal cortex. The entorhinal cortex also receives direct connections from the cingulate, insula, orbitofrontal, and superior temporal cortices. (Adapted from Paller KA, Neurocognitive foundations of human memory. In: Medin DL, ed.: *The Psychology of Learning and Motivation*. Vol. 40. San Diego, CA: Academic Press; 2008:121; and Gluck MA, Mercado E, Myers CE.: *Learning and Memory: From Brain to Behavior*. New York: Worth; 2008:109, Fig. 3.16.)

Retrograde Amnesia

Memory loss in amnesia typically affects recent memories more than remote memories (Fig. 2.4-4). Temporally graded amnesia has been demonstrated retrospectively in studies of amnesic patients and prospectively in studies of monkeys, rats, mice, and rabbits. These findings have important implications for understanding the nature of the memory storage process. Memories are dynamic, not static. As time passes after learning, some memories are forgotten, whereas others become stronger due to a process of *consolidation* that depends on cortical, medial temporal, and diencephalic structures.

FIGURE 2.4-4

A. Temporally limited retrograde amnesia for free recall of 251 news events. Scores were aligned relative to the onset of amnesia in patients ($N = 6$) and to a corresponding time point in age-matched and education-matched healthy individuals ($N = 12$). The time period after the onset of amnesia is labeled AA (anterograde amnesia) to designate that this time point assessed memory for events that occurred after the onset of amnesia. Standard errors ranged from 2 to 10 percent. Brain damage in the patient group was limited primarily to the hippocampal region. **B.** Temporally limited retrograde amnesia in rats with lesions of the hippocampus and subiculum. Rats learned to prefer an odorous food as the result of an encounter with another rat with that odor on its breath. Percent preference for the familiar food was observed for three training-surgery intervals. At 1 day after learning, the control group performed significantly better than the rats with lesions ($P < .05$). At 30 days, the two groups performed similarly, and both groups performed well above chance. Error bars show standard errors of the mean. (Adapted from Manns JR, Hopkins RO, Squire LR. Semantic memory and the human hippocampus. *Neuron*. 2003;38:127; and Clark RE, Broadbent NJ, Zola SM, Squire LR. Anterograde amnesia and temporally graded retrograde amnesia for a nonspatial memory task after lesions of hippocampus and subiculum. *J Neurosci*. 2002;22:4663, with permission.)

The study of retrograde amnesia has been important for understanding how memory changes over time. The dynamic nature of memory storage can be conceptualized as follows. An event is experienced and encoded by virtue of a collection of cortical regions that are involved in representing a combination of different event features. At the same time, the hippocampus and adjacent cortex receive pertinent high-level information from all sensory modalities. Later, when the original event is recalled, the same set of cortical regions is activated. If a subset of the cortical regions is activated, the hippocampus and related structures can facilitate recall by facilitating the activation of the remaining cortical regions (i.e., pattern completion). When the original event is retrieved and newly associated with other information, hippocampal-cortical networks can be modified. In this way, a gradual consolidation process occurs that changes the nature of memory storage (see Fig. 2.4-3). The neocortical components representing some events can become so effectively linked together that ultimately a memory can be retrieved without any contribution from the medial temporal lobe. As a result, amnesic patients can exhibit normal retrieval of remote facts and events, as well as autobiographical memories. Distributed neocortical regions are the permanent repositories of these enduring memories.

In contrast to what is observed after damage restricted to the hippocampus, extensive retrograde impairments for facts and events from the distant past can also occur. Damage to the frontal lobes, for example, can lead to difficulty in organizing memory retrieval. Accurate retrieval often begins with an activation of lifetime periods and proceeds to an identification of general classes of events and then more specific events, but this process becomes difficult following frontal damage. Damage to other cortical regions can also impair memory storage. Networks in anterolateral temporal cortex, for example, are critical for retrieving stored information because these areas are important for long-term storage itself. Patients with *focal retrograde amnesia* exhibit substantial retrograde memory impairments together with only moderately impaired new learning ability. Some capacity for new learning remains, presumably because medial temporal lobe structures are able to communicate with other areas of cortex that remain undamaged.

MULTIPLE TYPES OF MEMORY

Memory is not a single faculty of the mind but consists of various subtypes. Amnesia affects only one kind of memory, *declarative memory*. Declarative memory is what is ordinarily meant by the term *memory* in everyday language. Declarative memory supports the conscious recollection of facts and events. The classic impairment in amnesia thus concerns memory for routes, lists, faces, melodies, objects, and other verbal and nonverbal material, regardless of the sensory modality in which the material is presented.

Amnesic patients can display a broad impairment in these components of declarative memory while a number of other memory abilities are preserved. The heterogeneous set of preserved abilities is collectively termed *nondeclarative memory*. Nondeclarative memory includes skill learning, habit learning, simple forms of conditioning, and a phenomenon called priming. For these kinds of learning and memory, amnesic patients can perform normally.

In controlled laboratory settings, the acquisition of a variety of perceptual, perceptual-motor, and cognitive skills can be tested in isolation, and amnesic patients are found to acquire these skills at rates equivalent to the rates at which healthy individuals acquire the skills. For example, amnesic patients can learn to read mirror-reversed text normally, they exhibit the normal facilitation in reading speed with successive readings of normal prose, and they improve as rapidly as healthy individuals at speeded reading of repeating

nonwords. In addition, amnesic patients can, after seeing strings of letters generated by a finite-state rule system, classify novel strings of letters as rule based or not rule based. Classification performance is normal despite the fact that amnesic patients are impaired at remembering the events of training or the specific items they have studied.

Priming

Priming refers to a facilitation of the ability to detect or to identify a particular stimulus based on a specific recent experience. Many tests have been used to measure priming in amnesia and show that it is intact. For example, words might be presented in a study phase and then again, after a delay, in a test phase when a priming measure such as reading speed is obtained. Patients are instructed to read words as quickly as possible in such a test, and they are not informed that memory is being assessed.

In one priming test, patients named pictures of previously presented objects reliably faster than they named pictures of new objects, even after a delay of 1 week. This facilitation occurred at normal levels, despite the fact that the patients were markedly impaired at recognizing which pictures had been presented previously. Particularly striking examples of preserved priming come from studies of patient EP (Fig. 2.4-5), who exhibited intact priming for words but performed at chance levels when asked to recognize which words had been presented for study. This form of memory, termed *perceptual priming*, is thus a distinct class of memory that is independent of the medial temporal lobe regions typically damaged in amnesia.

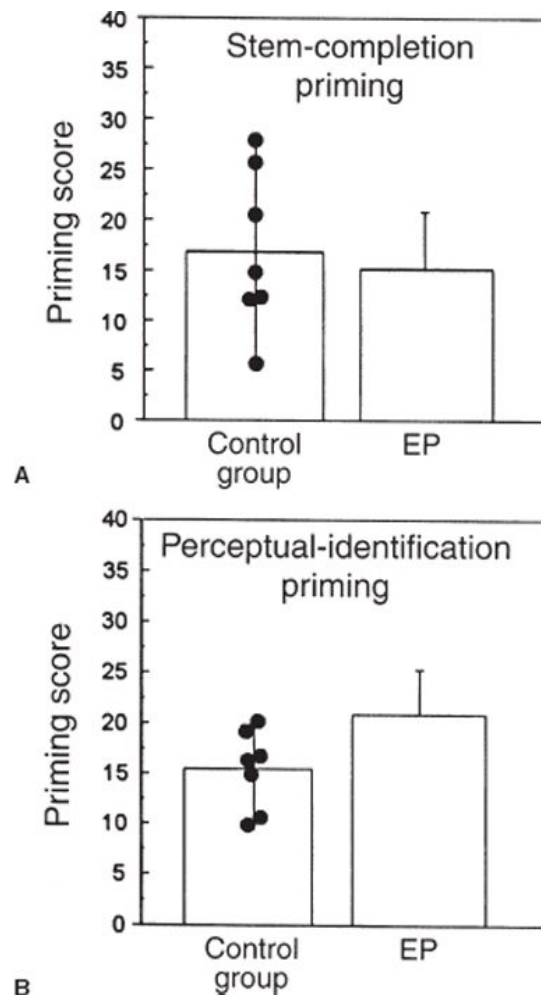

FIGURE 2.4-5

Preserved priming in patient EP relative to seven control subjects. **A.** Stem-completion priming on six separate tests. Priming reflected a tendency for subjects to complete three-letter stems with previously encountered words when they were instructed to produce the first word to come to mind (e.g., MOT_ completed to form MOTEL). Priming scores were calculated as percentage correct for studied words minus percentage correct for baseline words (guessing). **B.** Perceptual-identification priming on 12 separate tests. Subjects attempted to read 48 words that were visually degraded. Priming scores were calculated as percentage correct identification of previously studied words minus percentage correct identification of nonstudied words. Brackets indicate standard error of the mean. (Data from Hamann SB, Squire LR. Intact perceptual memory in the absence of conscious memory. *Behav Neurosci.* 1997;111:850.) (Reprinted from Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: A neuroanatomical and neuropsychological profile of patient E.P. *J Neurosci.* 2000;20:7024, with permission.)

Another form of priming reflects improved access to meaning rather than percepts. For example, subjects study a list of words, including *tent* and *belt*, and then are asked to free associate to other words. Thus, they are given words such as *canvas* and *strap* and asked to produce the first word that comes to mind. The result is that subjects are more likely to produce *tent* in response to *canvas* and to produce *belt* in response to *strap* than if the words *tent* and *belt* had not been presented recently. This effect, called *conceptual priming*, is also preserved in amnesic patients, even though they fail to recognize the same words on a conventional memory test (Fig. 2.4-6).

FIGURE 2.4-6

Preserved conceptual priming in amnesia. In the free association test, subjects studied a set of words (e.g., *lemon*) and 5 minutes later viewed cue words that included associates of the studied words (e.g., *orange*). Subjects were asked to produce the first word that came to mind in response to each cue word. Results are shown separately for the control group (CON; $n = 12$), amnesic patients with large medial temporal lobe lesions (MTL; $n = 2$), and amnesic patients with lesions believed to be limited to the hippocampal region (H; $n = 3$). The **left panel** shows conceptual priming scores computed as the percentage of studied words produced in the free association test minus a baseline measure of the likelihood of producing those words by chance. All of the groups performed similarly in the conceptual priming test. The **right panel** shows results from a yes–no recognition memory test using comparable words. Both patient groups were impaired relative to the control group. The *dashed line* indicates chance performance. The data points for the MTL and H groups show the scores of individual patients averaged across four separate tests. *Brackets* show standard errors of the mean for the control group. (Reprinted from Levy DA, Stark CEL, Squire LR. Intact conceptual priming in the absence of declarative memory. *Psychol Sci.* 2004;15:680, with permission.)

Not all types of priming are preserved in amnesia. Some priming tests have been designed to examine the formation of new associations. When priming tests are based not on preexisting knowledge but on the acquisition of new associative knowledge, priming tends to be impaired. In other words, priming in certain complex situations can require the same type of linkage among multiple cortical regions that is critical for declarative memory.

Memory Systems

Table 2.4-2 depicts one scheme for conceptualizing multiple types of memory. Declarative memory depends on medial temporal and midline diencephalic structures along with large portions of the neocortex. This system provides for the rapid learning of facts (*semantic memory*) and events (*episodic memory*). Nondeclarative memory depends on several different brain systems. Habits depend on the neocortex and the neostriatum, and the cerebellum is important for the conditioning of skeletal musculature, the amygdala for emotional learning, and the neocortex for priming.

Table 2.4-2
Types of Memory

- A. Declarative memory
 1. Facts
 2. Events
- B. Nondeclarative memory
 1. Skills and habits
 2. Priming
 3. Simple classical conditioning
 4. Nonassociative learning

Declarative memory and nondeclarative memory differ in important ways. Declarative memory is phylogenetically more recent than nondeclarative memory. In addition, declarative memories are available to conscious recollection. The flexibility of declarative memory permits the retrieved information to be available to multiple response systems. Nondeclarative memory is inaccessible to awareness and is expressed only by engaging specific processing systems. Nondeclarative memories are stored as changes within these processing systems—changes that are encapsulated such that the stored information has limited accessibility to other processing systems.

Semantic memory, which concerns general knowledge of the world, has often been categorized as a separate form of memory. Facts that are committed to memory typically become independent of the original episodes in which the facts were learned. Amnesic patients can sometimes acquire information that would ordinarily be learned as facts, but the patients learn it by relying on a different brain system than the system that supports declarative memory.

Consider a test requiring the concurrent learning of eight object pairs. Healthy individuals can rapidly learn which the correct object in each pair is, whereas severely amnesic patients like EP learn only gradually over many weeks, and at the start of each session they cannot describe the task, the instructions, or the objects. In patients who do not have severe amnesia, factual information is typically acquired as consciously accessible declarative knowledge. In these cases, the brain structures that remain intact within the medial temporal lobe presumably support learning. In contrast, when factual information is acquired as nondeclarative knowledge, as in the case of EP's learning of pairs of objects, learning likely occurs directly as a habit, perhaps supported by the neostriatum. Humans thus appear to have a robust capacity for habit learning that operates outside of awareness and independent of the medial temporal lobe structures that are damaged in amnesia.

Frontal Contributions to Memory

Although amnesia does not occur after limited frontal damage, the frontal lobes are fundamentally important for declarative memory. Patients with frontal lesions have poor memory for the context in which information was acquired, they have difficulty in unaided recall, and they may even have some mild difficulty on tests of item recognition. More generally, patients with frontal lesions have difficulty implementing memory retrieval strategies and evaluating and monitoring their memory performance.

NEUROIMAGING AND MEMORY

The understanding of memory derived from studies of amnesia has been extended through studies using various methods for monitoring

brain activity in healthy individuals. For example, activation of posterior prefrontal regions with positron emission tomography (PET) and functional MRI have shown that these regions are involved in strategic processing during retrieval, as well as in working memory. Anterior frontal regions near the frontal poles have been linked with functions such as evaluating the products of retrieval. Frontal connections with posterior neocortical regions support the organization of retrieval and the manipulation of information in working memory. Consistent with the evidence from patients with frontal lesions, frontal–posterior networks can be viewed as instrumental in the retrieval of declarative memories and in the online processing of new information.

Neuroimaging has also identified contributions to memory made by parietal cortex. Multiple parietal regions (including inferior and superior parietal lobules, precuneus, posterior cingulate, and retrosplenial cortex) are activated in conjunction with remembering recent experiences. Although many functions have been hypothesized to explain this parietal activity, a single consensus position has not yet been reached, and it may be the case that several different functions are relevant.

Neuroimaging studies have also illuminated priming phenomena and how they differ from declarative memory. Perceptual priming appears to reflect changes in early stages of the cortical pathways that are engaged during perceptual processing. For example, in the case of stem-completion priming, in which subjects study a list of words (e.g., MOTEL) and then are tested with a list of stems (e.g., MOT_) and with instructions to complete each stem with the first word to come to mind, neuroimaging and divided visual-field studies have implicated visual processing systems in extrastriate cortex, especially in the right hemisphere. In contrast, conscious recollection of remembered words engages brain areas at later stages of processing. Neural mechanisms supporting priming and declarative memory retrieval have also been distinguished in brain electrical activity recorded from the scalp (Fig. 2.4-7). In sum, priming differs from declarative memory in that it is signaled by brain activity that occurs earlier and that originates in different brain regions.

FIGURE 2.4-7

Brain potentials associated with perceptual priming versus declarative memory retrieval. Paller et al. (2003) studied 16 volunteers, who took a memory test involving three sorts of faces: new faces, faces they had seen recently and remembered well, and faces they had seen but did not remember because the faces had been presented too briefly to process effectively. In a companion experiment with a priming test, speeded responses were found, indicative of priming. Frontal recordings of brain waves elicited by the primed faces included negative potentials from 200 to 400 ms after face presentation that differed from the brain waves elicited by new faces. These differences were particularly robust for trials with the fastest responses (data shown were from trials with responses faster than the median reaction time). Remembered faces uniquely elicited positive brain waves that began about 400 ms after face presentation. Brain potential correlates of face recollection occurred later than those for perceptual priming and were larger over posterior brain regions. (Adapted from Paller KA, Hutson CA, Miller BB, Boehm SG. Neural manifestations of memory with and without awareness. *Neuron*. 2003;38:507, with permission.)

Hippocampal activity associated with the formation and retrieval of declarative memories has also been investigated with neuroimaging. In keeping with the neuropsychological evidence, the hippocampus appears to be involved in the recollection of recent events (Fig. 2.4-8). Retrieval-related hippocampal activity has been observed in memory tests with many different types of stimuli. The hippocampus is also active during the initial storage of information. Whereas left inferior prefrontal cortex is engaged as a result of attempts to encode a word, hippocampal activity at encoding is more closely associated with whether encoding leads to a stable memory that can later be retrieved (Fig. 2.4-9). These findings confirm and extend the idea that medial temporal and frontal regions are important for memory storage and that they make different contributions.

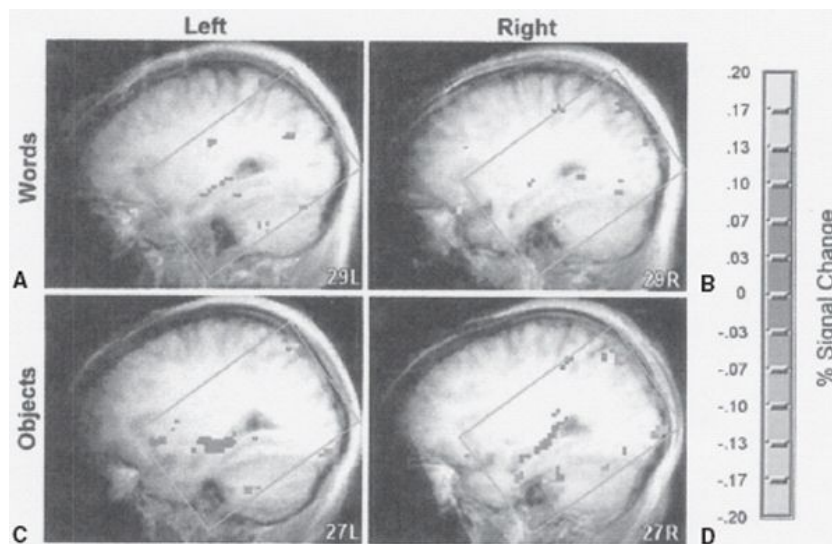

FIGURE 2.4-8

Activity in the left and right hippocampal regions measured with functional magnetic resonance imaging (fMRI) during declarative memory retrieval. Data were collected from 11 participants who saw words at study and test and from 11 different participants who saw pictures of namable objects at study and test. Recognition memory accuracy was 80.2 percent correct for words and 89.9 percent correct for objects. Areas of significant fMRI signal change (targets vs. foils) are shown in sagittal sections as color overlays on averaged structural images. The green box indicates the area in which reliable data were available for all subjects. With words, retrieval-related activity was observed in the hippocampus on the left side (A) but not on the right side (B). With namable objects, retrieval-related activity was observed in the hippocampus on both the left side (C) and the right side (D). (Reprinted from Stark CE, Squire LR. Functional magnetic resonance imaging (fMRI) activity in the hippocampal region during recognition memory. *J Neurosci.* 2000;20:7776, with permission.)

FIGURE 2.4-9

Functional activations of prefrontal and medial temporal regions that were predictive of later memory performance. Single words were presented visually, each followed by an instruction to remember (R cue) or to forget (F cue). Trials were sorted based on the remember or forget instruction and on subsequent recognition performance. Activity in the left inferior prefrontal cortex and left hippocampus was predictive of subsequent recognition but for different reasons. Left inferior prefrontal activation (A) was associated with the encoding attempt, in that responses were largest for trials with a cue to remember, whether or not the word was actually recognized later. The time course of activity in this region (B) was computed based on responses that were time locked to word onset (time 0). Left inferior prefrontal activity increased for words that were later remembered, but there was a stronger association with encoding attempt, because responses were larger for words followed by an R cue that were later forgotten than for words followed by an F cue that were later remembered. In contrast, left parahippocampal and posterior hippocampal activation (C) was associated with encoding success. As shown by the time course of activity in this region (D), responses were largest for words that were subsequently remembered, whether the cue was to remember or to forget. (Reprinted from Reber PJ, Siwec RM, Gitelman DR, Parrish TB, Mesulam MM, Paller KA. Neural correlates of successful encoding identified using functional magnetic resonance imaging. *J Neurosci.* 2002;22:9541, with permission.)

SLEEP AND MEMORY

The speculation that memories are processed during sleep has a long history. Freud noted that dreams can reveal fragments of recent experiences in the form of day residues. Although many questions about how and why memories may be processed during sleep remain unresolved, recent experiments have provided new empirical support to bolster the idea that memory processing during sleep serves an adaptive function. It is now clear that memory performance can be facilitated when sleep occurs after initial learning, and that sleep-related facilitation can be observed for many different types of memory.

Memory storage appears to be specifically aided by processing during deep sleep within a few hours after learning, especially in stages 3 and 4 (slow-wave sleep). Some results indicate that slow-wave sleep facilitates the storage of declarative memories but not nondeclarative memories. Direct evidence for this proposal has been obtained using stimulation with olfactory stimuli (Fig. 2.4-10), stimulation with direct current electrical input at the approximate frequency of electroencephalographic slow waves, and other methods. Furthermore, neuronal recordings in animals have revealed a phenomenon of hippocampal replay, in which activity patterns expressed during the day are later observed during sleep. In summary, declarative memories acquired during waking can be processed again during sleep, and this processing can influence the likelihood of subsequent memory retrieval when the individual is awake. The facilitation of declarative memory is typically manifest as a reduction in the amount of forgetting that occurs, not as an improvement in memory.

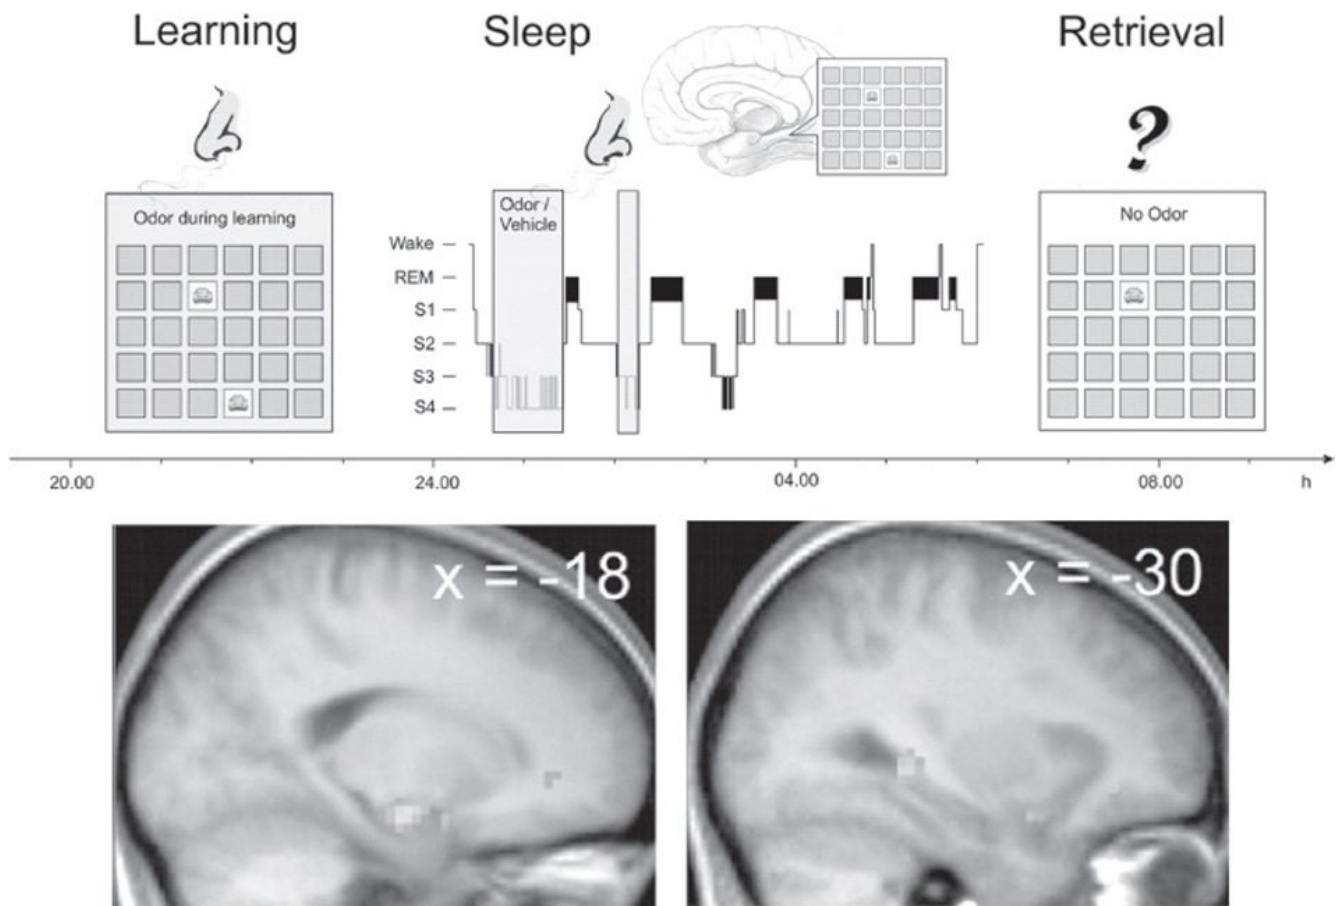

FIGURE 2.4-10

Evidence for memory processing during sleep. Subjects first learned object–location associations when a rose odor was present. Following learning, subjects slept wearing a device for delivering odors to the nose, and the rose odor was administered during the first two slow-wave sleep periods of the night (in 30-second periods to prevent habituation). Memory facilitation was observed when object–location associations were tested the following morning in the absence of odor stimulation. Facilitated memory was not found when stimulation occurred during slow-wave sleep but not during learning, when stimulation occurred during learning and then during rapid-eye-movement (REM) sleep, or when subjects were kept awake. Moreover, odor stimulation during slow-wave sleep was found to produce anterior and posterior hippocampal activation (**lower panels**). (Reprinted from Rasch B, Büchel C, Gais S, Born J. Odor cues during slow-wave sleep prompt declarative memory consolidation. *Science*. 2007;315:1426, with permission.)

ASSESSMENT OF MEMORY FUNCTIONS

A variety of quantitative methods are available to assess memory functions in neurological and psychiatric patients. Quantitative methods are useful for evaluating and following patients longitudinally, as well as for carrying out a one-time examination to determine the status of memory function. It is desirable to obtain information about the severity of memory dysfunction, as well as to determine whether memory is selectively affected or whether memory problems are occurring, as they often do, against a background of additional intellectual deficits. Although some widely available tests, such as the Wechsler Memory Scale, provide useful measures of memory, most single tests assess memory rather narrowly. Even general-purpose neuropsychological batteries provide for only limited testing of memory functions. A complete assessment of memory usually involves a number of specialized tests that sample intellectual functions, new learning capacity, remote memory, and memory self-report.

The assessment of general intellectual functions is central to any neuropsychological examination. In the case of memory testing, information about intellectual functions provides information about a patient's general test-taking ability and a way to assess the selectivity of memory impairment. Useful tests include the Wechsler Adult Intelligence Scale; a test of object naming, such as the Boston Naming Test; a rating scale to assess the possibility of global dementia; a test of word fluency; and specialized tests of frontal lobe function.

New Learning Capacity

Memory tests are sensitive to impaired new learning ability when they adhere to either of two important principles. First, tests are sensitive to memory impairment when more information is presented than can be held in immediate memory. For example, one might ask patients to memorize a list of ten faces, words, sentences, or digits, given that ten items is more than can be held in mind. The paired-associate learning task is an especially sensitive test of this kind. In the paired-associate task, the examiner asks the patient to learn a list of unrelated pairs of words (for example, queen–garden, office–river) and then to respond to the first word in each pair by recalling the second word.

Second, tests are sensitive to memory impairment when a delay, filled with distraction, is interposed between the learning phase and the test phase. In that case, examiners typically ask patients to learn a small amount of information and then distract them for several minutes by conversation to prevent rehearsal. Recollection is then assessed for the previously presented material. Memory can be tested by unaided recall of previously studied material (free recall), by presenting a cue for the material to be remembered (cued recall), or by testing recognition memory. In multiple-choice tests of recognition memory, the patient tries to select previously studied items from a group of studied and unstudied items. In yes–no recognition tests, patients see studied and unstudied items one at a time and are asked to say “yes” if the item was presented previously and “no” if it was not. These methods for assessing recently learned material vary in terms of their sensitivity for detecting memory impairment, with free recall being most sensitive, cued recall intermediate, and recognition least sensitive.

The specialization of function of the two cerebral hemispheres in humans means that left and right unilateral damage is associated with different kinds of memory problems. Accordingly, different kinds of memory tests must be used when unilateral damage is a possibility. In general, damage to medial temporal or diencephalic structures in the left cerebral hemisphere causes difficulty in remembering verbal material, such as word lists and stories. Damage to medial temporal or diencephalic structures in the right cerebral hemisphere impairs memory for faces, spatial layouts, and other nonverbal material that is typically encoded without verbal labels. Left medial temporal

damage can lead to impaired memory for spoken and written text. Right medial temporal damage can lead to impaired learning of spatial arrays, whether the layouts are examined by vision or by touch. A useful way to test for nonverbal memory is to ask a patient to copy a complex geometric figure and then, after a delay of several minutes, without forewarning, ask the patient to reproduce it.

Remote Memory

Evaluations of retrograde memory loss should attempt to determine the severity of any memory loss and the time period that it covers. Most quantitative tests of remote memory are composed of material in the public domain that can be corroborated. For example, tests have been used that concern news events, photographs of famous persons, or former one-season television programs. An advantage of these methods is that one can sample large numbers of events and can often target particular time periods. A disadvantage is that these tests are not so useful for detecting memory loss for information learned during the weeks or months immediately before the onset of amnesia. Most remote memory tests sample time periods rather coarsely and cannot detect a retrograde memory impairment that covers only a few months.

In contrast, autobiographical memory tests can potentially provide fine-grained information about a patient's retrograde memory. In the word-probe task, first used by Francis Galton in 1879, patients are asked to recollect specific episodes from their past in response to single word cues (e.g., bird and ticket) and to date the episodes. The number of episodes recalled tends to be systematically related to the time period from which the episode is taken. Most memories normally come from recent time periods (the last 1 to 2 months), whereas patients with amnesia often exhibit temporally graded retrograde amnesia, drawing few episodic memories from the recent past but producing as many remote autobiographical memories as do normal subjects (see Fig. 2.4-4).

Memory Self-Reports

Patients can often supply descriptions of their memory problems that are extremely useful for understanding the nature of their impairment. Tests of the ability to judge one's memory abilities are called tests of *metamemory*. Self-rating scales are available that yield quantitative and qualitative information about memory impairment. As a result, it is possible to distinguish memory complaints associated with depression from memory complaints associated with amnesia. Depressed patients tend to rate their memory as poor in a rather undifferentiated way, endorsing equally all of the items on a self-rating form. By contrast, amnesic patients tend to endorse some items more than others; that is, there is a pattern to their memory complaints. Amnesic patients do not report difficulty in remembering very remote events or in following what is being said to them, but they do report having difficulty remembering an event a few minutes after it happens. Indeed, self-reports can match rather closely the description of memory dysfunction that emerges from objective tests. Specifically, new-learning capacity is affected, immediate memory is intact, and very remote memory is intact. Some amnesic patients, however, tend to markedly underestimate their memory impairment. In patients with Korsakoff's syndrome, for example, their poor metamemory stems from frontal lobe dysfunction. In any case, querying patients in some detail about their sense of impairment and administering self-rating scales are valuable and informative adjuncts to more formal memory testing.

Psychogenic Amnesia

Patients sometimes exhibit memory impairment that differs markedly from the typical patterns of memory loss that follow brain damage. For example, some cases of amnesia present with a sudden onset of retrograde amnesia, a loss of personal identity, and minimal anterograde amnesia. These patients may even be unable to recall their name. Given the psychological forces that prompt the onset of amnesia in these cases, they are commonly termed *psychogenic amnesia*, or sometimes *hysterical amnesia*, *functional amnesia*, or *dissociative amnesia*.

Differentiating psychogenic amnesia from a memory disorder that results from frank neurological injury or disease is often straightforward. Psychogenic amnesias typically do not affect new-learning capacity. Patients enter the hospital able to record a continuing procession of daily events. By contrast, new-learning problems tend to be at the core of neurological amnesia. The main positive symptom in psychogenic amnesia is extensive and severe retrograde amnesia. Patients may be unable to recollect pertinent information from childhood or from some part of their past. Formal neuropsychological testing has shown that the pattern of memory deficits varies widely from patient to patient. This variability may reflect a patient's commonsense concepts of memory, even when symptoms are not the result of conscious attempts to simulate amnesia. Some patients may perform poorly only when asked to remember past autobiographical events. Other patients also may fail at remembering past news events. Some patients perform well when memory tests appear to assess general knowledge, such as remembering the names of celebrities or cities. Learning new material is usually intact, perhaps because such tests appear to concern the present moment, not traveling into the past. Occasionally, patients with psychogenic amnesia exhibit broad memory deficits such that they cannot perform previously familiar skills or identify common objects or common vocabulary words.

By contrast, patients with neurological amnesia never forget their name, and remote memory for the events of childhood and adolescence is typically normal, unless there is damage to the lateral temporal or frontal lobes. Patients with psychogenic amnesia sometimes have evidence of head trauma or brain injury, but nevertheless the pattern of deficits cannot be taken as a straightforward result of neurological insult. The clinician's challenge is not to distinguish psychogenic amnesia from neurological amnesia, but to distinguish psychogenic amnesia from malingering. Indeed, the diagnosis of psychogenic amnesia can be difficult to substantiate and may be met with skepticism by hospital staff. Some features that argue in favor of a genuine psychogenic disorder include: (1) memory test scores that are not as low as possible, and never worse than chance levels; (2) memory access that is improved by hypnosis or amobarbital (Amytal) interview; and (3) a significant premorbid psychiatric history. In some cases, psychogenic amnesia has been observed to clear after a period of days, but in many cases it has persisted as a potentially permanent feature of the personality.

IMPLICATIONS

Memory Distortion

Current understanding of the biology of memory has significant implications for several fundamental issues in psychiatry. Given the selective and constructive nature of autobiographical remembering and the imperfect nature of memory retrieval more generally, it is surprising that memory is so often accurate. How much can we trust our memories? Subjective feelings of confidence are apparently not perfect indicators of retrieval accuracy. Moreover, memory distortion can clearly lead to unfortunate consequences, such as when mistaken eyewitness testimony harms an innocent individual.

In fact it is possible to remember with confidence events that never happened. For example, it is possible to confuse an event that was only imagined or dreamed about with an event that actually occurred. One factor that contributes to memory distortion is that similar brain regions are important both for visual imagery and for the long-term storage of visual memories (Fig. 2.4-11). Another factor that contributes to memory distortion is that memory functions best in remembering the gist of an event, not the particulars from which the gist is derived. In a noted demonstration, people listen to a list of words: *Candy, sour, sugar, tooth, heart, taste, dessert, salt, snack, syrup, eat, and flavor*. Subsequently, when asked to write down the words they heard, 40 percent of them wrote down the word *sweet*, even though this word did not appear in the list. Thus, many people in this demonstration failed to discriminate between the words that had been presented and a word that was strongly associated to all the words but had not itself been presented. The word *sweet* can be thought of as a gist word, a word that represents the other words and that captures the meaning of the whole list. Presumably, the words in the study list evoked a thought of the word *sweet*, either at the time of learning or during the memory test, and people then tended to confuse merely thinking of the word with actually hearing it.

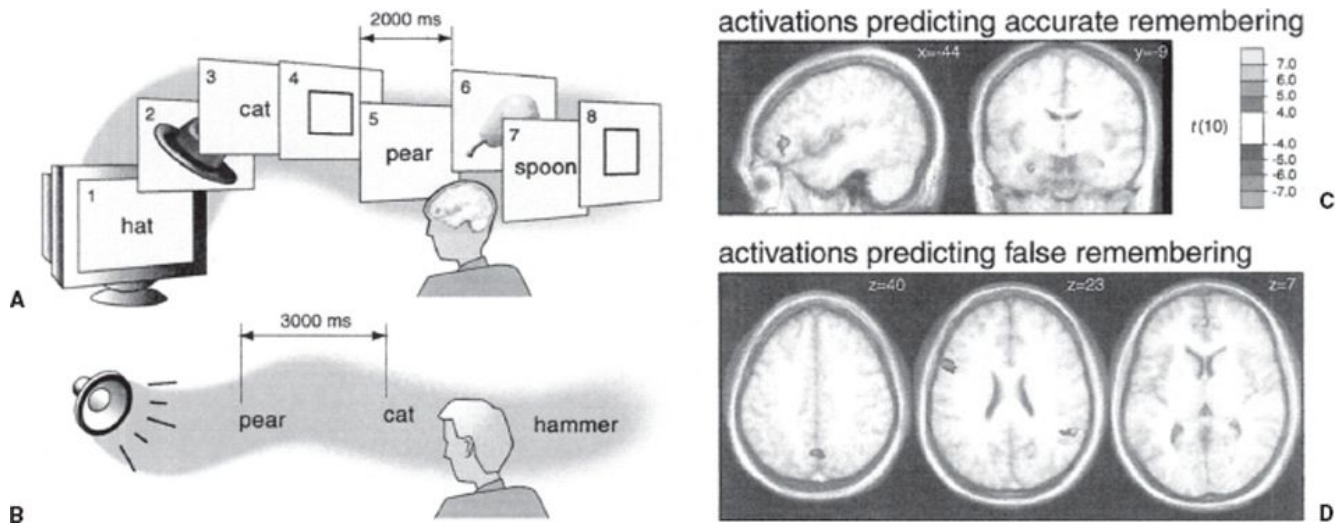

FIGURE 2.4-11

Neural substrates of false memories. **A.** Functional magnetic resonance imaging data were acquired in a learning phase, when subjects read names of objects and visualized the referents. One half of the names were followed 2 seconds later by a picture of the object. **B.** In a surprise memory test given outside of the scanner, subjects listened to object names and decided whether they had seen a picture of the corresponding object. On some trials, subjects claimed to have seen a picture of an object that they had only imagined. **C.** Results showed that the left inferior prefrontal cortex and the left anterior hippocampus were more active during learning in response to pictures later remembered compared to pictures later forgotten. **D.** Several different brain areas showed a greater response to words in the learning phase that were later falsely remembered as pictures compared to words not misremembered. Activations that predicted false remembering were found in a brain network important for the generation of visual imagery in response to object names (precuneus, inferior parietal cortex, and anterior cingulate, shown in the left, middle, and right images, respectively). (Reprinted from Gonsalves B, Reber PJ, Gitelman DR, Parrish TB, Mesulam MM, Paller KA. Neural evidence that vivid imagining can lead to false remembering. *Psychol Sci.* 2004;15:655, with permission.)

The reconstructive nature of recollection means that the interpretation of eyewitness testimony is not straightforward. Whole episodes are not available in the neocortex, but rather must be pieced together based on fragmentary components and in the context of potentially misleading influences present at the time of retrieval. Studies in adults and in children have documented that illusory memories can be created. Children are particularly susceptible to these effects, especially when subjected to leading questions and false suggestions.

In view of these features of memory, when a memory for childhood abuse is remembered after many years, it is prudent to ask whether the memory is accurate. Genuine examples of memory recovery have been documented, whereby an individual produces a veridical memory for a past traumatic event after not recalling the event for extended time periods. Numerous examples of apparent memory recovery have also been subsequently discovered to be instances of false memory. Unfortunately, there is no perfect method, in the absence of independent corroboration, for determining whether a recollective experience is based on a real event.

Infantile Amnesia

The biology of memory has also provided insights relevant to the phenomenon of infantile amnesia—the apparent absence of conscious memory for experiences from approximately the first 3 years of life. Traditional views of infantile amnesia have emphasized repression (psychoanalytic theory) and retrieval failure (developmental psychology). A common assumption has been that adults retain memories of early events but cannot bring them into consciousness. However, it now appears that the capacity for declarative memory does not become fully available until approximately the third year of life, whereas nondeclarative memory emerges early in infancy (e.g., classical conditioning and skill learning). Thus, infantile amnesia results not from the adult's failure to retrieve early memories, but from the child's failure to store them adequately in the first place.

Nevertheless, studies in young infants show that a rudimentary capacity for declarative memory is present even at a few months of age. As a child develops, memories can be retained across increasingly long intervals, and what is represented becomes correspondingly richer and more full of detail. Medial temporal and diencephalic regions seem to be sufficiently developed during these early months and years. What limits the capacity for declarative memory appears to be the gradual development and differentiation of the neocortex.

As the neocortex develops, the memories represented there become more complex, language abilities allow for more elaborate verbal descriptions of events, and a developing sense of self supports autobiographical knowledge. As new strategies emerge for organizing incoming information, declarative memories become more persistent, more richly encoded, and better interconnected with other information. It is not the case that fully formed childhood memories are stored but cannot be retrieved. The perspective consistent with current understanding of the biology of memory is that declarative memories formed very early in life are fragmentary, simple, and tied to the specific context of an infant's understanding of the world. They are unlike typical declarative memories in adults, which are imbued with meaning and a complex understanding of events.

Memories and the Unconscious

The existence of multiple memory systems also has implications for issues central to psychoanalytic theory, including the construct of the *unconscious*. How one believes that past experience influences current behavior depends on what view one takes of the nature of memory. By the traditional view, memory is a unitary faculty, and representations in memory vary mainly in strength and accessibility. Material that is unconscious is below some threshold of accessibility but could potentially be made available to consciousness.

The modern, biological view begins with the distinction between a kind of memory that can be brought to mind—declarative memory—and other kinds of memory that are, by their nature, unconscious. Stored nondeclarative memories are expressed through performance without affording any conscious memory content. Our personalities are shaped by nondeclarative memories in the form of numerous habits and conditioned responses. In this view, one's behavior is indeed affected by events from early life, but the effects of early experience persist in a nondeclarative form without necessarily including an explicit, conscious record of the events. Learned behavior can be expressed through altered dispositions, preferences, conditioned responses, habits, and skills, but exhibiting such behavior need not be accompanied by awareness that behavior is being influenced by past experience, nor is there a necessity that any particular past experience has been recorded as a complete episode. That is, an influence from early experience does not require a memory of any specific episode. One can be afraid of dogs without remembering being knocked down by a dog as a child. In this case, the fear of dogs is not experienced as a memory. It is experienced as a part of personality. Furthermore, a strong fear of dogs carries with it no implication that the brain retains a specific record of an early experience that subsequently resulted in a fear of dogs.

Behavioral change can occur by one's acquiring new habits that supersede old ones or by becoming sufficiently aware of a habit that one can to some extent isolate it, countermand it, or limit the stimuli that elicit it. However, one need not become aware of any early formative event in the same sense that one knows the content of a declarative memory. The unconscious does not become conscious. Various forms of nondeclarative memory simply influence behavior without having the additional capacity for these influences to become accessible to conscious awareness.

2.5 Normality and Mental Health

There has been an implicit assumption that mental health could be defined as the antonym of mental illness. In other words, mental health was the absence of psychopathology and synonymous with *normal*. Achieving mental health through the alleviation of gross pathologic signs and symptoms of illness is also the definition of the mental health model strongly advocated by third-party payers. Indeed, viewing mental health as simply the absence of mental illness is at the heart of much of the debate concerning mental health policies. The great epidemiological studies of the last half-century also focused on who was mentally ill, and not who was well.

DEFINING MENTAL HEALTH

Several steps are necessary in defining positive mental health. The first step is to note that “average” is not healthy; it always includes mixing in with the healthy the prevalent amount of psychopathology in the population. For example, in the general population, being of “average” weight or eyesight is unhealthy, and if all sources of biopsychosocial pathology were excluded from the population, the average IQ would be significantly greater than 100.

The second step in discussing mental health is to appreciate the caveat that what is healthy sometimes depends on geography, culture, and the historical moment. Sickle cell trait is unhealthy in New York City, but in the tropics, where malaria is endemic, the sickling of red blood cells may be lifesaving.

The third step is to make clear whether one is discussing *trait* or *state*. Who is physically healthier—an Olympic miler disabled by a simple but temporary (state) sprained ankle or a type 1 diabetic (trait) with a temporarily normal blood sugar? In cross-cultural studies such differences become especially important. Superficially, an Indian mystic in a state of trance may resemble a person with catatonic schizophrenia, but the mystic does not resemble someone in the schizophrenic condition over time.

The fourth and most important step is to appreciate the twofold danger of “contamination by values.” On one hand, cultural anthropology teaches us how fallacious any definition of mental health can be. Competitiveness and scrupulous neatness may be healthy in one culture and regarded as personality disorders in another. Furthermore, if mental health is “good,” what is it good for? The self or the society? For “fitting in” or for creativity? For happiness or survival? And who should be the judge?

MODELS OF MENTAL HEALTH

This chapter contrasts six different empirical approaches to mental health. First, mental health can be conceptualized as *above normal* and a mental state that is objectively desirable, as in Sigmund Freud's definition of mental health which is the capacity to work and to love. Second, from the viewpoint of healthy adult development, mental health can be conceptualized as *maturity*. Third, mental health can be conceptualized in terms of *positive psychology*—as epitomized by the presence of multiple human strengths. Fourth, mental health can be conceptualized as *emotional intelligence* and successful object relations. Fifth, mental health can be conceptualized as *subjective well-being*—a mental state that is subjectively experienced as happy, contented, and desired. Sixth, mental health can be conceptualized as *resilience*, as the capacity for successful adaptation and homeostasis.

Model A: Mental Health as Above Normal

This first perspective differs from the traditional medical approach to health and illness. No manifest psychopathology equals mental health. In this medical model, if one were to put all individuals on a continuum, normality would encompass the major portion of adults, and abnormality would be the small remainder. This definition of health correlates with the traditional role model of the doctor who attempts to free his patient from grossly observable signs of illness. In other words, in this context health refers to a reasonable, rather than an optimal, state of functioning. Yet, as already pointed out, mental health is not normal; it is above average. Some believe that true mental health is the exception, not the rule. Moreover, until recently some believed that mental health was imaginary.

Model B: Mental Health as Maturity

Unlike other organs of the body that are designed to stay the same, the brain is designed to be plastic. Therefore, just as optimal brain development requires almost a lifetime, so does the assessment of positive mental health. A 10-year-old's lungs and kidneys are more likely to reflect optimal function than are those of a 60-year-old, but that is not true of a 10-year-old's central nervous systems. To some extent, then, adult mental health reflects a continuing process of maturational unfolding. Statistically, physically healthy 70-year-olds are mentally healthier than they were at age 30 years; for example, Laura Carstensen found through prospective studies that individuals are less depressed and show greater emotional modulation at age 70 years than they did at age 30 years.

However, if prospective studies of adult development reveal that the immature brain functions less well than the mature brain, does that mean that adolescents are mentally healthier than toddlers? Are the middle-aged mentally healthier than adolescents? The answer is both yes and no, but the question illustrates that in order to understand mental health we must first understand what we mean by maturity.

To confirm the hypothesis that maturity and positive mental health are almost synonymous, it is necessary to study the behavior and emotional states of persons over a lifetime. Although such longitudinal studies have come to fruition only recently, all of them illustrate the association of maturity with increasing mental health. After age 50 years, of course, the association between mental health and maturity is

contingent on a healthy central nervous system. The ravages of illnesses like brain trauma, major depression, arteriosclerosis, Alzheimer's, and alcoholism must all be avoided.

The association of mental health to maturity is probably mediated not only by progressive brain myelination into the sixth decade but also by the evolution of emotional and social intelligence through experience. Erik Erikson conceptualized that such development produced a "widening social radius." In such a view, life after age 50 years was no longer to be a staircase leading downward, as in the Pennsylvania Dutch cartoons of life-span development, but a path leading outward. In Erikson's model the adult social radius expanded over time through the mastery of certain tasks such as "Identity versus Identity Diffusion," "Intimacy versus Isolation," "Generativity versus Stagnation," and "Integrity versus Despair."

Identity. In such a model the social radius of each adult developmental task fits inside the next. First, adolescents must achieve an *Identity* that allows them to become separate from their parents, for mental health and adult development cannot evolve through a false self. The task of *Identity* requires mastering the last task of childhood: sustained separation from social, residential, economic, and ideological dependence on family of origin. Identity is not just a product of egocentricity, of running away from home, or of marrying to get out of a dysfunctional family. There is a world of difference between the instrumental act of running away from home and the developmental task of knowing where one's family values end and one's own values begin. Such separation derives as much from the identification and internalization of important adolescent friends and nonfamily mentors as it does from simple biological maturation. For example, our accents become relatively fixed by age 16 years and reflect those of our adolescent peer group rather than the accents of our parents.

Intimacy. Then, young adults should develop *Intimacy*, which permits them to become reciprocally, and not selfishly, involved with a partner. However, living with just one other person in an interdependent, reciprocal, committed, and contented fashion for years and years may seem neither desirable nor possible to a young adult. Once achieved, however, the capacity for intimacy may seem as effortless and desirable as riding a bicycle. Sometimes the relationship is with a person of the same gender; sometimes it is completely asexual; and sometimes, as in religious orders, the interdependence is with a community. Superficially, mastery of intimacy may take very different guises in different cultures and epochs, but "mating-for-life" and "marriage-type love" are developmental tasks built into the developmental repertoires of many warm-blooded species, including ours.

Career Consolidation. *Career Consolidation* is a task that is usually mastered together with or that follows the mastery of intimacy. Mastery of this task permits adults to find a career as valuable as they once found play. On a desert island one can have a hobby but not a career, for careers involve being of value to other people. There are four crucial developmental criteria that transform a "job" or hobby into a "career": Contentment, compensation, competence, and commitment. Obviously, such a career can be "wife and mother"—or, in more recent times, "husband and father." To the outsider the process of Career Consolidation often appears "selfish," but without such "selfishness" one becomes "selfless" and has no "self" to give away in the next stage of generativity. Persons with schizophrenia and individuals with severe personality disorder often manifest a lifelong inability to achieve either intimacy or sustained, gratifying employment.

Generativity. *Generativity* involves the demonstration of a clear capacity to care for and guide the next generation. Research reveals that sometime between age 35 and 55 years our need for achievement declines and our need for community and affiliation increases. Depending on the opportunities that the society makes available, generativity can mean serving as a consultant, guide, mentor, or coach to young adults in the larger society. Like leadership, generativity means to be in a caring relationship in which one gives up much of the control that parents retain over young children. Good mentors learn "to hold loosely" and to share responsibility. Generativity reflects the capacity to give the self—finally completed through mastery of the first three tasks of adult development—away. Its mastery is strongly correlated with successful adaptation to old age. This is because in old age there are inevitable losses, and these may overwhelm us if we have not continued to grow beyond our immediate family.

Integrity. Finally, in old age it is common to feel that some life exists after death and that one is part of something greater than one's self. Thus, the last life task in Erikson's words is *Integrity*, the task of achieving some sense of peace and unity with respect both to one's life and to the whole world. Erikson described integrity as "an experience which conveys some world order and spiritual sense. No matter how dearly paid for, it is the acceptance of one's one and only life cycle as something that had to be and that, by necessity, permitted of no substitutions."

It must be kept in mind that mastery of one life task is not necessarily healthier than mastery of another, for adult development is neither a foot race nor a moral imperative. Rather, these sequential tasks are offered as a road map to help clinicians make sense of where they are and where their patients might be located. One can be a mature 20-year-old, that is, healthy. One can be an immature 50-year-old, which may be unhealthy. Nevertheless, acquiring a social radius that extends beyond the person by definition allows more flexibility and thus is usually healthier than self-preoccupation. Generativity by age 40 to 50 years offers a powerful predictor of a contented old age.

Model C: Mental Health as Positive or "Spiritual" Emotions

This model defines both mental and spiritual health as the amalgam of the positive emotions that bind us to other human beings. Love, hope, joy, forgiveness, compassion, faith, awe, and gratitude comprise the important positive and "moral" emotions included in this model. Of great importance, these selected positive emotions all involve human connection. None of the emotions listed is just about the self. These positive emotions appear to be a common denominator of all major faiths. Omitted from the list are five other positive emotions—excitement, interest, contentment (happiness), humor, and a sense of mastery, for a person can feel these latter five emotions alone on a desert island.

Negative emotions originating in the hypothalamus such as fear and anger are elaborated in the human amygdala (larger in humans than in other mammals). Of tremendous importance to individual survival, the negative emotions are all about "me." In contrast, positive emotions, apparently generated in the limbic system and unique to mammals, have the potential to free the self from the self. People feel both the emotions of vengeance and of forgiveness deeply, but the long-term results of these two emotions are very different. Negative emotions are crucial for survival in present time. The positive emotions are more expansive and help us to broaden and build. In future time, they widen one's tolerance for strangers, expand one's moral compass, and enhance one's creativity. Whereas negative emotions narrow attention and miss the forest for the trees, positive emotions, especially joy, make thought patterns more flexible, creative, integrative, and efficient.

The effect of positive emotion on the autonomic (visceral) nervous system has much in common with the relaxation response to meditation. In contrast to the metabolic and cardiac arousal that the fight-or-flight response of negative emotion induces in our *sympathetic* autonomic nervous system, positive emotion via our *parasympathetic* nervous system reduces basal metabolism, blood pressure, heart rate, respiratory rate, and muscle tension. Functional magnetic resonance imaging (fMRI) studies of Kundalini yoga practitioners demonstrate that meditation increases the activity of the hippocampus and the right lateral amygdala, which in turn leads to parasympathetic stimulation and the sensation of deep peacefulness.

Positive emotions have a biological basis, which means that they have evolved through natural selection. The prosocial emotions probably reflect adaptations that permitted the survival of relatively defenseless *Homo sapiens* and their extremely defenseless children in the African

savannah 1 to 2 million years ago.

Evidence for Positive Emotions. It has taken recent developments in neuroscience and ethology to make positive emotions a subject fit for scientific study. For example, infantile autism, a not uncommon genetic disorder of emotional attachment, was not discovered until 1943 by a Johns Hopkins child psychiatrist, Leo Kanner—in his son. Until then it was not possible for medicine to articulate a positive emotion as basic, but as cognitively subtle, as attachment. Today, the congenital lack of empathy and difficulties of attachment in childhood autism can be recognized by any competent pediatrician.

To locate positive emotion in the mammalian limbic system has been a slow, arduous process. In 1955, James Olds, an innovative neuropsychologist, observed that 35 of 41 electrode placements within the limbic system of rats, but only 2 of 35 placements outside of the limbic system, proved sufficiently rewarding to lead to self-stimulation. Also in the 1950s, neurobiologist Paul MacLean pointed out that the limbic structures govern our mammalian capacity not only to remember (cognition), but also to play (joy), to cry out at separation (faith/trust), and to take care of our own (love). Except for rudimentary memory, reptiles express none of these qualities.

Studies using fMRI demonstrated that when individuals subjectively experience existential states of fear, sadness, or pleasure, blood flow increases in limbic areas and decreases in many higher brain areas. Various studies have located human pleasurable experiences (tasting chocolate, winning money, admiring pretty faces, enjoying music, and experiencing orgasmic ecstasy) in limbic areas—especially in the orbitofrontal region, anterior cingulate, and insula. These diverse structures are closely integrated and organized to help us to seek and to recognize all that falls under the rubric of mammalian love and human spirituality.

The *anterior cingulate gyrus* links valence and memory to create attachment. Along with the hippocampus, the anterior cingulate is the brain region most responsible for making the past meaningful. In terms of mediating attachment, the anterior cingulate receives one of the richest dopaminergic innervations of any cortical area. Thus, the cingulate gyrus provides motivational salience not only for lovers, but also for drug addicts. The anterior cingulate is crucial in directing who we should approach and who we should avoid. Maternal touch, body warmth, and odor via the limbic system and especially via the anterior cingulate regulate a rat pup's behavior, neurochemistry, endocrine release, and circadian rhythm. Brain imaging studies reveal that the anterior cingulate gyrus is aroused neither by facial recognition of friends per se nor by sexual arousal per se. Rather, anterior cingulate fMRI images light up when a lover gazes at a picture of a partner's face or when a new mother hears her infant's cry.

Perhaps no area of the brain is more ambiguous in its evolutionary heritage or more crucial to mental health than our *prefrontal cortex*. The prefrontal cortex is in charge of estimating rewards and punishments and plays a critical role in adapting and regulating our emotional response to new situations. Thus, the prefrontal lobes are deeply involved in emotional, "moral," and "spiritual" lives.

From an evolutionary standpoint the human frontal lobes are not different from those of chimpanzees in terms of number of neurons. Rather, it is the frontal lobe white matter (the connectivity between neurons through myelinated fibers) that accounts for larger frontal lobes of humans. This connectivity to the limbic system underscores its "executive" function, which includes the ability to delay gratification, comprehend symbolic language, and, most important, to establish temporal sequencing. By being able to connect memory of the past to "memory of the future," the frontal lobes establish for *Homo sapiens* predictable cause and effect.

Surgical or traumatic ablation of the ventromedial prefrontal cortex can turn a conscientious, responsible adult into a moral imbecile without any other evidence of intellectual impairment.

The *insula* is another part of the limbic system that is only beginning to be understood. The insula is a medial cortical gyrus located between the amygdala and the frontal lobe. The brain has no sensation; humans feel emotion only in their bodies. The insula helps to bring these visceral feelings into consciousness: The pain in one's heart of grief, the warmth in one's heart of love, and the tightness in one's gut from fear all make their way into consciousness through the insula.

Both the limbic anterior cingulate and insula appear to be active in the positive emotions of humor, trust, and empathy. The higher apes are set apart from other mammals by a unique neural component called the spindle cell. Humans have 20 times more spindle cells than either chimps or gorillas (adult chimpanzees average about 7,000 spindle cells; human newborns have four times more; and human adults have almost 200,000 spindle cells). Monkeys and other mammals, with the possible exception of whales and elephants, are totally lacking in these special cells. These large, cigar-shaped spindle or "von Economo" neurons appear to be central to the governance of social emotions and moral judgment. Spindle cells may have helped the Great Apes and humans integrate their mammalian limbic systems with their expanding neocortices. Spindle cells are concentrated in the anterior cingulate cortex, the prefrontal cortex, and the insula. More recently, scientists have discovered a special group of "mirror neurons" that reside in the insula and anterior cingulate. These neurons are more highly developed in humans than in primates and appear to mediate empathy—the experience of "feeling" the emotions of another.

Although the practical applications of this newest model of mental health are still many years away, these findings provide further evidence that the brain and mind are one. In several studies the prosocial biological activity of the anterior cingulate cortex and insula was highest in individuals with the highest levels of social awareness (based on objectively scored tests). In other words, there are not only biological individual differences for negative mental health, but also for positive mental health.

Model D: Mental Health as Socioemotional Intelligence

High socioemotional intelligence reflects above-average mental health in the same way that a high intelligence quotient (IQ) reflects above-average intellectual aptitude. Such emotional intelligence lies at the heart of positive mental health. In the *Nicomachean Ethics*, Aristotle defined socioemotional intelligence as follows: "Anyone can become angry—that is easy. But to be angry with the right person, to the right degree, at the right time, for the right purpose, and in the right way—that is not easy."

All emotions exist to assist basic survival. Although the exact number of primary emotions is arguable, seven emotions are currently distinguished according to characteristic facial expressions connoting anger, fear, excitement, interest, surprise, disgust, and sadness. The capacity to identify these different emotions in ourselves and in others plays an important role in mental health. The benefits of being able to read feelings from nonverbal cues have been demonstrated in almost a score of countries. These benefits included being better emotionally adjusted, more popular, and more responsive to others. Empathic children, without being more intelligent, do better in school and are more popular than their peers. The Head Start Program, a program of the United States Department of Health and Human Services that provides education and other services for low-income children and their families, found that early school success was achieved not by intelligence but by knowing what kind of behavior is expected, knowing how to rein in the impulse to misbehave, being able to wait, and knowing how to get along with other children. At the same time the child must be able to communicate his or her needs and turn to teachers for help.

Ethologically, emotions are critical to mammalian communication. Because such communications are not always consciously recognized, the more skillful individuals are in identifying their emotions, the more skilled the individual will be in communicating with others and in empathically recognizing their emotions. Put differently, the more one is skilled in empathy, the more one will be valued by others, and thus the greater will be social supports, self-esteem, and intimate relationships.

Social and emotional intelligence can be defined by the following criteria:

- ▶ Accurate conscious perception and monitoring of one's emotions.
- ▶ Modification of emotions so that their expression is appropriate. This involves the capacity to self-soothe personal anxiety and to shake off hopelessness and gloom.
- ▶ Accurate recognition of and response to emotions in others.
- ▶ Skill in negotiating close relationships with others.
- ▶ Capacity for focusing emotions (motivation) toward a desired goal. This involves delayed gratification and adaptively displacing and

channeling impulse.

Some behavioral scientists divide emotions into positive and negative, as if negative emotions were unhealthy (this point of view was emphasized in Model C). This tendency is an oversimplification. As with pus, fever, and cough, so the negative emotions of sadness, fear, and anger are also important to healthy self-preservation. On one hand, positive emotions like joy, love, interest, and excitement are associated with subjective contentment; on the other hand, although negative emotions interfere with contentment, their expression can be equally healthy.

Advances in Studying Emotional Intelligence. Over the last 15 years, three important empirical steps have been taken in our understanding of the relationship of socioemotional intelligence to positive mental health.

The first step is that both fMRI studies and neurophysiological experimentation have led to advances in our understanding of the integration of prefrontal cortex with the limbic system, especially with the amygdala and its connections. As noted in the previous model, these research advances have brought us closer to understanding emotions as neurophysiological phenomena rather than as Platonic abstractions. The prefrontal cortex is the region of the brain responsible for working memory, and the frontal lobes, through their connections to the amygdala, hippocampus, and other limbic structures, encode emotional learning in a manner quite distinct from both conventional conditioning and declarative memory.

The second step has been the slow but steady progress in conceptualizing and measuring “emotional intelligence.” Over the last decade measures of emotional intelligence have evolved rapidly.

The third advance is the use of videotape to chart emotional interaction. Videos of sustained family interactions reveal that the most important aspect of healthy infant development, of adolescent development, and of marital harmony is how partners or parents respond to emotion in others. To ignore, to punish, and to be intimidated or contemptuous of how another feels spells disaster. Children of emotionally attuned parents are better at handling their own emotions and are more effective at soothing themselves when upset. Such children even manifest lower levels of stress hormones and other physiological indicators of emotional arousal.

There are now many exercises in handling relationships that help couples, business executives, and diplomats to become more skilled at conflict resolution and negotiation. In the last decade, there has also been an increasing effort to teach schoolchildren core emotional and social competencies, sometimes called “emotional literacy.” The relevance of these advances in psychology to psychiatry include teaching emotion recognition and differentiation in eating disorders and teaching anger modulation and finding creative solutions to social predicaments for behavior disorders.

Model E: Mental Health as Subjective Well-Being

Positive mental health does not just involve being a joy to others; one must also experience subjective well-being. Long before humankind considered definitions of mental health, they pondered criteria for subjective happiness. For example, objective social support accomplishes little if subjectively the individual cannot feel loved. Thus, capacity for subjective well-being becomes an important model of mental health.

Subjective well-being is never categorical. Healthy blood pressure is the objective absence of hypotension and hypertension, but happiness is less neutral. Subjective well-being is not just the absence of misery, but the presence of positive contentment. Nevertheless, if happiness is an inescapable dimension of mental health, happiness is often regarded with ambivalence. If through the centuries philosophers have sometimes regarded happiness as the highest good, psychologists and psychiatrists have tended to ignore it.

Subjective happiness can have maladaptive as well as adaptive facets. The search for happiness can appear selfish, narcissistic, superficial, and banal. Pleasures can come easily and be soon gone. Happiness is often based on illusion or on dissociative states. Illusory happiness is seen in the character structure associated with bipolar and dissociative disorders. Maladaptive happiness can bring temporary bliss but has no sticking power. In the Study of Adult Development, scaled measures of “happiness” had little predictive power and, often, insignificant association with other subjective and objective measures of contentment. It is because of such ambiguity of meaning that, throughout this section, the term *subjective well-being* will be substituted for happiness.

Empirical Evidence. The mental health issues involved in subjective well-being are complicated and clouded by historical relativism, value judgment, and illusion. Europeans have always been skeptical of the American concern with happiness. Only in the last decade have investigators pointed out that a primary function of positive emotional states and optimism is that they facilitate self-care. Subjective well-being makes available personal resources that can be directed toward innovation and creativity in thought and action. Thus, subjective well-being, like optimism, becomes an antidote to learned helplessness. Again, controlling for income, education, weight, smoking, drinking, and disease, happy people are only half as likely to die at an early age or become disabled as unhappy people.

A distinction can be made between *pleasure* and *gratification*. Pleasure is in the moment, is closely allied with happiness, and involves the satisfaction of impulse and of biological needs. Pleasure is highly susceptible to habituation and satiety. If pleasure involves satisfaction of the senses and emotions, gratification involves joy, purpose, and the satisfaction of “being the best you can be” and of meeting aesthetic and spiritual needs.

Subjective (unhappy) distress can be healthy. As ethologically minded investigators have long pointed out, subjective negative affects (e.g., fear, anger, and sadness) can be healthy reminders to seek environmental safety and not to wallow in subjective well-being. If positive emotions facilitate optimism and contentment, fear is the first protection against external threat; sadness protests against loss and summons help, and anger signals trespass.

Clarifying Subjective Well-Being. Since the 1970s investigators have made a serious effort to attend to definitional and causal parameters of subjective well-being and thereby address important questions. One such question is: Is subjective well-being more a function of environmental good fortune or a function of an inborn, genetically based temperament? Put differently, does subjective well-being reflect trait or state? If subjective well-being reflects a safe environment and the absence of stress, it should fluctuate over time, and those individuals who are happy in one domain or time in their lives might not be happy in another.

A second question, but one related to the first, is what is cause and what is effect. Are happy people more likely to achieve enjoyable jobs and good marriages, or does conjugal stability and career contentment lead to subjective well-being? Or are such positive associations the result of still a third factor? For example, the absence of a genetic tendency for alcoholism, for major depression, for trait neuroticism, and even for the presence of a chronic wish to give socially desirable answers (impression management) might facilitate both subjective well-being and reports of good marriage and career contentment.

As with physiological homeostasis, evolution has prepared humans to make subjective adjustments to environmental conditions. Thus, one can adapt to good and bad events so that one does not remain in a state of either elation or despair. However, humans have a harder time adjusting to their genes. Studies of adopted-away twins have demonstrated that half of the variance in subjective well-being is due to heritability. The subjective well-being of monozygotic twins raised apart is more similar than the subjective well-being of heterozygous twins raised together. Among the heritable factors making a significant contribution to high subjective well-being are low trait neuroticism, high trait extraversion, absence of alcoholism, and absence of major depression. In contrast to tested intelligence, when heritable variables are controlled, subjective well-being is not affected by environmental factors like income, parental social class, age, and education.

If subjective well-being were due largely to the meeting of basic needs, then there should be a relatively low correlation between subjective well-being in work and subjective well-being in recreational settings or between subjective well-being in social versus subjective well-being in solitary settings. Because women experience more objective clinical depression than men, the fact that gender is not a determining factor in subjective well-being is interesting. One explanation is that women appear to report both positive and

negative affects more vividly than men. In one study, gender accounted for only 1 percent of the variance in happiness but 13 percent of the variance in the intensity of reported emotional experiences.

Other Sources of Well-Being. In some instances environment *can* be important to subjective well-being. Young widows remain subjectively depressed for years. Even though their poverty has been endured for centuries, respondents in very poor nations, like India and Nigeria, report lower subjective well-being than do other, more prosperous nations. The loss of a child never stops aching. Although achieving concrete goals like money and fame does not lead to a sustained increase in subjective well-being, social comparison, like watching one's next-door neighbor become richer than you, exerts a negative effect on subjective well-being.

The maintenance of self-efficacy, agency, and autonomy make additional environmental contributions to subjective well-being. For example, elders will use discretionary income to live independently even though this means living alone rather than with relatives. Subjective well-being is usually higher in democracies than in dictatorships. Assuming responsibility for favorable or unfavorable outcomes (internalization) is another major factor leading to subjective well-being. Placing the blame elsewhere (externalization) significantly reduces subjective well-being. In other words, the mental mechanisms of paranoia and projection make people feel worse rather than better.

Refined methods of measurement of subjective states of mind have included the Positive and Negative Affect Scale (PANAS), which assesses both positive and negative affect, each with ten affect items. The *Satisfaction with Life Scale* represents the most recent evolution of a general life satisfaction scale. Most recently the widely validated Short Form 36 (SF-36) has allowed clinicians to assess the subjective cost/benefits of clinical interventions. Because short-lived environmental variables can distort subjective well-being, consensus is emerging that naturalistic experience-sampling methods are the most valid way to assess subjective well-being. With such sampling methods, research subjects are contacted by beeper at random times during the day for days or weeks and at each interval are asked to assess their subjective well-being. This method provides a more stable report of subjective well-being. Finally, to tease verbal self-report from actual subjective experience, physiological measures of stress (e.g., measuring galvanic skin response and salivary cortisol and filming facial expression by concealed cameras) have also proven useful.

Model F: Mental Health as Resilience

There are three broad classes of coping mechanisms that humans use to overcome stressful situations. First, there is the way in which an individual elicits help from appropriate others: Namely *consciously seeking social support*. Second, there are *conscious cognitive strategies* that individuals intentionally use to master stress. Third, there are *adaptive involuntary coping mechanisms* (often called “defense mechanisms”) that distort our perception of internal and external reality in order to reduce subjective distress, anxiety, and depression.

Involuntary Coping Mechanisms. Involuntary coping mechanisms reduce conflict and cognitive dissonance during sudden *changes* in internal and external reality. If such changes in reality are not “distorted” and “denied,” they can result in disabling anxiety or depression, or both. Such homeostatic mental “defenses” shield us from sudden changes in the four lodestars of conflict: impulse (affect and emotion), reality, people (relationships), and social learning (conscience). First, such involuntary mental mechanisms can restore psychological homeostasis by ignoring or deflecting sudden increases in the lodestar of impulse—affect and emotion. Psychoanalysts call this lodestar “id,” religious fundamentalists call it “sin,” cognitive psychologists call it “hot cognition,” and neuroanatomists point to the hypothalamic and limbic regions of brain.

Second, such involuntary mental mechanisms can provide a mental time-out to adjust to sudden changes in *reality* and self-image, which cannot be immediately integrated. Individuals who initially responded to the television images of the sudden destruction of New York City's World Trade Center as if it were a movie provide a vivid example of the denial of an external reality that was changing too fast for voluntary adaptation. Sudden good news—the instant transition from student to physician or winning the lottery—can evoke involuntary mental mechanisms as often as can an unexpected accident or a diagnosis of leukemia.

Third, involuntary mental mechanisms can mitigate sudden unresolvable conflict with important *people*, living or dead. People become a lodestar of conflict when one cannot live with them and yet cannot live without them. Death is such an example; another is an unexpected proposal of marriage. Internal representations of important people may continue to cause conflict for decades after they are dead yet continue to evoke involuntary mental response.

Finally, the fourth source of conflict or anxious depression is social learning or conscience. Psychoanalysts call it “super ego,” anthropologists call it “taboos,” behaviorists call it “conditioning,” and neuroanatomists point to the associative cortex and the amygdala. This lodestar is not just the result of admonitions from our parents that we absorb before age 5 years, but it is formed by our whole identification, with culture, and sometimes by irreversible learning resulting from overwhelming trauma.

Healthy Involuntary Mental Mechanisms. Longitudinal studies from both Berkeley's Institute of Human Development and Harvard's Study of Adult Development have illustrated the importance of the mature defenses to mental health.

HUMOR. Humor makes life easier. With humor one sees all, feels much, but does not act. Humor permits the discharge of emotion without individual discomfort and without unpleasant effects upon others. Mature humor allows individuals to look directly at what is painful, whereas dissociation and slapstick distract the individual to look somewhere else. Yet, like the other mature defenses, humor requires the same delicacy as building a house of cards—timing is everything.

ALTRUISM. When used to master conflict, altruism involves an individual getting pleasure from giving to others what the individual would have liked to receive. For example, using reaction formation, a former alcohol abuser works to ban the sale of alcohol in his town and annoys his social drinking friends. Using altruism, the same former alcoholic serves as an Alcoholics Anonymous sponsor to a new member—achieving a transformative process that may be lifesaving to both giver and receiver. Obviously, many acts of altruism involve free will, but others involuntarily soothe unmet needs.

SUBLIMATION. The sign of a successful sublimation is neither careful cost accounting nor shrewd compromise, but rather psychic alchemy. By analogy, sublimation permits the oyster to transform an irritating grain of sand into a pearl. In writing his Ninth Symphony, the deaf, angry, and lonely Beethoven transformed his pain into triumph by putting Schiller's “Ode to Joy” to music.

SUPPRESSION. Suppression is a defense that modulates emotional conflict or internal/external stressors through stoicism. Suppression minimizes and postpones but does not ignore gratification. Empirically, this is the defense most highly associated with other facets of mental health. Used effectively, suppression is analogous to a well-trimmed sail; every restriction is precisely calculated to exploit, not hide, the winds of passion. Evidence that suppression is not simply a conscious “cognitive strategy” is provided by the fact that jails would empty if delinquents could learn to just say “No.”

ANTICIPATION. If suppression reflects the capacity to keep current impulse in mind and control it, anticipation is the capacity to keep affective response to an unbearable future event in mind in manageable doses. The defense of anticipation reflects the capacity to perceive future danger affectively as well as cognitively and by this means to master conflict in small steps. Examples are the fact that moderate amounts of anxiety before surgery promote postsurgical adaptation and that anticipatory mourning facilitates the adaptation of parents of children with leukemia.

Psychiatry needs to understand how best to facilitate the transmutation of less-adaptive defenses into more-adaptive defenses. One

suggestion has been first to increase social supports and interpersonal safety and second to facilitate the intactness of the central nervous system (e.g. rest, nutrition, and sobriety). The newer forms of integrative psychotherapies using videotape can also catalyze such change by allowing patients to actually see their involuntary coping style.

Contributions of the Sociocultural Sciences

3.1 Sociobiology and Ethology

SOCIOBIOLOGY

The term *sociobiology* was coined in 1975 by Edward Osborne Wilson, an American biologist whose book, which is called *Sociobiology*, emphasized the role of evolution in shaping behavior. Sociobiology is the study of human behavior based on the transmission and modification of genetically influenced behavioral traits. It explores the ultimate question of *why* specific behaviors or other phenotypes came to be.

EVOLUTION

Evolution is described as any change in the genetic makeup of a population. It is the foundational paradigm from which all of biology arises. It unites ethology, population biology, ecology, anthropology, game theory, and genetics. Charles Darwin (1809–1882) posited that natural selection operates via differential reproduction, in a competitive environment, whereby certain individuals are more successful than others. Given that differences among individuals are at least somewhat heritable, any comparative advantage will result in a gradual redistribution of traits in succeeding generations, such that favored characteristics will be represented in greater proportion over time. In Darwin's terminology, *fitness* meant reproductive success.

Competition. Animals vie with one another for resources and territory, the area that is defended for the exclusive use of the animal and that ensures access to food and reproduction. The ability of one animal to defend a disputed territory or resource is called *resource holding potential*, and the greater this potential, the more successful the animal.

Aggression. Aggression serves both to increase territory and to eliminate competitors. Defeated animals can emigrate, disperse, or remain in the social group as subordinate animals. A dominance hierarchy in which animals are associated with one another in subtle but well-defined ways is part of every social pattern.

Reproduction. Because behavior is influenced by heredity, those behaviors that promote reproduction and survival of the species are among the most important. Men tend to have a higher variance in reproductive success than do women, thus inclining men to be competitive with other men. Male–male competition can take various forms; for example, sperm can be thought of as competing for access to the ovum. Competition among women, although genuine, typically involves social undermining rather than overt violence. Sexual dimorphism, or different behavioral patterns for males and females, evolves to ensure the maintenance of resources and reproduction.

Altruism. *Altruism* is defined by sociobiologists as a behavior that reduces the personal reproductive success of the initiator while increasing that of the recipient. According to traditional Darwinian theory, altruism should not occur in nature because, by definition, selection acts against any trait whose effect is to decrease its representation in future generations; and yet, an array of altruistic behaviors occurs among free-living mammals as well as humans. In a sense, altruism is selfishness at the level of the gene rather than at the level of the individual animal. A classic case of altruism is the female worker classes of certain wasps, bees, and ants. These workers are sterile and do not reproduce but labor altruistically for the reproductive success of the queen.

Another possible mechanism for the evolution of altruism is group selection. If groups containing altruists are more successful than those composed entirely of selfish members, the altruistic groups succeed at the expense of the selfish ones, and altruism evolves. But within each group, altruists are at a severe disadvantage relative to selfish members, however well the group as a whole does.

Implications for Psychiatry. Evolutionary theory provides possible explanations for some disorders. Some may be manifestations of adaptive strategies. For example, cases of anorexia nervosa may be partially understood as a strategy ultimately caused to delay mate selection, reproduction, and maturation in situations where males are perceived as scarce. Persons who take risks may do so to obtain resources and gain social influence. An erotomanic delusion in a postmenopausal single woman may represent an attempt to compensate for the painful recognition of reproductive failure.

Studies of Identical Twins Reared Apart: Nature versus Nurture

Studies in sociobiology have stimulated one of the oldest debates in psychology. Does human behavior owe more to nature or to nurture? Curiously, humans readily accept the fact that genes determine most of the behaviors of nonhumans, but tend to attribute their own behavior almost exclusively to nurture. In fact, however, recent data unequivocally identify our genetic endowment as an equally important, if not more important, factor.

The best “experiments of nature” permitting an assessment of the relative influences of nature and nurture are cases of genetically identical twins separated in infancy and raised in different social environments. If nurture is the most important determinant of behavior, they should behave differently. On the other hand, if nature dominates, each will closely resemble the other, despite their never having met. Several hundred pairs of twins separated in infancy, raised in separate environments, and then reunited in adulthood have been rigorously analyzed. Nature has emerged as a key determinant of human behavior.

Laura R and Catherine S were reunited at the age of 35. They were identical twins that had been adopted by two different families in Chicago. Growing up, neither twin was aware of the other's existence. As children each twin had a cat named Lucy, and both habitually cracked their knuckles. Laura and Catherine each began to have migraine headaches beginning at the age of 14. Both were elected valedictorian of their high school classes and majored in journalism in college. Each sister had married a man named John and had given birth to a daughter in wedlock. Both of their marriages fell apart within two years. Each twin maintained a successful rose garden and took morning spin classes at their local fitness center. Upon meeting, each twin discovered that the other had also named her daughter Erin and owned a German Sheppard named Rufus. They had similar voices, hand gestures, and mannerisms.

Jack Y and Oskar S, identical twins born in Trinidad in 1933 and separated in infancy by their parents' divorce, were first reunited at age 46. Oskar was raised by his Catholic mother and grandmother in Nazi-occupied Sudetenland, Czechoslovakia. Jack was raised by his

Orthodox Jewish father in Trinidad and spent time on an Israeli kibbutz. Each wore aviator glasses and a blue sport shirt with shoulder plackets, had a trim mustache, liked sweet liqueurs, stored rubber bands on his wrists, read books and magazines from back to front, dipped buttered toast in his coffee, flushed the toilet before and after using it, enjoyed sneezing loudly in crowded elevators to frighten other passengers, and routinely fell asleep at night while watching television. Each was impatient, squeamish about germs, andregarious.

Bessie and Jessie, identical twins separated at 8 months of age after their mother's death, were first reunited at age 18. Each had had a bout of tuberculosis, and they had similar voices, energy levels, administrative talents, and decision-making styles. Each had had her hair cut short in early adolescence. Jessie had a college-level education, whereas Bessie had had only 4 years of formal education; yet Bessie scored 156 on intelligence quotient testing and Jessie scored 153. Each read avidly, which may have compensated for Bessie's sparse education; she created an environment compatible with her inherited potential.

Neuropsychological Testing Results

A dominant influence of genetics on behavior has been documented in several sets of identical twins on the Minnesota Multiphasic Personality Inventory (MMPI). Twins reared apart generally showed the same degree of genetic influence across the different scales as twins reared together. Two particularly fascinating identical twin pairs, despite being reared on different continents, in countries with different political systems and different languages, generated scores more closely correlated across 13 MMPI scales than the already tight correlation noted among all tested identical twin pairs, most of whom had shared similar rearing.

Reared-apart twin studies report a high correlation ($r = 0.75$) for intelligence quotient (IQ) similarity. In contrast, the IQ correlation for reared-apart nonidentical twin siblings is 0.38, and for sibling pairs in general, is in the 0.45 to 0.50 range. Strikingly, IQ similarities are not influenced by similarities in access to dictionaries, telescopes, and original artwork; in parental education and socioeconomic status; or in characteristic parenting practices. These data overall suggest that tested intelligence is determined roughly two thirds by genes and one third by environment.

Studies of reared-apart identical twins reveal a genetic influence on alcohol use, substance abuse, childhood antisocial behavior, adult antisocial behavior, risk aversion, and visuomotor skills, as well as on psychophysiological reactions to music, voices, sudden noises, and other stimulation, as revealed by brain wave patterns and skin conductance tests. Moreover, reared-apart identical twins show that genetic influence is pervasive, affecting virtually every measured behavioral trait. For example, many individual preferences previously assumed to be due to nurture (e.g., religious interests, social attitudes, vocational interests, job satisfaction, and work values) are strongly determined by nature.

A selected glossary of some terms used in this section and other ethological terms is given in [Table 3.1-1](#).

 **Table 3.1-1**
Selected Glossary of Ethological Terms

Action-specific energy	Energy associated with the innate releasing mechanism and specific to a particular behavior pattern, which builds up if the releasing stimulus is not present to activate the behavior pattern; conversely, it is depleted by repetition.
Aggression	Intraspecific conflict manifested by physical attack or social signaling.
Appetitive behavior	Phase of behavior involving the active seeking of sign stimuli and thought to be driven by action-specific energy accumulating through inactivity of the specific behavior pattern.
Consummatory response	Phase of behavior whereby the energy driving the appetitive phase is released. Involves the perception of sign stimuli, the activation of the innate releasing mechanism (IRM), and the performance of the fixed action pattern (FAP).
Critical period	The time during which imprinting must occur, usually shortly after birth or early in life. Also known as "sensitive period."
Displacement activity	A set of behavior patterns occurring alongside an unrelated set of behavior patterns. Originally, irrelevant movements from one behavioral system occurring in the presence of powerful but thwarted drive from another behavior system.
Ethology	The biological study of behavior. From the Greek <i>ethos</i> , meaning custom, usage, manner, habit. The modern usage is attributed to Oskar Heinroth, Konrad Lorenz's teacher.
Fixed action pattern (FAP)	A genetically determined behavior pattern that is initiated by stimuli particular to the pattern and that consists of species-specific, stereotyped movements.
Imprinting	A specialized form of learning occurring early in life and often influencing behavior later in life. The exposure to the stimulus situation must occur during a particular period, the critical period, and the exposure can be of short duration and without obvious reward. The learning is particularly resistant to change.
Innate	Genetically determined behavior patterns; in theory not influenced by experience.
Innate releasing mechanism (IRM)	Sensory mechanism selectively responsive to specific external stimuli and responsible for triggering the stereotyped motor response.
Instinct	A developmental process resulting in species-typical behavior.
Redirection activity	The venting of one drive from two or more incompatible, but simultaneously activated, drives on some third animal or object.
Ritualization	Process of a behavior pattern being incorporated through evolution into a primary signaling function, frequently with exaggeration and embellishment of some of the movements.

ETHOLOGY

The systematic study of animal behavior is known as ethology. In 1973 the Nobel Prize in psychiatry and medicine was awarded to three ethologists, Karl von Frisch, Konrad Lorenz, and Nikolaas Tinbergen. Those awards highlighted the special relevance of ethology, not only for medicine, but also for psychiatry.

Konrad Lorenz

Born in Austria, Konrad Lorenz (1903–1989) is best known for his studies of imprinting. Imprinting implies that, during a certain short period of development, a young animal is

highly sensitive to a certain stimulus that then, but not at other times, provokes a specific behavior pattern. Lorenz described newly hatched goslings that are programmed to follow a moving object and thereby become imprinted rapidly to follow it and, possibly, similar objects. Typically, the mother is the first moving object the gosling sees, but should it see something else first, the gosling follows it. For instance, a gosling imprinted by Lorenz followed him and refused to follow a goose (Fig. 3.1-1). Imprinting is an important concept for psychiatrists to understand in their effort to link early developmental experiences with later behaviors.

Lorenz also studied the behaviors that function as sign stimuli—that is, social releasers—in communications between individual animals of the same species. Many signals have the character of fixed motor patterns that appear automatically; the reaction of other members of the species to the signals is equally automatic.

FIGURE 3.1-1

In a famous experiment, Konrad Lorenz demonstrated that goslings responded to him as if he were the natural mother. (Reprinted from Hess EH. Imprinting: An effect of an early experience. *Science*. 1959;130:133, with permission.)

Lorenz is also well known for his study of aggression. He wrote about the practical function of aggression, such as territorial defense by fish and birds. Aggression among members of the same species is common, but Lorenz pointed out that in normal conditions, it seldom leads to killing or even to serious injury. Although animals attack one another, a certain balance appears between tendencies to fight and flight, with the tendency to fight being strongest in the center of the territory and the tendency to flight strongest at a distance from the center.

In many works, Lorenz tried to draw conclusions from his ethological studies of animals that could also be applied to human problems. The postulation of a primary need for aggression in humans, cultivated by the pressure for selection of the best territory, is a primary example. Such a need may have served a practical purpose at an early time, when humans lived in small groups that had to defend themselves from other groups. Competition with neighboring groups could become an important factor in selection. Lorenz pointed out, however, that this need has survived the advent of weapons that can be used not merely to kill individuals but to wipe out all humans.

Nikolaas Tinbergen

Born in the Netherlands, Nikolaas Tinbergen (1907–1988), a British zoologist, conducted a series of experiments to analyze various aspects of animal behavior. He was also successful in quantifying behavior and in measuring the power or strength of various stimuli in eliciting specific behavior. Tinbergen described displacement activities, which have been studied mainly in birds. For example, in a conflict situation, when the needs for fight and for flight are of roughly equal strength, birds sometimes do neither. Rather, they display behavior that appears to be irrelevant to the situation (e.g., a herring gull defending its territory can start to pick grass). Displacement activities of this kind vary according to the situation and the species concerned. Humans can engage in displacement activities when under stress.

Lorenz and Tinbergen described innate releasing mechanisms, animals' responses triggered by releasers, which are specific environmental stimuli. Releasers (including shapes, colors, and sounds) evoke sexual, aggressive, or other responses. For example, big eyes in human infants evoke more caretaking behavior than do small eyes.

In his later work, Tinbergen, along with his wife, studied early childhood autistic disorder. They began by observing the behavior of autistic and normal children when they meet strangers, analogous to the techniques used in observing animal behavior. In particular, they observed in animals the conflict that arises between fear and the need for contact and noted that the conflict can lead to behavior similar to that of autistic children. They hypothesized that, in certain predisposed children, fear can greatly predominate and can also be provoked by stimuli that normally have a positive social value for most children. This innovative approach to studying infantile autistic disorder opened up new avenues of inquiry. Although their conclusions about preventive measures and treatment must be considered tentative, their method shows another way in which ethology and clinical psychiatry can relate to each other.

Karl von Frisch

Born in Austria, Karl von Frisch (1886–1982) conducted studies on changes of color in fish and demonstrated that fish could learn to distinguish among several colors and that their sense of color was fairly congruent with that of humans. He later went on to study the color vision and behavior of bees and is most widely known for his analysis of how bees communicate with one another—that is, their language, or what is known as their dances. His description of the exceedingly complex behavior of bees prompted an investigation of communication systems in other animal species, including humans.

Characteristics of Human Communication

Communication is traditionally seen as an interaction in which a minimum of two participants—a sender and a receiver—share the same goal: the exchange of accurate information. Although shared interest in accurate communication remains valid in some domains of animal signaling—notably such well-documented cases as the “dance of the bees,” whereby foragers inform other workers about the location of food

sources—a more selfish and, in the case of social interaction, more accurate model of animal communication has largely replaced this concept.

Sociobiological analyses of communication emphasize that because individuals are genetically distinct, their evolutionary interests are similarly distinct, although admittedly with significant fitness overlap, especially among kin, reciprocators, parents and offspring, and mated pairs. Senders are motivated to convey information that induces the receivers to behave in a manner that enhances the senders' fitness. Receivers, similarly, are interested in responding to communication only insofar as such response enhances their own fitness. One important way to enhance reliability is to make the signal costly; for example, an animal could honestly indicate its physical fitness, freedom from parasites and other pathogens, and possibly its genetic quality as well by growing elaborate and metabolically expensive secondary sexual characteristics such as the oversized tail of a peacock. Human beings, similarly, can signal their wealth by conspicuous consumption. This approach, known as the *handicap principle*, suggests that effective communication may require that the signaler engage in especially costly behavior to ensure success.

SUBHUMAN PRIMATE DEVELOPMENT

An area of animal research that has relevance to human behavior and psychopathology is the longitudinal study of nonhuman primates. Monkeys have been observed from birth to maturity, not only in their natural habitats and laboratory facsimiles but also in laboratory settings that involve various degrees of social deprivation early in life. Social deprivation has been produced through two predominant conditions: social isolation and separation. Socially isolated monkeys are raised in varying degrees of isolation and are not permitted to develop normal attachment bonds. Monkeys separated from their primary caretakers thereby experience disruption of an already developed bond. Social isolation techniques illustrate the effects of an infant's early social environment on subsequent development (Figs. 3.1-2 and 3.1-3), and separation techniques illustrate the effects of loss of a significant attachment figure. The name most associated with isolation and separation studies is Harry Harlow. A summary of Harlow's work is presented in Table 3.1-2.

FIGURE 3.1-2
Social isolate after removal of isolation screen.

FIGURE 3.1-3
Choo-choo phenomenon in peer-only-reared infant rhesus monkeys.

Table 3.1-2
Social Deprivation in Nonhuman Primates

Type of Social Deprivation	Effects
Total isolation (not allowed to develop caretaker or peer bond)	Self-orality, self-clasping, very fearful when placed with peers, unable to copulate. If impregnated, female is unable to nurture young (motherless mothers). If isolation goes beyond 6 months, no recovery is possible.
Mother-only reared	Fails to leave mother and explore. Terrified when finally exposed to peers. Unable to play or to copulate.
Peer-only reared	Engages in self-orality, grasps others in clinging manner, easily frightened, reluctant to explore, timid as adult, play is minimal.
Partial isolation (can see, hear, and smell other monkeys)	Stares vacantly into space, engages in self-mutilation, stereotyped behavior patterns.
Separation (taken from caretaker after bond has developed)	Initial protest stage changing to despair 48 hours after separation; refuses to play. Rapid reattachment when returned to mother.

(Adapted from work of Harry Harlow, M.D.)

In a series of experiments, Harlow separated rhesus monkeys from their mothers during their first weeks of life. During this time, the monkey infant depends on its mother for nourishment and protection, as well as for physical warmth and emotional security—*contact comfort*, as Harlow first termed it in 1958. Harlow substituted a surrogate mother made from wire or cloth for the real mother. The infants preferred the cloth-covered surrogate mother, which provided contact comfort, to the wire-covered surrogate, which provided food but no contact comfort (Fig. 3.1-4).

FIGURE 3.1-4
 Monkey infant with mother (left) and with cloth-covered surrogate (right).

Treatment of Abnormal Behavior

Stephen Suomi demonstrated that monkey isolates can be rehabilitated if they are exposed to monkeys that promote physical contact without threatening the isolates with aggression or overly complex play interactions. These monkeys were called therapist monkeys. To fill such a therapeutic role, Suomi chose young normal monkeys that would play gently with the isolates and approach and cling to them. Within 2 weeks, the isolates were reciprocating the social contact, and their incidence of abnormal self-directed behaviors began to decline significantly. By the end of the 6-month therapy period, the isolates were actively initiating play bouts with both the therapists and each other, and most of their self-directed behaviors had disappeared. The isolates were observed closely for the next 2 years, and their improved behavioral repertoires did not regress over time. The results of this and subsequent monkey-therapist studies underscored the potential reversibility of early cognitive and social deficits at the human level. The studies also served as a model for developing therapeutic treatments for socially retarded and withdrawn children.

Several investigators have argued that social separation manipulations with nonhuman primates provide a compelling basis for animal models of depression and anxiety. Some monkeys react to separations with behavioral and physiological symptoms similar to those seen in depressed human patients; both electroconvulsive therapy (ECT) and tricyclic drugs are effective in reversing the symptoms in monkeys. Not all separations produce depressive reactions in monkeys, just as separation does not always precipitate depression in humans, young and old.

Individual Differences

Recent research has revealed that some rhesus monkey infants consistently display fearfulness and anxiety in situations in which similarly reared peers show normal exploratory behavior and play. These situations generally involve exposure to a novel object or situation. Once the object or situation has become familiar, any behavioral differences between the anxiety-prone, or timid, infants and their outgoing peers disappear, but the individual differences appear to be stable during development. Infant monkeys at 3 to 6 months of age that are at high risk for fearful or anxious reactions tend to remain at high risk for such reactions, at least until adolescence.

Long-term follow-up study of these monkeys has revealed some behavioral differences between fearful and nonfearful female monkeys when they become adults and have their first infants. Fearful female monkeys who grow up in socially benign and stable environments typically become fine mothers, but fearful female monkeys who have reacted with depression to frequent social separations during childhood are at high risk for maternal dysfunction; more than 80 percent of these mothers either neglect or abuse their first offspring. Yet nonfearful female monkeys that encounter the same number of social separations but do not react to any of these separations with depression turn out to be good mothers.

EXPERIMENTAL DISORDERS

Stress Syndromes

Several researchers, including Ivan Petrovich Pavlov in Russia and W. Horsley Gantt and Howard Scott Liddell in the United States, studied the effects of stressful environments on animals, such as dogs and sheep. Pavlov produced a phenomenon in dogs, which he labeled *experimental neurosis*, by the use of a conditioning technique that led to symptoms of extreme and persistent agitation. The technique involved teaching dogs to discriminate between a circle and an ellipse and then progressively diminishing the difference between the two. Gantt used the term *behavior disorders* to describe the reactions he elicited from dogs forced into similar conflictual learning situations. Liddell described the stress response he obtained in sheep, goats, and dogs as *experimental neurasthenia*, which was produced in some cases by merely doubling the number of daily test trials in an unscheduled manner.

Learned Helplessness

The learned helplessness model of depression, developed by Martin Seligman, is a good example of an experimental disorder. Dogs were exposed to electric shocks from which they could not escape. The dogs eventually gave up and made no attempt to escape new shocks. The apparent giving up generalized to other situations, and eventually the dogs always appeared to be helpless and apathetic. Because the cognitive, motivational, and affective deficits displayed by the dogs resembled symptoms common to human depressive disorders, learned helplessness, although controversial, was proposed as an animal model of human depression. In connection with learned helplessness and the expectation of inescapable punishment, research on subjects has revealed brain release of endogenous opiates, destructive effects on the immune system, and elevation of the pain threshold.

A social application of this concept involves schoolchildren who have learned that they fail in school no matter what they do; they view themselves as helpless losers, and this self-concept causes them to stop trying. Teaching them to persist may reverse the process, with excellent results in self-respect and school performance.

Unpredictable Stress

Rats subjected to chronic unpredictable stress (crowding, shocks, irregular feeding, and interrupted sleep time) show decreases in movement and exploratory behavior; this finding illustrates the roles of unpredictability and lack of environmental control in producing stress. These behavioral changes can be reversed by antidepressant medication. Animals under experimental stress (Fig. 3.1-5) become tense, restless, hyperirritable, or inhibited in certain conflict situations.

FIGURE 3.1-5

The monkey on the **left**, known as the executive monkey, controls whether both will receive an electric shock. The decision-making task produces a state of chronic tension. Note the more relaxed attitude of the monkey on the **right**. (From U.S. Army photographs, with permission.)

Dominance

Animals in a dominant position in a hierarchy have certain advantages (e.g., in mating and feeding). Being more dominant than peers is associated with elation, and a fall in position in the hierarchy is associated with depression. When persons lose jobs, are replaced in organizations, or otherwise have their dominance or hierarchical status changed, they can experience depression.

Temperament

Temperament mediated by genetics plays a role in behavior. For example, one group of pointer dogs was bred for fearfulness and a lack of friendliness toward persons, and another group was bred for the opposite characteristics. The phobic dogs were extremely timid and fearful and showed decreased exploratory capacity, increased startle response, and cardiac arrhythmias. Benzodiazepines diminished these fearful, anxious responses. Amphetamines and cocaine aggravated the responses of genetically nervous dogs to a greater extent than they did the responses of the stable dogs.

Brain Stimulation

Pleasurable sensations have been produced in both humans and animals through self-stimulation of certain brain areas, such as the medial forebrain bundle, the septal area, and the lateral hypothalamus. Rats have engaged in repeated self-stimulation (2,000 stimulations per hour) to gain rewards. Catecholamine production increases with self-stimulation of the brain area, and drugs that decrease catecholamines decrease the process. The centers for sexual pleasure and opioid reception are closely related anatomically. Heroin addicts report that the so-called rush after intravenous injection of heroin is akin to an intense sexual orgasm.

Pharmacological Syndromes

With the emergence of biological psychiatry, many researchers have used pharmacological means to produce syndrome analogs in animal subjects. Two classic examples are the reserpine (Serpasil) model of depression and the amphetamine psychosis model of paranoid

schizophrenia. In the depression studies, animals given the norepinephrine-depleting drug reserpine exhibited behavioral abnormalities analogous to those of major depressive disorder in humans. The behavioral abnormalities produced were generally reversed by antidepressant drugs. These studies tended to corroborate the theory that depression in humans is, in part, the result of diminished levels of norepinephrine. Similarly, animals given amphetamines acted in a stereotypical, inappropriately aggressive, and apparently frightened manner that resembled paranoid psychotic symptoms in humans. Both of these models are considered too simplistic in their concepts of cause, but they remain as early paradigms for this type of research.

Studies have also been done on the effects of catecholamine-depleting drugs on monkeys during separation and reunion periods. These studies showed that catecholamine depletion and social separation can interact in a highly synergistic fashion and can yield depressive symptoms in subjects for whom mere separation or low-dose treatment by itself does not suffice to produce depression.

Reserpine has produced severe depression in humans and, as a result, is rarely used as either an antihypertensive (its original indication) or an antipsychotic. Similarly, amphetamine and its congeners (including cocaine) can induce psychotic behavior in persons who use it in overdose or over long periods of time.

SENSORY DEPRIVATION

The history of sensory deprivation and its potentially deleterious effects evolved from instances of aberrant mental behavior in explorers, shipwrecked sailors, and prisoners in solitary confinement. Toward the end of World War II, startling confessions, induced by brainwashing prisoners of war, caused a rise of interest in this psychological phenomenon brought about by the deliberate diminution of sensory input.

To test the hypothesis that an important element in brainwashing is prolonged exposure to sensory isolation, D. O. Hebb and his coworkers brought solitary confinement into the laboratory and demonstrated that volunteer subjects—under conditions of visual, auditory, and tactile deprivation for periods of up to 7 days—reacted with increased suggestibility. Some subjects also showed characteristic symptoms of the sensory deprivation state: anxiety, tension, inability to concentrate or organize thoughts, increased suggestibility, body illusions, somatic complaints, intense subjective emotional distress, and vivid sensory imagery—usually visual and sometimes reaching the proportions of hallucinations with a delusory quality.

Psychological Theories

Anticipating psychological explanation, Sigmund Freud wrote: “It is interesting to speculate what could happen to ego function if the excitations or stimuli from the external world were either drastically diminished or repetitive. Would there be an alteration in the unconscious mental processes and an effect upon the conceptualization of time?”

Indeed, under conditions of sensory deprivation, the abrogation of such ego functions as perceptual contact with reality and logical thinking brings about confusion, irrationality, fantasy formation, hallucinatory activity, and wish-dominated mental reactions. In the sensory-deprivation situation, the subject becomes dependent on the experimenter and must trust the experimenter for the satisfaction of such basic needs as feeding, toileting, and physical safety. A patient undergoing psychoanalysis may be in a kind of sensory deprivation room (e.g., a soundproof room with dim lights and a couch) in which primary-process mental activity is encouraged through free association.

Cognitive. Cognitive theories stress that the organism is an information-processing machine, whose purpose is optimal adaptation to the perceived environment. Lacking sufficient information, the machine cannot form a cognitive map against which current experience is matched. Disorganization and maladaptation then result. To monitor their own behavior and to attain optimal responsiveness, persons must receive continuous feedback; otherwise, they are forced to project outward idiosyncratic themes that have little relation to reality. This situation is similar to that of many psychotic patients.

Physiological Theories

The maintenance of optimal conscious awareness and accurate reality testing depends on a necessary state of alertness. This alert state, in turn, depends on a constant stream of changing stimuli from the external world, mediated through the ascending reticular activating system in the brainstem. In the absence or impairment of such a stream, as occurs in sensory deprivation, alertness drops away, direct contact with the outside world diminishes, and impulses from the inner body and the central nervous system may gain prominence. For example, idioretinal phenomena, inner ear noise, and somatic illusions may take on a hallucinatory character.

3.2 Transcultural Psychiatry

Culture is defined as a set of meanings, norms, beliefs, values, and behavior patterns shared by a group of people. These values include social relationships, language, nonverbal expression of thoughts and emotions, moral and religious beliefs, rituals, technology, and economic beliefs and practices, among other items. Culture has six essential components: (1) Culture is learned; (2) culture can be passed on from one generation to the next; (3) culture involves a set of meanings in which words, behaviors, events, and symbols have meanings agreed upon by the cultural group; (4) culture acts as a template to shape and orient future behaviors and perspectives within and between generations, and to take account of novel situations encountered by the group; (5) culture exists in a constant state of change; and (6) culture includes patterns of both subjective and objective components of human behavior. In addition, culture shapes which and how psychiatric symptoms are expressed; culture influences the meanings that are given to symptoms; and culture affects the interaction between the patient and the health care system, as well as between the patient and the physician and other clinicians with whom the patient and family interact.

Race is a concept, the scientific validity of which is now considered highly questionable, by which human beings are grouped primarily by physiognomy. Its effect on individuals and groups, however, is considerable, due to its reference to physical, biological, and genetic underpinnings, and because of the intensely emotional meanings and responses it generates. *Ethnicity* refers to the subjective sense of belonging to a group of people with a common national or regional origin and shared beliefs, values, and practices, including religion. It is part of every person's identity and self-image.

CULTURAL FORMULATION

Culture plays a role in all aspects of mental health and mental illness; therefore, a cultural assessment should be a component of every complete psychiatric assessment. The outline for cultural formulation found in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) is intended to give clinicians a framework for assessing the role of culture in psychiatric illness. Its purposes are (1) to enhance the application of diagnostic criteria in multicultural environments; (2) cultural conceptualizations of distress; (3) psychosocial stressors and cultural features of vulnerability and resilience; (4) to enable the clinician to systematically describe the patient's cultural and social reference groups and their relevance to clinical care; and (5) to identify the effect that cultural differences may have on the relationship between the patient and family and the treating clinician, as well as how such cultural differences affect the course and the outcome of treatment provided.

The outline for cultural formulation consists of five areas of assessment: (1) cultural identity of the individual; (2) cultural explanations of the individual's illness; (3) cultural factors related to psychosocial environment and levels of functioning; (4) cultural elements of the relationship between the individual and the clinician; and (5) overall cultural assessment for diagnosis and care.

Cultural Identity of the Individual

Cultural identity refers to the characteristics shared by a person's cultural group. Identity allows for a self-definition. Factors that comprise an individual's cultural identity include race, ethnicity, country of origin, language use, religious beliefs, socioeconomic status, migration history, experience of acculturation, and the degree of affiliation with the individual's group of origin. Cultural identity emerges throughout the individual's life and in social context. It is not a fixed trait of an individual or of the group of which the individual is part. An individual may have several cultural reference groups.

The clinician should encourage the patient to describe the component aspects of their cultural identity. Evaluating the cultural identity of the patient allows identification of potential areas of strength and support that may enhance treatment effectiveness, as well as vulnerabilities that may interfere with the progress of treatment. Eliciting this data permits identification of unresolved cultural conflicts that may be addressed during treatment. These conflicts can be between the various aspects of the patient's identity and between traditional and mainstream cultural values and behavioral expectations affecting the individual. Knowledge of the patient's cultural identity allows the clinician to avoid misconceptions based on inadequate background information or stereotypes related to race, ethnicity, and other aspects of cultural identity. In addition, it assists in building rapport because the clinician is attempting to understand the individual as a person and not just a representative of the cultural groups that have shaped the patient's identity.

Cultural Explanations of the Individual's Illness

The explanatory model of illness is the patient's understanding of and attempt to explain why he or she became ill. The explanatory model defines the culturally acceptable means of expression of the symptoms of the illness or *idioms of distress*, the particular way individuals within a specific cultural group report symptoms and their behavioral response to them that are heavily influenced by cultural values. The cultural explanations of illness may also help define the sick role or behavior the patient assumes. The explanatory model of illness includes the patient's beliefs about their prognosis and the treatment options they would consider. The patient's explanatory model may be only vaguely conceptualized or may be quite clearly defined, and it may include several conceptual perspectives that could be in conflict with one another. Formulation of a collaborative model that is acceptable to both the clinician and the patient is the sought-for end point, which would include an agreed upon set of symptoms to be treated and an outline of treatment procedures to be used.

Difficulties may arise when there are conceptual differences in the explanatory model of illness between clinician, patient, family, and community. Conflicts between the patient's and the clinician's explanatory models may lead to diminished rapport or treatment noncompliance. Conflicts between the patient's and the family's explanatory models of illness may result in lack of support from the family and family discord. Conflicts between the patient's and the community's explanatory models could lead to social isolation and stigmatization of the patient.

Examples of the more common explanatory models of illness include the *moral model*, the *religious model*, the *magical or supernatural explanatory model*, the *medical model*, and the *psychosocial stress model*. The *moral model* implies that the patient's illness is caused by a moral defect such as selfishness or moral weakness. The *religious model* suggests that the patient is being punished for a religious failing or transgression. The *magical or supernatural explanatory model* may involve attributions of sorcery or witchcraft as being the cause of the symptoms. The *medical model* attributes the patient's illness primarily to a biological etiology. The *psychosocial model* infers that overwhelming psychosocial stressors cause or are primary contributors to the illness.

Culture has both direct and indirect effects on help-seeking behavior. In many cultural groups an individual and his or her family may minimize symptoms due to stigma associated with seeking assistance for psychiatric disorders. Culture affects the patient's expectations of treatment, such as whether the clinician should assume an authoritarian, paternalistic, egalitarian, or nondirective demeanor in the treatment process.

Cultural Factors Related to Psychosocial Environment and Level of Functioning

An understanding of the patient's family dynamics and cultural values is integral to assessing the patient's psychosocial environment. The definition of what constitutes a family and the roles of individuals in the family differ across cultures. This includes an understanding of the patient's cultural group and its relationship to the mainstream culture or cultures. It includes the patient's life experience of racial and ethnic discrimination. For immigrants and refugees, it includes the individual's and family's perceptions of the openness of the host society toward people of their country and region of origin, their racial, ethnic, religious, and other attributes. The patient and family may identify strongly or weakly with communal sources of support familiar from their country or region of origin, or they may identify along the same gradient with communal sources of support in the host culture.

Cultural Elements of the Relationship Between the Individual and the Clinician

The cultural identity of the clinician and of the mental health team has an impact on patient care. The culture of the mental health care professional influences diagnosis and treatment. Clinicians who have an understanding of their own cultural identity may be better prepared to anticipate the cultural dynamics that may arise in interactions with people of diverse cultural backgrounds. Unacknowledged differences between the clinician's and patient's cultural identity can result in assessment and treatment that is unintentionally biased and stressful for all. Clinicians need to examine their assumptions about other cultures in order to be optimally effective in serving the culturally diverse patient populations that are the norm in most contemporary medical facilities.

Culture influences transference and counter-transference in the clinical relationship between people seeking psychiatric care and their treating clinicians. Transference relationships and dynamics are affected when the patient and clinician have different cultural background characteristics. A perceived social power differential between the patient and clinician could lead to overcompliance, to resistance in exploration of family and social conflict situations, or to the clinician being conceptualized as a cultural role model or stereotype.

Overall Cultural Assessment for Diagnosis and Care

The treatment plan should include the use of culturally appropriate health care and social services. Interventions also may be focused on the family and social levels. In making a psychiatric diagnosis the clinician should take into account principles of cultural relativism and not fall prone to category fallacy. Many psychiatric disorders show cross-cultural variation. Objective evaluation of the multiple possible effects of culture on psychopathology can be a challenging task for the clinician. Diagnostic dilemmas may arise in dealing with patients of diverse cultural backgrounds. Some of these dilemmas may include problems in judging distortion from reality, problems in assessing unfamiliar behaviors, and problems in distinguishing pathological from normal cultural behavior.

MIGRATION, ACCULTURATION, AND ACCULTURATIVE STRESS

From the time of the first major surge of immigration to the United States in the 1870s, and for the next 100 years, the predominant national sentiment toward immigrants, as in most other host countries, was that they should acculturate to the normative behaviors and values of the majority or mainstream culture of the host population. Most immigrants had the same wish to assimilate, to become part of the *melting pot*. This process of acculturative change can be seen as unidirectional, as individuals who identified themselves as part of immigrant, indigenous, and other minority groups both rejected and progressively lost distinctive aspects of their cultural heritage in favor of becoming part of the mainstream majority culture of the host country. In countries that encouraged this outcome of acculturation, people were expected to progress from unacculturated, through the gradient of minimally, moderately, and fully acculturated.

The intensity of acculturative stress experienced by immigrant and other minority groups, and the individuals comprising those groups, has been directly proportional to the openness of the host government and population. The central issue is to what extent are immigrants' and other minority groups' customs, values, and differences from the majority population of the host country accepted, encouraged, and welcomed as an enrichment of the host country, as opposed to being seen as alien and unwelcome. The *acceptance position* encourages the cultural integration of immigrants, whereas the *rejection position* encourages either cultural exclusion or cultural assimilation.

In order to assess the outcome of acculturative stress, for groups and their component individuals, two determining factors need to be considered. The first is the extent to which the group and its members value and wish to preserve their cultural uniqueness, including the language, beliefs, values, and social behaviors that define the group. The second factor is the mirror-image issue of the extent to which the group and its members value and wish to increase their contact and involvement with other groups, particularly the majority culture. This conceptual framework leads to four possible outcomes of acculturative stress that are not conceptualized along the unidirectional gradient from unacculturated to completely acculturated.

The four possible outcomes are *rejection*, *integration*, *assimilation*, and *marginalization*. *Rejection* is characterized by individuals' wishes, both conscious and intuitive, to maintain their cultural integrity, whether by actively resisting the incorporation of the values and social behavior patterns of another cultural group or groups with whom they have regular contact, or by disengaging themselves from contact with and the influence of those other cultural groups. Some religious cults are examples of rejection.

Integration, as an outcome of acculturative stress, derives from the wish to both maintain a firm sense of one's cultural heritage and not abandon those values and behavioral characteristics that define the uniqueness of one's culture of origin. At the same time, such individuals are able to incorporate enough of the value system and norms of behavior of the other cultural group with which they interact closely, to feel and behave like members of that cultural group, principally the majority host culture. Accordingly, the defining feature of integration is psychological: It is the gradual process of formulation of a bicultural identity, a sense of self that intertwines the unique characteristics of two cultures.

Assimilation is the psychological process of the conscious and unconscious giving up of the unique characteristics of one's culture of origin in favor of the more or less complete incorporation of the values and behavioral characteristics of another cultural group, usually, but not always, the majority culture. Examples include involuntary migration, when war and social upheaval necessitate such changes for purposes of survival. However, there are many other life circumstances, including racial, ethnic, and religious discrimination, that motivate people to overlook, suppress, or deny aspects of their cultural heritage in an attempt to have a seamless fit within another group. The price of such an effort, in terms of intrapsychic conflict, can be high.

Marginalization is defined by the psychological characteristics of rejection or the progressive loss of valuation of one's cultural heritage, while at the same time rejecting, or being alienated from, the defining values and behavioral norms of another cultural group, usually that of the majority population. This is the psychological outcome of acculturative stress that is closest to the concept of identity diffusion.

PSYCHIATRIC ASSESSMENT OF IMMIGRANTS AND REFUGEES

Migration History

Mental illness among immigrants and refugees may have been present before migration, may have developed during the immigration process, such as during months or years living in refugee camps, or presented for the first time in the country of immigration. The immigration process and premigration trauma may precipitate the manifestation of underlying symptoms or result in exacerbation of a pre-existing disorder. Obtaining a thorough migration history will assist in understanding background and precipitating stressors and help guide development of an appropriate treatment plan.

The premigration history includes inquiry about the patient's social support network, social and psychological functioning, and significant premigration life events. Information about the country and region of origin, the family history in the country of origin—including an understanding of family members who may have decided not to immigrate—educational and work experiences in the country of origin, and prior socioeconomic status should be obtained. In addition, premigration political issues, trauma, war, and natural disaster faced by the patient and family in the country or region of origin should be explored. For those who had to escape persecution, warfare, or natural disaster, what were the means of escape and what type of trauma was suffered prior to and during migration? Traumatic life events are not limited just to refugees. Immigration may result in losses of social networks, including family and friends; material losses, such as business, career, and property; and loss of the cultural milieu, including their familiar community and religious life. Premigration planning includes reasons for immigrating, duration and extent of planning, premigration aspirations, and beliefs about the host country. The type of migration experience, whether as voluntary immigrants or as unprepared refugees, can have profoundly different effects on migrants' mental health.

The Mental Status Examination

As with any patient, conducting a mental status examination is a central component of the psychiatric examination. However, its interpretation in culturally distinct groups and among immigrant populations requires caution, as it may be culturally biased. The patient's response is molded by his or her culture of origin, educational level, and type of acculturative adaptation. The components of the standardized mental status examination are the following: cooperation, appearance and behavior, speech, affect, thought process, thought content, cognition, insight, and judgment. Cultural differences are wide and varied in dress and grooming. Facial expressions and body movements used in the expression of affect may be more reflective of normal cultural manifestations than pathology. If the clinician is unfamiliar with the individual's culture and the patient's fluency in the language of the host country is limited, the clinician must use caution in interpreting disturbances of speech and thought process, perception, and affect. The presence of hallucinations, for example, can be easily misinterpreted, such as hearing encouraging or clarifying comments from deceased family members, normative experiences in many cultures. The clinician should not assume that the patient understands what the clinician is trying to communicate, and miscommunication

involving use of interpreters is a common problem. The cognitive examination may be particularly tricky. Education and literacy have an important and biasing role. The patient may need adequate time to fully express himself or herself through repeating questions and restating questions in the effort to reduce miscommunication. Asking about the meaning of proverbs unfamiliar to the patient may be an inappropriate means of determining abstract thinking. An accurate mental status examination can be accomplished when one allows additional time for clarification of concepts.

IMMIGRATION ACCULTURATION AND MENTAL HEALTH

Many countries have had difficulty coping with the surging numbers of migrants. This has led to greater restrictions on migrant numbers, partly in response to public sentiment that the social and cultural integrity of the nation has become threatened, even undermined, by waves of migrants from other countries and cultures. During the last 10 years, fears of terrorist violence and civil disruption have led many countries to adopt increasingly restrictive and sometimes punitive policies toward legal and illegal migrants, refugees, and asylum seekers. This trend has been observed in the United States, in some countries of the European Union, and in Australia.

RACIAL AND ETHNIC DIFFERENCES IN PSYCHIATRIC DISORDERS IN THE UNITED STATES

A number of community-based epidemiological studies in the United States have examined the rates of disorders across specific ethnic groups. These studies have found a lower than expected prevalence of psychiatric disorders among disadvantaged racial and ethnic minority groups in the United States. African Americans were found to have lower rates of major depression in the Epidemiological Catchment Area study. The lifetime prevalence rates for major depression for whites was 5.1 percent; for Hispanics, 4.4 percent; and for African Americans, 3.1 percent. African Americans, however, had higher rates for all lifetime disorders combined. This finding of differential rates could be explained by adjusting for socioeconomic status.

The National Comorbidity Study (NCS) found lower lifetime prevalence rates of mental illness among African Americans than whites, and in particular mood, anxiety, and substance use disorders. The lifetime rates for mood disorders were 19.8 percent for whites, 17.9 percent for Hispanic Americans, and 13.7 percent for African Americans. The National Health and Nutrition Examination Survey-III also found lifetime rates of major depression to be significantly higher among whites, 9.6 percent, than African Americans, 6.8 percent, or Mexican Americans, 6.7 percent. Although African Americans had lower lifetime risk of mood disorders than whites, once diagnosed they were more likely to remain persistently ill.

NCS rates for anxiety disorders were 29.1 percent among whites, 28.4 percent for Hispanic Americans, and 24.7 percent for African Americans. The rates for lifetime substance use disorders for the three groups, whites, Hispanic Americans, and African Americans, were 29.5, 22.9, and 13.1 percent, respectively. Hispanic Americans, and in particular Mexican Americans, were found to be at lower risk for substance use and anxiety disorders than whites. In an epidemiological study conducted in Florida, substantially lower rates were observed among African Americans for both depressive disorders and substance use disorders. The lower rate for substance use disorders was also found in the National Epidemiological Survey on Alcohol and Related Conditions, with whites having a prevalence rate of 1-year alcohol use disorders of 8.9 percent, Hispanic Americans, 8.9 percent, African Americans, 6.9 percent, Asian Americans, 4.5 percent, and Native Americans, 12.2 percent. This study also found lower lifetime rates for major depression among Hispanic Americans, 10.9 percent, compared to whites, 17.8 percent. In 2007, the National Survey of American Life compared rates of major depression between Caribbean blacks, African Americans, and whites. Although there were no significant differences in 1-year prevalence between the three groups, lifetime rates were highest among whites, 17.9 percent, followed by Caribbean blacks, 12.9 percent, and African Americans, 10.4 percent. The chronicity of major depressive disorder was higher for both African Americans and Caribbean blacks, approximately 56 percent, while much lower for whites, 38.6 percent. This study was consistent with findings from the NCS that concluded that members of disadvantaged racial and ethnic groups in the United States do not have an increased risk for psychiatric disorders; however, once diagnosed, they do tend to have more persistent disorders.

Although African Americans have a lower prevalence rate for mood, anxiety, and substance use disorders, this may not be the case for schizophrenia. The Child Health and Development Study found that African Americans were about threefold more likely than whites to be diagnosed with schizophrenia. The association may be partly explained by African American families having lower socioeconomic status, a significant risk factor for schizophrenia.

A more detailed examination of differences across racial groups was included in the National Comorbidity Study Replication (NCS-R). Non-Hispanic African Americans and Hispanic Americans were at significantly lower risk than non-Hispanic whites for anxiety disorders and mood disorders. Non-Hispanic African Americans had lower rates of substance use disorders than non-Hispanic whites. More specifically, both minority groups were at lower risk for depression, generalized anxiety disorder, and social phobia. In addition, Hispanic Americans had lower risk for dysthymia, oppositional-defiant disorder, and attention-deficit/hyperactivity disorder. Non-Hispanic African Americans had lower risk for panic disorder, substance use disorders, and early onset impulse-control disorders. The lower rates among Hispanic Americans and African Americans compared to non-Hispanic whites appear to be due to reduced lifetime risk of disorders, as opposed to persistence of chronic disorders. The researchers concluded that the pattern of racial-ethnic differences in risk for psychiatric disorders suggests the presence of protective factors that originate in childhood and have generalized effects, as the lower lifetime risk for both Hispanic Americans and African Americans begins prior to age 10 for depression and anxiety disorders. The retention of ethnic identification and participation in communal, religious, and other activities have been suggested as protective factors that may decrease the lifetime risk for psychiatric disorders in close-knit ethnic minority communities. Cultural differences in response to psychiatric diagnostic survey items may be another possible explanation for these findings. However, disadvantaged ethnic groups usually overreport in studies measuring psychological distress, whereas these studies find lower rates.

DISCRIMINATION, MENTAL HEALTH, AND SERVICE UTILIZATION

Disparities in Mental Health Services

Studies, including recent ones, have shown that racial and ethnic minorities in the United States receive more limited mental health services than whites. Analysis of medical expenditures in the United States has shown that the mental health care system provides comparatively less care to African Americans and Hispanic Americans than to whites, even after controlling for income, education, and availability of health insurance. African Americans have about a 10 percent probability of receiving any mental health expenditure, compared to 20 percent for whites. Hispanic Americans are about 40 percent less likely than whites to receive any mental health expenditure. Total mental health expenditure for Hispanic Americans is about 60 percent less than for whites.

In addition, studies conducted over the last 25 years have shown that regardless of disorder diagnosed, African American psychiatric patients are more likely than white patients to be treated as inpatients, hospitalized involuntarily, placed in seclusion or restraints without evidence of greater degree of violence, and treated with higher doses of antipsychotic medications. These differences are not due to the greater severity of the disorders between white and African American patients. One hypothesis for this discrepancy of treatment between African American and white patients is that whites are more likely to seek out mental health care voluntarily than African Americans, and African Americans are more likely to enter the mental health care system through more coercive and less voluntary referral systems. African Americans are also more likely than whites to use emergency room services, resulting in more crisis-oriented help seeking and service utilization. Once hospitalized in an institution with predominantly white staff, African American patients may receive differential care as a result of discrimination. That is, service personnel who are not familiar with the illness concepts and behavioral norms of nonwhite groups, tend to assess minorities as more severely ill and more dangerous than patients of their own racial or ethnic group; consequently, such patients tend more often than white patients to be hospitalized involuntarily, placed in seclusion or restraints, and treated with higher doses

of antipsychotic medications.

African American patients assessed in psychiatric emergency services are more likely to be diagnosed with schizophrenia and substance abuse than matched white patients. White patients are more often diagnosed with a mood disorder. The cultural distance between the clinician and the patient can affect the degree of psychopathology inferred and the diagnosis given. These differences in diagnosis by race have also been found when comparable research diagnostic instruments have been used for patient assessment. Semistructured diagnostic instruments based on explicit diagnostic criteria do not necessarily eliminate racial disparities in diagnostic outcomes. It appears that the process that clinicians use to link symptom observations to diagnostic constructs may differ, in particular for schizophrenia, between African American and white patients. The pattern of psychotic symptoms that predicts a clinician making a diagnosis of schizophrenia in African American and white patients is different. Among African Americans patients loose associations, inappropriate affect, auditory hallucinations, and vague speech increased the likelihood of a diagnosis of schizophrenia. Positive predictors for white patients were vague speech and loose associations. In addition, auditory hallucinations are more frequently attributed to African American patients.

African Americans are less likely to have had outpatient treatment and longer delays in seeking care, and they present more severely ill. The reason for hospitalization was also different between African Americans and whites. African American patients were more likely to be admitted for some form of behavioral disturbance, whereas white patients were more likely to be admitted for cognitive or affective disturbances. In addition, African Americans were more likely to have police or emergency service involvement, despite no racial differences in violence, suicidality, or substance use when assessed. Furthermore, African American patients are more likely, even after controlling for health insurance status, to be referred to public rather than private in-patient psychiatric facilities, suggesting racial bias in psychiatric emergency room assessment and recommended treatment.

African American patients diagnosed with major depression are less likely to receive antidepressant medications than whites, and less likely to be treated with electroconvulsive therapy. These findings cannot be explained by demographic or socioeconomic differences. One explanation may be that there are conscious or unconscious biases in psychiatrists' treatment decisions. Although both African Americans and Hispanic Americans were less likely to fill an antidepressant prescription when diagnosed with depression, once a prescription was filled, they were just as likely as whites to receive an adequate course of treatment. These findings indicate that initiating care for depression is the biggest hurdle in overcoming these disparities. African American patients have been found to be more likely to be treated with depot rather than oral neuroleptics compared to whites, after controlling for the type and severity of illness. When treated with antipsychotic drugs, African Americans are less likely to receive second-generation antipsychotics than whites, placing them at increased risk for tardive dyskinesia and dystonia. These differences in antipsychotic prescribing patterns may be due to physicians' concern over an increased risk of diabetes among African Americans compared with whites, or may be due to physicians perceiving their symptoms differently. Disparities in mental health care for African Americans and Hispanic Americans have also been noted in studies conducted with adolescents.

A disparity in prescription drug use for mental illness also has been found among Hispanic Americans and Asian Indian Americans. From 1996 to 2000, Asian Indian Americans were found to use prescription drugs 23.6 percent less than whites, whereas the differences between whites and African Americans and between whites and Hispanic Americans were 8.3 and 6.1 percent, respectively. Disparities in mental health service use among Asian American immigrants may be linked to language-based discrimination, although racial bias cannot be excluded. A study of Chinese Americans found a higher level of use of informal services and help seeking from friends and relatives for emotional problems. Those Chinese Americans who reported experiencing language-based discrimination had a more negative attitude toward formal mental health services.

Data on racial and ethnic differences in mental health counseling and psychotherapy are similar to the psychopharmacological studies showing disparities for minorities. A study examining visits to primary care physicians based on the National Ambulatory Medical Care Survey from 1997 to 2000 found that primary care physicians provided similar or higher rates of general health counseling to African American than white patients. However, the rates of mental health counseling were significantly lower for African American patients. The lower rate of mental health counseling among African Americans may be due to decreased reporting of depressive symptoms, inadequate communication between African American patients and their primary care physicians, and decreased willingness to discuss mental health issues. On the other hand, another study utilizing the Medical Expenditure Panel Survey from 2000 found that African Americans were more likely than Hispanic Americans or whites to receive an adequate course of psychotherapy for depression. These findings suggest that initiating treatment is the biggest hurdle, and that once they are engaged in treatment, African Americans have high compliance with psychotherapy.

RESEARCH IN TRANSCULTURAL PSYCHIATRY

There are three perspectives, among other possible approaches, that offer great promise for future research in cultural psychiatry. The first would be based on identification of specific fields in general psychiatry that could be the subject of focused research from a cultural perspective. Topics of epidemiology and neurobiology could be assessed in this way. The former would address issues primarily in the public health arena, including stigmatization, racism, and the process of acculturation. A number of cultural variables should be considered in conducting cultural psychiatry research, including language, religion, traditions, beliefs, ethics, and gender orientation.

The second would aim at the exploration of key concepts and/or instruments in culturally relevant clinical research. There are four key concepts: *idioms of distress*, *social desirability*, *ethnographic data*, and *explanatory models*. *Idioms of distress* are the specific ways in which different cultures or societies report ailments; behavioral responses to threatening or pathogenic factors; and the uniqueness in the style of description, nomenclature, and assessment of stress. *Social desirability* stems from the similarities or differences among cultures vis-à-vis the actual experiencing of stressful events. Members of some cultures may be more or less willing to suffer physical or emotional problems, thus showing different levels of vulnerability or resignation, resilience or acceptance. Issues of stigma in different cultural contexts contribute to this level of desirability or rejection. Third, *ethnographic data* should be included, together with strictly clinical data and laboratory analyses or tests, as well as narratives of life that enrich the descriptive aspects of the condition and expand on the surrounding sociocultural and interpersonal and environmental aspects of the experience. The fourth concept is *explanatory models*. Each culture explains pathology of any kind in its own distinctive way. The explanation includes not only the presumptive original cause, but also the impact of the adduced factors and the interpersonal exchanges and interactions that lead to the culturally accepted clinical diagnosis.

A third approach attempts to combine the first two by examining different areas of research on the basis of the clinical dimensions of cultural psychiatry. This deals with conceptual, operational, and topical issues in the field now and in the future, including their biocultural connections.

Conceptual Issues in Cultural Psychiatry

One of the primary issues in research in cultural psychiatry is the conceptual differentiation between culture and environment. Although generally accepted as the conceptual opposite of genetic, environment represents a very broad, polymorphic concept. It is therefore important to establish that, while perhaps part of that environmental set, culture and cultural factors in health and disease are terms of a different, even unique, nature.

To what extent does culture apply to the clinical realities of psychiatry? Culture plays a role in both normality and psychopathology. The role of culture in psychiatric diagnosis is an excellent example of this conceptual issue. Furthermore, culture has an impact on treatment approaches, based on both conventional medical and psychiatric knowledge, and on the explanatory models. Finally, cultural variables have a role in prognosis and outcome.

A conceptual debate exists between those who advocate an *evidence-based* approach to research and practice, versus those who assign a *value-based* view to everything clinical, more so if influenced by cultural factors. The value-based approach invokes issues such as poverty, unemployment, internal and external migration, and natural and manmade disasters. Evidence may be found to support both positions in scientific research.

Operational Issues in Cultural Psychiatry

The dichotomy of normality and abnormality in human behavior is a crucial operational issue. Culture plays a definitive role in shaping these approaches. This raises the notion of relativism, a strong conceptual pillar in cultural psychiatry. Normality is a relative idea; that is, it varies in different cultural contexts.

Another operational issue is that of the choice of cultural variables. Each one has a specific weight and impact on the occurrence of symptoms, syndromes, or clinical entities in psychiatry. Some of them may be essential in the assessment of a clinical topic, namely, language, education, religion, and gender orientation. An additional operational factor is the description, assessment, and testing of the strengths and weaknesses of an individual patient. Aspects of an individual's behavior, attitudes, disposition, sociability, occupational skills, and other factors are culturally determined.

Culture plays a significant role in the perception of severity of symptoms, the disruption of the individual's functionality, and quality of life. The assessment of severity is also the result of the meaning attributed to causal or pathogenic factors of psychopathology. Judgments about level of dysfunction and the quality of a patient's life involve elusive concepts such as happiness, well-being, and peace of mind.

Research on cultural psychiatry issues needs to take into account representativeness of the study populations and generalizability of the findings. Methodological rigor needs to be applied to the collection of demographic data, delineation of and differentiation between ethnic groups or subgroups, and measurement of demographic variables, symptoms, diagnosis, and culturally specific constructs.

Many tests and questionnaires used in clinical settings and research have been developed on English-speaking Western subjects and may not be appropriate for use among ethnic minority patients or non-English-speaking individuals due to lack of cultural equivalence. Translating items is insufficient to achieve linguistic equivalence, as the meaning and connotation changes and idioms of expression differ between languages. In addition, norms also may differ between ethnic groups, and tests need to be standardized with representative patients.

The complexity of translating an instrument varies depending on how much the construct being measured differs between the two cultures. There are four different approaches to translation. An ethnocentric approach is one in which the researcher assumes that the concepts completely overlap in the two cultures. The instrument is used with individuals who differ from the population in which the instrument was originally developed and normed. The pragmatic approach assumes that there is some overlap between the two cultures and attempts are made to measure the overlapping aspects of the construct, *emic* aspects. An *emic plus etic* approach goes one step further and also attempts to measure culture-specific aspects of the construct. Lastly, sometimes translation is not possible when the concepts do not overlap at all within the two cultures.

3.3 Culture-Bound Syndromes

Cross-cultural mental health professionals have introduced a number of terms to refer to and describe culture-specific forms of expressing and diagnosing emotional distress. The term *culture bound* was used in the past to describe patterned behaviors of distress or illness whose phenomenology appeared distinct from psychiatric categories and were considered unique to particular cultural settings. The clear implication was that Western psychiatric categories were not culture bound, but rather universal, and that proper characterization would disclose a simple translation key for non-Western syndromes. The dichotomy between syndromes that are “culture free,” emerging from Euro-American and European societies, and those that are “culture bound,” emerging from everywhere else, is of course patently false. Culture suffuses all forms of psychological distress, the familiar as well as the unfamiliar.

CULTURE-BOUND SYNDROMES AND THEIR RELATIONSHIP TO PSYCHIATRIC DIAGNOSES

Only a few of the many cultural forms of expressing distress have received sustained research attention with integration of cultural and psychiatric research methods. This chapter focuses on some of those syndromes from diverse cultural regions, which have received the most intensive research and have been shown to be associated with psychiatric categories: *Amok*, *ataques de nervios*, possession syndrome, and *shenjing shuairuo*.

Amok

Amok is a dissociative episode that is characterized by a period of depression followed by an outburst of violent, aggressive, or homicidal behavior. Episodes tend to be caused by a perceived insult and are often accompanied by persecutory ideas, automation, amnesia, and exhaustion. Patients return to premorbid states following the episode. *Amok* seems to be prevalent only among males. The term originated in Malaysia, but similar behavior patterns can be found in Laos, Philippines, Polynesia (*cafard* or *cathard*), Papua New Guinea, and Puerto Rico (*mal de peleá*), and among the Navajo (*iich'aa*).

Phenomenology. A prototypical episode is composed of the following elements:

1. Exposure to a stressful stimulus or subacute conflict, eliciting in the subject feelings of anger, loss, shame, and lowered self-esteem. The stressor usually appears minor in proportion to the resulting behavior (e.g., argument with a coworker, verbal insult), but may

- occasionally be severe (i.e., death of a loved one).
2. A period of social withdrawal and brooding over the precipitating conflict, often involving aimless wandering, and sometimes accompanied by visual perceptual alterations.
 3. Transition, usually sudden, to frenzied and extremely violent homicidality, with or without a brief prodromal stage of preparation (e.g., subject may locate preferred weapon or reach suddenly for whatever implement is available).
 4. Indiscriminate selection of victims who may or may not symbolically represent the original actors in the conflict (e.g., subject attacks only Chinese people who are strangers to him, after a conflict with a Chinese coworker). Occasionally, the subject also attacks animals or objects in his path, or wounds himself, sometimes severely. The subject perseveres at these violent activities despite external attempts to bring him under control.
 5. Verbalizations, when present, may be frenzied and guttural, or express internal conflict (e.g., ask forgiveness of a relative before killing him) or split consciousness (e.g., subject admits to a positive relationship with the victim, but denies this for his “spear”).
 6. Cessation may be spontaneous, but usually results from being overpowered or killed. It is typically abrupt and leads to change in consciousness, usually stupor or sleep.
 7. Subsequent partial or total amnesia and report of “unconsciousness” or description of “darkened vision” (*mata gelap*) during the acute episode.
 8. Perceptual disturbances or affective decompensations may occur for days or weeks after the acute attack. Psychosis or depression sometimes ensues.

Epidemiology. Epidemiological rates of *amok* in Malaysia and Indonesia are unknown and may vary regionally and over time. From the available data, *amok* appears to follow an endemic pattern in Malayo-Indonesia with some epidemic increases, the reverse of which has been found for *amok*-like attacks in Laos.

Amok is essentially unknown in women (only one case was found in the literature, and it was considered atypical in that no deaths occurred). It is thought to occur more frequently in men of Malay extraction, Muslim religion, low education, and rural origin, who are between the ages of 20 and 45 years.

Precipitants. Precipitants of *amok* in Malaysia and Indonesia typically consisted of experiences eliciting in the subject marked feelings of loss, shame, anger, or lowered self-esteem. Although specific triggers were very diverse in nature and presentation, including sudden and gradual stressors, most consisted of interpersonal or social conflicts superficially appearing to generate only mild to moderate stress. These include arguments with coworkers, nonspecific family tensions, feelings of social humiliation, bouts of possessive jealousy, gambling debts, and job loss. Rarely, however, *amok* was precipitated by a severe stressor, such as the simultaneous death of the spouse and child of the subject.

Additional Clinical Features. It is unclear whether *amok* episodes are associated with indirect suicidal intent on the part of the subject. Anecdotes and cultural views supporting a connection are available, but interviews with surviving subjects have tended to refute the association.

Rates of relapse are unknown. It is considered very likely in the popular view, leading currently in Malaysia to permanent psychiatric hospitalization of surviving subjects, and, in the past, to banishment or execution.

Treatment. Afflicted individuals in 20th-century Malaysia have been exempted from legal or moral responsibility for acts committed while in a state of *amok* by means of a kind of “insanity defense,” which characterizes the attack as “unconscious” and beyond the subject’s control. They were subsequently hospitalized, sometimes permanently, and frequently received diagnoses of schizophrenia and were treated with antipsychotic medication. Alternatively, trials have sometimes resulted in criminal verdicts and prolonged imprisonment.

Ataque de Nervios

Ataque de nervios is an idiom of distress principally reported among Latinos from the Caribbean, but recognized among many Latin American and Latin Mediterranean groups. Commonly reported symptoms include uncontrollable shouting, attacks of crying, trembling, heat in the chest rising into the head, and verbal or physical aggression. Dissociative experiences, seizure-like or fainting episodes, and suicidal gestures are prominent in some attacks but absent in others. A general feature of an *ataque de nervios* is a sense of being out of control. *Ataques de nervios* frequently occur as a direct result of a stressful event relating to the family (e.g., news of a death of a close relative, a separation or divorce from a spouse, conflicts with a spouse or children, or witnessing an accident involving a family member). People may experience amnesia for what occurred during the *ataque de nervios*, but they otherwise return rapidly to their usual level of functioning.

Ataque de nervios (attack of nerves, in Spanish) is a syndrome indigenous to various Latin American cultures, notably those of the Hispanic Caribbean (Puerto Rico, Cuba, and the Dominican Republic). It has received considerable attention in the psychiatric and anthropological literature since the mid-1950s, mostly in Puerto Rican communities on the island and in populations within the United States.

Phenomenology. An *ataque de nervios* can be described as prototypically composed of the following elements:

1. Exposure to a frequently sudden, stressful stimulus, typically eliciting feelings of fear, grief, or anger, and involving a person close to the subject, such as a spouse, child, family member, or friend. Severity of the trigger ranges from mild-moderate (i.e., marital argument, disclosure of migration plans) to extreme (i.e., physical or sexual abuse, acute bereavement).
2. Initiation of the episode is immediate upon exposure to the stimulus, or after a period of brooding or emotional “shock.”
3. Once the acute attack begins, rapid evolution of an intense affective storm follows, characterized by a primary affect usually congruent with the stimulus (such as anger, fear, grief) and a sense of loss of control (*emotional expressions*).
4. These are accompanied by all or some of the following:
 - A. *bodily sensations*: Trembling, chest tightness, headache, difficulty breathing, heart palpitations, heat in the chest, paresthesias of diverse location, difficulty moving limbs, faintness, blurred vision, or dizziness (*mareos*).
 - B. Behaviors (*action dimension*): Shouting, crying, swearing, moaning, breaking objects, striking out at others or at self, attempting to harm self with nearest implement, falling to the ground, shaking with convulsive movements, or lying “as if dead.”
5. Cessation may be abrupt or gradual, but it is usually rapid, and often results from the ministrations of others, involving expressions of concern, prayers, or use of rubbing alcohol (*alcoholado*). There is return of ordinary consciousness and reported exhaustion.
6. The attack is frequently followed by partial or total amnesia for the events of the episode, and descriptions such as the following for the acute attack: Loss of consciousness, depersonalization, mind going blank, and/or general unawareness of surroundings (*alterations in consciousness*). However, some *ataques* appear to exhibit no alterations in consciousness.

Epidemiology. Risk factors for *ataque de nervios* span a range of social and demographic characteristics. The strongest predictors of *ataque* are female gender, lower formal education, and disrupted marital status (i.e., divorced, widowed, or separated). *Ataque* sufferers also

reported less satisfaction in their social interactions generally and specifically with their spouses. In addition, people who experienced an *ataque de nervios* were more likely to describe their health as only fair or poor, to seek help for an emotional problem, and to take medications for this purpose. Persons with *ataque* also reported deriving less satisfaction from leisure time activities and feeling overwhelmed more often.

Precipitants. Prototypically, *ataque de nervios* was linked by sufferers to an acute precipitating event or to the summation of many life episodes of suffering brought to a head by a trigger that overwhelmed the person's coping ability. In 92 percent of cases, the *ataque* was directly provoked by a distressing situation, and 73 percent of the time it began within minutes or hours of the event. A majority of first *ataques* (81 percent) occurred in the presence of others, as opposed to when the sufferer was alone, and led to a the person receiving help (67 percent). Unlike the typical experience of persons with panic disorder, most patients reported feeling better (71 percent) or feeling relieved (81 percent) after their first *ataque*. The first episodes of *ataque de nervios* are closely tied to the interpersonal world of the sufferer and they result in an unburdening (*desahogarse*) of one's life problems, at least temporarily.

Additional Clinical Features. The association between *ataque de nervios* and a sense of loss of control and of being overwhelmed highlight the importance of the association between the cultural syndrome and other behaviors associated with acute emotional dysregulation. Most concerning among these is the strong relationship between *ataques* and suicidal ideation and attempts. Other related behaviors include loss of aggression control, expressed as attacks on people or property, and dissociative experiences, both of which are related to the acute *ataque* experience.

Specific Cultural Factors. The complex relationship between *ataque de nervios* and psychiatric diagnosis may be clarified in reference to its broader popular nosology. In the Hispanic Caribbean and other areas of Latin America, *ataque* is part of a popular nosology of *nervios* (nerves), composed of other related categories. Experiences of adversity are linked in this nosology to ensuing "alterations" of the nervous system, which result in its impaired functioning, including the peripheral nerves. This quasi-anatomical damage is evidenced in emotional symptoms, including interpersonal susceptibility, anxiety, and irritability, as well as in physically mediated symptoms, such as trembling, palpitations, and decreased concentration.

Treatment. No treatment studies of *ataque de nervios* have ever been conducted. Typical treatment involves, first, ensuring the safety of the person and those around him or her, given the association between *ataque*, suicidality, and uncontrolled aggressivity. "Talking the person down" is usually helpful, accompanied by expressions of support from relatives and other loved ones; the use of rubbing alcohol (*alcoholado*) to help calm the person is a culturally prescribed way of expressing this support.

"Telling the story" of what led to the *ataque* usually constitutes the principal therapeutic approach in subsequent stages of treatment. Because one of the main functions of the attack is to communicate a feeling of being overwhelmed, indicating receipt of the message and the desire to offer support are usually perceived as therapeutic. The person should be allowed to set the pace of disclosure and to give enough details and circumstances to feel "unburdened" (*desahogado[a]*).

In the case of single or occasional *ataques* in the absence of a psychiatric diagnosis, brief follow-up is usually sufficient. This may be discussed with the patient and the family as a way of ensuring a full return to the previous healthy state. For recurrent *ataques*, treatment depends on the associated psychopathology, the nature of the precipitants (including traumatic exposure), the degree of family conflict or support, the social context, the previous treatment experiences, and the patient's and family's expectations, among other factors.

Psychotherapy is typically the mainstay of treatment, given the usual source of the overwhelmed behavior in the interpersonal milieu. Pharmacotherapy may also be useful in the treatment of *ataque*-related psychopathology; primary emphasis should be placed on treating the underlying disorder. Given the slow crescendo of many *ataques*, judicious use of short-acting benzodiazepines also has a role in helping abort an impending episode. However, this should not be the main form of treatment for recurrent *ataques*, since it only forestalls the principal function of the syndrome as a mode of communication. Instead, psychotherapy and a social activism stance by the therapist that acknowledges the origins of adversity among low-income Latinos in socioeconomic disenfranchisement and ethnic/racial discrimination are usually required to address the interpersonal and sociocultural roots of *ataque de nervios*.

Possession Syndrome

Involuntary possession trance states are very common presentations of emotional distress around the world. Cognate experiences have been reported in extremely diverse cultural settings, including India, Sri Lanka, Hong Kong, China, Japan, Malaysia, Niger, Uganda, Southern Africa, Haiti, Puerto Rico, and Brazil, among others. *Possession syndrome* is an umbrella English-language term used to describe South Asian presentations of involuntary possession trance that encompasses multiple names in regional languages and dialects of India and Sri Lanka. These presentations are seen as a form of illness by the person's cultural group because they are involuntary, they cause distress, and they do not occur as a normal part of a collective cultural or religious ritual or performance.

Phenomenology. It is important to distinguish at the outset between possession syndrome, as an instance of possession trance, and the broader category of possession. The latter refers to a general ideology describing the full range of direct spirit influences on human affairs including effects on physical, psychological, spiritual, social, and ecological realms. By contrast, as a subset of general possession experience, possession trance refers to specific alterations in consciousness, memory, behavior, and identity attributed to direct spirit influence. In addition to pathological possession trance states, South Asian cultures authorize multiple examples of normal possession and possession trance. When voluntary and normative, these states are typically seen as instances of religious devotion, mystical ecstasy, social commentary, asceticism, interpersonal relations, existential reflection, and the study of consciousness. This chapter discusses possession syndrome as a pathological entity with an established phenomenology, that is, as a special case in the general continuum of etiological ideas regarding possession illnesses. A prototypical episode is composed of the following elements:

1. Onset occurs typically due to subacute conflict or stress and shows considerable variation. It may be gradual and nonspecific (e.g., diverse somatic complaints, such as dizziness, headaches, abdominal discomfort, hot-cold flashes, listlessness, or difficulty breathing) or sudden and specific, in the form of an abrupt transition to an altered state of consciousness.
2. Behavior during the altered state consists of some or all of the following:
 - A. Dramatic, semi-purposeful movements, such as head bobbing, bodily shaking, thrashing, gyrating, or falling to the ground, accompanied by guttural, incoherent verbalizations, such as mumbling, moaning, or shrieking.
 - B. Aggressive or violent actions directed at self or at others, including spitting, striking, and impulsive suicidal or homicidal gestures. Verbalizations may be coherent and consist of derogatory comments or threats of violence directed against significant others or against the subject (in the third person) and typically considered by observers to be uncharacteristic of the subject's usual behavior.
 - C. Specific gestures, comments or requests denoting the appearance of a known possessing personality by (1) reference to standard attributes of culturally recognizable figures or (2) the name and degree of relation of deceased family members or acquaintances.
3. In all cases, this state is marked by the emergence of one or several secondary personalities distinct from that of the subject. Their specific identities, which may remain undisclosed for some time, adhere to cultural norms regulating permissible agents of possession, which vary by religion, region, and caste. Acceptable agents include spirits of deceased family members, in-law relations, or known village

acquaintances who died under specific conditions of distress, and minor supernatural figures of the Hindu pantheon (rarely major deities) and the Islamic spiritual world.

4. Possession by the secondary personality(ies) is episodic, resulting in alternation between the usual personality of the subject and the altered state. The subject in his or her usual identity appears in a daze, exhausted, distressed, or confused about the situation and may report visual or auditory perceptual disturbances regarding the possessing agent, as well as “unconsciousness” and partial or total amnesia for the altered state.
5. Frequently, the specific identities of possessing personalities remain undisclosed for some time, requiring the active ministrations of family members and the intervention of specialized indigenous practitioners. The process of disclosure is conceived as a struggle between the family members and the beneficent agents possessing the healer on the one side, and the troublesome possessing personalities on the other. It is characterized by remarkable reactivity on the part of the subject to environmental cues, including direct questioning, strategic neglect, and aggressive manipulation.
6. Outcome is variable. Total recovery is often reported at the cessation of a single acute episode, which may be of several weeks’ duration. Alternatively, prolonged morbidity may result, or even, rarely, death.

Data on the epidemiology, precipitants, and associated psychopathology of subjects with possession syndrome in South Asia is limited by methodological considerations. These include lack of representative community samples and nonsystematic definitions of the syndrome, which shows considerable regional variation.

Epidemiology. Possession syndrome is more common in women, with a female-to-male ratio of approximately 3 to 1 in both community and psychiatric cohorts. Age of onset is usually between 15 and 35 years, but many cases reportedly begin in childhood. Attacks may persist well into middle age, and geriatric cases have also been reported.

Precipitants. Precipitants of possession syndrome are varied but typically consist of marked social or family conflicts, or stressful life transitions, of subacute duration, eliciting strong feelings of vulnerability in persons without firm emotional support. Examples encountered in the literature included marital conflict, abuse, and neglect, at times associated with alcoholism; arrival of a new bride to the home of her husband’s family; delay in arranging marriage, or in consummating it; forced marriage; widowhood; postpartum status; loss of family social standing; death of a family member; difficulty finding employment and financial difficulties; alienation from family support; and subordination to other family members and in-laws.

Specific Cultural Factors. Possession syndrome constitutes a normative cultural category throughout India and Sri Lanka. It may present initially in a variety of forms, linked by the attribution of spirit etiology. When it presents in a nonspecific fashion, indigenous diagnosis is confirmed by the appearance of the altered state during the therapeutic ritual. It is considered an affliction by its painful, involuntary nature and attributed to the intervention of specific spiritual agencies acting independently or at the behest of a witch. Certain castes and persons in transitional states (e.g., puerperium) are considered most vulnerable to spirit attack, especially when deprived of emotional and material support.

Treatment. Specialized indigenous practitioners and ritual therapies are generally available and widely utilized, but psychiatric treatment is typically avoided. Indigenous treatments include neutralization of the conflict or stress via the communal rituals involved in exorcism, as well as the reformulation of the suffering into beneficent individual and communal practice via initiation into a spirit devotion cult, such as the Siri cult of South India, or education into the roles of oracle (diviner), exorcist, or, rarely, avatar (divine incarnation).

Shenjing Shuairuo

Shenjing shuairuo (“weakness of the nervous system” in Mandarin Chinese) is a translation and cultural adaptation of the term “neurasthenia,” which was transmitted into China from the West and from Japan in the 1920s and 1930s. Revived in its modern form by the American neurologist George Beard since 1868, his formulation of neurasthenia (Greek for “lack of nerve strength”) originally denoted a heterogeneous syndrome of lassitude, pain, poor concentration, headache, irritability, dizziness, insomnia, and over 50 other symptoms. It was considered at first an “American disease,” resulting from the “pressures” of a rapidly modernizing society, but was later adopted by European diagnosticians. Its pathophysiology was thought to derive from a lowering of nervous system function on a physical rather than emotional basis, due to excessive demand on its use, especially among the educated and wealthier classes. In Soviet psychiatry, buttressed by Pavlovian research, it was a central component of mental health nosology, which became especially influential in Chinese psychiatry after the communist revolution of 1949.

Although neurasthenia declined in importance in Western classification systems during the 20th century, *Shenjing shuairuo* underwent marked popular and professional development in mainland China, Taiwan, Hong Kong, in Chinese migrant communities, and in Japan, where a similar syndrome is labeled *shinkei suiijaku*. From a peak in about 1980, when it may have constituted up to 80 percent of all “neurotic” diagnoses in Chinese societies, *Shenjing shuairuo* has undergone intense psychiatric and anthropological re-examination. Currently, it features prominently in the second edition revised *Chinese Classification of Mental Disorders* (CCMD-2-R), under the section on “other neuroses.” The CCMD-2-R diagnosis requires three symptoms out of five nonhierarchical symptom clusters, organized as weakness, emotional, excitement, and nervous symptoms, as well as a fifth category of sleep disturbances. Like other neurotic disorders in the Chinese manual, the condition must last at least 3 months, and should (1) lower the efficiency of work, study, or social function; (2) cause mental distress; or (3) precipitate treatment seeking.

Phenomenology. Given the evolution of diagnostic practice regarding *shenjing shuairuo* in Chinese societies over the last decades, which may be labeled the professional approximation of the condition, or its “disease” aspect, phenomenological description in this chapter is based instead on clinical histories of self-identified sufferers, or the “illness” aspect of the syndrome. The following elements are prototypical:

1. Onset is usually gradual, sometimes spanning several years, and typically emerges out of a conflictive, frustrating, or worrying situation that involves work, family, and other social settings, or their combination. A sense of powerlessness in changing the precipitating situation appears central to most illness accounts of the syndrome.
2. Symptoms show substantial individual variation, but usually involve at least some of the following spontaneous complaints: Insomnia, affective dysphoria, headache, bodily pains and distortions (e.g., “swelling” of the head), dizziness, difficulty concentrating, tension and anxiety, worry, fatigue, weakness, gastrointestinal problems, and “troubled vexation” (*fan nao*). This last emotion has been described as a form of irritability mixed with worry and distress over “conflicting thoughts and unfulfilled desires,” that may be partially concealed for the sake of preserving social harmony.
3. The sufferer frequently seeks the sick role, attributing his or her difficulties in meeting work, school, or other social expectations to the syndrome. Sources of treatment vary substantially across Chinese communities, depending on the availability of formal and traditional service sectors.
4. Course is variable and may respond closely to changing interpersonal and social circumstances. Amelioration of the precipitating

stressor(s) typically brings about substantial improvement, although residual symptoms appear common.
5. Response to treatment may be strongly mediated by the illness role and its relationship to the intractability of precipitating stressors.

Precipitants. Empirical assessment of the precipitants of *shenjing shuairuo* has found high rates of work-related stressors, which were made more intractable by the centrally directed nature of mainland Chinese society. These included unwelcome work assignments, job postings that caused family separations, harsh criticism at work, excessive workloads, monotonous tasks, and feelings of inadequacy or incompatibility of skills and responsibilities. Students usually described less severe study-related precipitants, particularly school failure or anxiety over the mismatch between personal or family aspirations and performance. Other interpersonal and family-related stressors included romantic disappointments, marital conflict, and the death of a spouse or other relative. Chinese etiological understandings of the syndrome commonly invert the Western view of “psychosomatic” presentations, whereby social-interpersonal precipitants cause psychological distress that is displaced onto bodily experience.

Additional Clinical Features. Clinical course of the syndrome may depend on the associated psychiatric comorbidity and on the degree of persistence of the precipitating stressors. One longitudinal study found complete resolution of *shenjing shuairuo* symptoms and good social adjustment 20 years from the index diagnosis in 83 of 89 cases. Only one case was receiving continued treatment, and no subjects reported the onset of depressive disorder subsequent to the *shenjing shuairuo* diagnosis.

Chinese psychiatrists have carried out numerous studies of neurophysiological and cognitive function in *shenjing shuairuo* patients since the 1950s. Most have reported abnormalities compared to normal controls, including in tests of polysomnography, electroencephalography, psychogalvanic reflexes, gastric function, and memory function. These findings need to be replicated with well-controlled samples using contemporary diagnostic instruments.

Specific Cultural Factors. The evolving definitions of *shenjing shuairuo* have emerged from a tradition of syncretism in Chinese medicine between indigenous illness understandings and international contributions. Nineteenth-century Western notions of a weakened nervous system due to overuse (neurasthenia) found an ancient cognate expression in Chinese concepts of bodily meridians or channels (*jing*) binding vital organs in balanced networks along which forces (e.g., *qi*, vital energy, in *yin* and *yang* forms) could be disrupted from their normal harmonious flow. This gave rise to *shenjing shuairuo*, an illness whereby the *jing* that carry *shen*—spirit or vitality, the capacity of the mind to form ideas and the desire of the personality to live life—have become *shuai* (degenerate) and *ruo* (weak) following undue nervous excitement.

Treatment. When accessing formal sectors of care, most patients used both Western-trained physicians and traditional Chinese doctors. Nonpsychiatric medical settings were preferred, including neurology and general medicine clinics, in concert with cultural understandings of the somatopsychic etiology of *shenjing shuairuo*, which emphasize its physical mediation. The modality of treatment was usually traditional Chinese medicines, which were prescribed by both Western-trained and Chinese-style doctors. This conformed to the balanced status still ascribed to both types of training among Chinese physicians. Polypharmacy was common, combining sedatives, traditional herbs, antianxiety agents, vitamins, and other tonics. Despite active suppression of religious healing in China, almost a quarter of patients were also engaged in such treatment.

Theories of Personality and Psychopathology

4.1 Sigmund Freud: Founder of Classic Psychoanalysis

Psychoanalysis was the child of Sigmund Freud's genius. He put his stamp on it from the very beginning, and it can be fairly stated that, although the science and theory of psychoanalysis has advanced far beyond Freud, his influence is still strong and pervasive. In recounting the progressive stages in the evolution of the origins of Freud's psychoanalytic thinking, it is useful to keep in mind that Freud himself was working against the background of his own neurological training and expertise and in the context of the scientific thinking of his era.

The science of psychoanalysis is the bedrock of psychodynamic understanding and forms the fundamental theoretical frame of reference for a variety of forms of therapeutic intervention, embracing not only psychoanalysis itself but various forms of psychoanalytically oriented psychotherapy and related forms of therapy employing psychodynamic concepts. Currently considerable interest has been generated in efforts to connect psychoanalytic understandings of human behavior and emotional experience with emerging findings of neuroscientific research. Consequently, an informed and clear understanding of the fundamental facets of psychoanalytic theory and orientation are essential for the student's grasp of a large and significant segment of current psychiatric thinking.

At the same time, psychoanalysis is undergoing a creative ferment in which classical perspectives are constantly being challenged and revised, leading to a diversity of emphases and viewpoints, all of which can be regarded as representing aspects of psychoanalytic thinking. This has given rise to the question as to whether psychoanalysis is one theory or more than one. The divergence of multiple theoretical variants raises the question of the degree to which newer perspectives can be reconciled to classical perspectives.

The spirit of creative modifications in theory was inaugurated by Freud himself. Some of the theoretical modifications of the classic theory after Freud have attempted to reformulate basic analytic propositions while still retaining the spirit and fundamental insights of a Freudian perspective; others have challenged and abandoned basic analytic insights in favor of divergent paradigms that seem radically different and even contradictory to basic analytic principles.

Although there is more than one way to approach the diversity of such material, the decision has been made to organize this material along roughly historical lines, tracing the emergence of analytic theory or theories over time, but with a good deal of overlap and some redundancy. But there is an overall pattern of gradual emergence, progressing from early drive theory to structural theory to ego psychology to object relations, and on to self psychology, intersubjectivism, and relational approaches.

Psychoanalysis today is recognized as having three crucial aspects: it is a therapeutic technique, a body of scientific and theoretical knowledge, and a method of investigation. This section focuses on psychoanalysis as both a theory and a treatment, but the basic tenets elaborated here have wide applications to nonpsychoanalytic settings in clinical psychiatry.

LIFE OF FREUD

Sigmund Freud (1856–1939) was born in Freiberg, a small town in Moravia, which is now part of the Czech Republic. When Freud was 4 years old, his father, a Jewish wool merchant, moved the family to Vienna, where Freud spent most of his life. Following medical school, he specialized in neurology and studied for a year in Paris with Jean-Martin Charcot. He was also influenced by Ambroise-Auguste Liébeault and Hippolyte-Marie Bernheim, both of whom taught him hypnosis while he was in France. After his education in France, he returned to Vienna and began clinical work with hysterical patients. Between 1887 and 1897, his work with these patients led him to develop psychoanalysis. [Figures 4.1-1](#) and [4.1-2](#) show Freud at age 47 and 79, respectively.

BEGINNINGS OF PSYCHOANALYSIS

In the decade from 1887 to 1897, Freud immersed himself in the serious study of the disturbances in his hysterical patients, resulting in discoveries that contributed to the beginnings of psychoanalysis. These slender beginnings had a threefold aspect: Emergence of psychoanalysis as a method of investigation, as a therapeutic technique, and as a body of scientific knowledge based on an increasing fund of information and basic theoretical propositions. These early researches flowed out of Freud's initial collaboration with Joseph Breuer and then, increasingly, from his own independent investigations and theoretical developments.

THE CASE OF ANNA O

Breuer was an older physician, a distinguished and well-established medical practitioner in the Viennese community (Fig. 4.1-3). Knowing Freud's interests in hysterical pathology, Breuer told him about the unusual case of a woman he had treated for approximately 1.5 years, from December 1880 to June 1882. This woman became famous under the pseudonym *Fräulein Anna O*, and study of her difficulties proved to be one of the important stimuli in the development of psychoanalysis.

FIGURE 4.1-3
Joseph Breuer (1842–1925).

Anna O was, in reality, Bertha Pappenheim, who later became independently famous as a founder of the social work movement in Germany. At the time she began to see Breuer, she was an intelligent and strong-minded young woman of approximately 21 years of age who had developed a number of hysterical symptoms in connection with the illness and death of her father. These symptoms included paralysis of the limbs, contractures, anesthetics, visual and speech disturbances, anorexia, and a distressing nervous cough. Her illness was

also characterized by two distinct phases of consciousness: One relatively normal, but the other reflected a second and more pathological personality.

Anna was very fond of and close to her father and shared with her mother the duties of nursing him on his deathbed. During her altered states of consciousness, Anna was able to recall the vivid fantasies and intense emotions she had experienced while caring for her father. It was with considerable amazement, both to Anna and Breuer, that when she was able to recall, with the associated expression of affect, the scenes or circumstances under which her symptoms had arisen, the symptoms would disappear. She vividly described this process as the “talking cure” and as “chimney sweeping.”

Once the connection between talking through the circumstances of the symptoms and the disappearance of the symptoms themselves had been established, Anna proceeded to deal with each of her many symptoms, one after another. She was able to recall that on one occasion, when her mother had been absent, she had been sitting at her father’s bedside and had had a fantasy or daydream in which she imagined that a snake was crawling toward her father and was about to bite him. She struggled forward to try to ward off the snake, but her arm, which had been draped over the back of the chair, had gone to sleep. She was unable to move it. The paralysis persisted, and she was unable to move the arm until, under hypnosis, she was able to recall this scene. It is easy to see how this kind of material must have made a profound impression on Freud. It provided convincing demonstration of the power of unconscious memories and suppressed affects in producing hysterical symptoms.

In the course of the somewhat lengthy treatment, Breuer had become increasingly preoccupied with his fascinating and unusual patient and, consequently, spent more and more time with her. Meanwhile, his wife had grown increasingly jealous and resentful. As soon as Breuer began to realize this, the sexual connotations of it frightened him, and he abruptly terminated the treatment. Only a few hours later, however, he was recalled urgently to Anna’s bedside. She had never alluded to the forbidden topic of sex during the course of her treatment, but she was now experiencing hysterical childbirth. Freud saw the phantom pregnancy as the logical outcome of the sexual feelings she had developed toward Breuer in response to his therapeutic attention. Breuer himself had been quite unaware of this development, and the experience was quite unnerving. He was able to calm Anna down by hypnotizing her, but then he left the house in a cold sweat and immediately set out with his wife for Venice on a second honeymoon.

According to a version that comes from Freud through Ernest Jones, the patient was far from cured and later had to be hospitalized after Breuer’s departure. It seems ironic that the prototype of a cathartic cure was, in fact, far from successful. Nevertheless, the case of Anna O provided an important starting point for Freud’s thinking and a crucial juncture in the development of psychoanalysis.

THE INTERPRETATION OF DREAMS

In his landmark publication *The Interpretation of Dreams* in 1900, Freud presented a theory of the dreaming process that paralleled his earlier analysis of psychoneurotic symptoms. He viewed the dream experience as a conscious expression of unconscious fantasies or wishes not readily acceptable to conscious waking experience. Thus, dream activity was considered to be one of the normal manifestations of unconscious processes.

The dream images represented unconscious wishes or thoughts, disguised through a process of symbolization and other distorting mechanisms. This reworking of unconscious contents constituted the dream work. Freud postulated the existence of a “censor,” pictured as guarding the border between the unconscious part of the mind and the preconscious level. The censor functioned to exclude unconscious wishes during conscious states but, during regressive relaxation of sleep, allowed certain unconscious contents to pass the border, only after transformation of these unconscious wishes into disguised forms experienced in the manifest dream contents by the sleeping subject. Freud assumed that the censor worked in the service of the ego—that is, as serving the self-preservative objectives of the ego. Although he was aware of the unconscious nature of the processes, he tended to regard the ego at this point in the development of his theory more restrictively as the source of conscious processes of reasonable control and volition.

The analysis of dreams elicits material that has been repressed. These unconscious thoughts and wishes include nocturnal sensory stimuli (sensory impressions such as pain, hunger, thirst, urinary urgency), the day residue (thoughts and ideas that are connected with the activities and preoccupations of the dreamer’s current waking life), and repressed unacceptable impulses. Because motility is blocked by the sleep state, the dream enables partial but limited gratification of the repressed impulse that gives rise to the dream.

Freud distinguished between two layers of dream content. The *manifest* content refers to what is recalled by the dreamer; the *latent* content involves the unconscious thoughts and wishes that threaten to awaken the dreamer. Freud described the unconscious mental operations by which latent dream content is transformed into manifest dream as the *dream work*. Repressed wishes and impulses must attach themselves to innocent or neutral images to pass the scrutiny of the dream censor. This process involves selection of apparently meaningless or trivial images from the dreamer’s current experience, images that are dynamically associated with the latent images that they resemble in some respect.

Condensation

Condensation is the mechanism by which several unconscious wishes, impulses, or attitudes can be combined into a single image in the manifest dream content. Thus, in a child’s nightmare, an attacking monster may come to represent not only the dreamer’s father but may also represent some aspects of the mother and even some of the child’s own primitive hostile impulses as well. The converse of condensation can also occur in the dream work, namely, an irradiation or diffusion of a single latent wish or impulse that is distributed through multiple representations in the manifest dream content. The combination of mechanisms of condensation and diffusion provides the dreamer with a highly flexible and economic device for facilitating, compressing, and diffusing or expanding the manifest dream content, which is derived from latent or unconscious wishes and impulses.

Displacement

The mechanism of *displacement* refers to the transfer of amounts of energy (cathexis) from an original object to a substitute or symbolic representation of the object. Because the substitute object is relatively neutral—that is, less invested with affective energy—it is more acceptable to the dream censor and can pass the borders of repression more easily. Thus, whereas symbolism can be taken to refer to the substitution of one object for another, displacement facilitates distortion of unconscious wishes through transfer of affective energy from one object to another. Despite the transfer of cathectic energy, the aim of the unconscious impulse remains unchanged. For example, in a dream, the mother may be represented visually by an unknown female figure (at least one who has less emotional significance for the dreamer), but the naked content of the dream nonetheless continues to derive from the dreamer’s unconscious instinctual impulses toward the mother.

Symbolic Representation

Freud noted that the dreamer would often represent highly charged ideas or objects by using innocent images that were in some way connected with the idea or object being represented. In this manner, an abstract concept or a complex set of feelings toward a person could be symbolized by a simple, concrete, or sensory image. Freud noted that symbols have unconscious meanings that can be discerned through the patient’s associations to the symbol, but he also believed that certain symbols have universal meanings.

Secondary Revision

The mechanisms of condensation, displacement, and symbolic representation are characteristic of a type of thinking that Freud referred to as *primary process*. This primitive mode of cognitive activity is characterized by illogical, bizarre, and absurd images that seem incoherent. Freud believed that a more mature and reasonable aspect of the ego works during dreams to organize primitive aspects of dreams into a more coherent form. *Secondary revision* is Freud's name for this process, in which dreams become somewhat more rational. The process is related to mature activity characteristic of waking life, which Freud termed *secondary process*.

Affects in Dreams

Secondary emotions may not appear in the dream at all, or they may be experienced in somewhat altered form. For example, repressed rage toward a person's father may take the form of mild annoyance. Feelings may also appear as their opposites.

Anxiety Dreams

Freud's dream theory preceded his development of a comprehensive theory of the ego. Hence, his understanding of dreams stresses the importance of discharging drives or wishes through the hallucinatory contents of the dream. He viewed such mechanisms as condensation, displacement, symbolic representation, projection, and secondary revision primarily as facilitating the discharge of latent impulses, rather than as protecting dreamers from anxiety and pain. Freud understood anxiety dreams as reflecting a failure in the protective function of the dream-work mechanisms. The repressed impulses succeed in working their way into the manifest content in a more or less recognizable manner.

Punishment Dreams

Dreams in which dreamers experience punishment represented a special challenge for Freud because they appear to represent an exception to his wish fulfillment theory of dreams. He came to understand such dreams as reflecting a compromise between the repressed wish and the repressing agency or conscience. In a punishment dream, the ego anticipates condemnation on the part of the dreamer's conscience if the latent unacceptable impulses are allowed direct expression in the manifest dream content. Hence, the wish for punishment on the part of the patient's conscience is satisfied by giving expression to punishment fantasies.

TOPOGRAPHICAL MODEL OF THE MIND

The publication of *The Interpretation of Dreams* in 1900 heralded the arrival of Freud's topographical model of the mind, in which he divided the mind into three regions: the conscious system, the preconscious system, and the unconscious system. Each system has its own unique characteristics.

The Conscious

The conscious system in Freud's topographical model is the part of the mind in which perceptions coming from the outside world or from within the body or mind are brought into awareness. Consciousness is a subjective phenomenon whose content can be communicated only by means of language or behavior. Freud assumed that consciousness used a form of neutralized psychic energy that he referred to as *attention cathexis*, whereby persons were aware of a particular idea or feeling as a result of investing a discrete amount of psychic energy in the idea or feeling.

The Preconscious

The preconscious system is composed of those mental events, processes, and contents that can be brought into conscious awareness by the act of focusing attention. Although most persons are not consciously aware of the appearance of their first-grade teacher, they ordinarily can bring this image to mind by deliberately focusing attention on the memory. Conceptually, the preconscious interfaces with both unconscious and conscious regions of the mind. To reach conscious awareness, contents of the unconscious must become linked with words and thus become preconscious. The preconscious system also serves to maintain the repressive barrier and to censor unacceptable wishes and desires.

The Unconscious

The unconscious system is dynamic. Its mental contents and processes are kept from conscious awareness through the force of censorship or repression, and it is closely related to instinctual drives. At this point in Freud's theory of development, instincts were thought to consist of sexual and self-preserved drives, and the unconscious was thought to contain primarily the mental representations and derivatives of the sexual instinct.

The content of the unconscious is limited to wishes seeking fulfillment. These wishes provide the motivation for dream and neurotic symptom formation. This view is now considered reductionist.

The unconscious system is characterized by *primary process thinking*, which is principally aimed at facilitating wish fulfillment and instinctual discharge. It is governed by the pleasure principle and, therefore, disregards logical connections; it has no concept of time, represents wishes as fulfillments, permits contradictions to exist simultaneously, and denies the existence of negatives. The primary process is also characterized by extreme mobility of drive cathexis; the investment of psychic energy can shift from object to object without opposition. Memories in the unconscious have been divorced from their connection with verbal symbols. Hence, when words are reapplied to forgotten memory traits, as in psychoanalytic treatment, the verbal recathexis allows the memories to reach consciousness again.

The contents of the unconscious can become conscious only by passing through the preconscious. When censors are overpowered, the elements can enter consciousness.

Limitations of the Topographical Theory

Freud soon realized that two main deficiencies in the topographical theory limited its usefulness. First, many patients' defense mechanisms that guard against distressing wishes, feelings, or thoughts were themselves not initially accessible to consciousness. Thus, repression cannot be identical with preconscious, because by definition this region of the mind is accessible to consciousness. Second, Freud's patients frequently demonstrated an unconscious need for punishment. This clinical observation made it unlikely that the moral agency making the demand for punishment could be allied with anti-instinctual forces that were available to conscious awareness in the preconscious. These difficulties led Freud to discard the topographical theory, but certain concepts derived from the theory continue to be useful, particularly, primary and secondary thought processes, the fundamental importance of wish fulfillment, the existence of a dynamic unconscious, and a tendency toward regression under frustrating conditions.

INSTINCT OR DRIVE THEORY

After the development of the topographical model, Freud turned his attention to the complexities of instinct theory. Freud was determined

to anchor his psychological theory in biology. His choice led to terminological and conceptual difficulties when he used terms derived from biology to denote psychological constructs. *Instinct*, for example, refers to a pattern of species-specific behavior that is genetically derived and, therefore, is more or less independent of learning. Modern research demonstrating that instinctual patterns are modified through experiential learning, however, has made Freud's instinctual theory problematic. Further confusion has stemmed from the ambiguity inherent in a concept on the borderland between the biological and the psychological: Should the mental representation aspect of the term and the physiological component be integrated or separated? Although *drive* may have been closer than instinct to Freud's meaning, in contemporary usage, the two terms are often used interchangeably.

In Freud's view, an instinct has four principal characteristics: source, impetus, aim, and object. The *source* refers to the part of the body from which the instinct arises. The *impetus* is the amount of force or intensity associated with the instinct. The *aim* refers to any action directed toward tension discharge or satisfaction, and the *object* is the target (often a person) for this action.

Instincts

Libido. The ambiguity in the term *instinctual drive* is also reflected in the use of the term *libido*. Briefly, Freud regarded the sexual instinct as a psychophysiological process that had both mental and physiological manifestations. Essentially, he used the term *libido* to refer to "the force by which the sexual instinct is represented in the mind." Thus, in its accepted sense, libido refers specifically to the mental manifestations of the sexual instinct. Freud recognized early that the sexual instinct did not originate in a finished or final form, as represented by the stage of genital primacy. Rather, it underwent a complex process of development, at each phase of which the libido had specific aims and objects that diverged in varying degrees from the simple aim of genital union. The libido theory thus came to include all of these manifestations and the complicated paths they followed in the course of psychosexual development.

Ego Instincts. From 1905 on, Freud maintained a dual instinct theory, subsuming sexual instincts and ego instincts connected with self-preservation. Until 1914, with the publication of *On Narcissism*, Freud had paid little attention to ego instincts; in this communication, however, Freud invested ego instinct with libido for the first time by postulating an ego libido and an object libido. Freud thus viewed narcissistic investment as an essentially libidinal instinct and called the remaining nonsexual components the *ego instincts*.

Aggression. When psychoanalysts today discuss the dual instinct theory, they are generally referring to libido and aggression. Freud, however, originally conceptualized aggression as a component of the sexual instincts in the form of sadism. As he became aware that sadism had nonsexual aspects to it, he made finer gradations, which enabled him to categorize aggression and hate as part of the ego instincts and the libidinal aspects of sadism as components of the sexual instincts. Finally, in 1923, to account for the clinical data he was observing, he was compelled to conceive of aggression as a separate instinct in its own right. The source of this instinct, according to Freud, was largely in skeletal muscles, and the aim of the aggressive instincts was destruction.

Life and Death Instincts. Before designating aggression as a separate instinct, Freud, in 1920, subsumed the ego instincts under a broader category of life instincts. These were juxtaposed with death instincts and were referred to as *Eros* and *Thanatos* in *Beyond the Pleasure Principle*. The life and death instincts were regarded as forces underlying the sexual and aggressive instincts. Although Freud could not provide clinical data that directly verified the death instinct, he thought the instinct could be inferred by observing *repetition compulsion*, a person's tendency to repeat past traumatic behavior. Freud thought that the dominant force in biological organisms had to be the death instinct. In contrast to the death instinct, *eros* (the life instinct) refers to the tendency of particles to reunite or bind to one another, as in sexual reproduction. The prevalent view today is that the dual instincts of sexuality and aggression suffice to explain most clinical phenomena without recourse to a death instinct.

Pleasure and Reality Principles

In 1911, Freud described two basic tenets of mental functioning: the pleasure principle and the reality principle. He essentially recast the primary process and secondary process dichotomy into the pleasure and reality principles and thus took an important step toward solidifying the notion of the ego. Both principles, in Freud's view, are aspects of ego functioning. The *pleasure principle* is defined as an inborn tendency of the organism to avoid pain and to seek pleasure through the discharge of tension. The *reality principle*, on the other hand, is considered to be a learned function closely related to the maturation of the ego; this principle modifies the pleasure principle and requires delay or postponement of immediate gratification.

Infantile Sexuality

Freud set forth the three major tenets of psychoanalytic theory when he published *Three Essays on the Theory of Sexuality*. First, he broadened the definition of sexuality to include forms of pleasure that transcend genital sexuality. Second, he established a developmental theory of childhood sexuality that delineated the vicissitudes of erotic activity from birth through puberty. Third, he forged a conceptual linkage between neuroses and perversions.

Freud's notion that children are influenced by sexual drives has made some persons reluctant to accept psychoanalysis. Freud noted that infants are capable of erotic activity from birth, but the earliest manifestations of infantile sexuality are basically nonsexual and are associated with such bodily functions as feeding and bowel-bladder control. As libidinal energy shifts from the oral zone to the anal zone to the phallic zone, each stage of development is thought to build on and to subsume the accomplishments of the preceding stage. The *oral stage*, which occupies the first 12 to 18 months of life, centers on the mouth and lips and is manifested in chewing, biting, and sucking. The dominant erotic activity of the anal stage, from 18 to 36 months of age, involves bowel function and control. The *phallic stage*, from 3 to 5 years of life, initially focuses on urination as the source of erotic activity. Freud suggested that phallic erotic activity in boys is a preliminary stage leading to adult genital activity. Whereas the penis remains the principal sexual organ throughout male psychosexual development, Freud postulated that females have two principal erotogenic zones: the vagina and the clitoris. He thought that the clitoris was the chief erotogenic focus during the infantile genital period but that erotic primacy shifted to the vagina after puberty. Studies of human sexuality have subsequently questioned the validity of this distinction.

Freud discovered that in the psychoneuroses, only a limited number of the sexual impulses that had undergone repression and were responsible for creating and maintaining the neurotic symptoms were normal. For the most part, these were the same impulses that were given overt expression in the perversions. The neuroses, then, were the negative of perversions.

Object Relationships in Instinct Theory

Freud suggested that the choice of a love object in adult life, the love relationship itself, and the nature of all other object relationships depend primarily on the nature and quality of children's relationships during the early years of life. In describing the libidinal phases of psychosexual development, Freud repeatedly referred to the significance of a child's relationships with parents and other significant persons in the environment.

The awareness of the external world of objects develops gradually in infants. Soon after birth, they are primarily aware of physical sensations, such as hunger, cold, and pain, which give rise to tension, and caregivers are regarded primarily as persons who relieve their

tension or remove painful stimuli. Recent infant research, however, suggests that awareness of others begins much sooner than Freud originally thought. Table 4.1-1 provides a summary of the stages of psychosexual development and the object relationships associated with each stage. Although the table goes only as far as young adulthood, development is now recognized as continuing throughout adult life.

 **Table 4.1-1**
Stages of Psychosexual Development

<i>Oral Stage</i>	
Definition	Earliest stage of development in which the infant's needs, perceptions, and modes of expression are primarily centered in mouth, lips, tongue, and other organs related to oral zone and around the sucking reflex.
Description	Oral zone maintains dominance in psychic organization through approximately first 18 months of life. Oral sensations include thirst, hunger, pleasurable tactile stimulations evoked by the nipple or its substitute, and sensations related to swallowing and satiation. Oral drives consist of two components: libidinal and aggressive. States of oral tension lead to seeking oral gratification, as in quiescence at the end of nursing. Oral triad consists of wishes to eat, sleep, and reach that relaxation that occurs at the end of sucking just before onset of sleep. Libidinal needs (oral erotism) predominate in early oral phase, whereas they are mixed with more aggressive components later (oral sadism). Oral aggression is expressed in biting, chewing, spitting, or crying. Oral aggression is connected with primitive wishes and fantasies of biting, devouring, and destroying.
Objectives	To establish a trusting dependence on nursing and sustaining objects, establish comfortable expression and gratification of oral libidinal needs without excessive conflict or ambivalence from oral sadistic wishes.
Pathological traits	Excessive oral gratifications or deprivation can result in libidinal fixations contributing to pathological traits. Such traits can include excessive optimism, narcissism, pessimism (as in depressive states), or demandingness. Envy and jealousy are often associated with oral traits.
Character traits	Successful resolution of the oral phase results in capacities to give to and receive from others without excessive dependence or envy and to rely on others with a sense of trust as well as with a sense of self-reliance and self-trust. Oral characters are often excessively dependent and require others to give to them and look after them and are often extremely dependent on others for maintaining self-esteem. These are readily amalgamated with narcissistic needs.
<i>Anal Stage</i>	
Definition	The stage of psychosexual development promoted by maturation of neuromuscular control over sphincters, particularly the anal sphincter, permitting greater voluntary control over retention or expulsion of feces.
Description	This period extends roughly from 1 to 3 years of age, marked by recognizable intensification of aggressive drives mixed with libidinal components in sadistic impulses. Acquisition of voluntary sphincter control is associated with an increasing shift from passivity to activity. Conflicts over anal control and struggles with parents over retaining or expelling feces in toilet training give rise to increased ambivalence, together with conflicts over separation, individuation, and independence. Anal erotism refers to sexual pleasure in anal functioning, both in retaining precious feces and presenting them as a precious gift to the parent. Anal sadism refers to expression of aggressive wishes connected with discharging feces as powerful and destructive weapons. These wishes are often displayed in fantasies of bombing or explosions.
Objectives	The anal period is marked by greater striving for independence and separation from dependence on and control of parents. Objectives of sphincter control without overcontrol (fecal retention) or loss of control (messing) are matched by attempts to achieve autonomy and independence without excessive shame or self-doubt from loss of control.
Pathological traits	Maladaptive character traits, often apparently inconsistent, derive from anal erotism and defenses against it. Orderliness, obstinacy, stubbornness, willfulness, frugality, and parsimony are features of anal character. When defenses against anal traits are less effective, anal character reveals traits of heightened ambivalence, lack of tidiness, messiness, defiance, rage, and sadomasochistic tendencies. Anal characteristics and defenses are typically seen in obsessive-compulsive neuroses.
Character traits	Successful resolution of the anal phase provides the basis for development of personal autonomy, a capacity for independence and personal initiative without guilt, a capacity for self-determining behavior without a sense of shame or self-doubt, a lack of ambivalence, and a capacity for willing cooperation without either excessive willfulness or self-diminution or defeat.
<i>Urethral Stage</i>	
Definition	This stage was not explicitly treated by Freud but serves as a transitional stage between anal and phallic stages. It shares some characteristics of anal phase and some from subsequent phallic phase.
Description	Characteristics of the urethral phase are often subsumed under phallic phase. Urethral erotism, however, refers to pleasure in urination as well as pleasure in urethral retention analogous to anal retention. Similar issues of performance and control are related to urethral functioning. Urethral functioning may also have sadistic quality, often reflecting persistence of anal sadistic urges. Loss of urethral control, as in enuresis, may frequently have regressive significance that reactivates anal conflicts.
Objectives	At stake are issues of control and urethral performance and loss of control. It is not clear whether or to what extent objectives of urethral functioning differ from those of anal period, except that they are expressed in a later developmental stage.
Pathological traits	The predominant urethral trait is competitiveness and ambition, probably related to compensation for shame due to loss of urethral control. This may instigate development of penis envy, related to feminine sense of shame and inadequacy in being unable to match male urethral performance. This may also be related to issues of control and shaming.
Character traits	Besides healthy effects analogous to those from the anal period, urethral competence provides a sense of pride and self-competence based on performance. Urethral performance is an area in which the small boy can imitate and try to match his father's more adult performance. Resolution of urethral conflicts sets the stage for budding gender identity and subsequent identifications.

<i>Phallic Stage</i>	
Definition	Phallic stage begins sometime during year 3 and continues until approximately the end of year 5.
Description	The phallic phase is characterized by a primary focusing of sexual interests, stimulation, and excitement in the genital area. The penis becomes the organ of principal interest to children of both sexes, with lack of penis in females being considered as evidence of castration. The phallic phase is associated with an increase in genital masturbation accompanied by predominantly unconscious fantasies of sexual involvement with the opposite-sex parent. Threats of castration and the related anxiety are connected with guilt over masturbation and oedipal wishes. During this phase oedipal involvement and conflict are established and consolidated.
Objectives	To focus erotic interest in genital area and genital functions. This lays the foundation for gender identity and serves to integrate residues of previous stages into a predominantly genital–sexual orientation. Establishing the oedipal situation is essential for furtherance of subsequent identifications, serving as a basis for important and perduring dimensions of character organization.
Pathological traits	Derivation of pathological traits from phallic–oedipal involvement is sufficiently complex and subject to such a variety of modifications that it encompasses nearly the whole of neurotic development. Issues, however, focus on castration in males and penis envy in females. Patterns of internalization developed from resolution of the Oedipus complex provide another important focus of developmental distortions. The influence of castration anxiety and penis envy, defenses against them, and patterns of identification are primary determinants of the development of human character. They also subsume and integrate residues of previous psychosexual stages, so that fixations or conflicts deriving from preceding stages can contaminate and modify oedipal resolution.
Character traits	The phallic stage provides the foundation for an emerging sense of sexual identity, curiosity without embarrassment, initiative without guilt, as well as mastery not only over objects and persons in the environment but also over internal processes and impulses. Resolution of the oedipal conflict gives rise to internal structural capacities for regulation of drive impulses and their direction to constructive ends. The internal sources of such regulation are the ego and super-ego, based on introjections and identifications derived primarily from parental figures.
<i>Latency Stage</i>	
Definition	This is the stage of relative instinctual quiescence or inactivity of sexual drive during the period from the resolution of the Oedipus complex until pubescence (from about 5 to 6 years until about 11 to 13 years).
Description	The institution of the superego at the close of the oedipal period and further maturation of ego functions allow for considerably greater degrees of control of instinctual impulses and motives. Sexual interests are generally thought to be quiescent. This is a period of primarily homosexual affiliations for both boys and girls, as well as a sublimation of libidinal and aggressive energies into energetic learning and play activities, exploring the environment, and becoming more proficient in dealing with the world of things and persons around them. It is a period for development of important skills. The relative strength of regulatory elements often gives rise to patterns of behavior that are somewhat obsessive and hypercontrolling.
Objectives	The primary objective is further integration of oedipal identifications and consolidation of gender and sex-role identity. Relative quiescence and control of instinctual impulses allow for development of ego apparatuses and mastery of skills. Further identificatory components may be added to the oedipal ones on the basis of broadening contacts with other significant figures outside the family (e.g., teachers, coaches, and other adult figures).
Pathological traits	Dangers in the latency period can arise either from the lack of development of inner controls or an excess of them. Lack of control can lead to failure to sufficiently sublimate energies in the interest of learning and the development of skills; an excess of inner control, however, can lead to premature closure of personality development and precocious elaboration of obsessive character traits.
Character traits	The latency period is frequently regarded as a period of relatively unimportant inactivity in the developmental schema. More recently, greater respect has been gained for the developmental processes in this period. Important consolidations and additions are made to basic, post-oedipal identifications and to processes of integrating and consolidating previous attainments in psychosexual development and establishing decisive patterns of adaptive functioning. The child can develop a sense of industry and capacity for mastery of objects and concepts that allows autonomous functioning and a sense of initiative without risk of failure or defeat or a sense of inferiority. These are all important attainments that need to be further integrated, ultimately as the essential basis for a mature adult life of satisfaction in work and love.
<i>Genital Stage</i>	
Definition	The genital or adolescent phase extends from the onset of puberty from approximately ages 11 to 13 until young adulthood. Current thinking tends to subdivide this stage into preadolescent, early adolescent, middle adolescent, late adolescent, and even postadolescent periods.
Description	Physiological maturation of systems of genital (sexual) functioning and attendant hormonal systems leads to intensification of instinctual, particularly libidinal, drives. This produces a regression in personality organization, which reopens conflicts of previous stages of psychosexual development and provides opportunity for re-resolution of these conflicts in the context of achieving a mature sexual and adult identity. This period has been described as a “second individuation.”
Objectives	Primary objectives are the ultimate separation from dependence on and attachment to parents and establishment of mature, nonincestuous, heterosexual object relations. Related are the achievement of a mature sense of personal identity and acceptance and integration of adult roles and functions that permit new adaptive integrations with social expectations and cultural values.
Pathological traits	Pathological deviations due to failure to achieve successful resolution of this stage of development are multiple and complex. Defects can arise from a whole spectrum of psychosexual residues, since the developmental task of adolescence is in a sense a partial reopening, reworking, and reintegration of all of these aspects of development. Previous unsuccessful resolutions and fixations in various phases or aspects of psychosexual development will produce pathological defects in the emerging adult personality and defects in identity formation.
Character traits	Successful resolution and reintegration of previous psychosexual stages in the adolescent genital phase set the stage normally for a fully mature personality with the capacity for full and satisfying genital potency and a self-integrated and consistent sense of identity. This provides the basis for a capacity for self-realization and meaningful participation in areas of work, love, and in creative and productive application to satisfying and meaningful goals and values.

Concept of Narcissism

According to Greek myth, Narcissus, a beautiful youth, fell in love with his reflection in the water of a pool and drowned in his attempt to embrace his beloved image. Freud used the term *narcissism* to describe situations in which an individual’s libido was invested in the ego itself rather than in other persons. This concept of narcissism presented him with vexing problems for his instinct theory and essentially violated his distinction between libidinal instincts and ego or self-preservative instincts. Freud’s understanding of narcissism led him to use the term to describe a wide array of psychiatric disorders, very much in contrast to the term’s contemporary use to describe a specific personality disorder. Freud grouped several disorders together as the narcissistic neuroses, in which a person’s libido is withdrawn from objects and turned inward. He believed that this withdrawal of libidinal attachment to objects accounted for the loss of reality testing in patients who were psychotic; grandiosity and omnipotence in such patients reflected excessive libidinal investment in the ego.

Freud did not limit his use of narcissism to psychoses. In states of physical illness and hypochondriasis, he observed that libidinal investment was frequently withdrawn from external objects and from outside activities and interests. Similarly, he suggested that in normal sleep, libido was also withdrawn and reinvested in a sleeper’s own body. Freud regarded homosexuality as an instance of a narcissistic form of object choice, in which persons fall in love with an idealized version of themselves projected onto another person. He also found narcissistic manifestations in the beliefs and myths of primitive people, especially those involving the ability to influence external events through the magical omnipotence of thought processes. In the course of normal development, children also exhibit this belief in their own omnipotence.

Freud postulated a state of primary narcissism at birth in which the libido is stored in the ego. He viewed the neonate as completely narcissistic, with the entire libidinal investment in physiological needs and their satisfaction. He referred to this self-investment as *ego libido*. The infantile state of self-absorption changes only gradually, according to Freud, with the dawning awareness that a separate person—the mothering figure—is responsible for gratifying an infant’s needs. This realization leads to the gradual withdrawal of the libido from the self and its redirection toward the external object. Hence, the development of object relations in infants parallels the shift from primary narcissism to object attachment. The libidinal investment in the object is referred to as *object libido*. If a developing child suffers rebuffs or trauma from the caretaking figure, object libido may be withdrawn and reinvested in the ego. Freud called this regressive posture *secondary narcissism*.

Freud used the term *narcissism* to describe many different dimensions of human experience. At times, he used it to describe a perversion in which persons used their own bodies or body parts as objects of sexual arousal. At other times, he used the term to describe a developmental phase, as in the state of primary narcissism. In still other instances, the term referred to a particular object choice. Freud distinguished love objects who are chosen “according to the narcissistic type,” in which case the object resembles the subject’s idealized or fantasized self-image, from objects chosen according to the “anaclitic,” in which the love object resembles a caretaker from early in life. Finally, Freud also used the word *narcissism* interchangeably and synonymously with *self-esteem*.

EGO PSYCHOLOGY

Although Freud had used the construct of the ego throughout the evolution of psychoanalytic theory, ego psychology as it is known today really began with the publication in 1923 of *The Ego and the Id*. This landmark publication also represented a transition in Freud's thinking from the topographical model of the mind to the tripartite structural model of ego, id, and superego. He had observed repeatedly that not all unconscious processes can be relegated to a person's instinctual life. Elements of the conscience, as well as functions of the ego, are clearly also unconscious.

Structural Theory of the Mind

The structural model of the psychic apparatus is the cornerstone of ego psychology. The three provinces—id, ego, and superego—are distinguished by their different functions.

Id. Freud used the term *id* to refer to a reservoir of unorganized instinctual drives. Operating under the domination of the primary process, the id lacks the capacity to delay or modify the instinctual drives with which an infant is born. The id, however, should not be viewed as synonymous with the unconscious, because both the ego and the superego have unconscious components.

Ego. The ego spans all three topographical dimensions of conscious, preconscious, and unconscious. Logical and abstract thinking and verbal expression are associated with conscious and preconscious functions of the ego. Defense mechanisms reside in the unconscious domain of the ego. The ego, the executive organ of the psyche, controls motility, perception, contact with reality, and, through the defense mechanisms available to it, the delay and modulation of drive expression.

Freud believed that the id is modified as a result of the impact of the external world on the drives. The pressures of external reality enable the ego to appropriate the energies of the id to do its work. As the ego brings influences from the external world to bear on the id, it simultaneously substitutes the reality principle for the pleasure principle. Freud emphasized the role of conflict within the structural model and observed that conflict occurs initially between the id and the outside world, only to be transformed later to conflict between the id and the ego.

The third component of the tripartite structural model is the superego. The superego establishes and maintains an individual's moral conscience on the basis of a complex system of ideals and values internalized from parents. Freud viewed the superego as the heir to the Oedipus complex. Children internalize parental values and standards at about the age of 5 or 6 years. The superego then serves as an agency that provides ongoing scrutiny of a person's behavior, thoughts, and feelings; it makes comparisons with expected standards of behavior and offers approval or disapproval. These activities occur largely unconsciously.

The ego ideal is often regarded as a component of the superego. It is an agency that prescribes what a person should do according to internalized standards and values. The superego, by contrast, is an agency of moral conscience that *proscribes*—that is, dictates what a person should not do. Throughout the latency period and thereafter, persons continue to build on early identifications through their contact with admired figures who contribute to the formation of moral standards, aspirations, and ideals.

Functions of the Ego

Modern ego psychologists have identified a set of basic ego functions that characterizes the operations of the ego. These descriptions reflect the ego activities that are generally regarded as fundamental.

Control and Regulation of Instinctual Drives. The development of the capacity to delay or postpone drive discharge, like the capacity to test reality, is closely related to the early childhood progression from the pleasure principle to the reality principle. This capacity is also an essential aspect of the ego's role as mediator between the id and the outside world. Part of infants' socialization to the external world is the acquisition of language and secondary process or logical thinking.

Judgment. A closely related ego function is judgment, which involves the ability to anticipate the consequences of actions. As with control and regulation of instinctual drives, judgment develops in parallel with the growth of *secondary process thinking*. The ability to think logically allows assessment of how contemplated behavior may affect others.

Relation to Reality. The mediation between the internal world and external reality is a crucial function of the ego. Relations with the outside world can be divided into three aspects: the sense of reality, reality testing, and adaptation to reality. The *sense of reality* develops in concert with an infant's dawning awareness of bodily sensations. The ability to distinguish what is outside the body from what is inside is an essential aspect of the sense of reality, and disturbances of body boundaries, such as depersonalization, reflect impairment in this ego function. *Reality testing*, an ego function of paramount importance, refers to the capacity to distinguish internal fantasy from external reality. This function differentiates persons who are psychotic from those who are not. *Adaptation to reality* involves persons' ability to use their resources to develop effective responses to changing circumstances on the basis of previous experience with reality.

Object Relationships. The capacity to form mutually satisfying relationships is related in part to patterns of internalization stemming from early interactions with parents and other significant figures. This ability is also a fundamental function of the ego, in that satisfying relatedness depends on the ability to integrate positive and negative aspects of others and self and to maintain an internal sense of others even in their absence. Similarly, mastery of drive derivatives is also crucial to the achievement of satisfying relationships. Although Freud did not develop an extensive object relations theory, British psychoanalysts, such as Ronald Fairbairn (1889–1964) and Michael Balint (1896–1970), elaborated greatly on the early stages in infants' relationships with need-satisfying objects and on the gradual development of a sense of separateness from the mother. Another of their British colleagues, Donald W. Winnicott (1896–1971), described the *transitional object* (e.g., a blanket, teddy bear, or pacifier) as the link between developing children and their mothers. A child can separate from the mother because a transitional object provides feelings of security in her absence. The stages of human development and object relations theory are summarized in [Table 4.1-2](#).

Table 4.1-2
Parallel Lines of Development

Instinctual Phases	Separation-Individuation	Object Relations	Psychosocial Crises
Oral	Autism, symbiosis	Primary narcissism, need-satisfying	Trust or mistrust
Anal	Differentiation, practicing, rapprochement	Need-satisfying, object constancy	Autonomy or shame, self-doubt
Phallic	Object constancy, Oedipal complex	Object constancy, ambivalence	Initiative or guilt
Latency	—	—	Industry or inferiority
Adolescence	Genitality, secondary individuation	Object love	Identity or identity confusion
Adulthood	Mature genitality	—	Intimacy or isolation, generativity or stagnation, integrity or despair

Synthetic Function of the Ego. First described by Herman Nunberg in 1931, the *synthetic function* refers to the ego's capacity to integrate diverse elements into an overall unity. Different aspects of self and others, for example, are synthesized into a consistent representation that endures over time. The function also involves organizing, coordinating, and generalizing or simplifying large amounts of data.

Primary Autonomous Ego Functions. Heinz Hartmann described the so-called primary autonomous functions of the ego as rudimentary apparatuses present at birth that develop independently of intrapsychic conflict between drives and defenses. These functions include perception, learning, intelligence, intuition, language, thinking, comprehension, and motility. In the course of development, some of these conflict-free aspects of the ego may eventually become involved in conflict. They will develop normally if the infant is raised in what Hartmann referred to as an *average expectable environment*.

Secondary Autonomous Ego Functions. Once the sphere where primary autonomous function develops becomes involved with conflict, so-called *secondary autonomous ego functions* arise in the defense against drives. For example, a child may develop caretaking functions as a reaction formation against murderous wishes during the first few years of life. Later, the defensive functions may be neutralized or deinstinctualized when the child grows up to be a social worker and cares for homeless persons.

Defense Mechanisms

At each phase of libidinal development, specific drive components evoke characteristic ego defenses. The anal phase, for example, is associated with reaction formation, as manifested by the development of shame and disgust in relation to anal impulses and pleasures.

Defenses can be grouped hierarchically according to the relative degree of maturity associated with them. Narcissistic defenses are the most primitive and appear in children and persons who are psychotically disturbed. Immature defenses are seen in adolescents and some nonpsychotic patients. Neurotic defenses are encountered in obsessive-compulsive and hysterical patients as well as in adults under stress. [Table 4.1-3](#) lists the defense mechanisms according to George Valliant's classification of the four types.

Table 4.1-3
Classification of Defense Mechanisms

Narcissistic-Psychotic Defenses

These defenses are usually found as part of a psychotic process, but may also occur in young children and adult dreams or fantasies. They share the common note of avoiding, negating, or distorting reality.

Projection	Perceiving and reacting to unacceptable inner impulses and their derivatives as though they were outside the self. On a psychotic level, this takes the form of frank delusions about external reality, usually persecutory, includes both perception of one's own feelings and those of another with subsequent acting on the perception (psychotic paranoid delusions). Impulses may derive from id or superego (hallucinated recriminations).
Denial	Psychotic denial of external reality, unlike repression, affects perception of external reality more than perception of internal reality. Seeing, but refusing to acknowledge what one sees, or hearing and negating what is actually heard are examples of denial and exemplify the close relationship of denial to sensory experience. Not all denial, however, is necessarily psychotic. Like projection, denial may function in the service of more neurotic or even adaptive objectives. Denial avoids becoming aware of some painful aspect of reality. At the psychotic level, the denied reality may be replaced by a fantasy or delusion.
Distortion	Grossly reshaping the experience of external reality to suit inner needs, including unrealistic megalomaniac beliefs, hallucinations, wish-fulfilling delusions, and employing sustained feelings of delusional grandiosity, superiority, or entitlement.

Immature Defenses

These mechanisms are fairly common in preadolescent years and in adult character disorders. They are often mobilized by anxieties related to intimacy or its loss. Although they are regarded as socially awkward and undesirable, they often moderate with improvement in interpersonal relationships or with increased personal maturity.

Acting out	The direct expression of an unconscious wish or impulse in action to avoid being conscious of the accompanying affect. The unconscious fantasy, involving objects, is lived out and impulsively enacted in behavior, thus gratifying the impulse more than the prohibition against it. On a chronic level, acting out involves giving in to impulses to avoid the tension that would result from postponement of their expression.
Blocking	An inhibition, usually temporary in nature, of affects especially, but possibly also thinking and impulses. It is close to repression in its effects but has a component of tension arising from the inhibition of the impulse, affect, or thought.
Hypochondriasis	Transformation of reproach toward others arising from bereavement, loneliness, or unacceptable aggressive impulses, into self-reproach in the form of somatic complaints of pain, illness, and so forth. Real illness may also be overemphasized or exaggerated for its evasive and regressive possibilities. Thus, responsibility may be avoided, guilt may be circumvented, and instinctual impulses may be warded off.
Introjection	In addition to the developmental functions of the process of introjection, it also can serve specific defensive functions. The introjection of a loved object involves the internalization of characteristics of the object with the goal of ensuring closeness to and constant presence of the object. Anxiety consequent to separation or tension arising out of ambivalence toward the object is thus diminished. If the object is lost, introjection nullifies or negates the loss by taking on characteristics of the object, thus in a sense internally preserving the object. Even if the object is not lost, the internalization usually involves a shift of cathexis reflecting a significant alteration in the object relationship. Introjection of a feared object serves to avoid anxiety through internalizing the aggressive characteristic of the object, thereby putting the aggression under one's own control. The aggression is no longer felt as coming from outside, but is taken within and utilized defensively, thus turning the subject's weak, passive position into an active, strong one. The classic example is "identification with the aggressor." Introjection can also take place out of a sense of guilt in which the self-punishing introject is attributable to the hostile-destructive component of an ambivalent tie to an object. Thus, the self-punitive qualities of the object are taken over and established within one's self as a symptom or character trait, which effectively represents both the destruction and the preservation of the object. This is also called <i>identification with the victim</i> .
Passive-aggressive behavior	Aggression toward an object expressed indirectly and ineffectively through passivity, masochism, and turning against the self.
Projection	On a nonpsychotic level, projection involves attributing one's own unacknowledged feelings to others; it includes severe prejudice, rejection of intimacy through suspiciousness, hypervigilance to external danger, and injustice collecting. Projection operates correlatively to introjection, such that the material of the projection derives from the internalized but usually unconscious configuration of the subject's introjects. At higher levels of function, projection may take the form of misattributing or misinterpreting motives, attitudes, feelings, or intentions of others.
Regression	A return to a previous stage of development or functioning to avoid the anxieties or hostilities involved in later stages. A return to earlier points of fixation embodying modes of behavior previously given up. This is often the result of a disruption of equilibrium at a later phase of development. This reflects a basic tendency to achieve instinctual gratification or to escape instinctual tension by returning to earlier modes and levels of gratification when later and more differentiated modes fail or involve intolerable conflict.
Schizoid fantasy	The tendency to use fantasy and to indulge in autistic retreat for the purpose of conflict resolution and gratification.
Somatization	The defensive conversion of psychic derivatives into bodily symptoms; tendency to react with somatic rather than psychic manifestations. Infantile somatic responses are replaced by thought and affect during development (desomatization); regression to earlier somatic forms or response (resomatization) may result from unresolved conflicts and may play an important role in psychophysiological and psychosomatic reactions.

Neurotic Defenses

These are common in apparently normal and healthy individuals as well as in neurotic disorders. They function usually in the alleviation of distressing affects and may be expressed in neurotic forms of behavior. Depending on circumstances, they can also have an adaptive or socially acceptable aspect.

Controlling	The excessive attempt to manage or regulate events or objects in the environment in the interest of minimizing anxiety and solving internal conflicts.
Displacement	Involves a purposeful, unconscious shifting of impulses or affective investment from one object to another in the interest of solving a conflict. Although the object is changed, the instinctual nature of the impulse and its aim remain unchanged.
Dissociation	A temporary but drastic modification of character or sense of personal identity to avoid emotional distress; it includes fugue states and hysterical conversion reactions.
Externalization	A general term, correlative to internalization, referring to the tendency to perceive in the external world and in external objects components of one's own personality, including instinctual impulses, conflicts, moods, attitudes, and styles of thinking. It is a more general term than projection, which is defined by its derivation from and correlation with specific introjects.
Inhibition	The unconsciously determined limitation or renunciation of specific ego functions, singly or in combination, to avoid anxiety arising out of conflict with instinctual impulses, superego, or environmental forces or figures.
Intellectualization	The control of affects and impulses by way of thinking about them instead of experiencing them. It is a systematic excess of thinking, deprived of its affect, to defend against anxiety caused by unacceptable impulses.
Isolation	The intrapsychic splitting or separation of affect from content resulting in repression of either idea or affect or the displacement of affect to a different or substitute content.
Rationalization	A justification of attitudes, beliefs, or behavior that might otherwise be unacceptable by an incorrect application of justifying reasons or the invention of a convincing fallacy.
Reaction formation	The management of unacceptable impulses by permitting expression of the impulse in antithetical form. This is equivalently an expression of the impulse in the negative. Where instinctual conflict is persistent, reaction formation can become a character trait on a permanent basis, usually as an aspect of obsessional character.
Repression	Consists of the expelling and withholding from conscious awareness of an idea or feeling. It may operate either by excluding from awareness what was once experienced on a conscious level (secondary repression) or it may curb ideas and feelings before they have reached consciousness (primary repression). The "forgetting" associated with repression is unique in that it is often accompanied by highly symbolic behavior, which suggests that the repressed is not really forgotten. The important discrimination between repression and the more general concept of defense has been discussed.
Sexualization	The endowing of an object or function with sexual significance that it did not previously have, or possesses to a lesser degree, to ward off anxieties connected with prohibited impulses.

Mature Defenses

These mechanisms are healthy and adaptive throughout the life cycle. They are socially adaptive and useful in the integration of personal needs and motives, social demands, and interpersonal relations. They can underlie seemingly admirable and virtuous patterns of behavior.

Altruism	The vicarious but constructive and instinctually gratifying service to others, even to the detriment of the self. This must be distinguished from altruistic surrender, which involves a masochistic surrender of direct gratification or of instinctual needs in favor of fulfilling the needs of others to the detriment of the self, with vicarious satisfaction only being gained through introjection.
Anticipation	The realistic anticipation of or planning for future inner discomfort: Implies overly concerned planning, worrying, and anticipation of dire and dreadful possible outcomes.
Asceticism	The elimination of directly pleasurable affects attributable to an experience. The moral element is implicit in setting values on specific pleasures. Asceticism is directed against all "base" pleasures perceived consciously, and gratification is derived from the renunciation.
Humor	The overt expression of feelings without personal discomfort or immobilization and without unpleasant effect on others. Humor allows one to bear, and yet focus on, what is too terrible to be borne, in contrast to wit, which always involves distraction or displacement away from the affective issue.
Sublimation	The gratification of an impulse whose goal is retained but whose aim or object is changed from a socially objectionable one to a socially valued one. Libidinal sublimation involves a desexualization of drive impulses and the placing of a value judgment that substitutes what is valued by the superego or society. Sublimation of aggressive impulses takes place through pleasurable games and sports. Unlike neurotic defenses, sublimation allows instincts to be channeled rather than dammed up or diverted. Thus, in sublimation, feelings are acknowledged, modified, and directed toward a relatively significant person or goal so that modest instinctual satisfaction results.
Suppression	The conscious or semiconscious decision to postpone attention to a conscious impulse or conflict.

Adapted from Vaillant GE. *Adaptation to Life*. Boston: Little Brown; 1977; Semrad E. The operation of ego defenses in object loss. In: Monrarity DM, ed. *The Loss of Loved Ones*. Springfield, IL: Charles C Thomas; 1967; and Bibring GL, Dwyer TF, Huntington DS, Valenstein AA. A study of the psychological principles in pregnancy and of the earliest mother-child relationship: Methodological considerations. *Psychoanal Stud Child*. 1961;16:25.

Theory of Anxiety

Freud initially conceptualized anxiety as "dammed up libido." Essentially, a physiological increase in sexual tension leads to a corresponding increase in libido, the mental representation of the physiological event. The *actual neuroses* are caused by this buildup. Later, with the development of the structural model, Freud developed a new theory of a second type of anxiety that he referred to as *signal anxiety*. In this model, anxiety operates at an unconscious level and serves to mobilize the ego's resources to avert danger. Either external or internal sources of danger can produce a signal that leads the ego to marshal specific defense mechanisms to guard against, or reduce, instinctual excitation.

Freud's later theory of anxiety explains neurotic symptoms as the ego's partial failure to cope with distressing stimuli. The drive derivatives associated with danger may not have been adequately contained by the defense mechanisms used by the ego. In phobias, for example, Freud explained that fear of an external threat (e.g., dogs or snakes) is an externalization of an internal danger.

Danger situations can also be linked to developmental stages and, thus, can create a developmental hierarchy of anxiety. The earliest danger situation is a fear of disintegration or annihilation, often associated with concerns about fusion with an external object. As infants mature and recognize the mothering figure as a separate person, separation anxiety, or fear of the loss of an object, becomes more prominent. During the oedipal psychosexual stage, girls are most concerned about losing the love of the most important figure in their lives, their mother. Boys are primarily anxious about bodily injury or castration. After resolution of the oedipal conflict, a more mature form of anxiety occurs, often termed *superego anxiety*. This latency-age concern involves the fear that internalized parental representations, contained in the superego, will cease to love, or will angrily punish, the child.

Character

In 1913, Freud distinguished between neurotic symptoms and personality or character traits. *Neurotic symptoms* develop as a result of the failure of repression; *character traits* owe their existence to the success of repression, that is, to the defense system that achieves its aim through a persistent pattern of reaction formation and sublimation. In 1923, Freud also observed that the ego can only give up important objects by identifying with them or introjecting them. This accumulated pattern of identifications and introjections also contributes to character formation. Freud specifically emphasized the importance of superego formation in the character construction.

Contemporary psychoanalysts regard character as a person's habitual or typical pattern of adaptation to internal drive forces and to external environmental forces. *Character* and *personality* are used interchangeably and are distinguished from the ego in that they largely refer to styles of defense and of directly observable behavior rather than to feeling and thinking.

Character is also influenced by constitutional temperament; the interaction of drive forces with early ego defenses and with environmental influences; and various identifications with, and internalizations of, other persons throughout life. The extent to which the ego has developed a capacity to tolerate the delay of impulse discharge and to neutralize instinctual energy determines the degree to which such character traits emerge in later life. Exaggerated development of certain character traits at the expense of others can lead to personality disorders or produce a vulnerability or predisposition to psychosis.

CLASSIC PSYCHOANALYTIC THEORY OF NEUROSES

The classic view of the genesis of neuroses regards conflict as essential. The conflict can arise between instinctual drives and external reality or between internal agencies, such as the id and the superego or the id and the ego. Moreover, because the conflict has not been worked through to a realistic solution, the drives or wishes that seek discharge have been expelled from consciousness through repression or another defense mechanism. Their expulsion from conscious awareness, however, does not make the drives any less powerful or influential. As a result, the unconscious tendencies (e.g., the disguised neurotic symptoms) fight their way back into consciousness. This theory of the development of neurosis assumes that a rudimentary neurosis based on the same type of conflict existed in early childhood.

Deprivation during the first few months of life because of absent or impaired caretaking figures can adversely affect ego development. This impairment, in turn, can result in failure to make appropriate identifications. The resulting ego difficulties create problems in mediating between the drives and the environment. Lack of capacity for constructive expression of drives, especially aggression, can lead some children to turn their aggression on themselves and become overtly self-destructive. Parents who are inconsistent, excessively harsh, or overly indulgent can influence children to develop disordered superego functioning. Severe conflict that cannot be managed through symptom formation can lead to extreme restrictions in ego functioning and fundamentally impair the capacity to learn and develop new skills.

Traumatic events that seem to threaten survival can break through defenses when the ego has been weakened. More libidinal energy is then required to master the excitation that results. The libido thus mobilized, however, is withdrawn from the supply that is normally applied to external objects. This withdrawal further diminishes the strength of the ego and produces a sense of inadequacy. Frustrations or disappointments in adults may revive infantile longings that are then dealt with through symptom formation or further regression.

In his classic studies, Freud described four different types of childhood neuroses, three of which had later neurotic developments in adult life. This well-known series of cases shown in tabulated form in Table 4.1-4 exemplifies some of Freud's important conclusions: (1) neurotic reactions in the adult are associated frequently with neurotic reactions in childhood; (2) the connection is sometimes continuous but more often is separated by a latent period of nonneurosis; and (3) infantile sexuality, both fantasized and real, occupies a memorable place in the early history of the patient.

 **Table 4.1-4**
Classic Psychoneurotic Reactions of Childhood

	Conversion Reaction (Dora)	Phobic Reaction (Hans)	Obsessive-Compulsive Reaction (Rat Man)	Mixed Neurotic Reaction (Wolf Man)
Family history	Striking family history of psychiatric and physical illness	Both parents treated for neurotic conflict but not severe	No family history of mental illness	Striking family history of psychiatric and physical illness
Symptoms	Enuresis and masturbation, 6-8 yrs; onset of neurosis at 8; migraine, nervous cough, and hoarseness at 12; aphonia at 16; "appendicitis" at 16; convulsions at 16; facial neuralgia at 19; change of personality at 8 from "wild creature" to quiet child	Compulsive questions at 3 to 3 1/2 yrs in regard to sex difference; jealous reaction to sibling birth at 3 1/2; overt castration threat; overt masturbation at 3 1/2; overeating and constipation at 4 to 5; phobic reaction at 4 to 5; attack of flu at 5 worsens phobia; tonsillectomy at 5 worsens phobia	Naughty period at 3 to 4 yrs; marked timidity after beating by father at 4; recognizing people by their smells as a child (Renifleur); precocious ego development; onset of obsessive ideas at 6 to 7	Tractable and quiet up to 3 1/4 yrs; "naughty" period at 3 1/4 to 4 yrs; phobias at 4 to 5 with nightmares; obsessional reaction at 6 to 7 (pious ceremonials). Disappearance of neuroses at 8
Causes	Seduction by older man; father's illness; father's affair	Seductive care by mother; sibling birth at 3 1/2	Seduction by governess at 4; death of sibling at 4; beating by father at 4	Seduction by older sister at 3 1/4; mother's illness; conflict between maid and governess

(Courtesy of E. James Anthony, M.D.)

Certain differences are worth noting in the four cases shown in Table 4.1-4. First, the phobic reactions tend to start at about 4 or 5 years of age, the obsessional reactions between 6 and 7 years, and the conversion reactions at 8 years. The degree of background disturbance is greatest in the conversion reaction and the mixed neurosis, and it seems only slight in the phobic and obsessional reactions. The course of the phobic reaction seems little influenced by severe traumatic factors, whereas traumatic factors, such as sexual seductions, play an important role in the three other subgroups. It was during this period that Freud elaborated his seduction hypothesis for the cause of the neuroses, in terms of which the obsessive-compulsive and hysterical reactions were alleged to originate in active and passive sexual experiences.

TREATMENT AND TECHNIQUE

The cornerstone of psychoanalytic technique is free association, in which patients say whatever comes to mind. Free association does more than provide content for the analysis: It also induces the necessary regression and dependency connected with establishing and working through the transference neurosis. When this development occurs, all the original wishes, drives, and defenses associated with the infantile neuroses are transferred to the person of the analyst.

As patients attempt to free associate, they soon learn that they have difficulty saying whatever comes to mind, without censoring certain thoughts. They develop conflicts about their wishes and feelings toward the analyst that reflect childhood conflicts. The *transference* that develops toward the analyst may also serve as resistance to the process of free association. Freud discovered that *resistance* was not simply a stoppage of a patient's associations, but also an important revelation of the patient's internal object relations as they were externalized and manifested in the transference relationship with the analyst. The systematic analysis of transference and resistance is the essence of psychoanalysis. Freud was also aware that the analyst might have transferences to the patient, which he called *countertransference*.

Countertransference, in Freud's view, was an obstacle that the analyst needed to understand so that it did not interfere with treatment. In this spirit, he recognized the need for all analysts to have been analyzed themselves. Variations in transference and their descriptions are contained in Table 4.1-5. The basic mechanisms by which transferences are effected—displacement, projection, and projective identification—are described in Table 4.1-6.

 **Table 4.1-5**
Transference Variants

Libidinal Transferences

Follow the classic model and usually in milder forms as positive *transference reactions* but can take the form of more intense and disturbing *erotic transferences*. They are derivatives of phallic-oedipal, libidinal impulses and may be permeated variously by pre-genital influences. They can occur with varying degrees of intensity, and in mild forms, may not even require interpretation if they contribute to and support the therapeutic relation. Sigmund Freud recommended that they call for interpretation only when they begin to serve as a resistance.

Aggressive Transferences

Take the form either of negative or more pathological paranoid transferences. *Negative transferences* are seen at all levels of psychopathology but can predominate in some borderline patients who tend to see the therapeutic relationship in terms of power and victimization, regarding the therapist as omnipotent and powerful, whereas the patient experiences him- or herself as helpless, weak, and vulnerable. Negative transferences are identifiable in varying degrees in all analyses and usually require specific intervention and interpretation.

Transferences of Defense

Opposed to *transferences of impulse*; defense against impulses finds its way into the transference rather than the impulses themselves. In this form of transference, attention shifts from drives to the ego's defensive functioning so that transference is no longer merely repetition of instinctual cathexes but includes aspects of ego functioning as well.

Transference Neurosis

Involves the re-creation or more ample expression of the patient's neurosis enacted anew within the analytical relation and at least theoretically mirroring aspects of the infantile neurosis. The transference neurosis usually develops in the middle phase of analysis, when the patient, at first eager for improved mental health, no longer consistently displays such motivation but engages in a continuing battle with the analyst over the desire to attain some kind of emotional satisfaction from the analyst so that this becomes the most compelling reason for continuing analysis. At this point of the treatment, the transference emotions become more important to the patient than alleviation of distress sought initially, and the major, unresolved, unconscious problems of childhood begin to dominate the patient's behavior. They are now reproduced in the transference, with all their pent-up emotion.

The transference neurosis is governed by three outstanding characteristics of instinctual life in early childhood: the pleasure principle (before effective reality testing), ambivalence, and repetition compulsion. Emergence of the transference neurosis is usually a slow and gradual process, although in certain patients with a propensity for *transference regression*, particularly more hysterical patients, elements of transference and transference neurosis may manifest themselves relatively early in the analytical process. One situation after another in the life of the patient is analyzed and progressively interpreted until the original infantile conflict is sufficiently revealed. Only then does the transference neurosis begin to subside. At that point, termination begins to emerge as a more central concern.

Contemporary opinion is divided to its importance and centrality, whether it forms to the extent Freud believed, and whether it is necessary for successful analysis—for some, it remains an essential vehicle for analytical interpretation and therapeutic effectiveness; for others, it may never develop or, to the extent that it does, may play a less central role in the process of cure.

Transference Psychosis

Occurs when failure of reality testing leads to loss of self-object differentiation and diffusion of self and object boundaries. This may reflect an attempt to re-use with an omnipotent object, investing the self with omnipotent powers as defense against underlying fears of vulnerability and powerlessness. Transference psychosis can also include negative transference elements in which fusion carries the threat of engulfment and loss of self that may precipitate a *paranoid transference reaction*.

Narcissistic Transferences

Clarified by Heinz Kohut (1971) as variations of patterns of projection of archaic narcissistic configurations onto the therapist. They are based on projections of narcissistic introjective configurations, both superior and inferior—the superior form reflecting narcissistic superiority, grandiosity, and enhanced self-esteem, and the inferior opposite qualities of inferiority, self-depletion, and diminished self-esteem. The therapist comes to represent, in Kohut's terms, either the grandiose self in *mirror transferences* or the idealized parental imago in *idealizing transferences*. In idealizing transferences, all power and strength are attributed to the idealizing object, leaving the subject feeling empty and powerless when separated from that object. Union with the idealized object enables the subject to regain narcissistic equilibrium. Idealizing transferences may reflect developmental disturbances in the idealized parent imago, particularly at the time of formation of the ego ideal by introjection of the idealized object. In some individuals, narcissistic fixation leads to development of the grandiose self. Reactivation in analysis of the grandiose self provides the basis of mirror transference formation, which occur in three forms: *archaic merger transference*, a less archaic *alter-ego or twinship transference*, and *mirror transference in the narrow sense*. In the most primitive merger transference, the analyst is experienced only as an extension of the subject's grandiose self and, thus, becomes the repository of the patient's grandiosity and exhibitionism. In the alter-ego or twinship transference, activation of the grandiose self leads to experience of the narcissistic object as similar to the grandiose self. In the most mature form of mirror transference, the analyst is experienced as a separate person but, nonetheless, one who becomes important to the patient and is accepted by him or her only to the degree that he or she is responsive to the narcissistic needs of the reactivated grandiose self.

Self-Object Transferences

Represent extensions of the self-psychology paradigm beyond merely narcissistic configurations. The self-object involves investment of the self in the object so that the object comes to serve a self-sustaining function that the self cannot perform for itself—either in maintaining fragile self-cohesion or in regulating self-esteem. The other, thus, is not experienced as an autonomous and separate object or agency in its own right but as present only to serve the needs of the self. Transference in this sense reflects a continuing developmental need that seeks satisfaction in the analytical relation.

Self-object transferences reflect the underlying need structure the patient brings to the therapeutic relationship based on the predominant pattern of self-object deprivation or frustration and the corresponding seeking for the appropriate form of self-object involvement. These configurations have been described as the *understimulated self*, the *overstimulated self*, the *overburdened self*, and the *fragmenting self*. Other descriptions of self-object need translate patterns of transference interaction based on narcissistic dynamics into the perspective of the relationship between self and self-object, as in mirror-hungry personalities and ideal-hungry personalities. Variations on the mirroring transference theme include the alter-ego-hungry personality, the merger-hungry personality, and, in contrast, the contact-shunning personality. In transferences derived from such personality configurations, the classic meaning of transference has undergone radical modification. Rather than displacements or projections from earlier object relational contexts, the patient brings to bear a need based in his or her own currently deficient capacity and defective character structure—a need to involve the object in a dependent relationship to complete or stabilize his or her own psychic integration.

Transitional Relatedness

This transference model is based on Donald Winnicott's notion of the transitional object. Transference in more primitive character structures is regarded as a form of *transitional object relation* in which the therapist is perceived as outside the self but is invested with qualities from the patient's own archaic self-image. The transference field in this view is envisioned as a transitional space in which the transference illusion is allowed to play itself out.

Transference as Psychic Reality

Reflects the need of each participant in analysis to draw the other into a stance corresponding to his or her own intrapsychic configuration and needs as a reflection of the individual subject's psychic reality. This regards the classic view of transference, based on displacement or projection from past objects, as inadequate, resulting in further diffusion of meaning of transference as equivalent to the individual's capacity to create a meaningful world or to inform the world with meaning. In this rendition, transference becomes equivalent to the patient's psychic reality so that any distinction between the meanings given to reality and the meanings inherent in transference is lost. Transference in these terms becomes all-encompassing, and whatever distinguishing and dynamic significance it may have had fades into obscurity. In this form of transference, no definable mechanism seems to be at work other than whatever is involved in the subject's psychic reality. The subject's view of his or her environment and impression of objects of his or her experience, including the analytical object, are indistinguishable from ordinary cognitive and affective processes characterizing personal involvement and responsiveness to the world about him or her.

Transference as Relational or Intersubjective

The relational or intersubjective view of transference as emerging from or cocreated by the subjective interaction between analyst and analysand transforms transference into an interactive phenomenon in which individual intrapsychic contributions from either participant are obscured. Transference in this sense is not anything individual to, or intrapsychically derived from, the patient but is based on the present ongoing interaction between analyst and patient coconstructing transference. On these terms, analysis of transference has little to do with past derivatives and everything to do with the ongoing relation with the analyst, primarily in the form of interpersonal enactments. Transference in this sense is no longer a one-person phenomenon but reflects a two-person transference-countertransference interaction. The supposition is that no such thing as transference exists without countertransference and no such thing as countertransference exists without transference. The patient is thus relieved of any burden of a personal dynamic unconscious reflecting developmental vicissitudes and residues of a life history. Transference is created anew in the immediacy of present analytical interaction as the product of mutual influence and communication between analyst and analysand, probably relying on some form of mutual projective identification to sustain the interactive connotation.

 **Table 4.1-6**
Transference Mechanisms

Displacement

The basic mechanism of classic transference paradigms in which an object representation derived from any level or combination of levels of the subject's developmental experience is displaced to the representation of the new object, namely, the analyst, in the therapeutic relationship. Displacement is the basic mechanism for libidinally based transferences, both positive and erotic, as well as for aggressive and especially negative transferences. By and large, displacement transferences tend to play a more dominant role in neurotic disorders in which phallic-oedipal (and to a lesser degree preoedipal) dynamics tend to play a dominant, although not exclusive, role.

Projection

Process by which qualities or characteristics of the self-as-object, usually involving introjections or self-representations, are attributed to an external object, and the subsequent interaction with the object is determined by the projected characteristics. Thus, the analyst or object may be seen as sadistic—that is, as possessing the sadistic character of the analysand or subject, an aspect of the subject's self that is denied or disowned by the subject. Projection tends to play a more prominent, although again not exclusive, role in formation of transferences in more primitive character disorders but can be found in variously modified forms throughout the spectrum of neuroses. Because projections derive primarily from the configuration of introjects constituting the patient's self-as-object, the effect of projective or externalizing transferences is that the image of the therapist comes to represent part of the patient's own self-organization rather than simply an object representation.

Projections derived from destructive introjects can provide the basis for both negative and paranoid transference reactions. Those based on the victim or introject result in the patient relating to the therapist as his or her victim and him- or herself assuming a hostile or sadistic position as a destructive aggressor or victimizer to the therapist's victim. Then again, projection based on the aggressor or introject results in the patient relating to the therapist as an aggressor and him- or herself assuming a weak, vulnerable, or masochistic position in which he or she becomes a passive and vulnerable victim to the therapist's destructive aggression. Similar patterns can take place around narcissistic issues involving introjective configurations of narcissistic superiority and inferiority.

Projective dynamics in self-object transferences, however, seem to involve more than narcissistic projections because these forms of transference tend to draw the analyst into meeting the pathological needs of the self. If anything is projected, it is an infantile wished-for imago, one lacking earlier in the patient's experience, as, for example, an empathic and idealized parental figure. On the other hand, transitional transferences, despite their considerable overlap with self-object phenomena, tend to involve a more explicit projective element as the self-related contribution to the transitional experience.

Projective Identification

The concept of projective identification was first proposed by Melanie Klein, arguing that the projection of impulses or feelings into another person brought about an identification with that person based on attribution of one's own qualities to that other. This attribution served as the basis for a sense of empathy and connection with the other. On these terms, projective identification was a fantasy taking place solely in the mind of the one projecting.

Projective identification is often appealed to as a mechanism of transference, or more exactly transference-countertransference interactions, particularly in Kleinian usage. Confusion arises from the failure to clearly distinguish between projection and projective identification. The notion of projective identification added to the basic concept of projection of the notes of diffusion of ego boundaries, a loss or diminishing of self-object differentiation, and inclusion of the object as part of the self.

Later elaborations of the notion of projective identification transformed it from a one-body to a two-body phenomenon, describing interaction between two subjects, one of whom projects something onto or into the other, whereon the other introjects or internalizes what has been projected. Instead of the projection and introjection taking place in the same subject, the projection now takes place in one and the internalization in the other. This latter usage has led to extensive extrapolation of the concept of projective identification to apply to all sorts of object relations, including transference. The emphasis in Kleinian transference is less on the influence of the past on the present but rather the influence of the internal world on the external in the here-and-now interaction with the analyst.

Analysts after Freud began to recognize that countertransference was not only an obstacle but also a source of useful information about the patient. In other words, the analyst's feelings in response to the patient reflect how other persons respond to the patient and provide some indication of the patient's own internal object relations. By understanding the intense feelings that occur in the analytic relationship, the analyst can help the patient broaden understanding of past and current relationships outside the analysis. The development of insight into neurotic conflicts also expands the ego and provides an increased sense of mastery.

▲ 4.2 Erik H. Erikson

Erik H. Erikson (Fig 4.2-1) was one of America's most influential psychoanalysts. Throughout six decades in the United States, he distinguished himself as an illuminator and expositor of Freud's theories and as a brilliant clinician, teacher, and pioneer in psychohistorical investigation. Erikson created an original and highly influential theory of psychological development and crisis occurring in periods that extended across the entire life cycle. His theory grew out of his work first as a teacher, then as a child psychoanalyst, next as an anthropological field worker, and, finally, as a biographer. Erikson identified dilemmas or polarities in the ego's relations with the family and larger social institutions at nodal points in childhood, adolescence, and early, middle, and late adulthood. Two of his psychosexual historical studies, *Young Man Luther* and *Gandhi's Truth* (published in 1958 and 1969 respectively), were widely hailed as profound explorations of how crucial circumstances can interact with the crises of certain great persons at certain moments in time. The interrelationships of the psychological development of the person and the historical developments of the times were more fully explored in *Life History and the Historical Moment*, written by Erikson in 1975.

FIGURE 4.2-1
Erik Erikson (1902-1994).

Erik Homburger Erikson was born June 15, 1902 in Frankfurt, Germany, the son of Danish parents. He died in 1994. His father abandoned his mother before he was born, and he was brought up by his mother, a Danish Jew, and her second husband, Theodor Homburger, a German-Jewish pediatrician. Erikson's parents chose to keep his real parentage a secret from him, and for many years he was known as Erik Homburger. Erikson never knew the identity of his biological father; his mother withheld that information from him all her life. The man who introduced the term "identity crisis" into the language undoubtedly struggled with his own sense of identity. Compounding his parents' deception about his biological father—their "loving deceit," as he called it—was the fact that, as a blond, blue-eyed, Scandinavian-looking son of a Jewish father, he was taunted as a "goy" among Jews, at the same time being called a Jew by his classmates. His being a Dane living in Germany added to his identity confusion. Erikson was later to describe himself as a man of the borders. Much of what he was to study was concerned with how group values are implanted in the very young, how young people grasp onto group identity in the limbo period between childhood and adulthood, and how a few persons, like Gandhi, transcend their local, national, and even temporal identities to form a small band of people with wider sympathies who span the ages.

The concepts of identity, identity crisis, and identity confusion are central to Erikson's thought. In his first book *Childhood and Society* (published in 1950) Erikson observed that "the study of identity...becomes as strategic in our time as the study of sexuality was in Freud's time." By identity, Erikson meant a sense of sameness and continuity "in the inner core of the individual" that was maintained amid external change. A sense of identity, emerging at the end of adolescence, is a psychosocial phenomenon preceded in one form or another by an identity crisis; that crisis may be conscious or unconscious, with the person being aware of the present state and future directions but also unconscious of the basic dynamics and conflicts that underlie those states. The identity crisis can be acute and prolonged in some people.

The young Erikson did not distinguish himself in school, although he did show artistic talent. On graduation, he chose to spend a year traveling through the Black Forest, Italy, and the Alps, pondering life, drawing, and making notes. After that year of roaming, he studied art in his home city of Karlsruhe and later in Munich and Florence.

In 1927 Peter Blos, a high school friend, invited Erikson to join him in Vienna. Blos, not yet a psychoanalyst, had met Dorothy Burlingham, a New Yorker who had come to Vienna to be psychoanalyzed; she had brought her four children with her and hired Blos to tutor them. Blos was looking for a fellow teacher in his new school for the children of English and American parents and students of his new discipline of psychoanalysis. Erikson accepted his offer.

Blos and Erikson organized their school in an informal manner—much in the style of the so-called progressive or experimental schools popular in the United States. Children were encouraged to participate in curriculum planning and to express themselves freely. Erikson, still very much the artist, taught drawing and painting, but he also exposed his pupils to history and to foreign ways of life, including the cultures of the American Indian and Eskimo.

During that period Erikson became involved with the Freud family, friends of Mrs. Burlingham. He became particularly close to Anna Freud, with whom he began psychoanalysis. Anna Freud, who had been an elementary school teacher, was at that time formulating the new science of child psychiatry, trying to turn attention from the adult's corrective backward look to a neurosis-preventative study of childhood itself. Under Anna Freud's tutelage Erikson began more and more to turn his attention to childhood, both his own and that of the children whom he saw in the classroom. Analysis was not then the rigidly structured procedure into which it later developed; Erikson met with Miss Freud daily for his analytic hour and frequently saw her socially as well, as part of the circle of Freud's followers and associates. Still undecided about his future, Erikson continued to teach school, at the same time studying psychoanalysis at the Vienna Psychoanalytic Institute. He also studied to become accredited as a Montessori teacher.

In 1929 he married Joan Mowat Serson, an American of Canadian birth, and he was hastily made a full member, rather than an associate member, of the Vienna Psychoanalytic Society—unorthodoxy that allowed him to leave a Vienna threatened by fascism immediately after his graduation in 1933. Earlier, Erikson had met the Viennese Hanns Sachs, co-founder along with Otto Rank of the psychoanalytically oriented journal *Imago*. Sachs—who had settled in Boston, where he was associated with the Harvard Medical School—was sure that Erikson would be welcome at Harvard and suggested that he make Boston his home. After a brief stay in Denmark, the Eriksons moved to Boston, where he became the city's only child analyst. He held positions at the Harvard Medical School and at Massachusetts General Hospital, served as a consultant at the Judge Baker Guidance Center, and maintained a private practice.

Erikson was much influenced by Cambridge's circle of young social scientists, including anthropologists Margaret Mead and Ruth Benedict. Exposure to the views of those vigorous thinkers helped to shape his theories of child psychology and his cross-cultural approach to human development. Classical psychoanalysis had traditionally concerned itself with pathology and with treating disturbed people, but Erikson found himself more and more interested in the normal personality and in applying his own observations about how young people function and how childhood play affects character formation. Although he remained in the Boston area only three years, he established a solid reputation as a skilled clinician and researcher before moving to Yale University's Institute of Human Relations. There he furthered an interest sparked at Harvard in the work of American anthropologists. In 1938 he traveled to South Dakota to study the children of the Sioux Indians of the Pine Ridge Reservation. His observations about how communal and historical forces powerfully influence child rearing became an important contribution to psychology and to the study of humans in society.

In 1939 Erikson moved to a post at Berkeley, from which he studied the Yurok Indians, a group of salmon fishers. He left Berkeley in 1950 after refusing to sign what he called a vague, fearful addition to the loyalty oath. He resettled at the Austen Riggs Center in Stockbridge, Massachusetts, working with young people. In 1960 he was appointed to a professorship at Harvard. After his retirement from Harvard, Erikson in 1972 joined Mount Zion Hospital in San Francisco as senior consultant in psychiatry. Until his death in 1994 he continued to focus on many of his earlier interests, examining the individual in this historical context and elaborating on concepts of the human life cycle, especially those of old age.

EPIGENETIC PRINCIPLE

Erikson's formulations were based on the concept of *epigenesis*, a term borrowed from embryology. His *epigenetic principle* holds that development occurs in sequential, clearly defined stages, and that each stage must be satisfactorily resolved for development to proceed smoothly. According to the epigenetic model, if successful resolution of a particular stage does not occur, all subsequent stages reflect that failure in the form of physical, cognitive, social, or emotional maladjustment.

Relation to Freudian Theory

Erikson accepted Freud's concepts of instinctual development and infantile sexuality. For each of Freud's psychosexual stages (e.g., oral, anal, and phallic), Erikson described a corresponding zone with a specific pattern or mode of behavior. Thus, the oral zone is associated with sucking or taking-in behavior; the anal zone is associated with holding on and letting go. Erikson emphasized that the development of the ego is more than the result of intrapsychic wants or inner psychic energies. It is also a matter of mutual regulation between growing children and a society's culture and traditions.

Eight Stages of the Life Cycle

Erikson's conception of the eight stages of ego development across the life cycle is the centerpiece of his life's work, and he elaborated the conception throughout his subsequent writings (Table 4.2-1). The eight stages represent points along a continuum of development in which physical, cognitive, instinctual, and sexual changes combine to trigger an internal crisis the resolution of which results in either psychosocial regression or growth and the development of specific virtues. In *Insight and Responsibility* Erikson defined virtue as "inherent strength," as in the active quality of a medicine or liquor. He wrote in *Identity: Youth and Crisis* that "crisis" refers not to a "threat of catastrophe, but to a turning point, a crucial period of increased vulnerability and heightened potential, and therefore, the ontogenetic source of generational strength and maladjustment."

Table 4.2-1
Erikson's Psychosocial Stages

Psychosocial Stage	Associated Virtue	Related Forms of Psychopathology	Positive and Negative Forerunners of Identity Formation	Enduring Aspects of Identity Formation
Trust vs. mistrust (birth—)	Hope	Psychosis Addictions Depression	Mutual recognition vs. autistic isolation	Temporal perspective vs. time confusion
Autonomy vs. shame and doubt (–18 months—)	Will	Paranoia Obsessions Compulsions Impulsivity	Will to be oneself vs. self-doubt	Self-certainty vs. self-consciousness
Initiative vs. guilt (–3 years—)	Purpose	Conversion disorder Phobia Psychosomatic disorder Inhibition	Anticipation of roles vs. role inhibition	Role experimentation vs. role fixation
Industry vs. inferiority (–5 years—)	Competence	Creative inhibition Inertia	Task identification vs. sense of futility	Apprenticeship vs. work paralysis
Identity vs. role confusion (–13 years—)	Fidelity	Delinquent behavior Gender-related identity disorders Borderline psychotic episodes		Identity vs. identity confusion
Intimacy vs. isolation (–20s—)	Love	Schizoid personality disorder Distantiation		Sexual polarization vs. bisexual confusion
Generativity vs. stagnation (–40s—)	Care	Mid-life crisis Premature invalidism		Leadership and followership vs. abdication of responsibility
Integrity vs. despair (–60s—)	Wisdom	Extreme alienation Despair		Ideological commitment vs. confusion of values

(Adapted from Erikson E. *Insight and Responsibility*. New York: WW Norton; 1964; Erikson E. *Identity: Youth and Crisis*. New York: WW Norton; 1968, with permission.)

Stage 1: Trust versus Mistrust (Birth to about 18 Months). In *Identity: Youth and Crisis*, Erikson noted that the infant “lives through and loves with” its mouth. Indeed, the mouth forms the basis of its first mode or pattern of behavior, that of incorporation. The infant is taking the world in through the mouth, eyes, ears, and sense of touch. The baby is learning a cultural modality that Erikson termed *to get*, that is, to receive what is offered and elicit what is desired. As the infant’s teeth develop and it discovers the pleasure of biting, it enters the second oral stage, the active-incorporative mode. The infant is no longer passively receptive to stimuli; it reaches out for sensation and grasps at its surroundings. The social modality shifts to that of *taking and holding* on to things.

The infant’s development of basic trust in the world stems from its earliest experiences with its mother or primary caretaker. In *Childhood and Society*, Erikson asserts that trust depends not on “absolute quantities of food or demonstrations of love, but rather on the quality of maternal relationship.” A baby whose mother can anticipate and respond to its needs in a consistent and timely manner despite its oral aggression will learn to tolerate the inevitable moments of frustration and deprivation. The defense mechanisms of introjection and projection provide the infant with the means to internalize pleasure and externalize pain such that “consistency, continuity, and sameness of experience provide a rudimentary sense of ego identity.” Trust will predominate over mistrust, and hope will crystallize. For Erikson, the element of society corresponding to this stage of ego identity is religion, as both are founded on “trust born of care.”

In keeping with his emphasis on the epigenetic character of psychosocial change, Erikson conceived of many forms of psychopathology as examples of what he termed *aggravated development crisis*, development, which having gone awry at one point, affects subsequent psychosocial change. A person who, as a result of severe disturbances in the earliest dyadic relationships, fails to develop a basic sense of trust or the virtue of hope may be predisposed as an adult to the profound withdrawal and regression characteristic of schizophrenia. Erikson hypothesized that the depressed patient’s experience of being empty and of being no good is an outgrowth of a developmental derailment that causes oral pessimism to predominate. Addictions may also be traced to the mode of oral incorporation.

Stage 2: Autonomy versus Shame and Doubt (about 18 Months to about 3 Years). In the development of speech and sphincter and muscular control, the toddler practices the social modalities of *holding on and letting go*, and experiences the first stirrings of the virtue that Erikson termed *will*. Much depends on the amount and type of control exercised by adults over the child. Control that is exerted too rigidly or too early defeats the toddler’s attempts to develop its own internal controls, and regression or false progression results. Parental control that fails to protect the toddler from the consequences of his or her own lack of self-control or judgment can be equally disastrous to the child’s development of a healthy sense of autonomy. In *Identity: Youth and Crisis*, Erikson asserted: “This stage, therefore, becomes decisive for the ratio between loving good will and hateful self-insistence, between cooperation and willfulness, and between self-expression and compulsive self-restraint or meek compliance.”

Where that ratio is favorable, the child develops an appropriate sense of autonomy and the capacity to “have and to hold”; where it is unfavorable, doubt and shame will undermine free will. According to Erikson, the principle of law and order has at its roots this early preoccupation with the protection and regulation of will. In *Childhood and Society*, he concluded, “The sense of autonomy fostered in the child and modified as life progresses, serves (and is served by) the preservation in economic and political life of a sense of justice.”

A person who becomes fixated at the transition between the development of hope and autonomous will, with its residue of mistrust and doubt, may develop paranoid fears of persecution. When psychosocial development is derailed in the second stage, other forms of pathology may emerge. The perfectionism, inflexibility, and stinginess of the person with an obsessive-compulsive personality disorder may stem from conflicting tendencies to hold on and to let go. The ruminative and ritualistic behavior of the person with an obsessive-compulsive disorder may be an outcome of the triumph of doubt over autonomy and the subsequent development of a primitively harsh conscience.

Stage 3: Initiative versus Guilt (about 3 Years to about 5 Years). The child’s increasing mastery of locomotor and language skills expands its participation in the outside world and stimulates omnipotent fantasies of wider exploration and conquest. Here the youngster’s mode of participation is active and intrusive; its social modality is that of being on the make. The intrusiveness is manifested in the child’s fervent curiosity and genital preoccupations, competitiveness, and physical aggression. The Oedipus complex is in ascendance as the child competes with the same-sex parent for the fantasized possession of the other parent. In *Identity: Youth and Crisis*, Erikson wrote that “jealousy and rivalry now come to a climax in a final contest for a favored position with one of the parents: the inevitable and necessary failure leads to guilt and anxiety.”

Guilt over the drive for conquest and anxiety over the anticipated punishment are both assuaged in the child through repression of the forbidden wishes and development of a superego to regulate its initiative. This conscience, the faculty of self-observation, self-regulation, and self-punishment, is an internalized version of parental and societal authority. Initially, the conscience is harsh and uncompromising; however, it constitutes the foundation for the subsequent development of morality. Having renounced oedipal ambitions, the child begins to look outside the family for arenas in which it can compete with less conflict and guilt. This is the stage that highlights the child's expanding initiative and forms the basis for the subsequent development of realistic ambition and the virtue of *purpose*. As Erikson noted in *Childhood and Society*, "The 'oedipal' stage sets the direction toward the possible and the tangible which permits the dreams of early childhood to be attached to the goals of an active adult life." Toward this end, social institutions provide the child with an economic ethos in the form of adult heroes who begin to take the place of their storybook counterparts.

When there has been an inadequate resolution of the conflict between initiative and guilt, a person may ultimately develop a conversion disorder, inhibition, or phobia. Those who overcompensate for the conflict by driving themselves too hard may experience sufficient stress to produce psychosomatic symptoms.

Stage 4: Industry versus Inferiority (about 5 Years to about 13 Years). With the onset of latency, the child discovers the pleasures of production. He or she develops industry by learning new skills and takes pride in the things made. Erikson wrote in *Childhood and Society* that the child's "ego boundaries include his tools and skills: the work principle teaches him the pleasure of work completion by steady attention and persevering diligence." Across cultures, this is a time when the child receives systematic instruction and learns the fundamentals of technology as they pertain to the use of basic utensils and tools. As children work, they identify with their teachers and imagine themselves in various occupational roles.

A child who is unprepared for this stage of psychosocial development, either through insufficient resolution of previous stages or by current interference, may develop a sense of inferiority and inadequacy. In the form of teachers and other role models, society becomes crucially important in the child's ability to overcome that sense of inferiority and to achieve the virtue known as competence. In *Identity: Youth and Crisis*, Erikson noted: "This is socially a most decisive stage. Since industry involves doing things beside and with others, a first sense of division of labor and of differential opportunity, that is, a sense of the technological ethos of a culture, develops at this time."

The pathological outcome of a poorly navigated stage of industry versus inferiority is less well defined than in previous stages, but it may concern the emergence of a conformist immersion into the world of production in which creativity is stifled and identity is subsumed under the worker's role.

Stage 5: Identity versus Role Confusion (about 13 Years to about 21 Years). With the onset of puberty and its myriad social and physiological changes, the adolescent becomes preoccupied with the question of identity. Erikson noted in *Childhood and Society* that youth are now "primarily concerned with what they appear to be in the eyes of others as compared to what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day." Childhood roles and fantasies are no longer appropriate, yet the adolescent is far from equipped to become an adult. In *Childhood and Society*, Erikson writes that the integration that occurs in the formation of ego identity encompasses far more than the summation of childhood identifications. "It is the accrued experience of the ego's ability to integrate these identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles."

The formation of cliques and an identity crisis occur at the end of adolescence. Erikson calls the crisis normative because it is a normal event. Failure to negotiate this stage leaves adolescents without a solid identity; they suffer from identity diffusion or role confusion, characterized by not having a sense of self and by confusion about their place in the world. Role confusion can manifest in such behavioral abnormalities as running away, criminality, and overt psychosis. Problems in gender identity and sexual role may manifest at this time. Adolescents may defend against role diffusion by joining cliques or cults or by identifying with folk heroes. Intolerance of individual differences is a way in which the young person attempts to ward off a sense of identity loss. Falling in love, a process by which the adolescent may clarify a sense of identity by projecting a diffused self-image onto the partner and seeing it gradually assume a more distinctive shape, and an overidentification with idealized figures are means by which the adolescent seeks self-definition. With the attainment of a more sharply focused identity, the youth develops the virtue of *fidelity*—faithfulness not only to the nascent self-definition but also to an ideology that provides a version of self-in-world. As Erik Erikson, Joan Erikson, and Helen Kivnick wrote in *Vital Involvement in Old Age*, "Fidelity is the ability to sustain loyalties freely pledged in spite of the inevitable contradictions of value systems. It is the cornerstone of identity and receives inspiration from confirming ideologies and affirming companionships." Role confusion ensues when the youth is unable to formulate a sense of identity and belonging. Erikson held that delinquency, gender-related identity disorders, and borderline psychotic episodes can result from such confusion.

Stage 6: Intimacy versus Isolation (about 21 Years to about 40 Years). Freud's famous response to the question of what a normal person should be able to do well, "Lieben und arbeiten" (to love and to work), is one that Erikson often cited in his discussion of this psychosocial stage, and it emphasizes the importance he placed on the virtue of love within a balanced identity. Erikson asserted in *Identity: Youth and Crisis* that Freud's use of the term love referred to "the generosity of intimacy as well as genital love; when he said love and work, he meant a general work productiveness which would not preoccupy the individual to the extent that he might lose his right or capacity to be a sexual and a loving being."

Intimacy in the young adult is closely tied to fidelity; it is the ability to make and honor commitments to concrete affiliations and partnerships even when that requires sacrifice and compromise. The person who cannot tolerate the fear of ego loss arising out of experiences of self-abandonment (e.g., sexual orgasm, moments of intensity in friendships, aggression, inspiration, and intuition) is apt to become deeply isolated and self-absorbed. *Distantiation*, an awkward term coined by Erikson to mean "the readiness to repudiate, isolate, and, if necessary, destroy those forces and persons whose essence seems dangerous to one's own," is the pathological outcome of conflicts surrounding intimacy and, in the absence of an ethical sense where intimate, competitive, and combative relationships are differentiated, forms the basis for various forms of prejudice, persecution, and psychopathology.

Erikson's separation of the psychosocial task of achieving identity from that of achieving intimacy, and his assertion that substantial progress on the former task must precede development on the latter have engendered much criticism and debate. Critics have argued that Erikson's emphasis on separation and occupationally based identity formation fails to take into account the importance for women of continued attachment and the formation of an identity based on relationships.

Stage 7: Generativity versus Stagnation (about 40 Years to about 60 Years). Erikson asserted in *Identity: Youth and Crisis* that "generativity is primarily the concern for establishing and guiding the next generation." The term *generativity* applies not so much to rearing and teaching one's offspring as it does to a protective concern for all the generations and for social institutions. It encompasses productivity and creativity as well. Having previously achieved the capacity to form intimate relationships, the person now broadens the investment of ego and libidinal energy to include groups, organizations, and society. *Care* is the virtue that coalesces at this stage. In *Childhood and Society* Erikson emphasized the importance to the mature person of feeling needed. "Maturity needs guidance as well as encouragement from what has been produced and must be taken care of." Through generative behavior, the individual can pass on knowledge and skills while obtaining a measure of satisfaction in having achieved a role with senior authority and responsibility in the tribe.

When persons cannot develop true generativity, they may settle for pseudoengagement in occupation. Often, such persons restrict their

focus to the technical aspects of their roles, at which they may now have become highly skilled, eschewing greater responsibility for the organization or profession. This failure of generativity can lead to profound personal stagnation, masked by a variety of escapisms, such as alcohol and drug abuse, and sexual and other infidelities. Mid-life crisis or premature invalidism (physical and psychological) can occur. In this case, pathology appears not only in middle-aged persons but also in the organizations that depend on them for leadership. Thus, the failure to develop at midlife can lead to sick, withered, or destructive organizations that spread the effects of failed generativity throughout society; examples of such failures have become so common that they constitute a defining feature of modernity.

Stage 8: Integrity versus Despair (about 60 Years to Death). In *Identity: Youth and Crisis*, Erikson defined integrity as “the acceptance of one’s one and only life cycle and of the persons who have become significant to it as something that had to be and that, by necessity, permitted of no substitutions.” From the vantage point of this stage of psychosocial development, the individual relinquishes the wish that important persons in his life had been different and is able to love in a more meaningful way—one that reflects accepting responsibility for one’s own life. The individual in possession of the virtue of wisdom and a sense of integrity has room to tolerate the proximity of death and to achieve what Erikson termed in *Identity: Youth and Crisis* a “detached yet active concern with life.”

Erikson underlined the social context for this final stage of growth. In *Childhood and Society*, he wrote, “The style of integrity developed by his culture or civilization thus becomes the ‘patrimony’ of his soul.... In such final consolidation, death loses its sting.”

When the attempt to attain integrity has failed, the individual may become deeply disgusted with the external world and contemptuous of persons as well as institutions. Erikson wrote in *Childhood and Society* that such disgust masks a fear of death and a sense of despair that “time is now short, too short for the attempt to start another life and to try out alternate roads to integrity.” Looking back on the eight ages of man, he noted the relation between adult integrity and infantile trust, “Healthy children will not fear life if their elders have integrity enough not to fear death.”

PSYCHOPATHOLOGY

Each stage of the life cycle has its own psychopathological outcome if it is not mastered successfully.

Basic Trust

An impairment of basic trust leads to basic mistrust. In infants, social trust is characterized by ease of feeding, depth of sleep, smiling, and general physiological homeostasis. Prolonged separation during infancy can lead to hospitalism or anaclitic depression. In later life, this lack of trust may be manifested by dysthymic disorder, a depressive disorder, or a sense of hopelessness. Persons who develop and rely on the defense of projection—in which, according to Erikson, “we endow significant persons with the evil which actually is in us”—experienced a sense of social mistrust in the first years of life and are likely to develop paranoid or delusional disorders. Basic mistrust is a major contributor to the development of schizoid personality disorder and, in most severe cases, to the development of schizophrenia. Substance-related disorders can also be traced to social mistrust; substance-dependent personalities have strong oral-dependency needs and use chemical substances to satisfy themselves because of their belief that human beings are unreliable and, at worst, dangerous. If not nurtured properly, infants may feel empty, starved not just for food but also for sensual and visual stimulation. As adults, they may become seekers after stimulating thrills that do not involve intimacy and that help ward off feelings of depression.

Autonomy

The stage in which children attempt to develop into autonomous beings is often called the *terrible twos*, referring to toddlers’ willfulness at this period of development. If shame and doubt dominate over autonomy, compulsive doubting can occur. The inflexibility of the obsessive personality also results from an overabundance of doubt. Too rigorous toilet training, commonplace in today’s society, which requires a clean, punctual, and deodorized body, can produce an overly compulsive personality that is stingy, meticulous, and selfish. Known as anal personalities, such persons are parsimonious, punctual, and perfectionistic (the three P’s).

Too much shaming causes children to feel evil or dirty and may pave the way for delinquent behavior. In effect, children say, “If that’s what they think of me, that’s the way I’ll behave.” Paranoid personalities feel that others are trying to control them, a feeling that may have its origin during the stage of autonomy versus shame and doubt. When coupled with mistrust, the seeds are planted for persecutory delusions. Impulsive disorder may be explained as a person’s refusing to be inhibited or controlled.

Initiative

Erikson stated: “In pathology, the conflict over initiative is expressed either in hysterical denial, which causes the repression of the wish or the abrogation of its executive organ by paralysis or impotence; or in overcompensatory showing off, in which the scared individual, so eager to ‘duck,’ instead ‘sticks his neck out.’” In the past, hysteria was the usual form of pathological regression in this area, but a plunge into psychosomatic disease is now common.

Excessive guilt can lead to a variety of conditions, such as generalized anxiety disorder and phobias. Patients feel guilty because of normal impulses, and they repress these impulses, with resulting symptom formation. Punishment or severe prohibitions during the stage of initiative versus guilt can produce sexual inhibitions. Conversion disorder or specific phobia can result when the oedipal conflict is not resolved. As sexual fantasies are accepted as unrealizable, children may punish themselves for these fantasies by fearing harm to their genitals. Under the brutal assault of the developing superego, they may repress their wishes and begin to deny them. If this pattern is carried forward, paralysis, inhibition, or impotence can result. Sometimes, in fear of not being able to live up to what others expect, children may develop psychosomatic disease.

Industry

Erikson described industry as a “sense of being able to make things and make them well and even perfectly.” When children’s efforts are thwarted, they are made to feel that personal goals cannot be accomplished or are not worthwhile, and a sense of inferiority develops. In adults, this sense of inferiority can result in severe work inhibitions and a character structure marked by feelings of inadequacy. For some persons, the feelings may result in a compensatory drive for money, power, and prestige. Work can become the main focus of life, at the expense of intimacy.

Identity

Many disorders of adolescence can be traced to identity confusion. The danger is role diffusion. Erikson stated:

Where this is based on a strong previous doubt to one’s sexual identity, delinquent and outright psychotic incidents are not uncommon. If diagnosed and treated correctly, those incidents do not have the same fatal significance that they have at other ages. It is primarily the inability to settle on an occupational identity that disturbs young persons. Keeping themselves together, they temporarily overidentify, to the point of apparent complete loss of identity, with the heroes of cliques and crowds.

Other disorders during the stage of identity versus role diffusion include conduct disorder, disruptive behavior disorder, gender identity disorder, schizophreniform disorder, and other psychotic disorders. The ability to leave home and live independently is an important task

during this period. An inability to separate from the parent and prolonged dependence may occur.

Intimacy

The successful formation of a stable marriage and family depends on the capacity to become intimate. The years of early adulthood are crucial for deciding whether to get married and to whom. Gender identity determines object choice, either heterosexual or homosexual, but making an intimate connection with another person is a major task. Persons with schizoid personality disorder remain isolated from others because of fear, suspicion, the inability to take risks, or the lack of a capacity to love.

Generativity. From about 40 to 65 years, the period of middle adulthood, specific disorders are less clearly defined than in the other stages described by Erikson. Persons who are middle aged show a higher incidence of depression than younger adults, which may be related to middle-aged persons' disappointments and failed expectations as they review the past, consider their lives, and contemplate the future. The increased use of alcohol and other psychoactive substances also occurs during this time.

Integrity. Anxiety disorders often develop in older persons. In Erikson's formulation, this development may be related to persons' looking back on their lives with a sense of panic. Time has run out, and chances are used up. The decline in physical functions can contribute to psychosomatic illness, hypochondriasis, and depression. The suicide rate is highest in persons over the age of 65. Persons facing dying and death may find it intolerable not to have been generative or able to make significant attachments in life. Integrity, for Erikson, is characterized by an acceptance of life. Without acceptance, persons feel despair and hopelessness that can result in severe depressive disorders.

TREATMENT

Although no independent eriksonian psychoanalytic school exists in the same way that freudian and jungian schools do, Erikson made many important contributions to the therapeutic process. Among his most important contributions is his belief that establishing a state of trust between doctor and patient is the basic requirement for successful therapy. When psychopathology stems from basic mistrust (e.g., depression), a patient must reestablish trust with the therapist, whose task, as that of the good mother, is to be sensitive to the patient's needs. The therapist must have a sense of personal trustworthiness that can be transmitted to the patient.

Techniques

For Erikson, a psychoanalyst is not a blank slate in the therapeutic process, as the psychoanalyst commonly is in freudian psychoanalysis. To the contrary, effective therapy requires that therapists actively convey to patients the belief that they are understood. This is done through both empathetic listening and by verbal assurances, which enable a positive transference built on mutual trust to develop.

Beginning as an analyst for children, Erikson tried to provide this mutuality and trust while he observed children recreating their own worlds by structuring dolls, blocks, vehicles, and miniature furniture into the dramatic situations that were bothering them. Then, Erikson correlated his observations with statements by the children and their family members. He began treatment of a child only after eating an evening meal with the entire family, and his therapy was usually conducted with much cooperation from the family. After each regressive episode in the treatment of a schizophrenic child, for instance, Erikson discussed with every member of the family what had been going on with them before the episode. Only when he was thoroughly satisfied that he had identified the problem did treatment begin. Erikson sometimes provided corrective information to the child—for instance, telling a boy who could not release his feces and had made himself ill from constipation that food is not an unborn infant.

Erikson often turned to play, which, along with specific recommendations to parents, proved fruitful as a treatment modality. Play, for Erikson, is diagnostically revealing and thus helpful for a therapist who seeks to promote a cure, but it is also curative in its own right. Play is a function of the ego and gives children a chance to synchronize social and bodily processes with the self. Children playing with blocks or adults playing out an imagined dramatic situation can manipulate the environment and develop the sense of control that the ego needs. Play therapy is not the same for children and adults, however. Children create models in an effort to gain control of reality; they look ahead to new areas of mastery. Adults use play to correct the past and to redeem their failures.

Mutuality, which is important in Erikson's system of health, is also vital to a cure. Erikson applauded Freud for the moral choice of abandoning hypnosis, because hypnosis heightens both the demarcation between the healer and the sick and the inequality that Erikson compares with the inequality of child and adult. Erikson urged that the relationship of the healer to the sick person be one of equals "in which the observer who has learned to observe himself teaches the observed to become self-observant."

Dreams and Free Association

As with Freud, Erikson worked with the patient's associations to the dream as the "best leads" to understanding the dream's meaning. He valued the first association to the dream, which he believed to be powerful and important. Ultimately, Erikson listened for "a central theme which, once found, gives added meaning to all the associated material."

Erikson believed that interpretation was the primary therapeutic agent, sought as much by the patient as by the therapist. He emphasized free-floating attention as the method that enabled discovery to occur. Erikson once described this attentional stance by commenting that in clinical work, "You need a history and you need a theory, and then you must forget them both and let each hour stand for itself." This frees both parties from counterproductive pressures to advance in the therapy and allows them both to notice the gaps in the patient's narrative that signal the unconscious.

Goals

Erikson discussed four dimensions of the psychoanalyst's job. The patient's desire to be cured and the analyst's desire to cure is the first dimension. Mutuality exists in that patient and therapist are motivated by cure, and labor is divided. The goal is always to help the patient's ego get stronger and cure itself. The second dimension Erikson called objectivity-participation. Therapists must keep their minds open. "Neuroses change," wrote Erikson. New generalizations must be made and arranged in new configurations. The third dimension runs along the axis of knowledge-participation. The therapist "applies selected insights to more strictly experimental approaches." The fourth dimension is tolerance-indignation. Erikson stated: "Identities based on Talmudic argument, on messianic zeal, on punitive orthodoxy, on faddist sensationalism, on professional and social ambition" are harmful and tend to control patients. Control widens the gap of inequality between the doctor and the patient and makes realization of the recurrent idea in Erikson's thought—mutuality—difficult.

According to Erikson, therapists have the opportunity to work through past unresolved conflicts in the therapeutic relationship. Erikson encouraged therapists not to shy away from guiding patients; he believes that therapists must offer patients both prohibitions and permissions. Nor should therapists be so engrossed in patients' past life experiences that current conflicts are overlooked.

The goal of therapy is to recognize how patients have passed through the various stages of the life cycle and how the various crises in each stage have or have not been mastered. Equally important, future stages and crises must be anticipated, so that they can be negotiated and mastered appropriately. Unlike Freud, Erikson does not believe that the personality is so inflexible that change cannot occur in middle and late adulthood. For Erikson, psychological growth and development occur throughout the entire span of the life cycle.

The Austen Riggs Center in Stockbridge, Massachusetts, is a repository of Erikson's work and many of his theories are put into practice there. Erik's wife, Joan, developed an activities program at the Austen Riggs Center as an "interpretation-free zone," where patients could take up work roles or function as students with artists and craftspersons, without the burden of the patient role. This workspace encouraged the play and creativity required for the patients' work development to parallel the process of their therapy.

4.3 Other Psychodynamic Schools

The men and women discussed in this chapter contributed to psychiatric thought and practice in the early and middle years of the 20th century. Many of these theories of psychopathology evolved as direct offshoots of Freudian psychoanalysis. This, however, derived from various aspects of psychology, such as learning theory and quantitative methods of personality assessment. The theories selected for the discussion in this section have stood the test of time and are most relevant for psychiatry.

Brief synopses of the theories that exert the greatest influence on current psychiatric thought are listed below in alphabetical order of their proponent. Each of these theories contains insights that merit consideration because they enhance our understanding of the complexities of human behavior. They also illustrate the diversity of theoretical orientation that characterizes psychiatry today.

KARL ABRAHAM (1877–1925)

Karl Abraham, one of Sigmund Freud's earliest disciples, was the first psychoanalyst in Germany. He is best known for his explication of depression from a psychoanalytic perspective and for his elaboration of Freud's stages of psychosexual development. Abraham divided the oral stage into a biting phase and a sucking phase; the anal stage into a destructive-expulsive (anal-sadistic) phase and a mastering-retentive (anal-erotic) phase; and the phallic stage into an early phase of partial genital love (true phallic phase) and a later mature genital phase. Abraham also linked the psychosexual stages to specific syndromes. For example, he postulated that obsessional neurosis resulted from fixation at the anal-sadistic phase and depression from fixation at the oral stage.

ALFRED ADLER (1870–1937)

Alfred Adler (Fig. 4.3-1) was born in Vienna, Austria, where he spent most of his life. A general physician, he became one of the original four members of Freud's circle in 1902. Adler never accepted the primacy of the libido theory, the sexual origin of neurosis, or the importance of infantile wishes. Adler thought that aggression was far more important, specifically in its manifestation as a striving for power, which he believed to be a masculine trait. He introduced the term *masculine protest* to describe the tendency to move from a passive, feminine role to a masculine, active role. Adler's theories are collectively known as *individual psychology*.

FIGURE 4.3-1
Alfred Adler. (print includes signature). (Courtesy of Alexandra Adler.)

Adler saw individuals as unique, unified biological entities whose psychological processes fit together into an individual lifestyle. He also postulated a principle of dynamism, in which every individual is future-directed and moves toward a goal. Adler also emphasized the interface between individuals and their social environment: the primacy of action in the real work over fantasy.

Adler coined the term *inferiority complex* to refer to a sense of inadequacy and weakness that is universal and inborn. A developing child's self-esteem is compromised by a physical defect, and Adler referred to this phenomenon as *organ inferiority*. He also thought that a basic inferiority tied to children's oedipal longings could never be gratified.

Adler was one of the first developmental theorists to recognize the importance of children's birth order in their families of origin. The firstborn child reacts with anger to the birth of siblings and struggles against giving up the powerful position of only child. They tend not to share and become conservative. The second-born child must constantly strive to compete with the firstborn. Youngest children feel secure because they have *never* been displaced. Adler thought that a child's sibling position results in lifelong influences on character and lifestyle.

The primary therapeutic approach in Adlerian therapy is encouragement, through which Adler believed his patients could overcome feelings of inferiority. Consistent human relatedness, in his view, leads to greater hope, less isolation, and greater affiliation with society. He believed that patients needed to develop a greater sense of their own dignity and worth and renewed appreciation of their abilities and strengths.

FRANZ ALEXANDER (1891–1964)

Franz Alexander (Fig. 4.3-2) emigrated from his native Germany to the United States, where he settled in Chicago and founded the Chicago Institute for Psychoanalysis. He wrote extensively about the association between specific personality traits and certain psychosomatic ailments, a point of view that came to be known as the *specificity hypothesis*. Alexander fell out of favor with classic analysts for advocating the *corrective emotional experience* as part of analytic technique. In this approach, Alexander suggested that an analyst must deliberately adopt a particular mode of relatedness with a patient to counteract noxious childhood influences from the patient's parents. He believed that the trusting, supportive relationship between patient and analyst enabled the patient to master childhood traumas and to grow from the experience.

GORDON ALLPORT (1897–1967)

Gordon Allport (Fig. 4.3-3), a psychologist in the United States, is known as the founder of the humanistic school of psychology, which holds that each person has an inherent potential for autonomous function and growth. At Harvard University, he taught the first course in the psychology of personality offered at a college in the United States.

FIGURE 4.3-3
Gordon Allport. (© Bettmann/Corbis.)

Allport believed that a person's only real guarantee of personal existence is a sense of self. Selfhood develops through a series of stages, from awareness of the body to self-identity. Allport used the term *proprium* to describe strivings related to maintenance of self-identity and self-esteem. He used the term *traits* to refer to the chief units of personality structure. *Personal dispositions* are individual traits that represent the essence of an individual's unique personality. Maturity is characterized by a capacity to relate to others with warmth and intimacy and an expanded sense of self. In Allport's view, mature persons have security, humor, insight, enthusiasm, and zest. Psychotherapy is geared to helping patients realize these characteristics.

MICHAEL BALINT (1896–1970)

Michael Balint was considered a member of the independent or middle group of object relations theorists in the United Kingdom. Balint believed that the urge for the primary love object underlies virtually all psychological phenomena. Infants wish to be loved totally and unconditionally, and when a mother is not forthcoming with appropriate nurturance, a child devotes his or her life to a search for the love missed in childhood. According to Balint, the *basic fault* is the feeling of many patients that something is missing. As with Ronald Fairbairn and Donald W. Winnicott, Balint understood this deficit in internal structure to result from maternal failures. He viewed all psychological motivations as stemming from the failure to receive adequate maternal love.

Unlike Fairbairn, however, Balint did not entirely abandon drive theory. He suggested that libido, for example, is both pleasure seeking and object seeking. He also worked with seriously disturbed patients, and like Winnicott, he thought that certain aspects of psychoanalytic treatment occur at a more profound level than that of the ordinary verbal explanatory interpretations. Although some material involving genital psychosexual stages of development can be interpreted from the perspective of intrapsychic conflict, Balint believed that certain preverbal phenomena are reexperienced in analysis and that the relationship itself is decisive in dealing with this realm of early experience.

ERIC BERNE (1910–1970)

Eric Berne (Fig. 4.3-4) began his professional life as a training and supervising analyst in classic psychoanalytic theory and technique, but ultimately developed his own school, known as *transactional analysis*. A *transaction* is a stimulus presented by one person that evokes a corresponding response in another. Berne defined psychological games as stereotyped and predictable transactions that persons learn in childhood and continue to play throughout their lives. *Strokes*, the basic motivating factors of human behavior, consist of specific rewards, such as approval and love. All persons have three ego states that exist within them: the *child*, which represents primitive elements that become fixed in early childhood; the *adult*, which is the part of the personality capable of objective appraisals of reality; and the *parent*, which is an introject of the values of a person's actual parents. The therapeutic process is geared toward helping patients understand whether they are functioning in the child, adult, or parent mode in their interactions with others. As patients learn to recognize characteristic games played again and again throughout life, they can ultimately function in the adult mode as much as possible in interpersonal relationships.

FIGURE 4.3-4
Eric Berne. (Courtesy of Wide World Photos.)

WILFRED BION (1897–1979)

Wilfred Bion expanded Melanie Klein's concept of *projective identification* to include an interpersonal process in which a therapist feels coerced by a patient into playing a particular role in the patient's internal world. He also developed the notion that the therapist must contain what the patient has projected so that it is processed and returned to the patient in modified form. Bion believed that a similar process occurs between mother and infant. He also observed that "psychotic" and "nonpsychotic" aspects of the mind function simultaneously as suborganizations. Bion is probably best known for his application of psychoanalytic ideas to groups. Whenever a group gets derailed from its task, it deteriorates into one of three basic states: dependency, pairing, or fight-flight.

JOHN BOWLBY (1907–1990)

John Bowlby is generally considered the founder of attachment theory. He formed his ideas about attachment in the 1950s while he was consulting with the World Health Organization (WHO) on the problems of homelessness in children. He stressed that the essence of attachment is *proximity* (i.e., the tendency of a child to stay close to the mother or caregiver). His theory of the mother–infant bond was firmly rooted in biology and drew extensively from ethology and evolutionary theory. A basic sense of security and safety is derived from a continuous and close relationship with a caregiver, according to Bowlby. This readiness for attachment is biologically driven, and Bowlby stressed that attachment is reciprocal. Maternal bonding and care giving are always intertwined with the child's attachment behavior. Bowlby felt that without this early proximity to the mother or caregiver, the child does not develop a *secure base*, which he considered a launching pad for independence. In the absence of a secure base, the child feels frightened or threatened, and development is severely compromised. Bowlby and attachment theory are discussed in detail in Section 2.2.

RAYMOND CATTELL (1905–1998)

Raymond Cattell obtained his Ph.D. in England before moving to the United States. He introduced the use of *multivariate analysis* and *factor analysis*—statistical procedures that simultaneously examine the relations among multiple variables and factors—to the study of personality. By examining a person's life record objectively, using personal interviewing and questionnaire data, Cattell described a variety of traits that represent the building blocks of personality.

Traits are both biologically based and environmentally determined or learned. Biological traits include sex, gregariousness, aggression, and parental protectiveness. Environmentally learned traits include cultural ideas, such as work, religion, intimacy, romance, and identity. An important concept is the *law of coercion* to the biosocial mean, which holds that society exerts pressure on genetically different persons to conform to social norms. For example, a person with a strong genetic tendency toward dominance is likely to receive social encouragement for restraint, whereas the naturally submissive person will be encouraged toward self-assertion.

RONALD FAIRBAIRN (1889–1964)

Ronald Fairbairn, a Scottish analyst who worked most of his life in relative isolation, was one of the major psychoanalytic theorists in the British school of object relations. He suggested that infants are not primarily motivated by the drives of libido and aggression but are by an object-seeking instinct. Fairbairn replaced the Freudian ideas of energy, ego, and id with the notion of *dynamic structures*. When an infant encounters frustration, a portion of the ego is defensively split off in the course of development and functions as an entity in relation to internal objects and to other subdivisions of the ego. He also stressed that both an object and an object *relationship* are internalized during development, so that a self is always in relationship to an object, and the two are connected with an affect.

SÁNDOR FERENCZI (1873–1933)

Although Sándor Ferenczi, a Hungarian analyst, had been analyzed by Freud and was influenced by him, he later discarded Freud's techniques and introduced his own method of analysis. He understood the symptoms of his patients as related to sexual and physical abuse

in childhood and proposed that analysts need to love their patients in a way that compensates for the love they did not receive as children. He developed a procedure known as *active therapy*, in which he encouraged patients to develop an awareness of reality through active confrontation by the therapist. He also experimented with *mutual analysis*, in which he would analyze his patient for a session and then allow the patient to analyze him for a session.

VIKTOR FRANKL (1905–1997)

An Austrian neurologist and philosopher, Viktor Frankl's distinctive view of human nature and psychopathology was profoundly shaped by his experience in Nazi concentration camps. There he came to the conclusion that even the most appalling circumstances could be endured if one found a way of making them meaningful. He described his experience in *Man's Search for Meaning*, a book that has been read by millions around the world.

Frankl was both a humanist and an existentialist. He believed that human beings shared with other animals somatic and psychological dimensions, but that humans alone also had a spiritual dimension that confers both freedom and responsibility. People find meaning in their lives through creative and productive work, through an appreciation of the world and others, and by freely adopting positive attitudes even in the face of suffering. Those who fail to find meaning face alienation, despair, and existential neuroses. Traditional societies provided a framework of meaning in religion and shared cultural values; in modern society, people must find their own sources of meaning, and Frankl attributed many social problems, such as drug abuse and suicide, to their failures to do so.

Because of the spiritual dimension, human beings show self-transcendence and self-distancing. The former refers to the capacity to put other values (for example, the well-being of a loved one) above self-interest. The latter is the ability to take an external perspective, as seen in a sense of humor. These capacities form the basis for therapeutic interventions in Frankl's version of psychotherapy known as logotherapy. Logo therapy is derived from the Greek word *logos*, which means thought or reason and Frankl believed that man instinctively attempts to find universal understanding and harmony in life experiences.

ANNA FREUD (1895–1982)

Anna Freud (Fig. 4.3-5), the daughter of Sigmund Freud, ultimately made her own set of unique contributions to psychoanalysis. Although her father focused primarily on repression as the central defense mechanism, Anna Freud greatly elaborated on individual defense mechanisms, including reaction formation, regression, undoing, introjection, identification, projection, turning against the self, reversal, and sublimation. She was also a key figure in the development of modern ego psychology in that she emphasized that there was “depth in the surface.” The defenses marshaled by the ego to avoid unacceptable wishes from the id were in and of themselves complex and worthy of attention. Up to that point, the primary focus had been on uncovering unconscious sexual and aggressive wishes. She also made seminal contributions to the field of child psychoanalysis and studied the function of the ego in personality development. She founded the Hampstead child therapy course and clinic in London in 1947 and served as its director.

ERICH FROMM (1900–1980)

Erich Fromm (Fig. 4.3-6) came to the United States in 1933 from Germany, where he had received his Ph.D. He was instrumental in founding the William Alanson White Institute for Psychiatry in New York. Fromm identified five character types that are common to, and determined by, Western culture; each person may possess qualities from one or more types. The types are (1) the *receptive personality* is passive; (2) the *exploitative personality* is manipulative; (3) the *marketing personality* is opportunistic and changeable; (4) the *hoarding personality* saves and stores; and (5) the *productive personality* is mature and enjoys love and work. The therapeutic process involves strengthening the person's sense of ethical behavior toward others and developing productive love, which is characterized by care, responsibility, and respect for other persons.

FIGURE 4.3-6
Erich Fromm. (© Bettmann/Corbis.)

KURT GOLDSTEIN (1878–1965)

Kurt Goldstein (Fig. 4.3-7) was born in Germany and received his M.D. from the University of Breslau. He was influenced by existentialism and Gestalt psychology—every organism has dynamic properties, which are energy supplies that are relatively constant and evenly distributed. When states of tension-disequilibrium occur, an organism automatically attempts to return to its normal state. What happens in one part of the organism affects every other part, a phenomenon known as *holocoenosis*.

FIGURE 4.3-7
Kurt Goldstein. (Courtesy of New York Academy of Medicine, New York.)

Self-actualization was a concept Goldstein used to describe persons' creative powers to fulfill their potentialities. Because each person has a different set of innate potentialities, persons strive for self-actualization along different paths. Sickness severely disrupts self-actualization. Responses to disruption of an organism's integrity may be rigid and compulsive; regression to more primitive modes of behavior is characteristic. One of Goldstein's major contributions was his identification of the *catastrophic reaction* to brain damage, in which a person becomes fearful and agitated and refuses to perform simple tasks because of the fear of possible failure.

KAREN HORNEY (1885–1952)

German born physician-psychoanalyst Karen Horney (Fig. 4.3-8), who emphasized the preeminence of social and cultural influences on psychosexual development, focused her attention on the differing psychology of men and women and explored the vicissitudes of marital relationships. She taught at the Institute of Psychoanalysis in Berlin before immigrating to the United States. Horney believed that a person's current personality attributes result from the interaction between the person and the environment and are not solely based on infantile libidinal strivings carried over from childhood. Her theory, known as *holistic psychology*, maintains that a person needs to be seen as a

unitary whole who influences, and is influenced by, the environment. She thought that the Oedipus complex was overvalued in terms of its contribution to adult psychopathology, but she also believed that rigid parental attitudes about sexuality led to excessive concern with the genitals.

FIGURE 4.3-8
Karen Horney. (Courtesy of the Association for the Advancement of Psychoanalysis, New York.)

She proposed three separate concepts of the self: the *actual self*, the sum total of a person's experience; the *real self*, the harmonious, healthy person; and the *idealized self*, the neurotic expectation or glorified image that a person feels he or she should be. A person's *pride system* alienates him or her from the real self by overemphasizing prestige, intellect, power, strength, appearance, sexual prowess, and other qualities that can lead to self-effacement and self-hatred. Horney also established the concepts of *basic anxiety* and *basic trust*. The therapeutic process, in her view, aims for *self-realization* by exploring distorting influences that prevent the personality from growing.

EDITH JACOBSON (1897–1978)

Edith Jacobson, a psychiatrist in the United States, believed that the structural model and an emphasis on object relations are not fundamentally incompatible. She thought that the ego, self-images, and object images exert reciprocal influences on one another's development. She also stressed that the infant's disappointment with the maternal object is not necessarily related to the mother's actual failure. In Jacobson's view, disappointment is related to a specific, drive-determined demand, rather than to a global striving for contact or engagement. She viewed an infant's experience of pleasure or "unpleasure" as the core of the early mother–infant relationship. Satisfactory experiences lead to the formation of good or gratifying images, whereas unsatisfactory experiences create bad or frustrating images. Normal and pathological development is based on the evolution of these self-images and object images. Jacobson believed that the concept of *fixation* refers to modes of object relatedness, rather than to modes of gratification.

CARL GUSTAV JUNG (1875–1961)

Carl Gustav Jung (Fig. 4.3-9), a Swiss psychiatrist, formed a psychoanalytic school known as *analytic psychology*, which includes basic ideas related to, but going beyond, Freud's theories. After initially being Freud's disciple, Jung broke with Freud over the latter's emphasis on infantile sexuality. He expanded on Freud's concept of the unconscious by describing the *collective unconscious* as consisting of all humankind's common, shared mythological and symbolic past. The collective unconscious includes *archetypes*—representational images and configurations with universal symbolic meanings. Archetypal figures exist for the mother, father, child, and hero, among others. Archetypes contribute to *complexes*, feeling-toned ideas that develop as a result of personal experience interacting with archetypal imagery. Thus, a mother complex is determined not only by the mother–child interaction but also by the conflict between archetypal expectation and actual experience with the real woman who functions in a motherly role.

FIGURE 4.3-9

Carl Gustav Jung (print includes signature). (Courtesy of National Library of Medicine, Bethesda, MD.)

Jung noted that there are two types of personality organizations: introversion and extroversion. *Introverts* focus on their inner world of thoughts, intuitions, emotions, and sensations; *extroverts* are more oriented toward the outer world, other persons, and material goods. Each person has a mixture of both components. The *persona*, the mask covering the personality, is the face a person presents to the outside world. The persona may become fixed, and the real person hidden from himself or herself. *Anima* and *animus* are unconscious traits possessed by men and women, respectively, and are contrasted with the persona. *Anima* refers to a man's undeveloped femininity, whereas *animus* refers to a woman's undeveloped masculinity.

The aim of jungian treatment is to bring about an adequate adaptation to reality, which involves a person fulfilling his or her creative potentialities. The ultimate goal is to achieve *individuation*, a process continuing throughout life whereby persons develop a unique sense of their own identity. This developmental process may lead them down new paths away from their previous directions in life.

OTTO KERNBERG (1928–PRESENT)

Otto Kernberg is perhaps the most influential object relations theorist in the United States. Influenced by both Klein and Jacobson, much of his theory is derived from his clinical work with patients who have borderline personality disorder. Kernberg places great emphasis on the splitting of the ego and the elaboration of good and bad self-configurations and object configurations. Although he has continued to use the structural model, he views the id as composed of self-images, object images, and their associated affects. Drives appear to manifest themselves only in the context of internalized interpersonal experience. Good and bad self-representations and object relations become associated, respectively, with libido and aggression. Object relations constitute the building blocks of both structure and drives. Goodness and badness in relational experiences precede drive cathexis. The dual instincts of libido and aggression arise from object-directed affective states of love and hate.

Kernberg proposed the term *borderline personality organization* for a broad spectrum of patients characterized by a lack of an integrated sense of identity, ego weakness, absence of superego integration, reliance on primitive defense mechanisms such as splitting and projective identification, and a tendency to shift into primary process thinking. He suggested a specific type of psychoanalytic psychotherapy for such patients in which transference issues are interpreted early in the process.

MELANIE KLEIN (1882–1960)

Melanie Klein (Fig. 4.3-10) was born in Vienna, worked with Abraham and Ferenczi, and later moved to London. Klein evolved a theory of internal object relations that was intimately linked to drives. Her unique perspective grew largely from her psychoanalytic work with children, in which she became impressed with the role of unconscious intrapsychic fantasy. She postulated that the ego undergoes a splitting process to deal with the terror of annihilation. She also thought that Freud's concept of the death instinct was central to understanding aggression, hatred, sadism, and other forms of "badness," all of which she viewed as derivatives of the death instinct.

FIGURE 4.3-10
Melanie Klein. (Courtesy of Melanie Klein and Douglas Glass.)

Klein viewed projection and introjection as the primary defensive operations in the first months of life. Infants project derivatives of the death instinct into the mother and then fear attack from the “bad mother,” a phenomenon that Klein referred to as *persecutory anxiety*. This anxiety is intimately associated with the *paranoid-schizoid position*, infants’ mode of organizing experience in which all aspects of infant and mother are split into good and bad elements. As the disparate views are integrated, infants become concerned that they may have harmed or destroyed the mother through the hostile and sadistic fantasies directed toward her. At this developmental point, children have arrived at the *depressive position*, in which the mother is viewed ambivalently as having both positive and negative aspects and as the target of a mixture of loving and hateful feelings. Klein was also instrumental in the development of child analysis, which evolved from an analytic play technique in which children used toys and played in a symbolic fashion that allowed analysts to interpret the play.

HEINZ KOHUT (1913–1981)

Heinz Kohut (Fig. 4.3-11) is best known for his writings on narcissism and the development of self-psychology. He viewed the development and maintenance of self-esteem and self-cohesion as more important than sexuality or aggression. Kohut described Freud’s concept of narcissism as judgmental, in that development was supposed to proceed toward object relatedness and away from narcissism. He conceived of two separate lines of development, one moving in the direction of object relatedness and the other in the direction of greater enhancement of the self.

FIGURE 4.3-11
Heinz Kohut. (Courtesy of New York Academy of Medicine, New York.)

In infancy, children fear losing the protection of the early mother–infant bliss and resort to one of three pathways to save the lost perfection: the grandiose self, the alter ego or twinship, and the idealized parental image. These three poles of the self manifest themselves in psychoanalytic treatment in terms of characteristic transferences, known as *self-object transferences*. The *grandiose self* leads to a *mirror transference*, in which patients attempt to capture the gleam in the analyst’s eye through exhibitionistic self-display. The *alter ego* leads to the *twinship transference*, in which patients perceive the analyst as a twin. The *idealized parental image* leads to an *idealizing transference*, in which patients feel enhanced self-esteem by being in the presence of the exalted figure of the analyst.

Kohut suggested that empathic failures in the mother lead to a developmental arrest at a particular stage when children need to use others to perform self-object functions. Although Kohut originally applied this formulation to narcissistic personality disorder, he later expanded it to apply to all psychopathology.

JACQUES LACAN (1901–1981)

Born in Paris and trained as a psychiatrist, Jacques Lacan founded his own institute, the Freudian School of Paris. He attempted to integrate the intrapsychic concepts of Freud with concepts related to linguistics and semiotics (the study of language and symbols). Whereas Freud saw the unconscious as a seething cauldron of needs, wishes, and instincts, Lacan saw it as a sort of language that helps to structure the world. His two principal concepts are that the unconscious is structured as a language and the unconscious is a discourse. Primary process thoughts are actually uncontrolled free-flowing sequences of meaning. Symptoms are signs or symbols of underlying processes. The role of the therapist is to interpret the semiotic text of the personality structure. Lacan's most basic phase is the mirror stage; it is here that infants learn to recognize themselves by taking the perspective of others. In that sense, the ego is not part of the self but, rather, is something outside of, and viewed by, the self. The ego comes to represent parents and society more than it represents the actual self of the person.

Lacan's therapeutic approach involves the need to become less alienated from the self and more involved with others. Relationships are often fantasized, which distorts reality and must be corrected. Among his most controversial beliefs was that the resistance to understanding the real relationship with the therapist can be reduced by shortening the length of the therapy session and that psychoanalytic sessions need to be standardized not to time but, rather, to content and process.

KURT LEWIN (1890–1947)

Kurt Lewin received his Ph.D. in Berlin, came to the United States in the 1930s, and taught at Cornell, Harvard, and the Massachusetts Institute of Technology. He adapted the field approach of physics to a concept called *field theory*. A *field* is the totality of coexisting, mutually interdependent parts. Behavior becomes a function of persons and their environment, which together make up the *life space*. The life space represents a field in constant flux, with *valences* or needs that require satisfaction. A hungry person is more aware of restaurants than someone who has just eaten, and a person who wants to mail a letter is aware of mailboxes.

Lewin applied field theory to groups. *Group dynamics* refers to the interaction among members of a group, each of whom depends on the others. The group can exert pressure on a person to change behavior, but the person also influences the group when change occurs.

ABRAHAM MASLOW (1908–1970)

Abraham Maslow (Fig. 4.3-12) was born in Brooklyn, New York, and completed both his undergraduate and graduate work at the University of Wisconsin. Along with Goldstein, Maslow believed in *self-actualization theory*—the need to understand the totality of a person. A leader in humanistic psychology, Maslow described a hierarchical organization of needs present in everyone. As the more primitive needs, such as hunger and thirst, are satisfied, more advanced psychological needs, such as affection and self-esteem, become the primary motivators. Self-actualization is the highest need.

FIGURE 4.3-12

Abraham H. Maslow. (© Bettmann/Corbis.)

A peak experience, frequently occurring in self-actualizers, is an episodic, brief occurrence in which a person suddenly experiences a powerful transcendental state of consciousness—a sense of heightened understanding, an intense euphoria, an integrated nature, unity with the universe, and an altered perception of time and space. This powerful experience tends to occur most often in the psychologically healthy and can produce long-lasting beneficial effects.

KARL A. MENNINGER (1893–1990)

Karl A. Menninger was one of the first physicians in the United States to receive psychiatric training. With his brother, Will, he pioneered the concept of a psychiatric hospital based on psychoanalytic principles and founded the Menninger Clinic in Topeka, Kansas. He also was a prolific writer; *The Human Mind*, one of his most popular books, brought psychoanalytic understanding to the lay public. He made a compelling case for the validity of Freud's death instinct in *Man Against Himself*. In *The Vital Balance*, his magnum opus, he formulated a unique theory of psychopathology. Menninger maintained a lifelong interest in the criminal justice system and argued in *The Crime of Punishment* that many convicted criminals needed treatment rather than punishment. Finally, his volume titled *Theory of Psychoanalytic Technique* was one of the few books to examine the theoretical underpinnings of psychoanalysts' interventions.

ADOLF MEYER (1866–1950)

Adolf Meyer (Fig. 4.3-13) came to the United States from Switzerland in 1892 and eventually became director of the psychiatric Henry Phipps Clinic of the Johns Hopkins Medical School. Not interested in metapsychology, he espoused a commonsense psychobiological methodology for the study of mental disorders, emphasizing the interrelationship of symptoms and individual psychological and biological functioning. His approach to the study of personality was biographical; he attempted to bring psychiatric patients and their treatment out of

isolated state hospitals and into communities and was also a strong advocate of social action for mental health. Meyer introduced the concept of *common sense psychiatry* and focused on ways in which a patient's current life situation could be realistically improved. He coined the concept of *ergasia*, the action of the total organism. His goal in therapy was to aid patients' adjustment by helping them modify unhealthy adaptations. One of Meyer's tools was an autobiographical life chart constructed by the patient during therapy.

FIGURE 4.3-13
Adolf Meyer. (From the National Library of Medicine, Bethesda, MD.)

GARDNER MURPHY (1895–1979)

Gardner Murphy (Fig. 4.3-14) was born in Ohio and received his Ph.D. from Columbia University. He was among the first to publish a comprehensive history of psychology and made major contributions to social, general, and educational psychology. According to Murphy, three essential stages of personality development are the stage of undifferentiated wholeness, the stage of differentiation, and the stage of integration. This development is frequently uneven, with both regression and progression occurring along the way. The four inborn human needs are visceral, motor, sensory, and emergency-related. These needs become increasingly specific in time as they are molded by a person's experiences in various social and environmental contexts. *Canalization* brings about these changes by establishing a connection between a need and a specific way of satisfying the need.

FIGURE 4.3-14
Gardner Murphy. (Courtesy of New York Academy of Medicine, New York.)

Murphy was interested in parapsychology. States such as sleep, drowsiness, certain drug and toxic conditions, hypnosis, and delirium tend to be favorable to paranormal experiences. Impediments to paranormal awareness include various intrapsychic barriers, conditions in the general social environment, and a heavy investment in ordinary sensory experiences.

HENRY MURRAY (1893–1988)

Henry Murray (Fig. 4.3-15) was born in New York City, attended medical school at Columbia University, and was a founder of the Boston Psychoanalytic Institute. He proposed the term *personology* to describe the study of human behavior. He focused on *motivation*, a need that is aroused by internal or external stimulation; once aroused, motivation produces continued activity until the need is reduced or satisfied. He developed the *Thematic Apperception Test* (TAT), a projective technique used to reveal both unconscious and conscious mental processes and problem areas.

FIGURE 4.3-15

Henry Murray. (Courtesy of New York Academy of Medicine, New York.)

FREDERICK S. PERLS (1893–1970)

Gestalt theory developed in Germany under the influence of several men: Max Wertheimer (1880–1943), Wolfgang Köhler (1887–1967), and Lewin. Frederick “Fritz” Perls (Fig. 4.3-16) applied Gestalt theory to a therapy that emphasizes the current experiences of the patient in the here and now, as contrasted to the there and then of psychoanalytic schools. In terms of motivation, patients learn to recognize their needs at any given time and the ways that the drive to satisfy these needs may influence their current behavior. According to the Gestalt point of view, behavior represents more than the sum of its parts. A *gestalt*, or a whole, both includes, and goes beyond, the sum of smaller, independent events; it deals with essential characteristics of actual experience, such as value, meaning, and form.

FIGURE 4.3-16

Fritz Perls. (Courtesy of the National Library of Medicine.)

SANDOR RADO (1890–1972)

Sandor Rado (Fig. 4.3-17) came to the United States from Hungary in 1945 and founded the Columbia Psychoanalytic Institute in New York. His theories of *adaptational dynamics* hold that the organism is a biological system operating under hedonic control, which is somewhat similar to Freud’s pleasure principle. Cultural factors often cause excessive hedonic control and disordered behavior by interfering with the

organism's ability for *self-regulation*. In therapy, the patient needs to relearn how to experience pleasurable feelings.

FIGURE 4.3-17
Sandor Rado. (Courtesy of New York Academy of Medicine.)

OTTO RANK (1884–1939)

An Austrian psychologist and a protégé of Sigmund Freud, Otto Rank (Fig. 4.3-18) broke with Freud in his 1924 publication, *The Trauma of the Birth*, and developed a new theory, which he called *birth trauma*. Anxiety is correlated with separation from the mother—specifically, with separation from the womb, the source of effortless gratification. This painful experience results in primal anxiety. Sleep and dreams symbolize the return to the womb.

FIGURE 4.3-18
Otto Rank. (Courtesy of New York Academy of Medicine.)

The personality is divided into impulses, emotions, and will. Children's impulses seek immediate discharge and gratification. As impulses are mastered, as in toilet training, children begin the process of will development. If will is carried too far, pathological traits (e.g., stubbornness, disobedience, and inhibitions) may develop.

WILHELM REICH (1897–1957)

Wilhelm Reich (Fig. 4.3-19), an Austrian psychoanalyst, made major contributions to psychoanalysis in the area of character formation and character types. The term *character armor* refers to the personality's defenses that serve as resistance to self-understanding and change. The four major character types are as follows: the *hysterical character* is sexually seductive, anxious, and fixated at the phallic phase of libido development; the *compulsive character* is controlled, distrustful, indecisive, and fixated at the anal phase; the *narcissistic character* is fixated at the phallic state of development, and if the person is male, he has contempt for women; and the *masochistic character* is long-suffering,

complaining, and self-deprecatory, with an excessive demand for love.

FIGURE 4.3-19
Wilhelm Reich. (Courtesy of New York Academy of Medicine.)

The therapeutic process, called *will therapy*, emphasizes the relationship between patient and therapist; the goal of treatment is to help patients accept their separateness. A definite termination date for therapy is used to protect against excessive dependence on the therapist.

CARL ROGERS (1902–1987)

Carl Rogers (Fig. 4.3-20) received his Ph.D. in psychology from Columbia University. After attending Union Theological Seminary in New York, Rogers studied for the ministry. His name is most clearly associated with the *person-centered theory* of personality and psychotherapy, in which the major concepts are self-actualization and self-direction. Specifically, persons are born with a capacity to direct themselves in the healthiest way toward a level of completeness called self-actualization. From his person-centered approach, Rogers viewed personality not as a static entity composed of traits and patterns but as a dynamic phenomenon involving ever-changing communications, relationships, and self-concepts.

FIGURE 4.3-20
Carl Rogers. (Courtesy of the National Library of Medicine.)

Rogers developed a treatment program called *client-centered psychotherapy*. Therapists attempt to produce an atmosphere in which clients can reconstruct their strivings for self-actualization. Therapists hold clients in unconditional positive regard, which is the total nonjudgmental acceptance of clients as they are. Other therapeutic practices include attention to the present, focus on clients' feelings, emphasis on process, trust in the potential and self-responsibility of clients, and a philosophy grounded in a positive attitude toward them, rather than a preconceived structure of treatment.

JEAN-PAUL SARTRE (1905–1980)

Born in Paris, Jean-Paul Sartre wrote plays and novels before turning to psychology. He was a German prisoner of war from 1940 to 1941 during World War II. Influenced by the ideas of Martin Heidegger, he developed what he called *existential psychoanalysis*. The reflective self was a key concept in Sartre's psychology. He recognized that humans alone could reflect on themselves as objects, so that the experience of "being" in humans is unique in the natural world. This capacity to reflect leads humans to impose a meaning on existence. For Sartre, this meaning allows a human being to create his or her own essence.

Sartre denied the realm of the unconscious; he thought that human beings were condemned to be free and to face the fundamental existential dilemma—their aloneness without a god to provide meaning. As a result, each individual creates values and meanings. Neurosis is an escape from freedom, which is the key to maintaining psychological health. Sartre

made no distinction between philosophy and psychology. Psychologists, as with philosophers, search for the truth about the world. Part of this truth, in Sartre's view, was the dialectic between consciousness and *being*. Consciousness introduces nothingness and is a negation of being-in-itself. Ideals are revealed in actions, not in professed beliefs.

B. F. SKINNER (1904–1990)

Burrhus Frederic Skinner (Fig. 4.3-21), commonly known as B. F. Skinner, received his Ph.D. in psychology from Harvard University, where he taught for many years. Skinner's seminal work in operant learning laid much of the groundwork for many current methods of behavior modification, programmed instruction, and general education. His global beliefs about the nature of behavior have been applied more widely, it can be argued, than those of any other theorist except, perhaps, Freud. His impact has been impressive in scope and magnitude.

FIGURE 4.3-21

B. F. Skinner. (Courtesy of New York Academy of Medicine, New York.)

Skinner's approach to personality was derived more from his basic beliefs about behavior than from a specific theory of personality per se. To Skinner, personality did not differ from other behaviors or sets of behaviors; it is acquired, maintained, and strengthened or weakened according to the same rules of reward and punishment that alter any other form of behavior. *Behaviorism*, as Skinner's basic theory is most commonly known, is concerned only with observable, measurable behavior that can be operationalized. Many abstract and mentalistic hallmarks of other dominant personality theories have little place in Skinner's framework. Concepts such as self, ideas, and ego are considered unnecessary for understanding behavior and are shunned. Through the process of operant conditioning and the application of basic principles of learning, persons are believed to develop sets of behavior that characterize their responses to the world of stimuli that they face in their lives. Such a set of responses is called *personality*.

HARRY STACK SULLIVAN (1892–1949)

Harry Stack Sullivan (Fig. 4.3-22) is generally acknowledged as the most original and distinctive American-born theorist in dynamic psychiatry. When psychiatrists use the term *parataxic distortion*, apply the concept of self-esteem, consider the importance of preadolescent peer groups in development, or view a patient's behavior as an interpersonal manipulation, they are applying concepts Sullivan first proposed.

FIGURE 4.3-22

Harry Stack Sullivan. (Courtesy of the National Library of Medicine.)

Sullivan described three modes of experiencing and thinking about the world. The *prototaxic mode* is undifferentiated thought that cannot separate the whole into parts or use symbols. It occurs normally in infancy and also appears in patients with schizophrenia. In the *parataxic mode*, events are causally related because of temporal or serial connections. Logical relationships, however, are not perceived. The *syntactic mode* is the logical, rational, and most mature type of cognitive functioning of which a person is capable. These three types of thinking and experiencing occur side by side in all persons; it is the rare person who functions exclusively in the syntactic mode.

The total configuration of personality traits is known as the *self-system*, which develops in various stages and is the outgrowth of interpersonal experiences, rather than an unfolding of intrapsychic forces. During infancy, anxiety occurs for the first time when infants' primary needs are not satisfied. During childhood, from 2 to 5 years, a child's main tasks are to learn the requirements of the culture and how to deal with powerful adults. As a juvenile, from 5 to 8 years, a child has a need for peers and must learn how to deal with them. In preadolescence, from 8 to 12 years, the capacity for love and for collaboration with another person of the same sex develops. This so-called *chum period* is the prototype for a sense of intimacy. In the history of patients with schizophrenia, this experience of chums is often missing. During adolescence, major tasks include the separation from the family, the development of standards and values, and the transition to heterosexuality.

The therapy process requires the active participation of the therapist, who is known as a *participant observer*. Modes of experience, particularly the parataxic, need to be clarified, and new patterns of behavior need to be implemented. Ultimately, persons need to see themselves as they really are, instead of as they think they are or as they want others to think they are.

Sullivan is best known for his creative psychotherapeutic work with severely disturbed patients. He believed that even the most psychotic patients with schizophrenia could be reached through the human relationship of psychotherapy.

DONALD W. WINNICOTT (1896–1971)

Donald W. Winnicott (Fig. 4.3-23) was one of the central figures in the British school of object relations theory. His theory of *multiple self-organizations* included a *true self*, which develops in the context of a responsive *holding environment* provided by a *good-enough mother*. When infants experience a traumatic disruption of their developing sense of self, however, a false self emerges and monitors and adapts to the conscious and unconscious needs of the mother; it thus provides a protected exterior behind which the true self is afforded a privacy that it requires to maintain its integrity.

FIGURE 4.3-23
Donald Winnicott. (Courtesy of New York Academy of Medicine, New York.)

Winnicott also developed the notion of the *transitional object*. Ordinarily a pacifier, blanket, or teddy bear, this object serves as a substitute for the mother during infants' efforts to separate and become independent. It provides a soothing sense of security in the absence of the mother.

The case history below illustrates how the different psychodynamic schools discussed in this chapter can be applied to the clinical observations of a patient.

Mr. A was a 26-year-old white man who had a history of bipolar I disorder. He was brought in for treatment after not completing the last required course for his advanced degree and being arrested for disturbing the peace. He had consistently lied to his family about where he stood with his coursework and about having skipped an examination that would have qualified him to use his professional degree. He had also not told them that he had been using marijuana almost daily for a number of years and occasionally used hallucinogens. His arrest for disorderly conduct was for swimming naked in an apartment complex in the middle of the night while under the influence of hallucinogens.

Mr. A's use of marijuana began early in college but became daily during graduate school. He was diagnosed as having bipolar I disorder early in his senior year at college after a clear episode of mania. His mood disorder was well controlled on lithium (Eskalith). During graduate school, he was episodically compliant with medications, preferring to try to maintain a state of hypomania. He saw a psychiatrist every 3 to 6 months for medication checks. During his 4 years in graduate school, he had two clear episodes of depression and began taking sertraline (Zoloft), 100 mg per day, with questionable benefit. Mr. A believed that he could be a great writer. He spent most of his time reading and trying to write. He dreamed of going to New York and becoming part of a group of avant-garde writers that would parallel the Algonquin Club of the 1930s or the Beat poets of the late 1940s. This aspiration and his marijuana abuse predated his development of bipolar I disorder. He attended class episodically, nonetheless performing adequately. His last class had no final examination but required a paper. He planned to write this paper in the form of a play, involving a dialogue between two thinkers from different times and cultures. His professor was very excited about this idea, but Mr. A kept postponing the task until he was forced to

extend his schooling by a year. His other major interest during this time involved growing and photographing flowers.

Mr. A was born and raised in a large city. His father had been very successful in commercial real estate, and his mother, after raising the children, used the substantial real estate holdings she inherited from her father to set up a business to manage them. Most of the money was placed in a trust for the patient and his siblings. His mother had total financial control of the trusts and doled out the proceeds to the children as they needed them. There was no family history of any psychiatric disorders.

The patient described his mother as very loving and caring but to the point of being intrusive and controlling. For example, the mother arranged the initial treatment but then was angry that the psychiatrist had not called her regularly to report on her adult son's progress. She was also critical of various aspects of the treatment as reported to her by her son. The patient's two older siblings had attended prestigious colleges and graduate schools but had returned home to work in the mother's real estate management company. The 30-year-old sister was living in the parents' home. The 35-year-old brother had lived at home for a time but then moved out to a location a few blocks away. There was a younger brother, still in college, who also smoked marijuana excessively. He tried to minimize the patient's problems to the family and tried to protect the patient, who desperately had not wanted to return home. Of note is that none of the children were married, although the two older ones had each had a couple of serious relationships.

The children seemed to regard the mother with affectionate amusement and bemusement. The father was seen as a very caring but undemonstrative man who put much energy into keeping the mother from becoming too upset and encouraged the children to do the same. The children often wanted to provoke the mother for her judgmental, detail-oriented intrusiveness. The father discouraged them but occasionally found their provocations amusing.

The family viewed itself as very close, with strong values oriented toward community service and family loyalty. The family belonged to a religious community but expressed their involvement primarily in social service and social action volunteer work, accompanied by very generous financial contributions.

The patient had been a very successful debater in high school and recalled his development as very positive but provided few details. He tended to place himself in the role of the outsider, an observer of humanity, which he saw as consonant with the role of a writer. He was proud to have bipolar I disorder and tried to regulate his medications so that he would be hypomanic much of the time, seeing this as enhancing his creativity. He viewed his use of marijuana in the same vein. One of the most distressing aspects to him of his depressive episodes was that marijuana no longer created a feeling of well-being but made him feel worse. His current depressive episode involved no neurovegetative symptoms. Rather, he presented as flat, numb, apathetic, ashamed, anhedonic, and anergic. He was particularly ashamed of being back in his hometown and of living with his parents.

The patient ostensibly understood and accepted his illness well and had read much about it. However, the family had responded to the information "with proper treatment, bipolars can live normal lives" as meaning that the information should be kept secret so that he should be treated normally. Mr. A, on the other hand, was very open with friends at graduate school about his illness and his pride in it and the creativity he associated with it.

The patient had two long-standing recurrent dreams. One involved him flying. The narrative line varied, but the flying theme recurred. Often, he had other magical powers in his dreams such as the ability to heal, to not be killed by bullets, to save the world or some group of people from mortal danger, and so on. The other recurrent dream was of a hotel lobby. These dreams regularly began with him entering a hotel lobby to meet a group of people, accompanied by a feeling of dread.

4.4 Positive Psychology

Positive psychology is an umbrella term describing the scientific study of what makes life most worth living. Research findings from positive psychology are intended to provide a more complete and balanced scientific understanding of the human experience. The new field of positive psychology calls for as much focus on strength as on weakness, as much interest in building the best things in life as in repairing the worst, and as much concern with making the lives of normal people fulfilling as with healing pathology.

Positive psychology does not replace business-as-usual psychology, which often focuses on people's problems and how to remedy them. Rather, positive psychology intends to complement and extend a problem-focused psychology. The attention of positive psychologists is increasingly turning to deliberate interventions that promote the well-being of individuals and groups, and again, these should be regarded as supplements to existing therapies.

Positive psychology studies what goes right in life, from birth to death. It is concerned with optimal experience—people being their best and doing their best. Everyone's life has peaks and valleys, and positive psychology does not deny the low points. Its signature premise is more nuanced: What is good about life is as genuine as what is bad and therefore deserves equal attention from psychologists. Positive psychology assumes that life entails more than avoiding or undoing problems and that explanations of the good life must do more than reverse accounts of distress and dysfunction.

EMPIRICAL FINDINGS

Although still a young field, positive psychology already has a canon of established findings worth considering. Indeed, positive psychology is a bottom-up field, very much defined by its empirical results. Discussed below are some of the things that have been learned about positive experiences, positive traits, positive relationships, and positive institutions.

When psychologists study self-reported happiness and life satisfaction, usually under the rubric of subjective well-being, they administer numerical rating scales. The consistent and perhaps surprising result is that most people in most circumstances most of the time score above the scale midpoint, whether they are multimillionaires in the United States or pavement dwellers in Calcutta. This conclusion holds across demographic characteristics like age, sex, ethnicity, and education, each of which has a surprisingly small association with avowed happiness.

The important correlates of happiness are social in nature. In contrast to the modest demographic correlates of happiness and well-being, consider the following robust correlates:

- ▶ Number of friends
- ▶ Being married
- ▶ Being extroverted
- ▶ Being grateful
- ▶ Being religious
- ▶ Pursuing leisure activities
- ▶ Employment (not income)

In a study that compared happy people to very happy people, there was one striking difference: good relationships with other people. Of the very happy people in the sample, all had close relationships with others. Psychology research documents very few necessary or sufficient conditions, but these data suggest that good social relationships may be a necessary condition for extreme happiness.

People who are successful in life's venues are of course happy, but the less obvious and more interesting finding from experimental and longitudinal research is that happiness actually foreshadows success in academic, vocational, and interpersonal realms.

Having good relationships with other people is the most important contributor to a satisfied life and may even be a necessary condition for happiness. Having a "best friend" at work is a strong predictor of satisfaction and even productivity. A good relationship is one in which the amount of positive communication considerably outweighs the amount of negative communication.

Positive psychologists have taken a close look at the features of positive communication, describing four ways in which a person can respond to someone else when something happens, including good events such as a raise at work:

- ▶ Active-constructive responding—an enthusiastic response: "That's great; I bet you'll receive many more raises."
- ▶ Active-destructive responding—a response that points out the potential downside: "Are they going to expect more of you now?"
- ▶ Passive-constructive responding—a muted response: "That's nice dear."
- ▶ Passive-destructive responding—a response that conveys disinterest: "It rained all day here."

Couples who use active-constructive responding have good marriages. The other responses, if they dominate, are associated with marital dissatisfaction. Although this research has only been done in the context of marriage, it may well generalize to other relationships.

Psychology and psychiatry have a long history of either ignoring religion or regarding it with suspicion. However, research findings have begun to accumulate showing that religion has certain benefits in a variety of psychological domains. Internalized religious beliefs may help a person to cope with problems and even avoid physical illness in the first place. Religiousness is robustly associated with longevity, happiness, and other indices of the life lived well.

People who are so poor that they cannot meet their basic needs of course are unhappy, but above extreme poverty, increased income has a surprisingly small relationship with life satisfaction.

Despite the small contribution of income to well-being, whether or not someone is working is much more strongly related to happiness. People who are employed and engaged in what they do are happy, regardless of the status or compensation associated with their job. Happiness and engagement lead people to regard their work as a calling and to be more productive at whatever they do, take fewer sick days, and even postpone their retirement.

According to Aristotle's notion of *eudaimonia*—being true to one's inner self (demon)—true happiness entails identifying one's virtues, cultivating them, and living in accordance with them. Contrast this notion with the equally venerable idea of *hedonism*—pursuing pleasure and avoiding pain—that is the foundation for *utilitarianism*, which in turn provides the underpinning of psychoanalysis and all but the most radical of the behaviorisms. Research shows that *eudaimonia* consistently trumps pleasure as a predictor of life satisfaction. Those who pursue *eudaimonic* goals and activities are more satisfied than those who pursue pleasure. This is not to say that hedonism is irrelevant to life satisfaction, just that all things being equal, hedonism contributes less to long-term happiness than does *eudaimonia*.

Although the study of positive institutions is in its infancy, there is agreement that institutions that allow people to flourish—whether families, schools, workplaces, or even entire societies—share a core of common characteristics:

- ▶ Purpose—a shared vision of the moral goals of the institution, one reinforced by remembrances and celebrations
- ▶ Safety—protection against threat, danger, and exploitation
- ▶ Fairness—equitable rules governing reward and punishment and the means for consistently enforcing them
- ▶ Humanity—mutual care and concern
- ▶ Dignity—the treatment of all people in the institution as individuals regardless of their position

Psychologists, at least in the United States, have long believed that the human condition can be improved by the intelligent application of what they have learned. Positive psychologists are no exception, and many have turned their attention to interventions that make people more happy, hopeful, virtuous, accomplished, and socially involved. In some cases, these applications are running in front of data that would support them, but in other cases, outcome research has been done. Even the most compelling research is not based on follow up that extends beyond a few years, and the research participants are usually motivated and willing volunteers. How well these interventions will generalize—across diverse people and over time—is therefore a research topic of high priority.

POSITIVE PSYCHOLOGY AND CLINICAL WORK

When positive psychology was first described, its stated goal was not to move people from -5 to zero—the goal of conventional psychology and psychiatry—but rather from $+2$ to $+5$, within the upper right-hand quadrant of [Figure 4.4-1](#). This emphasis on *promotion* as opposed to remediation is an important feature of a positive psychology perspective, but it does not do justice to this new field and its potential role in clinical work.

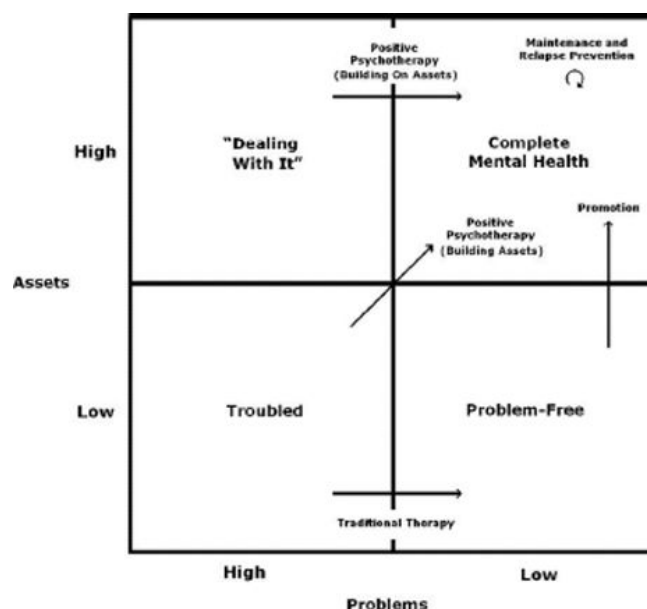

FIGURE 4.4-1

Mental health and mental illness. These are dimensions. Quadrants are shown for the purpose of illustration only. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:2942, with permission.)

Positive Psychology's Vision of Psychological Health

In its 1948 constitution, the World Health Organization (WHO) defined *health* as “a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.” In more recent years, this statement has been expanded to include the ability to lead a life that is socially and economically productive. This definition is an important declaration that health entails more than the absence of illness, but it is circular, inasmuch as “well-being” is a synonym for “health.” Work by positive psychologists makes this definition more concrete and thus useful as a guide for research and intervention.

If one can extrapolate from the sorts of topics that have been studied, positive psychology assumes that people are doing well when they experience more positive feelings than negative feelings, are satisfied with their lives as they have been lived, have identified what they do well and use these talents and strengths on an ongoing basis, are highly engaged in what they do, are contributing members of a social community, and have a sense of meaning and purpose in their lives. Physical health and safety, of course, provide an important context for psychological well-being. It is difficult to imagine a cultural group in which these components of the good life are not valued. Respect for human diversity need not entail extreme cultural relativism.

Note that this fuller characterization of health reflects the WHO definition and is drawn from research in all of the domains of concern to contemporary positive psychology. The relevant research cautions that health so defined is not unitary. No one can have it all, at least at the same time, given tradeoffs among the psychological states and traits that reflect doing well. Psychological health, therefore, needs to be described with a profile of features and not a single summary score. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5] describes hundreds of psychological problems, however there may be just as many different manifestations of the good life.

Theory of Psychopathology

As a perspective on topics that deserve scientific study, positive psychology has no single theory. Like much of contemporary psychology, it instead relies on midrange theories that draw on a variety of larger perspectives, from evolutionary to behavioral to cognitive to sociocultural models, to make sense of specific phenomena. Different topics are explained with different theories. The eventual integration of psychology may be a worthy goal, but it has not yet been achieved.

At this early point in the development of positive psychology, the lack of a consensual or integrated theory is not a problem. The psychological good life is not yet understood, and positive psychologists are still grappling with the right vocabulary to describe it. Accordingly, championing a single theory at the present time would be premature, even counterproductive.

It has been argued that positive psychology is a descriptive endeavor, not a prescriptive one. If this means that positive psychology should be an empirical science—informed by replicable facts—then this claim is reasonable and a defining feature of the entire field. If this means that positive psychology is assumption free or value neutral, the claim becomes much more difficult to defend. After all, positive psychologists make the value judgment that the “good” life is indeed good—that is, desirable, morally and otherwise—and the metatheoretical assumption that the good life can be studied with the conventional methods of psychology. In any event, positive psychology seems no more prescriptive than clinical psychology or psychiatry. It may even be less so, given the theoretical diversity of positive psychology as it now exists.

Positive Psychology Assessment

Assessment has long been a staple of psychology, and much of it has been tilted—understandably—toward identifying weaknesses, deficiencies, and problems. The positive psychology perspective is that business-as-usual assessment should be expanded (not replaced) by attention to areas of strength and competence. Low life satisfaction can occur in the absence of psychopathology, but it is nonetheless related to psychological and social problems. Conversely, high life satisfaction is linked to good functioning even in the presence of symptoms.

Positive psychologists have developed an impressive set of measurement instruments that allow someone doing assessment to break through the zero point of deficiency measures. For example, the healthiest that one can score on a typical measure of depression is zero, but this lumps together people who are blasé with those who are filled with zest and joy. The distinction seems well worth making, and the self-report surveys and interviews developed by positive psychologists allow it.

Most of the existing positive psychology measures were developed for research purposes, and they are most valid when aggregated to yield conclusions about groups of people. They can also be used ipsatively (i.e. forced to choose between two options), to describe the psychological characteristics of an individual and how they stay the same or change over time, but the cautious use of these descriptions is a point of discussion and a departure in treatment. None is a strong diagnostic test, and none should be treated as if it were. Such prudence is appropriate for all psychological assessment, but it is worth emphasizing in the special case of positive psychology measures.

Positive Psychology Techniques

Positive psychologists have demonstrated that brief interventions in the short term can increase happiness, satisfaction, and fulfillment. In some cases, there is also evidence that they can alleviate depression. For example, patients or clients can be asked to count their blessings:

Every night for 1 week, set aside 10 minutes before you go to bed. Use that time to write down three things that went really well on that day and why they went well. You may use a journal or your computer to write about the events, but it is important that you have a physical record of what you wrote. It is not enough to do this exercise in your head. The three things you list can be relatively small in importance or relatively large in importance. Next to each positive event in your list, answer the question, "Why did this good thing happen?"

They can also be asked to use their strengths in novel ways. They take the Values in Action Inventory of Strengths (VIA-IS) questionnaire online and identify their most signature strengths of character. Then they are instructed to use these strengths in their daily life:

Every day for the next 7 days use one of your top five strengths in a way that you have not before. You might use your strength in a new setting or with a new person. It's your choice.

Outcome research shows that a variety of psychotherapies are effective in alleviating problems and usually equally so, despite the different forms they take. One interpretation of the equal effectiveness of different therapies is that nonspecific factors common to all treatments are responsible. Perhaps the types of strategies being studied by positive psychologists reflect these common factors and give names to them. Strategies like instilling hope and building strengths may be the critical factors in the effectiveness of any therapy.

Some qualifications are in order if these techniques are used in the context of treatment. First, the therapist must ascertain a client's readiness to change in the particular ways requested in the exercise as well as the client's capacity to make the change. Like any psychotherapeutic procedure, these techniques cannot be imposed on the unwilling or the unable.

Second, none of these techniques is akin to a crash diet or an antibiotic. The degree to which they have lasting effects is related to how patients or clients integrate them into their regular behavioral routines. Counting blessings for a week will make a person happier for that week, but only if the person becomes habitually grateful will there be a more enduring effect. Research finds—not surprisingly—that the people who showed lasting benefits were those who continued to use the exercise.

Third, these exercises are typically presented as one size fits all, but there is no reason to think that they are equally useful for all patients or clients. Nothing is known about the match of an exercise with a client's particular presenting problems or goals or with a client's age, sex, social class, or ethnicity.

Fourth, little is known about the parameters of these interventions. For example, how many blessings should one count, and how frequently should this be done? With college students, counting blessings three times a week may be more effective in increasing happiness than counting them more frequently. Is this a general phenomenon or one specific to young adults attending college?

Fifth, all interventions run the risk of unintended harm, and although positive psychologists would like to believe that their techniques avoid iatrogenic effects, this assertion cannot be made with thorough confidence. For example, although optimism is related to mental and physical health, it would be simplistic and potentially hazardous to tell patients or clients that positive expectations will solve all their difficulties. Along these lines, if a positive psychology intervention overemphasizes a client's choice and responsibility, considerable damage could be done in cases of abuse and victimization, in which self-blame needs to be undone and certainly not encouraged. Interventions based on positive psychology should not preclude the use of existing therapeutic strategies when these are indicated.

Positive Psychotherapies

Positive psychotherapies are beginning to appear: therapeutic interventions based on the theories and findings of positive psychology. What distinguishes these emerging positive psychotherapies from conventional treatments is that their stated goal is not symptom reduction or relief but rather enhanced happiness, life satisfaction fulfillment, productivity, and the like—one or more components of positive psychology's vision of the good life. These new therapies target people with psychological problems as well as those without them. In the latter case, positive psychotherapies make contact with life coaching.

The possible field of positive psychotherapies is so broad that it needs narrowing, and somewhat arbitrarily, the focus here is on approaches characterized by an explicit *therapeutic alliance* between the positive psychologist and the patient or client. This feature goes by many names and has been variously defined, but its recurring themes include collaboration between therapist and client, an affective bond between them, and agreement on the goals and tasks of the intervention. Asking people to write about their goals or to perform acts of kindness, despite beneficial consequences, may or may not be instances of positive psychotherapy—what matters is the relational context of the request.

Taking Stock. The unique and explicit goal of emerging positive psychotherapies is to enhance well-being and to promote the good life among those with obvious psychological problems as well as those without them. They are also similar to more established therapies. Positive psychotherapies are short-term, structured interventions for individuals or small groups. Most can be placed in the cognitive-behavioral realm, although their techniques could be integrated easily into other treatment models. Most positive psychotherapies entail out-of-sessions exercises and homework assignments, the results of which are discussed in sessions. A number of positive psychotherapies rely on journal-keeping, and many of these therapies rely on ongoing assessment.

Like other cognitive-behavioral interventions, positive psychotherapies take issue with assumptions of the medical model that people in treatment are ill and that their problems are best described as discrete (present-or-absent) entities as in DSM-5. According to positive psychology, people's weaknesses and strengths exist in degrees.

As emphasized, research support is still accumulating. Enough outcome studies have been conducted to conclude that positive psychotherapies are more than just promising, with effect sizes in the small to moderate range typical of psychological interventions. Not known in most cases is how positive psychotherapies fare in direct comparison with conventional treatments for anxiety or depression. In addition, as already mentioned, the boundary conditions of effective positive psychotherapy are unknown.

Many positive psychologists would like to believe that a strengths-based approach to change is superior to one that focuses on the remediation of deficiencies, but this hypothesis has yet to be put to serious test. The even-handed suspicion is that attention to both strengths and weaknesses is critical and that no useful purpose is served by regarding these as mutually exclusive therapeutic strategies.

Examination and Diagnosis of the Psychiatric Patient

5.1 Psychiatric Interview, History, and Mental Status Examination

The psychiatric interview is the most important element in the evaluation and care of persons with mental illness. A major purpose of the initial psychiatric interview is to obtain information that will establish a criteria-based diagnosis. This process, helpful in the prediction of the course of the illness and the prognosis, leads to treatment decisions. A well-conducted psychiatric interview results in a multidimensional understanding of the biopsychosocial elements of the disorder and provides the information necessary for the psychiatrist, in collaboration with the patient, to develop a person-centered treatment plan.

Equally important, the interview itself is often an essential part of the treatment process. From the very first moments of the encounter, the interview shapes the nature of the patient–physician relationship, which can have a profound influence on the outcome of treatment. The settings in which the psychiatric interview takes place include psychiatric inpatient units, medical nonpsychiatric inpatient units, emergency rooms, outpatient offices, nursing homes, other residential programs, and correctional facilities. The length of time for the interview, and its focus, will vary depending on the setting, the specific purpose of interview, and other factors (including concurrent competing demands for professional services).

Nevertheless, there are basic principles and techniques that are important for all psychiatric interviews, and these will be the focus of this section. There are special issues in the evaluation of children that will not be addressed. This section focuses on the psychiatric interview of adult patients.

GENERAL PRINCIPLES

Agreement as to Process

At the beginning of the interview the psychiatrist should introduce himself or herself and, depending on the circumstances, may need to identify why he or she is speaking with the patient. Unless implicit (the patient coming to the office), consent to proceed with the interview should be obtained and the nature of the interaction and the approximate (or specific) amount of time for the interview should be stated. The patient should be encouraged to identify any elements of the process that he or she wishes to alter or add.

A crucial issue is whether the patient is, directly or indirectly, seeking the evaluation on a voluntary basis or has been brought involuntarily for the assessment. This should be established before the interview begins, and this information will guide the interviewer especially in the early stages of the process.

Privacy and Confidentiality

Issues concerning confidentiality are crucial in the evaluation/treatment process and may need to be discussed on multiple occasions. Health Insurance Portability and Accountability Act (HIPAA) regulations must be carefully followed, and the appropriate paperwork must be presented to the patient.

Confidentiality is an essential component of the patient–doctor relationship. The interviewer should make every attempt to ensure that the content of the interview cannot be overheard by others. Sometimes, in a hospital unit or other institutional setting, this may be difficult. If the patient is sharing a room with others, an attempt should be made to use a different room for the interview. If this is not feasible, the interviewer may need to avoid certain topics or indicate that these issues can be discussed later when privacy can be ensured. Generally, at the beginning, the interviewer should indicate that the content of the session(s) will remain confidential except for what needs to be shared with the referring physician or treatment team. Some evaluations, including forensic and disability evaluations, are less confidential and what is discussed may be shared with others. In those cases, the interviewer should be explicit in stating that the session is not confidential and identify who will receive a report of the evaluation. This information should be carefully and fully documented in the patient's record.

A special issue concerning confidentiality is when the patient indicates that he or she intends to harm another person. When the psychiatrist's evaluation suggests that this might indeed happen, the psychiatrist may have a legal obligation to warn the potential victim. (The law concerning notification of a potential victim varies by state.) Psychiatrists should also consider their ethical obligations. Part of this obligation may be met by appropriate clinical measures such as increasing the dose of antipsychotic medication or hospitalizing the patient.

Often members of the patient's family, including spouse, adult children, or parents, come with the patient to the first session or are present in the hospital or other institutional setting when the psychiatrist first sees the patient. If a family member wishes to talk to the psychiatrist, it is generally preferable to meet with the family member(s) and the patient together at the conclusion of the session and after the patient's consent has been obtained. The psychiatrist should not bring up material the patient has shared but listen to the input from family members and discuss items that the patient introduces during the joint session. Occasionally, when family members have not asked to be seen, the psychiatrist may feel that including a family member or caregiver might be helpful and raise this subject with the patient. This may be the case when the patient is not able to communicate effectively. As always, the patient must give consent except if the psychiatrist determines that the patient is a danger to himself or herself or others. Sometimes family members might telephone the psychiatrist. Except in an emergency, consent should be obtained from the patient before the psychiatrist speaks to the relative. As indicated above, the psychiatrist should not bring up material that the patient has shared but listen to the input from the family member. The patient should be told when a family member has contacted the psychiatrist even if the patient has given consent for this to occur.

In educational and, occasionally, forensic settings, there may be occasions when the session is recorded. The patient must be fully informed about the recording and how the recording will be used. The length of time the recording will be kept and how access to it will be restricted must be discussed. Occasionally in educational settings, one-way mirrors may be used as a tool to allow trainees to benefit from the observation of an interview. The patient should be informed of the use of the one-way mirror and the category of the observers and be reassured that the observers are also bound by the rules of confidentiality. The patient's consent for proceeding with the recording or use of the one-way mirror must be obtained, and it should be made clear that the patient's receiving care will not be determined by whether he or she agrees to its use. These devices will have an impact on the interview that the psychiatrist should be open to discussing as the session unfolds.

Respect and Consideration

As should happen in all clinical settings, the patient must be treated with respect, and the interviewer should be considerate of the circumstances of the patient's condition. The patient is often experiencing considerable pain or other distress and frequently is feeling vulnerable and uncertain of what may happen. Because of the stigma of mental illness and misconceptions about psychiatry, the patient may be especially concerned, or even frightened, about seeing a psychiatrist. The skilled psychiatrist is aware of these potential issues and interacts in a manner to decrease, or at least not increase, the distress. The success of the initial interview will often depend on the physician's ability to allay excessive anxiety.

Rapport/Empathy

Respect for and consideration of the patient will contribute to the development of rapport. In the clinical setting, rapport can be defined as the harmonious responsiveness of the physician to the patient and the patient to the physician. It is important that patients increasingly feel that the evaluation is a joint effort and that the psychiatrist is truly interested in their story. Empathic interventions (“*That must have been very difficult for you*” or “*I’m beginning to understand how awful that felt*”) further increase the rapport. Frequently a nonverbal response (raised eyebrows or leaning toward the patient) or a very brief response (“*Wow*”) will be similarly effective. Empathy is understanding what the patient is thinking and feeling and it occurs when the psychiatrist is able to put himself or herself in the patient’s place while at the same time maintaining objectivity. For the psychiatrist to truly understand what the patient is thinking and feeling requires an appreciation of many issues in the patient’s life. As the interview progresses, the patient’s story unfolds and patterns of behaviors become evident, and it becomes clearer what the patient may actually have experienced. Early in the interview, the psychiatrist may not be as fully confident of where the patient is or was (although the patient’s nonverbal cues can be very helpful). If the psychiatrist is uncertain about the patient’s experience, it is often best not to guess but to encourage the patient to continue. Head nodding, putting down one’s pen, leaning toward the patient, or a brief comment, “*I see,*” can accomplish this objective and simultaneously indicate that this is important material. In fact the large majority of empathic responses in an interview are nonverbal.

An essential ingredient in empathy is retaining objectivity. Maintaining objectivity is crucial in a therapeutic relationship and it differentiates empathy from identification. With identification, psychiatrists not only understand the emotion but also experience it to the extent that they lose the ability to be objective. This blurring of boundaries between the patient and psychiatrist can be confusing and distressing to many patients, especially to those who as part of their illness already have significant boundary problems (e.g., individuals with borderline personality disorder). Identification can also be draining to the psychiatrist and lead to disengagement and ultimately burnout.

Patient-Physician Relationship

The patient-physician relationship is the core of the practice of medicine. (For many years the term used was “physician-patient” or “doctor-patient,” but the order is sometimes reversed to reinforce that the treatment should always be patient centered.) Although the relationship between any one patient and physician will vary depending on each of their personalities and past experiences as well as the setting and purpose of the encounter, there are general principles that, when followed, help to ensure that the relationship established is helpful.

The patient comes to the interview seeking help. Even in those instances when the patient comes on the insistence of others (i.e., spouse, family, courts), help may be sought by the patient in dealing with the person requesting or requiring the evaluation or treatment. This desire for help motivates the patient to share with a stranger information and feelings that are distressing, personal, and often private. The patient is willing, to various degrees, to do so because of a belief that the doctor has the expertise, by virtue of training and experience, to be of help. Right from the very first encounter (sometimes the initial phone call), the patient’s willingness to share is increased or decreased depending on the verbal and often the nonverbal interventions of the physician and other staff. As the physician’s behaviors demonstrate respect and consideration, rapport begins to develop. This is increased as the patient feels safe and comfortable. If the patient feels secure that what is said in the interview remains confidential, he or she will be more open to sharing.

The sharing is reinforced by the nonjudgmental attitude and behavior of the physician. The patient may have been exposed to considerable negative responses, actual or feared, to their symptoms or behaviors, including criticism, disdain, belittlement, anger, or violence. Being able to share thoughts and feelings with a nonjudgmental listener is generally a positive experience.

There are two additional essential ingredients in a helpful patient-physician relationship. One is the demonstration by physicians that they understand what the patient is stating and emoting. It is not enough that the physician understands what the patient is relating, thinking, and feeling; this understanding must be conveyed to the patient if it is to nurture the therapeutic relationship. The interview is not just an intellectual exercise to arrive at a supportable diagnosis. The other essential ingredient in a helpful patient-physician relationship is the recognition by the patient that the physician cares. As the patient becomes aware that the physician not only understands but also cares, trust increases and the therapeutic alliance becomes stronger.

The patient-physician relationship is reinforced by the genuineness of the physician. Being able to laugh in response to a humorous comment, admit a mistake, or apologize for an error that inconvenienced the patient (e.g., being late for or missing an appointment) strengthens the therapeutic alliance. It is also important to be flexible in the interview and responsive to patient initiatives. If the patient brings in an item, for example, a photo that he or she wants to show the psychiatrist, it is good to look at it, ask questions, and thank the patient for sharing it. Much can be learned about the family history and dynamics from such a seemingly sidebar moment. In addition, the therapeutic alliance is strengthened. The psychiatrist should be mindful of the reality that there are no irrelevant moments in the interview room.

At times patients will ask questions about the psychiatrist. A good rule of thumb is that questions about the physician’s qualifications and position should generally be answered directly (e.g., board certification, hospital privileges). On occasion, such a question might actually be a sarcastic comment (“*Did you really go to medical school?*”). In this case it would be better to address the issue that provoked the comment rather than respond concretely. There is no easy answer to the question of how the psychiatrist should respond to personal questions (“*Are you married?*,” “*Do you have children?*,” “*Do you watch football?*”). Advice on how to respond will vary depending on several issues, including the type of psychotherapy being used or considered, the context in which the question is asked, and the wishes of the psychiatrist. Often, especially if the patient is being, or might be, seen for insight-oriented psychotherapy, it is useful to explore why the question is being asked. The question about children may be precipitated by the patient wondering if the psychiatrist has had personal experience in raising children, or more generally does the psychiatrist have the skills and experience necessary to meet the patient’s needs. In this instance, part of the psychiatrist’s response may be that he or she has had considerable experiences in helping people deal with issues of parenting. For patients being seen for supportive psychotherapy or medication management, answering the question, especially if it is not very personal, such as “*Do you watch football?*,” is quite appropriate. A major reason for not answering personal questions directly is that the interview may become psychiatrist centered rather than patient centered.

Occasionally, again depending on the nature of the treatment, it can be helpful for the psychiatrist to share some personal information even if it is not asked directly by the patient. The purpose of the self-revelation should always be to strengthen the therapeutic alliance to be helpful to the patient. Personal information should not be shared to meet the psychiatrist’s needs.

Conscious/Unconscious

In order to understand more fully the patient-physician relationship, unconscious processes must be considered. The reality is that the majority of mental activity remains outside of conscious awareness. In the interview, unconscious processes may be suggested by tangential references to an issue, slips of the tongue or mannerisms of speech, what is not said or avoided, and other defense mechanisms. For example, phrases such as “*to tell you the truth*” or “*to speak frankly*” suggest that the speaker does not usually tell the truth or speak frankly. In the initial interview it is best to note such mannerisms or slips but not to explore them. It may or may not be helpful to pursue them in subsequent sessions. In the interview, transference and countertransference are very significant expressions of unconscious processes. *Transference* is the process of the patient unconsciously and inappropriately displacing onto individuals in his or her current life those patterns of behavior and emotional reactions that originated with significant figures from earlier in life, often childhood. In the clinical

situation the displacement is onto the psychiatrist, who is often an authority figure or a parent surrogate. It is important that the psychiatrist recognizes that the transference may be driving the behaviors of the patient, and the interactions with the psychiatrist may be based on distortions that have their origins much earlier in life. The patient may be angry, hostile, demanding, or obsequious not because of the reality of the relationship with the psychiatrist but because of former relationships and patterns of behaviors. Failure to recognize this process can lead to the psychiatrist inappropriately reacting to the patient's behavior as if it were a personal attack on the psychiatrist.

Similarly, *countertransference* is the process where the physician unconsciously displaces onto the patient patterns of behaviors or emotional reactions as if he or she were a significant figure from earlier in the physician's life. Psychiatrists should be alert to signs of countertransference issues (missed appointment by the psychiatrist, boredom, or sleepiness in a session). Supervision or consultations can be helpful as can personal therapy in helping the psychiatrist recognize and deal with these issues.

Although the patient comes for help, there may be forces that impede the movement to health. Resistances are the processes, conscious or unconscious, that interfere with the therapeutic objectives of treatment. The patient is generally unaware of the impact of these feelings, thinking, or behaviors, which take many different forms including exaggerated emotional responses, intellectualization, generalization, missed appointments, or acting out behaviors. Resistance may be fueled by repression, which is an unconscious process that keeps issues or feelings out of awareness. Because of repression, patients may not be aware of the conflicts that may be central to their illness. In insight-oriented psychotherapy, interpretations are interventions that undo the process of repression and allow the unconscious thoughts and feelings to come to awareness so that they can be dealt with. As a result of these interventions, the primary gain of the symptom, the unconscious purpose that it serves, may become clear. In the initial session, interpretations are generally avoided. The psychiatrist should make note of potential areas for exploration in subsequent sessions.

Person-Centered and Disorder-Based Interviews

A psychiatric interview should be person (patient) centered. That is, the focus should be on understanding the patient and enabling the patient to tell his or her story. The individuality of the patient's experience is a central theme, and the patient's life history is elicited, subject to the constraints of time, the patient's willingness to share some of this material, and the skill of the interviewer. Adolf Meyer's "life-charts" were graphic representations of the material collected in this endeavor and were a core component of the "psychobiological" understanding of illness. The patient's early life experiences, family, education, occupation(s), religious beliefs and practices, hobbies, talents, relationships, and losses are some of the areas that, in concert with genetic and biological variables, contribute to the development of the personality. An appreciation of these experiences and their impact on the person is necessary in forming an understanding of the patient. It is not only the history that should be person centered. It is especially important that the resulting treatment plan be based on the patient's goals, not the psychiatrist's. Numerous studies have demonstrated that often the patient's goals for treatment (e.g., safe housing) are not the same as the psychiatrist's (e.g., decrease in hallucinations). This dichotomy can often be traced to the interview where the focus was not sufficiently person centered but rather was exclusively or largely symptom based. Even when the interviewer specifically asks about the patient's goals and aspirations, the patient, having been exposed on numerous occasions to what a professional is interested in hearing about, may attempt to focus on "acceptable" or "expected" goals rather than his or her own goals. The patient should be explicitly encouraged to identify his or her goals and aspirations in his or her own words.

Traditionally, medicine has focused on illness and deficits rather than strengths and assets. A person-centered approach focuses on strengths and assets as well as deficits. During the assessment, it is often helpful to ask the patient, "Tell me about some of the things you do best," or, "What do you consider your greatest asset?" A more open-ended question, such as, "Tell me about yourself," may elicit information that focuses more on either strengths or deficits depending on a number of factors including the patient's mood and self-image.

Safety and Comfort

Both the patient and the interviewer must feel safe. This includes physical safety. On occasion, especially in hospital or emergency room settings, this may require that other staff be present or that the door to the room where the interview is conducted be left ajar. In emergency room settings, it is generally advisable for the interviewer to have a clear, unencumbered exit path. Patients, especially if psychotic or confused, may feel threatened and need to be reassured that they are safe and the staff will do everything possible to ensure their safety. Sometimes it is useful to explicitly state, and sometimes demonstrate, that there are sufficient staff to prevent a situation from spiraling out of control. For some, often psychotic patients who are fearful of losing control, this can be reassuring. The interview may need to be shortened or quickly terminated if the patient becomes more agitated and threatening. Once issues of safety have been assessed (and for many outpatients this may be accomplished within a few seconds), the interviewer should inquire about the patient's comfort and continue to be alert to the patient's comfort throughout the interview. A direct question may be helpful in not only making the patient feel more comfortable but also in enhancing the patient-doctor relationship. This might include, "Are you warm enough?" or "Is that chair comfortable for you?" As the interview progresses, if the patient desires tissues or water it should be provided.

Time and Number of Sessions

For an initial interview, 45 to 90 minutes is generally allotted. For inpatients on a medical unit or at times for patients who are confused, in considerable distress, or psychotic, the length of time that can be tolerated in one sitting may be 20 to 30 minutes or less. In those instances, a number of brief sessions may be necessary. Even for patients who can tolerate longer sessions, more than one session may be necessary to complete an evaluation. The clinician must accept the reality that the history obtained is never complete or fully accurate. An interview is dynamic and some aspects of the evaluation are ongoing, such as how a patient responds to exploration and consideration of new material that emerges. If the patient is coming for treatment, as the initial interview progresses, the psychiatrist makes decisions about what can be continued in subsequent sessions.

PROCESS OF THE INTERVIEW

Before the Interview

For outpatients, the first contact with the psychiatrist office is often a telephone call. It is important that whomever is receiving the call understands how to respond if the patient is acutely distressed, confused, or expresses suicidal or homicidal intent. If the receiver of the call is not a mental health professional, the call should be transferred to the psychiatrist or other mental health professional, if available. If not available, the caller should be directed to a psychiatric emergency center or an emergency hotline. The receiver of the call should obtain the name and phone number of the caller and offer to initiate the call to the hotline if that is preferred by the caller.

Most calls are not of such an urgent nature. The receptionist (or whomever receives the call) should obtain the information that setting has deemed relevant for the first contact. Although the requested information varies considerably, it generally includes the name, age, address and telephone number(s) of the patient, who referred the patient, the reason for the referral, and insurance information. The patient is given relevant information about the office including length of time for the initial session, fees, and whom to call if there are additional questions. In many practices the psychiatrist will call the patient to discuss the reason for the appointment and to determine if indeed an appointment appears warranted. The timing of the appointment should reflect the apparent urgency of the problem. Asking the patient to bring information about past psychiatric and medical treatments as well as a list of medications (or preferably the medications themselves) can be very helpful. Frequently a patient is referred to the psychiatrist or a psychiatric facility. If possible, reviewing records that precede the

patient can be quite helpful. Some psychiatrists prefer not to read records prior to the initial interview so that their initial view of the patient's problems will not be unduly influenced by prior evaluations. Whether or not records are reviewed, it is important that the reason for the referral be understood as clearly as possible. This is especially important for forensic evaluations where the reason for the referral and the question(s) posed will help to shape the evaluation. Often, especially in the outpatient setting, a patient is referred to the psychiatrist by a primary care physician or other health care provider. Although not always feasible, communicating with the referring professional prior to the evaluation can be very helpful. It is critical to determine whether the patient is referred for only an evaluation with the ongoing treatment to be provided by the primary care physician or mental health provider (e.g., social worker) or if the patient is being referred for evaluation and treatment by the psychiatrist.

If the patient is referred by the court, a lawyer, or some other non-treatment-oriented agency such as an insurance company, the goals of the interview may be different from diagnosis and treatment recommendations. These goals can include determination of disability, questions of competence or capacity, or determining, if possible, the cause or contributors of the psychiatric illness. In these special circumstances, the patient and clinician are not entering a treatment relationship, and often the usual rules of confidentiality do not apply. This limited confidentiality must be explicitly established with the patient and must include a discussion of who will be receiving the information gathered during the interview.

The Waiting Room

When the patient arrives for the initial appointment, he or she is often given forms to complete. These generally include demographic and insurance information. In addition, the patient receives information about the practice (including contact information for evenings and weekends) and HIPAA-mandated information that must be read and signed. Many practices also ask for a list of medications, the name and address of the primary care physician, and identification of major medical problems and allergies. Sometimes the patient is asked what his or her major reason is for coming to the office. Increasingly, some psychiatrists ask the patient to fill out a questionnaire or a rating scale that identifies major symptoms. Such scales include the Patient Health Questionnaire 9 (PHQ-9) or the Quick Inventory of Depression Symptomatology Self Report (QIDS-SR), which are scales of depressive symptoms based on the *Diagnostic and Statistical Manual of Mental Diseases* (DSM).

The Interview Room

The interview room itself should be relatively soundproof. The decor should be pleasant and not distracting. If feasible, it is a good idea to give the patient the choice of a soft chair or a hard-back chair. Sometimes the choice of the chair or how the chair is chosen can reveal characteristics of the patient. Many psychiatrists suggest that the interviewer's chair and the patient's chair be of relatively equal height so that the interviewer does not tower over the patient (or vice versa). It is generally agreed that the patient and the psychiatrist should be seated approximately 4 to 6 feet apart. The psychiatrist should not be seated behind a desk. The psychiatrist should dress professionally and be well groomed. Distractions should be kept to a minimum. Unless there is an urgent matter, there should be no telephone or beeper interruptions during the interview. The patient should feel that the time has been set aside just for him or her and that for this designated time he or she is the exclusive focus of the psychiatrist's attention.

Initiation of the Interview

The patient is greeted in the waiting room by the psychiatrist who, with a friendly face, introduces himself or herself, extends a hand, and, if the patient reciprocates, gives a firm handshake. If the patient does not extend his or her hand, it is probably best not to comment at that point but warmly indicate the way to the interview room. The refusal to shake hands is probably an important issue, and the psychiatrist can keep this in mind for a potential inquiry if it is not brought up subsequently by the patient. Upon entering the interview room, if the patient has a coat, the psychiatrist can offer to take the coat and hang it up. The psychiatrist then indicates where the patient can sit. A brief pause can be helpful as there may be something the patient wants to say immediately. If not, the psychiatrist can inquire if the patient prefers to be called Mr. Smith, Thomas, or Tom. If this question is not asked, it is best to use the last name as some patients will find it presumptive to be called by their first name especially if the interviewer is many years younger. These first few minutes of the encounter, even before the formal interview begins, can be crucial to the success of the interview and the development of a helpful patient-doctor relationship. The patient, who is often anxious, forms an initial impression of the psychiatrist and begins to make decisions as to how much can be shared with this doctor. Psychiatrists can convey interest and support by exhibiting a warm, friendly face and other nonverbal communications such as leaning forward in their chair. It is generally useful for the psychiatrist to indicate how much time is available for the interview. The patient may have some questions about what will happen during this time, confidentiality, and other issues, and these questions should be answered directly by the psychiatrist. The psychiatrist can then continue with an open-ended inquiry, "*Why don't we start by you telling me what has led to your being here,*" or simply, "*What has led to your being here?*" Often the response to this question will establish whether or not the patient has been referred. When a referral has been made, it is important to elicit from the patient his or her understanding of why he or she has been referred. Not uncommonly, the patient may be uncertain as to why he or she has been referred or may even feel angry at the referrer, often a primary care physician.

Open-Ended Questions

As the patient responds to these initial questions, it is very important that the psychiatrist interacts in a manner that allows the patient to tell his or her story. This is the primary goal of the data collection part of the interview, to elicit the patient's story of his or her health and illness. In order to accomplish this objective, open-ended questions are a necessity. Open-ended questions identify an area but provide minimal structure as to how to respond. A typical open-ended question is, "*Tell me about your pain.*" This is in contrast to closed-ended questions that provide much structure and narrow the field from which a response may be chosen. "*Is your pain sharp?*" The ultimate closed-ended question leads to a "yes" or "no" answer. In the initial portion of the interview questions should be primarily open ended. As the patient responds, the psychiatrist reinforces the patient continuing by nodding or other supportive interventions. As the patient continues to share his or her story about an aspect of his or her health or illness, the psychiatrist may ask some increasingly closed-ended questions to understand some of the specifics of the history. Then, when that area is understood, the psychiatrist may make a transition to another area again using open-ended questions and eventually closed-ended questions until that area is well described. Hence, the interview should not be a single funnel of open-ended questions in the beginning and closed-ended questions at the end of the interview but rather a series of funnels, each of which begins with open-ended questions.

ELEMENTS OF THE INITIAL PSYCHIATRIC INTERVIEW

The interview is now well launched into the present illness. [Table 5.1-1](#) lists the sections or parts of the initial psychiatric interview. Although not necessarily obtained during the interview in exactly this order, these are the categories that conventionally have been used to organize and record the elements of the evaluation.

Table 5.1-1

Parts of the Initial Psychiatric Interview

- I. Identifying data
 - II. Source and reliability
 - III. Chief complaint
 - IV. Present illness
 - V. Past psychiatric history
 - VI. Substance use/abuse
 - VII. Past medical history
 - VIII. Family history
 - IX. Developmental and social history
 - X. Review of systems
 - XI. Mental status examination
 - XII. Physical examination
 - XIII. Formulation
 - XIV. DSM-5 diagnoses
 - XV. Treatment plan
-

The two overarching elements of the psychiatric interview are the patient history and the mental status examination. The patient history is based on the subjective report of the patient and in some cases the report of collaterals including other health care providers, family, and other caregivers. The mental status examination, on the other hand, is the interviewer's objective tool similar to the physical examination in other areas of medicine. The physical examination, although not part of the interview itself, is included because of its potential relevance in the psychiatric diagnosis and also because it usually is included as part of the psychiatric evaluation especially in the inpatient setting. (In addition, much relevant information can be verbally obtained by the physician as parts of the physical examination are performed.) Similarly, the formulation, diagnosis, and treatment plan are included because they are products of the interview and also influence the course of the interview in a dynamic fashion as the interview moves back and forth pursuing, for example, whether certain diagnostic criteria are met or whether potential elements of the treatment plan are realistic. Details of the psychiatric interview are discussed below.

I. Identifying Data

This section is brief, one or two sentences, and typically includes the patient's name, age, sex, marital status (or significant other relationship), race or ethnicity, and occupation. Often the referral source is also included.

II. Source and Reliability

It is important to clarify where the information has come from, especially if others have provided information or records reviewed, and the interviewer's assessment of how reliable the data are.

III. Chief Complaint

This should be the patient's presenting complaint, ideally in his or her own words. Examples include, "I'm depressed" or "I have a lot of anxiety."

A 64-year-old man presented in a psychiatric emergency room with a chief complaint, "I'm melting away like a snowball." He had become increasingly depressed over 3 months. Four weeks before the emergency room visit, he had seen his primary care physician who had increased his antidepressant medication (imipramine) from 25 to 75 mg and also added hydrochlorothiazide (50 mg) because of mild hypertension and slight pedal edema. Over the ensuing 4 weeks, the patient's condition deteriorated. In the emergency room he was noted to have depressed mood, hopelessness, weakness, significant weight loss, and psychomotor retardation and was described as appearing "depleted." He also appeared dehydrated, and blood work indicated he was hypokalemic. Examination of his medication revealed that the medication bottles had been mislabeled; he was taking 25 mg of imipramine (generally a nontherapeutic dose) and 150 mg of hydrochlorothiazide. He was indeed, "melting away like a snowball." Fluid and potassium replacement and a therapeutic dose of an antidepressant resulted in significant improvement.

IV. History of Present Illness

The present illness is a chronological description of the evolution of the symptoms of the current episode. In addition, the account should also include any other changes that have occurred during this same time period in the patient's interests, interpersonal relationships, behaviors, personal habits, and physical health. As noted above, the patient may provide much of the essential information for this section in response to an open-ended question such as, "Can you tell me in your own words what brings you here today?" Other times the clinician may have to lead the patient through parts of the presenting problem. Details that should be gathered include the length of time that the current symptoms have been present and whether there have been fluctuations in the nature or severity of those symptoms over time. ("I have been depressed for the past two weeks" vs. "I've had depression all my life"). The presence or absence of stressors should be established, and these may include situations at home, work, school, legal issues, medical comorbidities, and interpersonal difficulties. Also important are factors that alleviate or exacerbate symptoms such as medications, support, coping skills, or time of day. The essential questions to be answered in the history of the present illness include what (symptoms), how much (severity), how long, and associated factors. It is also important to identify why the patient is seeking help now and what are the "triggering" factors ("I'm here now because my girlfriend told me if I don't get help with this nervousness she is going to leave me."). Identifying the setting in which the illness began can be revealing and helpful in understanding the etiology of, or significant contributors to, the condition. If any treatment has been received for the current episode, it should be defined in terms of who saw the patient and how often, what was done (e.g., psychotherapy or medication), and the specifics of the modality used. Also, is that treatment continuing and, if not, why not? The psychiatrist should be alert for any hints of abuse by former therapists as this experience, unless addressed, can be a major impediment to a healthy and helpful therapeutic alliance.

Often it can be helpful to include a psychiatric review of systems in conjunction with the history of the present illness to help rule in or out psychiatric diagnoses with pertinent positives and negatives. This may help to identify whether there are comorbid disorders or disorders that are actually more bothersome to the patient but are not initially identified for a variety of reasons. This review can be split into four major categories of mood, anxiety, psychosis, and other (Table 5.1-2). The clinician will want to ensure that these areas are covered in the comprehensive psychiatric interview.

 **Table 5.1-2**
Psychiatric Review of Systems

1. Mood
 - A. Depression: Sadness, tearfulness, sleep, appetite, energy, concentration, sexual function, guilt, psychomotor agitation or slowing, interest. A common mnemonic used to remember the symptoms of major depression is SIGECAPS (Sleep, Interest, Guilt, Energy, Concentration, Appetite, Psychomotor agitation or slowing, Suicidality).
 - B. Mania: Impulsivity, grandiosity, recklessness, excessive energy, decreased need for sleep, increased spending beyond means, talkativeness, racing thoughts, hypersexuality.
 - C. Mixed/Other: Irritability, lability.
 2. Anxiety
 - A. Generalized anxiety symptoms: Where, when, who, how long, how frequent.
 - B. Panic disorder symptoms: How long until peak, somatic symptoms including racing heart, sweating, shortness of breath, trouble swallowing, sense of doom, fear of recurrence, agoraphobia.
 - C. Obsessive-compulsive symptoms: Checking, cleaning, organizing, rituals, hang-ups, obsessive thinking, counting, rational vs. irrational beliefs.
 - D. Posttraumatic stress disorder: Nightmares, flashbacks, startle response, avoidance.
 - E. Social anxiety symptoms.
 - F. Simple phobias, for example, heights, planes, spiders, etc.
 3. Psychosis
 - A. Hallucinations: Auditory, visual, olfactory, tactile.
 - B. Paranoia.
 - C. Delusions: TV, radio, thought broadcasting, mind control, referential thinking.
 - D. Patient's perception: Spiritual or cultural context of symptoms, reality testing.
 4. Other
 - A. Attention-deficit/hyperactivity disorder symptoms.
 - B. Eating disorder symptoms: Binging, purging, excessive exercising.
-

V. Past Psychiatric History

In the past psychiatric history, the clinician should obtain information about all psychiatric illnesses and their course over the patient's lifetime, including symptoms and treatment. Because comorbidity is the rule rather than the exception, in addition to prior episodes of the same illness (e.g., past episodes of depression in an individual who has a major depressive disorder), the psychiatrist should also be alert for the signs and symptoms of other psychiatric disorders. Description of past symptoms should include when they occurred, how long they lasted, and the frequency and severity of episodes.

Past treatment episodes should be reviewed in detail. These include outpatient treatment such as psychotherapy (individual, group, couple, or family), day treatment or partial hospitalization, inpatient treatment, including voluntary or involuntary and what precipitated the need for the higher level of care, support groups, or other forms of treatment such as vocational training. Medications and other modalities such as electroconvulsive therapy, light therapy, or alternative treatments should be carefully reviewed. One should explore what was tried (may have to offer lists of names to patients), how long and at what doses they were used (to establish adequacy of the trials), and why they were stopped. Important questions include what was the response to the medication or modality and whether there were side effects. It is also helpful to establish whether there was reasonable compliance with the recommended treatment. The psychiatrist should also inquire whether a diagnosis was made, what it was, and who made the diagnosis. Although a diagnosis made by another clinician should not be automatically accepted as valid, it is important information that can be used by the psychiatrist in forming his or her opinion.

Special consideration should be given to establishing a lethality history that is important in the assessment of current risk. Past suicidal ideation, intent, plan, and attempts should be reviewed including the nature of attempts, perceived lethality of the attempts, save potential, suicide notes, giving away things, or other death preparations. Violence and homicidality history will include any violent actions or intent. Specific questions about domestic violence, legal complications, and outcome of the victim may be helpful in defining this history more clearly. History of nonsuicidal self-injurious behavior should also be covered including any history of cutting, burning, banging head, and biting oneself. The feelings, including relief of distress, that accompany or follow the behavior should also be explored as well as the degree to which the patient has gone to hide the evidence of these behaviors.

VI. Substance Use, Abuse, and Addictions

A careful review of substance use, abuse, and addictions is essential to the psychiatric interview. The clinician should keep in mind that this information may be difficult for the patient to discuss, and a nonjudgmental style will elicit more accurate information. If the patient seems reluctant to share such information specific questions may be helpful (e.g., "Have you ever used marijuana?" or "Do you typically drink alcohol every day?"). History of use should include which substances have been used, including alcohol, drugs, medications (prescribed or not prescribed to the patient), and routes of use (oral, snorting, or intravenous). The frequency and amount of use should be determined, keeping in mind the tendency for patients to minimize or deny use that may be perceived as socially unacceptable. Also, there are many misconceptions about alcohol that can lead to erroneous data. The definition of alcohol may be misunderstood, for example, "No, I don't use alcohol," yet later in the same interview, "I drink a fair amount of beer." Also the amount of alcohol can be confused with the volume of the drink: "I'm not worried about my alcohol use. I mix my own drinks and I add a lot of water." in response to a follow-up question, "How much bourbon? Probably three or four shots?" Tolerance, the need for increasing amounts of use, and any withdrawal symptoms should be established to help determine abuse versus dependence. Impact of use on social interactions, work, school, legal consequences, and driving while intoxicated (DWI) should be covered. Some psychiatrists use a brief standardized questionnaire, the CAGE or RAPS4, to identify alcohol abuse or dependence.

CAGE includes four questions: Have you ever Cut down on your drinking? Have people Annoyed you by criticizing your drinking? Have you ever felt bad or Guilty about your drinking? Have you ever had a drink the first thing in the morning, as an Eye-opener, to steady your nerves or get rid of a hangover? The Rapid Alcohol Problem Screen 4 (RAPS4) also consists of four questions: Have you ever felt guilty after drinking (Remorse), could not remember things said or did after drinking (Amnesia), failed to do what was normally

expected after drinking (Perform), or had a morning drink (Starter)?

Any periods of sobriety should be noted including length of time and setting such as in jail, legally mandated, and so forth. A history of treatment episodes should be explored, including inpatient detoxification or rehabilitation, outpatient treatment, group therapy, or other settings including self-help groups, Alcoholics Anonymous (AA) or Narcotics Anonymous (NA), halfway houses, or group homes.

Current substance abuse or dependence can have a significant impact on psychiatric symptoms and treatment course. The patient's readiness for change should be determined including whether they are in the precontemplative, contemplative, or action phase. Referral to the appropriate treatment setting should be considered.

Other important substances and addictions that should be covered in this section include tobacco and caffeine use, gambling, eating behaviors, and Internet use. Exploration of tobacco use is especially important because persons abusing substances are more likely to die as a result of tobacco use than because of the identified abused substance. Gambling history should include casino visits, horse racing, lottery and scratch cards, and sports betting. Addictive type eating may include binge eating disorder. Overeaters Anonymous (OA) and Gamblers Anonymous (GA) are 12-step programs, similar to AA, for patients with addictive eating behaviors and gambling addictions.

VII. Past Medical History

The past medical history includes an account of major medical illnesses and conditions as well as treatments, both past and present. Any past surgeries should be also reviewed. It is important to understand the patient's reaction to these illnesses and the coping skills employed. The past medical history is an important consideration when determining potential causes of mental illness as well as comorbid or confounding factors and may dictate potential treatment options or limitations. Medical illnesses can precipitate a psychiatric disorder (e.g., anxiety disorder in an individual recently diagnosed with cancer), mimic a psychiatric disorder (hyperthyroidism resembling an anxiety disorder), be precipitated by a psychiatric disorder or its treatment (metabolic syndrome in a patient on a second-generation antipsychotic medication), or influence the choice of treatment of a psychiatric disorder (renal disorder and the use of lithium carbonate). It is important to pay special attention to neurological issues including seizures, head injury, and pain disorder. Any known history of prenatal or birthing problems or issues with developmental milestones should be noted. In women, a reproductive and menstrual history is important as well as a careful assessment of potential for current or future pregnancy. (*"How do you know you are not pregnant?"* may be answered with "Because I have had my tubes tied" or "I just hope I'm not.")

A careful review of all current medications is very important. This should include all current psychiatric medications with attention to how long they have been used, compliance with schedules, effect of the medications, and any side effects. It is often helpful to be very specific in determining compliance and side effects including asking questions such as, *"How many days of the week are you able to actually take this medication?"* or *"Have you noticed any change in your sexual function since starting this medication?"*, as the patient may not spontaneously offer this information, which may be embarrassing or perceived to be treatment interfering.

Nonpsychiatric medications, over-the-counter medications, sleep aids, herbal, and alternative medications should also be reviewed. These can all potentially have psychiatric implications including side effects or produce symptoms as well as potential medication interactions dictating treatment options. Optimally the patient should be asked to bring all medications currently being taken, prescribed or not, over-the-counter preparations, vitamins, and herbs to the interview.

Allergies to medications must be covered, including which medication and the nature of, the extent of, and the treatment of the allergic response. Psychiatric patients should be encouraged to have adequate and regular medical care. The sharing of appropriate information among the primary care physicians, other medical specialists, and the psychiatrist can be very helpful for optimal patient care. The initial interview is an opportunity to reinforce that concept with the patient. At times a patient may not want information to be shared with his or her primary care physician. This wish should be respected, although it may be useful to explore if there is some information that can be shared. Often patients want to restrict certain social or family information (e.g., an extramarital affair) but are comfortable with other information (medication prescribed) being shared.

VIII. Family History

Because many psychiatric illnesses are familial and a significant number of those have a genetic predisposition, if not cause, a careful review of family history is an essential part of the psychiatric assessment. Furthermore, an accurate family history helps not only in defining a patient's potential risk factors for specific illnesses but also the formative psychosocial background of the patient. Psychiatric diagnoses, medications, hospitalizations, substance use disorders, and lethality history should all be covered. The importance of these issues is highlighted, for example, by the evidence that, at times, there appears to be a familial response to medications, and a family history of suicide is a significant risk factor for suicidal behaviors in the patient. The interviewer must keep in mind that the diagnosis ascribed to a family member may or may not be accurate and some data about the presentation and treatment of that illness may be helpful. Medical illnesses present in family histories may also be important in both the diagnosis and the treatment of the patient. An example is a family history of diabetes or hyperlipidemia affecting the choice of antipsychotic medication that may carry a risk for development of these illnesses in the patient. Family traditions, beliefs, and expectations may also play a significant role in the development, expression, or course of the illness. Also the family history is important in identifying potential support as well as stresses for the patient and, depending on the degree of disability of the patient, the availability and adequacy of potential caregivers.

IX. Developmental and Social History

The developmental and social history reviews the stages of the patient's life. It is an important tool in determining the context of psychiatric symptoms and illnesses and may, in fact, identify some of the major factors in the evolution of the disorder. Frequently, current psychosocial stressors will be revealed in the course of obtaining a social history. It can often be helpful to review the social history chronologically to ensure all information is covered.

Any available information concerning prenatal or birthing history and developmental milestones should be noted. For the large majority of adult patients, such information is not readily available and when it is it may not be fully accurate. Childhood history will include childhood home environment including members of the family and social environment including the number and quality of friendships. A detailed school history including how far the patient went in school and how old he or she was at that level, any special education circumstances or learning disorders, behavioral problems at school, academic performance, and extracurricular activities should be obtained. Childhood physical and sexual abuse should be carefully queried.

Work history will include types of jobs, performance at jobs, reasons for changing jobs, and current work status. The nature of the patient's relationships with supervisors and coworkers should be reviewed. The patient's income, financial issues, and insurance coverage including pharmacy benefits are often important issues.

Military history, where applicable, should be noted including rank achieved, combat exposure, disciplinary actions, and discharge status. Marriage and relationship history, including sexual preferences and current family structure, should be explored. This should include the patient's capacity to develop and maintain stable and mutually satisfying relationships as well as issues of intimacy and sexual behaviors. Current relationships with parents, grandparents, children, and grandchildren are an important part of the social history. Legal history is also relevant, especially any pending charges or lawsuits. The social history also includes hobbies, interests, pets, and leisure time activities and how this has fluctuated over time. It is important to identify cultural and religious influences on the patient's life and current religious

beliefs and practices. A brief overview of the sexual history is given in [Table 5.1-3](#).

 **Table 5.1-3**
Sexual History

1. Screening questions
 - a. Are you sexually active?
 - b. Have you noticed any changes or problems with sex recently?
2. Developmental
 - a. Acquisition of sexual knowledge
 - b. Onset of puberty/menarche
 - c. Development of sexual identity and orientation
 - d. First sexual experiences
 - e. Sex in romantic relationship
 - f. Changing experiences or preferences over time
 - g. Sex and advancing age
3. Clarification of sexual problems
 - a. Desire phase
Presence of sexual thoughts or fantasies:
When do they occur and what is their object?
Who initiates sex and how?
 - b. Excitement phase
Difficulty in sexual arousal (achieving or maintaining erections, lubrication), during foreplay and preceding orgasm
 - c. Orgasm phase
Does orgasm occur?
Does it occur too soon or too late?
How often and under what circumstances does orgasm occur?
If orgasm does not occur, is it because of not being excited or lack of orgasm despite being aroused?
 - d. Resolution phase
What happens after sex is over (e.g., contentment, frustration, continued arousal)?

X. Review of Systems

The review of systems attempts to capture any current physical or psychological signs and symptoms not already identified in the present illness. Particular attention is paid to neurological and systemic symptoms (e.g., fatigue or weakness). Illnesses that might contribute to the presenting complaints or influence the choice of therapeutic agents should be carefully considered (e.g., endocrine, hepatic, or renal disorders). Generally, the review of systems is organized by the major systems of the body.

XI. Mental Status Examination

The mental status examination (MSE) is the psychiatric equivalent of the physical examination in the rest of medicine. The MSE explores all the areas of mental functioning and denotes evidence of signs and symptoms of mental illnesses. Data are gathered for the mental status examination throughout the interview from the initial moments of the interaction, including what the patient is wearing and their general presentation. Most of the information does not require direct questioning, and the information gathered from observation may give the clinician a different dataset than patient responses. Direct questioning augments and rounds out the MSE. The MSE gives the clinician a snapshot of the patient's mental status at the time of the interview and is useful for subsequent visits to compare and monitor changes over time. The psychiatric MSE includes cognitive screening most often in the form of the Mini-Mental Status Examination (MMSE), but the MMSE is not to be confused with the MSE overall. The components of the MSE are presented in this section in the order one might include them in the written note for organizational purposes, but as noted above, the data are gathered throughout the interview.

Appearance and Behavior. This section consists of a general description of how the patient looks and acts during the interview. Does the patient appear to be his or her stated age, younger or older? Is this related to the patient's style of dress, physical features, or style of interaction? Items to be noted include what the patient is wearing, including body jewelry, and whether it is appropriate for the context. For example, a patient in a hospital gown would be appropriate in the emergency room or inpatient unit but not in an outpatient clinic. Distinguishing features, including disfigurements, scars, and tattoos, are noted. Grooming and hygiene also are included in the overall appearance and can be clues to the patient's level of functioning.

The description of a patient's behavior includes a general statement about whether he or she is exhibiting acute distress and then a more specific statement about the patient's approach to the interview. The patient may be described as cooperative, agitated, disinhibited, disinterested, and so forth. Once again, appropriateness is an important factor to consider in the interpretation of the observation. If a patient is brought involuntarily for examination, it may be appropriate, certainly understandable, that he or she is somewhat uncooperative, especially at the beginning of the interview.

Motor Activity. Motor activity may be described as normal, slowed (bradykinesia), or agitated (hyperkinesia). This can give clues to diagnoses (e.g., depression vs. mania) as well as confounding neurological or medical issues. Gait, freedom of movement, any unusual or sustained postures, pacing, and hand wringing are described. The presence or absence of any tics should be noted, as should be jitteriness, tremor, apparent restlessness, lip-smacking, and tongue protrusions. These can be clues to adverse reactions or side effects of medications such as tardive dyskinesia, akathisia, or parkinsonian features from antipsychotic medications or suggestion of symptoms of illnesses such as attention-deficit/hyperactivity disorder.

Speech. Evaluation of speech is an important part of the MSE. Elements considered include fluency, amount, rate, tone, and volume. Fluency can refer to whether the patient has full command of the English language as well as potentially more subtle fluency issues such as stuttering, word finding difficulties, or paraphasic errors. (A Spanish-speaking patient with an interpreter would be considered not fluent in English, but an attempt should be made to establish whether he or she is fluent in Spanish.) The evaluation of the amount of speech refers to whether it is normal, increased, or decreased. Decreased amounts of speech may suggest several different things ranging from anxiety or disinterest to thought blocking or psychosis. Increased amounts of speech often (but not always) are suggestive of mania or hypomania. A

related element is the speed or rate of speech. Is it slowed or rapid (pressured)? Finally, speech can be evaluated for its tone and volume. Descriptive terms for these elements include irritable, anxious, dysphoric, loud, quiet, timid, angry, or childlike.

Mood. The terms *mood* and *affect* vary in their definition, and a number of authors have recommended combining the two elements into a new label “emotional expression.” Traditionally, *mood* is defined as the patient’s internal and sustained emotional state. Its experience is subjective, and hence it is best to use the patient’s own words in describing his or her mood. Terms such as “sad,” “angry,” “guilty,” or “anxious” are common descriptions of mood.

Affect. *Affect* differs from mood in that it is the expression of mood or what the patient’s mood appears to be to the clinician. Affect is often described with the following elements: quality, quantity, range, appropriateness, and congruence. Terms used to describe the quality (or tone) of a patient’s affect include dysphoric, happy, euthymic, irritable, angry, agitated, tearful, sobbing, and flat. Speech is often an important clue to assessment of affect but it is not exclusive. Quantity of affect is a measure of its intensity. Two patients both described as having depressed affect can be very different if one is described as mildly depressed and the other as severely depressed. Range can be restricted, normal, or labile. *Flat* is a term that has been used for severely restricted range of affect that is described in some patients with schizophrenia. Appropriateness of affect refers to how the affect correlates to the setting. A patient who is laughing at a solemn moment of a funeral service is described as having inappropriate affect. Affect can also be congruent or incongruent with the patient’s described mood or thought content. A patient may report feeling depressed or describe a depressive theme but do so with laughter, smiling, and no suggestion of sadness.

Thought Content. Thought content is essentially what thoughts are occurring to the patient. This is inferred by what the patient spontaneously expresses, as well as responses to specific questions aimed at eliciting particular pathology. Some patients may perseverate or ruminate on specific content or thoughts. They may focus on material that is considered obsessive or compulsive. *Obsessional thoughts* are unwelcome and repetitive thoughts that intrude into the patient’s consciousness. They are generally ego alien and resisted by the patient. *Compulsions* are repetitive, ritualized behaviors that patients feel compelled to perform to avoid an increase in anxiety or some dreaded outcome. Another large category of thought content pathology is delusions. *Delusions* are false, fixed ideas that are not shared by others and can be divided into bizarre and nonbizarre (nonbizarre delusions refer to thought content that is not true but is not out of the realm of possibility). Common delusions include grandiose, erotomanic, jealous, somatic, and persecutory. It is often helpful to suggest delusional content to patients who may have learned to not spontaneously discuss them. Questions that can be helpful include, “Do you ever feel like someone is following you or out to get you?” and “Do you feel like the TV or radio has a special message for you?” An affirmative answer to the latter question indicates an “idea of reference.” Paranoia can be closely related to delusional material and can range from “soft” paranoia, such as general suspiciousness, to more severe forms that impact daily functioning. Questions that elicit paranoia can include asking about the patient worrying about cameras, microphones, or the government.

Suicidality and homicidality fall under the category of thought content but here are discussed separately because of their particular importance in being addressed in every initial psychiatric interview. Simply asking if someone is suicidal or homicidal is not adequate. One must get a sense of ideation, intent, plan, and preparation. Although completed suicide is extremely difficult to accurately predict, there are identified risk factors, and these can be used in conjunction with an evaluation of the patient’s intent and plan for acting on thoughts of suicide.

Thought Process. Thought process differs from thought content in that it does not describe what the person is thinking but rather how the thoughts are formulated, organized, and expressed. A patient can have normal thought process with significantly delusional thought content. Conversely, there may be generally normal thought content but significantly impaired thought process. Normal thought process is typically described as linear, organized, and goal directed. With flight of ideas, the patient rapidly moves from one thought to another, at a pace that is difficult for the listener to keep up with, but all of the ideas are logically connected. The circumstantial patient overincludes details and material that is not directly relevant to the subject or an answer to the question but does eventually return to address the subject or answer the question. Typically the examiner can follow a circumstantial train of thought, seeing connections between the sequential statements. Tangential thought process may at first appear similar, but the patient never returns to the original point or question. The tangential thoughts are seen as irrelevant and related in a minor, insignificant manner. Loose thoughts or associations differ from circumstantial and tangential thoughts in that with loose thoughts it is difficult or impossible to see the connections between the sequential content. Perseveration is the tendency to focus on a specific idea or content without the ability to move on to other topics. The perseverative patient will repeatedly come back to the same topic despite the interviewer’s attempts to change the subject. Thought blocking refers to a disordered thought process in which the patient appears to be unable to complete a thought. The patient may stop midsentence or midthought and leave the interviewer waiting for the completion. When asked about this, patients will often remark that they don’t know what happened and may not remember what was being discussed. Neologisms refer to a new word or condensed combination of several words that is not a true word and is not readily understandable, although sometimes the intended meaning or partial meaning may be apparent. Word salad is speech characterized by confused, and often repetitious, language with no apparent meaning or relationship attached to it. A description of formal thought disorders is given in [Table 5.1-4](#).

 **Table 5.1-4**
Formal Thought Disorders

Circumstantiality. Overinclusion of trivial or irrelevant details that impede the sense of getting to the point.

Clang associations. Thoughts are associated by the sound of words rather than by their meaning (e.g., through rhyming or assonance).

Derailment. (Synonymous with loose associations.) A breakdown in both the logical connection between ideas and the overall sense of goal directedness. The words make sentences, but the sentences do not make sense.

Flight of ideas. A succession of multiple associations so that thoughts seem to move abruptly from idea to idea; often (but not invariably) expressed through rapid, pressured speech.

Neologism. The invention of new words or phrases or the use of conventional words in idiosyncratic ways.

Perseveration. Repetition of out of context words, phrases, or ideas.

Tangentiality. In response to a question, the patient gives a reply that is appropriate to the general topic without actually answering the question. Example:

Doctor: "Have you had any trouble sleeping lately?"

Patient: "I usually sleep in my bed, but now I'm sleeping on the sofa."

Thought blocking. A sudden disruption of thought or a break in the flow of ideas.

Perceptual Disturbances. Perceptual disturbances include hallucinations, illusions, depersonalization, and derealization.

Hallucinations are perceptions in the absence of stimuli to account for them. Auditory hallucinations are the hallucinations most frequently encountered in the psychiatric setting. Other hallucinations can include visual, tactile, olfactory, and gustatory (taste). In the North American culture, nonauditory hallucinations are often clues that there is a neurological, medical, or substance withdrawal issue rather than a primary psychiatric issue. In other cultures, visual hallucinations have been reported to be the most common form of hallucinations in schizophrenia. The interviewer should make a distinction between a true hallucination and a misperception of stimuli (illusion). Hearing the wind rustle through the trees outside one's bedroom and thinking a name is being called is an illusion. Hypnagogic hallucinations (at the interface of wakefulness and sleep) may be normal phenomena. At times patients without psychosis may hear their name called or see flashes or shadows out of the corners of their eyes. In describing hallucinations the interviewer should include what the patient is experiencing, when it occurs, how often it occurs, and whether or not it is uncomfortable (ego dystonic). In the case of auditory hallucinations, it can be useful to learn if the patient hears words, commands, or conversations and whether the voice is recognizable to the patient.

Depersonalization is a feeling that one is not oneself or that something has changed. Derealization is a feeling that one's environment has changed in some strange way that is difficult to describe.

Cognition. The elements of cognitive functioning that should be assessed are alertness, orientation, concentration, memory (both short and long term), calculation, fund of knowledge, abstract reasoning, insight, and judgment.

Note should be made of the patient's level of alertness. The amount of detail in assessing cognitive function will depend on the purpose of the examination and also what has already been learned in the interview about the patient's level of functioning, performance at work, handling daily chores, balancing one's checkbook, among others. In addition the psychiatrist will have already elicited data concerning the patient's memory for both remote and recent past. A general sense of intellectual level and how much schooling the patient has had can help distinguish intelligence and educational issues versus cognitive impairment that might be seen in delirium or dementia. [Table 5.1-5](#) presents an overview of the questions used to test cognitive function in the mental status examination.

 **Table 5.1-5**
Questions Used to Test Cognitive Functions in the Sensorium Section of the Mental Status Examination

1. Alertness	(Observation)
2. Orientation	What is your name? Who am I? What place is this? Where is it located? What city are we in?
3. Concentration	Starting at 100, count backward by 7 (or 3). Say the letters of the alphabet backward starting with Z. Name the months of the year backward starting with December.
4. Memory: Immediate	Repeat these numbers after me: 1, 4, 9, 2, 5.
Recent	What did you have for breakfast? What were you doing before we started talking this morning? I want you to remember these three things: a yellow pencil, a cocker spaniel, and Cincinnati. After a few minutes I'll ask you to repeat them.
Long term	What was your address when you were in the third grade? Who was your teacher? What did you do during the summer between high school and college?
5. Calculations	If you buy something that costs \$3.75 and you pay with a \$5 bill, how much change should you get? What is the cost of three oranges if a dozen oranges cost \$4.00?
6. Fund of knowledge	What is the distance between New York and Los Angeles? What body of water lies between South America and Africa?
7. Abstract reasoning	Which one does not belong in this group: a pair of scissors, a canary, and a spider? Why? How are an apple and an orange alike?

Abstract Reasoning. Abstract reasoning is the ability to shift back and forth between general concepts and specific examples. Having the patient identify similarities between like objects or concepts (apple and pear, bus and airplane, or a poem and a painting) as well as

interpreting proverbs can be useful in assessing one's ability to abstract. Cultural and educational factors and limitations should be kept in mind when assessing the ability to abstract. Occasionally, the inability to abstract or the idiosyncratic manner of grouping items can be dramatic.

Insight. Insight, in the psychiatric evaluation, refers to the patient's understanding of how he or she is feeling, presenting, and functioning as well as the potential causes of his or her psychiatric presentation. The patient may have no insight, partial insight, or full insight. A component of insight often is reality testing in the case of a patient with psychosis. An example of intact reality testing would be, "I know that there are not really little men talking to me when I am alone, but I feel like I can see them and hear their voices." As indicated by this example, the amount of insight is not an indicator of the severity of the illness. A person with psychosis may have good insight, while a person with a mild anxiety disorder may have little or no insight.

Judgment. Judgment refers to the person's capacity to make good decisions and act on them. The level of judgment may or may not correlate to the level of insight. A patient may have no insight into his or her illness but have good judgment. It has been traditional to use hypothetical examples to test judgment, for example, "What would you do if you found a stamped envelope on the sidewalk?" It is better to use real situations from the patient's own experience to test judgment. The important issues in assessing judgment include whether a patient is doing things that are dangerous or going to get him or her into trouble and whether the patient is able to effectively participate in his or her own care. Significantly impaired judgment can be cause for considering a higher level of care or more restrictive setting such as inpatient hospitalization. Table 5.1-6 lists some common questions for the psychiatric history and mental status.

 **Table 5.1-6**
Common Questions for Psychiatric History and Mental Status

Topic	Questions	Comments and Clinical Hints
Identifying data	Be direct in obtaining identifying data. Request specific answers.	If patient cannot cooperate, get information from family member or friend; if referred by a physician, obtain medical record.
Chief complaint (CC)	Why are you going to see a psychiatrist? What brought you to the hospital? What seems to be the problem?	Records answers verbatim; a bizarre complaint points to psychotic process.
History of present illness (HPI)	When did you first notice something happening to you? Were you upset about anything when symptoms began? Did they begin suddenly or gradually?	Record in patient's own words as much as possible. Get history of previous hospitalizations and treatment. Sudden onset of symptoms may indicate drug-induced disorder.
Previous psychiatric and medical disorders	Did you ever lose consciousness? Have a seizure?	Ascertain extent of illness, treatment, medications, outcomes, hospitals, doctors. Determine whether illness serves some additional purpose (secondary gain).
Personal history	Do you know anything about your birth? If so, from whom? How old was your mother when you were born? Your father?	Older mothers (>35) have high risk for Down syndrome babies; older fathers (>45) may contribute damaged sperm, producing deficits including schizophrenia.
Childhood	Toilet training? Bed-wetting? Sex play with peers? What is your first childhood memory?	Separation anxiety and school phobia are associated with adult depression; enuresis is associated with fire setting. Childhood memories before the age of 3 are usually imagined, not real.
Adolescence	Adolescents may refuse to answer questions, but they should be asked. Adults may distort memories of emotionally charged experiences. Sexual molestation?	Poor school performance is a sensitive indicator of emotional disorder. Schizophrenia begins in late adolescence.
Adulthood	Open-ended questions are preferable. Tell me about your marriage. Be nonjudgmental; What role does religion play in your life, if any? What is your sexual preference in a partner?	Depending on the chief complaint, some areas require more detailed inquiry. Manic patients frequently go into debt or are promiscuous. Overvalued religious ideas are associated with paranoid personality disorder.
Sexual history	Are there or have there been any problems or concerns about your sex life? How did you learn about sex? Has there been any change in your sex drive?	Be nonjudgmental. Asking <i>when</i> masturbation began is a better approach than asking <i>do you or did you ever</i> masturbate.
Family history	Have any members in your family been depressed? Alcoholic? In a mental hospital? Describe your living conditions. Did you have your own room?	Genetic loading in anxiety, depression, schizophrenia. Get medication history of family (medications effective in family members for similar disorders may be effective in patient).
Mental Status		
General appearance	Introduce yourself and direct patient to take a seat. In the hospital, bring your chair to bedside; do not sit on the bed.	Unkempt and disheveled in cognitive disorder, pinpoint pupils in narcotic addiction, withdrawal and stooped posture in depression.
Motoric behavior	Have you been more active than usual? Less active? You may ask about obvious mannerisms, such as, "I notice that your hand still shakes, can you tell me about that?" Stay aware of smells, such as alcoholism/ketoacidosis.	Fixed posturing, odd behavior in schizophrenia. Hyperactive with stimulant (cocaine) abuse and in mania. Psychomotor retardation in depression; tremors with anxiety or medication side effect (lithium). Eye contact is normally made during the interview. Minimal eye contact in schizophrenia. Scanning of environment in paranoid states.
Attitude during interview	You may comment about attitude: "You seem irritated about something; is that an accurate observation?"	Suspiciousness in paranoia; seductive in hysteria; apathetic in conversion disorder (<i>la belle indifférence</i>); punning (<i>witzelsucht</i>) in frontal lobe syndromes.
Mood	How do you feel? How are your spirits? Do you have thoughts that life is not worth living or that you want to harm yourself? Do you have plans to take your own life? Do you want to die? Has there been a change in your sleep habits?	Suicidal ideas in 25 percent of depressives; elation in mania. Early morning awakening in depression; decreased need for sleep in mania.
Affect	Observe nonverbal signs of emotion, body movements, facies, rhythm of voice (prosody). Laughing when talking about sad subjects, such as death, is inappropriate.	Changes in affect usual with schizophrenia: loss of prosody in cognitive disorder, catatonia. Do not confuse medication adverse effect with flat affect.
Speech	Ask patient to say "Methodist Episcopalian" to test for dysarthria.	Manic patients show pressured speech; paucity of speech in depression; uneven or slurred speech in cognitive disorders.

Perceptual disorders	Do you ever see things or hear voices? Do you have strange experiences as you fall asleep or upon awakening? Has the world changed in any way? Do you have strange smells?	Visual hallucinations suggest schizophrenia. Tactile hallucinations suggest cocaineism, delirium tremens (DTs). Olfactory hallucinations common in temporal lobe epilepsy.
Thought content	Do you feel people want to harm you? Do you have special powers? Is anyone trying to influence you? Do you have strange body sensations? Are there thoughts that you can't get out of your mind? Do you think about the end of the world? Can people read your mind? Do you ever feel the TV is talking to you? Ask about fantasies and dreams.	Are delusions congruent with mood (grandiose delusions with elated mood) or incongruent? Mood-incongruent delusions point to schizophrenia. Illusions are common in delirium. Thought insertion is characteristic of schizophrenia.
Thought process	Ask meaning of proverbs to test abstraction, such as, "People in glass houses should not throw stones." Concrete answer is, "Glass breaks." Abstract answers deal with universal themes or moral issues. Ask similarity between bird and butterfly (both alive), bread and cake (both food).	Loose associations point to schizophrenia; flight of ideas to mania; inability to abstract to schizophrenia, brain damage.
Sensorium	What place is this? What is today's date? Do you know who I am?	Delirium or dementia shows clouded or wandering sensorium. Orientation to person remains intact longer than orientation to time or place.
Remote memory (long-term memory)	Where were you born? Where did you go to school? Date of marriage? Birthdays of children? What were last week's newspaper headlines?	Patients with dementia of the Alzheimer's type retain remote memory longer than recent memory. Gaps in memory may be localized or filled in with confabulatory details. Hypermnesia is seen in paranoid personality.
Immediate memory (very short-term memory)	Ask patient to repeat six digits forward, then backward (normal responses). Ask patient to try to remember three nonrelated items; test patient after 5 minutes.	Loss of memory occurs with cognitive, dissociative, or conversion disorder. Anxiety can impair immediate retention and recent memory. Anterograde memory loss (amnesia) occurs after taking certain drugs, such as benzodiazepines. Retrograde memory loss occurs after head trauma.
Concentration and calculation	Ask patient to count from 1 to 20 rapidly; do simple calculations (2×4 , 4×9); do serial 7 test (i.e., subtract 7 from 100 and keep subtracting 7). How many nickels in \$1.35?	Rule out medical cause for any defects vs. anxiety or depression (pseudodementia). Make tests congruent with educational level of patient.
Information and intelligence	Distance from New York City to Los Angeles. Name some vegetables. What is the largest river in the United States?	Check educational level to results. Rule out mental retardation, borderline intellectual functioning.
Judgment	What is the thing to do if you find an envelope in the street that is sealed, stamped, and addressed?	Impaired in brain disease, schizophrenia, borderline intellectual functioning, intoxication.
Insight level	Do you think you have a problem? Do you need treatment? What are your plans for the future?	Impaired in delirium, dementia, frontal lobe syndrome, psychosis, borderline intellectual functioning.

(From Sadock BJ, Sadock V. *Kaplan and Sadock's Pocket Handbook of Clinical Psychiatry*. Philadelphia: Lippincott Williams & Wilkins, 2010, with permission.)

XII. Physical Examination

The inclusion and extent of physical examination will depend on the nature and setting of the psychiatric interview. In the outpatient setting, little or no physical examination may be routinely performed, while in the emergency room or inpatient setting, a more complete physical examination is warranted. Vital signs, weight, waist circumference, body mass index, and height may be important measurements to follow particularly given the potential effects of psychiatric medications or illnesses on these parameters. The Abnormal Involuntary Movement Scale (AIMS) is an important screening test to be followed when using antipsychotic medication to monitor for potential side effects such as tardive dyskinesia. A focused neurological evaluation is an important part of the psychiatric assessment.

In those instances where a physical examination is not performed the psychiatrist should ask the patient when the last physical examination was performed and by whom. As part of the communication with that physician, the psychiatrist should inquire about any abnormal findings.

XIII. Formulation

The culmination of the data-gathering aspect of the psychiatric interview is developing a formulation and diagnosis (diagnoses) as well as recommendations and treatment planning. In this part of the evaluation process, the data gathering is supplanted by data processing where the various themes contribute to a biopsychosocial understanding of the patient's illness. Although the formulation is placed near the end of the reported or written evaluation, actually it is developed as part of a dynamic process throughout the interview as new hypotheses are created and tested by further data that are elicited. The formulation should include a brief summary of the patient's history, presentation, and current status. It should include discussion of biological factors (medical, family, and medication history) as well as psychological factors such as childhood circumstances, upbringing, and past interpersonal interactions and social factors including stressors, and contextual circumstances such as finances, school, work, home, and interpersonal relationships. These elements should lead to a differential diagnosis of the patient's illness (if any) as well as a provisional diagnosis. Finally, the formulation should include a summary of the safety assessment, which contributes to the determination of level of care recommended or required.

XIV. Treatment Planning

The assessment and formulation will appear in the written note correlating to the psychiatric interview, but the discussion with the patient may only be a summary of this assessment geared toward the patient's ability to understand and interpret the information. Treatment planning and recommendations, in contrast, are integral parts of the psychiatric interview and should be explicitly discussed with the patient in detail.

The first part of treatment planning involves determining whether a treatment relationship is to be established between the interviewer and patient. Cases where this may not be the case include if the interview was done in consultation, for a legal matter or as a third-party review, or in the emergency room or other acute setting. If a treatment relationship is not being started, then the patient should be informed

as to what the recommended treatment is (if any). In certain cases this may not be voluntary (as in the case of an involuntary hospitalization). In most cases there should be a discussion of the options available so that the patient can participate in the decisions about next steps. If a treatment relationship is being initiated, then the structure of that treatment should be discussed. Will the main focus be on medication management, psychotherapy, or both? What will the frequency of visits be? How will the clinician be paid for service and what are the expectations for the patient to be considered engaged in treatment?

Medication recommendations should include a discussion of possible therapeutic medications, the risks and benefits of no medication treatment, and alternative treatment options. The prescriber must obtain informed consent from the patient for any medications (or other treatments) initiated.

Other clinical treatment recommendations may include referral for psychotherapy, group therapy, chemical dependency evaluation or treatment, or medical assessment. There also may be recommended psychosocial interventions including case management, group home or assisted living, social clubs, support groups such as a mental health alliance, the National Alliance for the Mentally Ill, and AA.

Collaboration with primary care doctors, specialists, or other clinicians should always be a goal, and proper patient consent must be obtained for this. Similarly, family involvement in a patient's care can often be a useful and integral part of treatment and requires proper patient consent.

A thorough discussion of safety planning and contact information should occur during the psychiatric interview. The clinician's contact information as well as after-hours coverage scheme should be reviewed. The patient needs to be informed of what he or she should do in the case of an emergency, including using the emergency room or calling 911 or crisis hotlines that are available.

TECHNIQUES

General principles of the psychiatric interview such as the patient–doctor relationship, open-ended interviewing, and confidentiality are described above. In addition to the general principles, there are a number of specific techniques that can be effective in obtaining information in a manner consistent with the general principles. These helpful techniques can be described as facilitating interventions and expanding interventions. There are also some interventions that are generally counterproductive and interfere with the goals of helping the patient tell his or her story and reinforcing the therapeutic alliance.

Facilitating Interventions

These are some of the interventions that are effective in enabling the patient to continue sharing his or her story and also are helpful in promoting a positive patient–doctor relationship. At times some of these techniques may be combined in a single intervention.

Reinforcement. Reinforcement interventions, although seemingly simplistic, are very important in the patient sharing material about himself or herself and other important individuals and events in the patient's life. Without these reinforcements, often the interview will become less productive. A brief phrase such as "I see," "Go on," "Yes," "Tell me more," "Hmm," or "Uh-huh" all convey the interviewer's interest in the patient continuing. It is important that these phrases fit naturally into the dialogue.

Reflection. By using the patient's words, the psychiatrist indicates that he or she has heard what the patient is saying and conveys an interest in hearing more.

Summarizing. Periodically during the interview it is helpful to summarize what has been identified about a certain topic. This provides the opportunity for the patient to clarify or modify the psychiatrist's understanding and possibly add new material. When new material is introduced, the psychiatrist may decide to continue with a further exploration of the previous discussion and return to the new information at a later point.

Education. At times in the interview it is helpful for the psychiatrist to educate the patient about the interview process.

Reassurance. It is often appropriate and helpful to provide reassurance to the patient. For example, accurate information about the usual course of an illness can decrease anxiety, encourage the patient to continue to discuss his or her illness, and strengthen his or her resolve to continue in treatment. It is generally inappropriate for psychiatrists to reassure patients when the psychiatrist does not know what the outcome will be. In these cases, psychiatrists can assure patients they will continue to be available and will help in whatever way they can.

Encouragement. It is difficult for many patients to come for a psychiatric evaluation. Often they are uncertain as to what will happen, and receiving encouragement can facilitate their engagement. Psychiatrists should be careful not to overstate the patient's progress in the interview. The psychiatrist may provide the patient feedback about his or her efforts, but the secondary message should be that there is more work to be done.

Acknowledgment of Emotion. It is important for the interviewer to acknowledge the expression of emotion by the patient. This frequently leads to the patient sharing more feelings and being relieved that he or she can do so. Sometimes a nonverbal action, such as moving a tissue box closer, can suffice or be used adjunctly. If the display of the emotion is clear (e.g., patient openly crying), then it is not helpful to comment directly on the expression of the emotion. It is better to comment on the associated feelings.

Humor. At times the patient may make a humorous comment or tell a brief joke. It can be very helpful if the psychiatrist smiles, laughs, or even, when appropriate, add another punch line. This sharing of humor can decrease tension and anxiety and reinforce the interviewer's genuineness. It is important to be certain that the patient's comment was indeed meant to be humorous and that the psychiatrist clearly conveys that he or she is laughing with the patient, not at the patient.

Silence. Careful use of silence can facilitate the progression of the interview. The patient may need time to think about what has been said or to experience a feeling that has arisen in the interview. The psychiatrist whose own anxiety results in any silence quickly being terminated can retard the development of insight or the expression of feeling by the patient. On the other hand, extended or repeated silences can deaden an interview and become a struggle as to who can outwait the other. If the patient is looking at his or her watch or looking about the room, then it might be helpful to comment, "*It looks like there are other things on your mind.*" If the patient has become silent and looks like he or she is thinking about the subject, then the psychiatrist might ask, "*What thoughts do you have about that?*"

Nonverbal Communication

In many good interviews, the most common facilitating interventions are nonverbal. Nodding of the head, body posture including leaning toward the patient, body positioning becoming more open, moving the chair closer to the patient, putting down the pen and folder, and facial expressions including arching of eyebrows all indicate that the psychiatrist is concerned, listening attentively, and engaged in the interview. Although these interventions can be very helpful, they can also be overdone especially if the same action is repeated too

frequently or done in an exaggerated fashion. The interviewer does not want to reinforce the popular caricature of a psychiatrist nodding his or her head repeatedly regardless of the content of what is being said or the emotion being expressed.

Expanding Interventions

There are a number of interventions that can be used to expand the focus of the interview. These techniques are helpful when the line of discussion has been sufficiently mined, at least for the time being, and the interviewer wants to encourage the patient to talk about other issues. These interventions are most successful when a degree of trust has been established in the interview and the patient feels that the psychiatrist is nonjudgmental about what is being shared.

Clarifying. At times carefully clarifying what the patient has said can lead to unrecognized issues or psychopathology.

A 62-year-old widow describes how it feels since her husband died 14 months ago. She repeatedly comments that “everything is empty inside.” The resident interprets this as meaning her world feels empty without her spouse and makes this interpretation on a few occasions. The patient’s nonverbal cues suggest that she is not on the same wavelength. The supervisor asks the patient to clarify what she means by “empty inside.” After some avoidance, the patient states that she is indeed empty inside; all her organs are missing—they have “disappeared.”

The resident’s interpretation may actually have been psychodynamically accurate, but a somatic delusion was not identified. The correct identification of what the patient was actually saying led to an exploration of other thoughts, and other delusions were uncovered. This vignette of “missing” the delusion is an example of the interviewer “normalizing” what the patient is saying. The interviewer was using secondary process thinking in understanding the words of the patient, while the patient was using primary process thinking.

Associations. As the patient describes his or her symptoms, there are other areas that are related to a symptom that should be explored. For example, the symptom of nausea leads to questions about appetite, bowel habits, weight loss, and eating habits. Also, experiences that are temporally related may be investigated. When a patient is talking about his or her sleeping pattern, it can be a good opportunity to ask about dreams.

Leading. Often, continuing the story can be facilitated by asking a “what,” “when,” “where,” or “who” question. Sometimes the psychiatrist may suggest or ask about something that has not been introduced by the patient but that the psychiatrist surmises may be relevant.

Probing. The interview may point toward an area of conflict, but the patient may minimize or deny any difficulties. Gently encouraging the patient to talk more about this issue may be quite productive.

Transitions. Sometimes transitions occur very smoothly. The patient is talking about her primary education major in college and the psychiatrist asks, “*Did that lead to your work after college?*” On other occasions, the transition means moving to a different area of the interview and a bridge statement is useful.

Redirecting. A difficult technique for unseasoned interviewers is redirecting the focus of the patient. If the interviewer is concentrating on reinforcing the patient’s telling of his or her story, it can be especially difficult to move the interview in a different direction. However, this is often crucial to a successful interview because of the time constraints and the necessity to obtain a broad overview of the patient’s life as well as the current problems. Also, the patient may, for conscious or often unconscious reasons, avoid certain important areas and need guidance in approaching these subjects. Redirection can be used when the patient changes the topic or when the patient continues to focus on a nonproductive or well-covered area.

Obstructive Interventions

Although supportive and expanding techniques facilitate the gathering of information and the development of a positive patient–doctor relationship, there are a number of other interventions that are not helpful for either task. Some of these activities are in the same categories as the more useful interventions but are unclear, unconnected, poorly timed, and not responsive to the patient’s issues or concerns.

Closed-Ended Questions. A series of closed-ended questions early in the interview can retard the natural flow of the patient’s story and reinforces the patient giving one word or brief answers with little or no elaboration.

Compound Questions. Some questions are difficult for patients to respond to because more than one answer is being sought.

Why Questions. Especially early in the psychiatric interview, “why” questions are often nonproductive. Very often the answer to that question is one of the reasons that the patient has sought help.

Judgmental Questions or Statements. Judgmental interventions are generally nonproductive for the issue at hand and also inhibit the patient from sharing even more private or sensitive material. Instead of telling a patient that a particular behavior was right or wrong, it would be better for the psychiatrist to help the patient reflect on how successful that behavior was.

Minimizing Patient’s Concerns. In an attempt to reassure patients, psychiatrists sometimes make the error of minimizing a concern. This can be counterproductive in that rather than being reassured, the patient may feel that the psychiatrist does not understand what he or she is trying to express. It is much more productive to explore the concern; there is likely much more material that has not yet been shared.

Premature Advice. Advice given too early is often bad advice because the interviewer does not yet know all of the variables. Also it can preempt the patient from arriving at a plan for himself or herself.

Premature Interpretation. Even if it is accurate, a premature interpretation can be counterproductive as the patient may respond defensively and feel misunderstood.

Transitions. Some transitions are too abrupt and may interrupt important issues that the patient is discussing.

Nonverbal Communication. The psychiatrist that repeatedly looks at a watch, turns away from the patient, yawns, or refreshes the computer screen conveys boredom, disinterest, or annoyance. Just as reinforcing nonverbal communications can be powerful facilitators of a good interview, these obstructive actions can quickly shatter an interview and undermine the patient–doctor relationship.

Closing of Interview

The last 5 to 10 minutes of the interview are very important and are often not given sufficient attention by inexperienced interviewers. It is important to alert the patient to the remaining time: “*We have to stop in about 10 minutes.*” Not infrequently, a patient will have kept an important issue or question until the end of the interview and having at least a brief time to identify the issue is helpful. If there is to be another session, then the psychiatrist can indicate that this issue will be addressed at the beginning of the next session or ask the patient to bring it up at that time. If the patient repeatedly brings up important information at the end of sessions, then this should be explored as to its meaning. If no such item is spontaneously brought up by the patient, then it can be useful to ask the patient if there are any other issues that have not been covered that the patient wanted to share. If such an issue can be dealt with in short order, then it should be; if not, then it can be put on the agenda for the next session. It can also be useful to give the patient an opportunity to ask a question: “*I’ve asked you a lot of questions today. Are there any other questions you’d like to ask me at this point?*”

If this interview was to be a single evaluative session, then a summary of the diagnosis and options for treatment should generally be shared with the patient (exceptions may be a disability or forensic evaluation for which it was established at the outset that a report would be made to the referring entity). If the patient was referred by a primary care physician, then the psychiatrist also indicates that he or she will communicate with the primary care physician and share the findings and recommendations. If this was not to be a single session and the patient will be seen again, then the psychiatrist may indicate that he or she and the patient can work further on the treatment plan in the next session. A mutually agreed upon time is arrived at and the patient is escorted to the door.

Motivational Interviewing

Motivational interviewing is a technique used to motivate the patient to change his or her maladaptive behavior. The therapist relies on empathy to convey understanding, provides support by noting the patient’s strengths, and explores the ambivalence and conflicting thoughts or feelings the patient may have about change. Guidance is provided in the interview by imparting information about issues (e.g., alcoholism, diabetes), while at the same time, getting the patient to talk about resistances to altering behavior. It has been used effectively in persons with substance-use disorders to get them to join AA, to help change lifestyles, or to enter psychotherapy. It has the potential to combine diagnosis and therapy in a single interview with the patient and can be applied to a wide range of mental disorders.

MEDICAL RECORD

Most psychiatrists take notes throughout the interview. Generally these are not verbatim recordings, except for the chief complaint or other key statements. Many psychiatrists use a form that covers the basic elements in the psychiatric evaluation. Occasionally, patients may have questions or concerns about the note taking. These concerns, which often have to do with confidentiality, should be discussed (and during this discussion notes should not be taken). After the discussion, it is rare for a patient to insist that notes not be taken. In fact, it is much more common for patients to feel comfortable about the note taking, feeling reassured that their experiences and feelings are important enough to be written. However, too much attention to the record can be distracting. It is important that eye contact be maintained as much as possible during the note taking. Otherwise patients will feel that the record is more important than what they are saying. Also, the interviewer may miss nonverbal communications that can be more important than the words being recorded.

Increasingly, the electronic health record (EHR) is now being used throughout medicine. There are great advantages of computerized records, including rapid retrieval of information, appropriately sharing data among various members of the health care team, access to important data in an emergency, decreasing errors, and as a tool for research and quality improvement activities. Evidence-based practice guidelines can also be integrated with EHRs so that information or recommendations can be provided at the point of service. However, the use of computers can also present significant challenges to the developing patient–physician relationship. Frequently, physicians using computers during an interview will turn away from the patient to enter data. Especially in a psychiatric interview, this can be very disruptive to a smooth and dynamic interaction. As improved technology becomes more widespread (e.g., the use of notepads held in the lap) and psychiatrists become more accustomed to using the equipment, some of these disruptions can be minimized.

CULTURAL ISSUES

Culture can be defined as a common heritage, a set of beliefs, and values that set expectations for behaviors, thoughts, and even feelings. A number of culture-bound syndromes that are unique to a particular population have been described (see [Section 3.3](#)). Culture can influence the presentation of illness, the decision when and where to seek care, the decision as to what to share with the physician, and the acceptance of and participation in treatment planning. Often, individuals from a minority population may be reluctant to seek help from a physician who is from the majority group especially for emotional difficulties. Some minority groups have strong beliefs in faith healers, and in some areas of the United States “root doctors” carry significant influence. These beliefs may not be apparent in the interview as the patient may have learned to be quite guarded about such matters. A patient may only report that he or she is “frightened” and not discuss the reality that this fear began when he or she realized someone was working “roots” on him or her. The psychiatrist needs to be alert to the possibility that the patient’s thoughts about what has happened may be unusual from a traditional Western medical perspective and at the same time recognize that these culturally shared beliefs are not indications of psychosis. By being humble, open, and respectful the psychiatrist increases the possibility of developing a trusting working relationship with the patient and learning more about the patient’s actual experiences.

The psychiatrist clearly understanding what the patient is saying and the patient clearly understanding what the psychiatrist is saying are obviously crucial for an effective interview. It is not just both being fluent in the language of the interview, but the psychiatrist should also be aware of common slang words and phrases that the patient, depending on their cultural background, may use. If the psychiatrist does not understand a particular phrase or comment, then he or she should ask for clarification. If the patient and psychiatrist are not both fluent in the same language, then an interpreter is necessary.

Interviewing with an Interpreter

When translation is needed, it should be provided by a non–family-member professional interpreter. Translation by family members is to be avoided because (1) a patient, with a family member as an interpreter, may justifiably be very reluctant to discuss sensitive issues including suicidal ideation or drug use and (2) family members may be hesitant to accurately portray a patient’s deficits. Both of these issues make accurate assessment very difficult.

It is helpful to speak with the interpreter prior to the interview to clarify the goals of the exam. If the interpreter does not primarily work with psychiatric patients, then it is important to highlight the need for verbatim translation even if the responses are disorganized or tangential. If the translator is not aware of this issue, then the psychiatrist may have difficulty diagnosing thought disorders or cognitive deficits. Occasionally, the patient will say several sentences in response to a question and the interpreter will remark, “He said it’s okay.” The interpreter should again be reminded that the psychiatrist wants to hear everything that the patient is saying.

It is helpful to place the chairs in a triangle so that the psychiatrist and patient can maintain eye contact. The psychiatrist should continue to refer to the patient directly to maintain the therapeutic connection rather than speaking to the interpreter. The examiner may need to take a more directive approach and interrupt the patient’s responses more frequently to allow for accurate and timely translation.

Once the interview is concluded, it may be helpful to again meet briefly with the interpreter. If the interpreter is especially

knowledgeable about the patient's cultural background, they may be able to provide helpful insights regarding cultural norms.

INTERVIEWING THE DIFFICULT PATIENT

Patients with Psychosis

Patients with psychotic illnesses are often frightened and guarded. They may have difficulty with reasoning and thinking clearly. In addition, they may be actively hallucinating during the interview, causing them to be inattentive and distracted. They may have suspicions regarding the purpose of the interview. All of these possibilities are reasons that the interviewer may need to alter the usual format and adapt the interview to match the capacity and tolerance of the patient.

Auditory hallucinations are the most common hallucinations in psychiatric illnesses in North America. Many patients will not interpret their experiences as hallucinations, and it is useful to begin with a more general question: *"Do you ever hear someone talking to you when no one else is there?"* The patient should be asked about the content of the hallucinations, the clarity, and the situations in which they occur. Often it is helpful to ask the patient about a specific instance and if he or she can repeat verbatim the content of the hallucination. It is important to specifically ask if the patient has ever experienced command hallucinations, hallucinations in which a patient is ordered to perform a specific act. If so, the nature of the commands should be clarified, specifically if the commands have ever included orders to harm himself or herself or others, and if the patient has ever felt compelled to follow the commands.

The validity of the patient's perception should not be dismissed, but it is helpful to test the strength of the belief in the hallucinations: *"Does it seem that the voices are coming from inside your head? Who do you think is speaking to you?"*

Other perceptual disturbances should be explored including visual, olfactory, and tactile hallucinations. These disturbances are less common in psychiatric illness and may suggest a primary medical etiology to the psychosis.

The psychiatrist should be alert for cues that psychotic processes may be part of the patient's experience during the interview. It is usually best to ask directly about such behaviors or comments.

By definition, patients with delusions have fixed false beliefs. With delusions, as with hallucinations, it is important to explore the specific details. Patients are often very reluctant to discuss their beliefs as many have had their beliefs dismissed or ridiculed. They may ask the interviewer directly if the interviewer believes the delusion. Although an interviewer should not directly endorse the false belief, it is rarely helpful to directly challenge the delusion, particularly in the initial exam. It can be helpful to shift the attention back to the patient's rather than the examiner's beliefs and acknowledge the need for more information: *"I believe that what you are experiencing is frightening and I would like to know more about your experiences."*

For patients with paranoid thoughts and behaviors it is important to maintain a respectful distance. Their suspiciousness may be increased by an overly warm interview. It may be helpful to avoid sustained direct eye contact as this may be perceived as threatening. Harry Stack Sullivan recommended that rather than sitting face to face with the patient who is paranoid, the psychiatrist might sit more side by side, "looking out" with the patient. Interviewers should keep in mind that they themselves may become incorporated into the paranoid delusions, and it is helpful to ask directly about such fears: *"Are you concerned that I am involved?"* The psychiatrist should also ask whether there is a specific target related to the paranoid thinking. When asked regarding thoughts about hurting others, the patient may not disclose plans for violence. Exploration of the patient's plan on how to manage his or her fears may elicit information regarding violence risk: *"Do you feel you need to protect yourself in any way? How do you plan to do so?"* If there is some expression of possible violence toward others, the psychiatrist then needs to do further risk assessment. This is further discussed in the section below on hostile, agitated, and violent patients.

Depressed and Potentially Suicidal Patients

The depressed patient may have particular difficulty during the interview as he or she may have cognitive deficits as a result of the depressive symptoms. The patients may have impaired motivation and may not spontaneously report their symptoms. Feelings of hopelessness may contribute to a lack of engagement. Depending on the severity of symptoms, patients may need more direct questioning rather than an open-ended format.

A suicide assessment should be performed for all patients including prior history, family history of suicide attempts and completed suicides, and current ideation, plan, and intent. An open-ended approach is often helpful: *"Have you ever had thoughts that life wasn't worth living?"* It is important to detail prior attempts. The lethality risk of prior attempts and any potential triggers for the attempt should be clarified. This can help with assessing the current risk.

The patient should be asked about any current thoughts of suicide, and if thoughts are present, what is the patient's intent. Some patients will describe having thoughts of suicide but do not intend to act on these thoughts or wish to be dead. They report that although the thoughts are present, they have no intent to act on the thoughts. This is typically referred to as passive suicidal ideation. Other patients will express their determination to end their life and are at higher risk. The presence of psychotic symptoms should be assessed. Some patients may have hallucinations compelling them to hurt themselves even though they do not have a desire to die.

If the patient reports suicidal ideation, they should be asked if they have a plan to end his or her life. The specificity of the plan should be determined and whether the patient has access to the means to complete the plan. The interviewer should pursue this line of questioning in detail if the patient has taken any preparatory steps to move forward with the plan. (A patient who has purchased a gun and has given away important items would be at high risk.)

If the patient has not acted upon these urges, then it is helpful to ask what has prevented him or her from acting on these thoughts: *"What do you think has kept you from hurting yourself?"* The patient may disclose information that may decrease their acute risk, such as religious beliefs that prohibit suicide or awareness of the impact of suicide on family members. This information is essential to keep in mind during treatment especially if these preventative factors change. (A patient who states he or she could never abandon a beloved pet may be at increased risk if the pet dies.)

Although the intent of the psychiatric interview is to build rapport and gather information for treatment and diagnosis, the patient's safety must be the first priority. If the patient is viewed to be at imminent risk, then an interview may need to be terminated and the interviewer must take action to secure the safety of the patient.

Hostile, Agitated, and Potentially Violent Patients

Safety for the patient and the psychiatrist is the priority when interviewing agitated patients. Hostile patients are often interviewed in emergency settings, but angry and agitated patients can present in any setting. If interviewing in an unfamiliar setting, then the psychiatrist should familiarize himself or herself with the office setup, paying particular attention to the chair placement. The chairs should ideally be placed in a way in which both the interviewer and patient could exit if necessary and not be obstructed. The psychiatrist should be aware of any available safety features (emergency buttons or number for security) and should be familiar with the facility's security plan. If the psychiatrist is aware in advance that the patient is agitated, then he or she can take additional preparatory steps such as having security closely available if necessary.

As increased stimulation can be agitating for a hostile patient, care should be taken to decrease excess stimulation as much as feasible. The psychiatrist should be aware of his or her own body position and avoid postures that could be seen as threatening, including clenched hands or hands behind the back.

The psychiatrist should approach the interview in a calm, direct manner and take care not to bargain or promise to elicit cooperation in the interview: “Once we finish here you will be able to go home.” These tactics may only escalate agitation.

As stated above, the priority must be safety. An intimidated psychiatrist who is fearful regarding his or her own physical safety will be unable to perform an adequate assessment. Similarly, a patient who feels threatened will be unable to focus on the interview and may begin to escalate thinking that he or she needs to defend himself or herself. An interview may need to be terminated early if the patient’s agitation escalates. Generally, unpremeditated violence is preceded by a period of gradually escalating psychomotor agitation such as pacing, loud speech, and threatening comments. At this point the psychiatrist should consider whether other measures are necessary, including assistance from security personnel or need for medication or restraint.

If the patient makes threats or gives some indication that he or she may become violent outside the interview setting, then further assessment is necessary. Because past history of violence is the best predictor of future violence, past episodes of violence should be explored as to setting, what precipitated the episode, and what was the outcome or potential outcome (if the act was interrupted). Also, what has helped in the past in preventing violent episodes (medication, timeout, physical activity, or talking to a particular person) should be explored. Is there an identified victim and is there a plan for the violent behavior? Has the patient taken steps to fulfill the plan? Depending on the answers to these questions the psychiatrist may decide to prescribe or increase antipsychotic medication, recommend hospitalization, and perhaps, depending on the jurisdiction, notify the threatened victim. (See discussion of confidentiality above.)

Deceptive Patients

Psychiatrists are trained to diagnose and treat psychiatric illness. Although psychiatrists are well trained in eliciting information and maintaining awareness for deception, these abilities are not foolproof. Patients lie or deceive their psychiatrists for many different reasons. Some are motivated by secondary gain (e.g., for financial resources, absence from work, or for a supply of medication). Some patients may deceive, not for an external advantage, but for the psychological benefits of assuming a sick role. As noted above, unconscious processes may result in events or feelings being outside the patient’s awareness.

There are no current biological markers to definitively validate a patient’s symptoms. Psychiatrists are dependent on the patient’s self-report. Given these limitations, it may be useful, especially when there is a question about the patient’s reliability (possibly related to inconsistencies in the patient’s report), to gather collateral information regarding the patient. This allows the psychiatrist to have a more broad understanding of the patient outside the interview setting, and discrepancies in symptom severity between self-report and collateral information may suggest deception. There are also some psychological tests that can help in further evaluating the reliability of the patient.

5.2 The Psychiatric Report and Medical Record

PSYCHIATRIC REPORT

This section complements the previous section, “Psychiatric Interview, History, and Mental Status Examination,” in that it provides a comprehensive outline on how to write the psychiatric report (see [Table 5.2-1](#)). The need to follow some sort of outline in gathering data about a person in order to make a psychiatric diagnosis is universally recognized. The one that follows calls for including a tremendous amount of potential information about the patient, not all of which need be obtained, depending on the circumstances in the case. Beginning clinicians are advised to get as much information as possible; more experienced clinicians can pick and choose among the series of questions they might ask. In all cases, however, the person is best understood within the context of his or her life events.

 **Table 5.2-1**
Psychiatric Report

I. Psychiatric History

- A. Identification: Name, age, marital status, sex, occupation, language if other than English, race, nationality, and religion if pertinent; previous admissions to a hospital for the same or a different condition; with whom the patient lives
- B. Chief complaint: Exactly why the patient came to the psychiatrist, preferably in the patient's own words; if that information does not come from the patient, note who supplied it
- C. History of present illness: Chronological background and development of the symptoms or behavioral changes that culminated in the patient's seeking assistance; patient's life circumstances at the time of onset; personality when well; how illness has affected life activities and personal relations—changes in personality, interests, mood, attitudes toward others, dress, habits, level of tenseness, irritability, activity, attention, concentration, memory, speech; psychophysiological symptoms—nature and details of dysfunction; pain—location, intensity, fluctuation; level of anxiety—generalized and nonspecific (free floating) or specifically related to particular situations, activities, or objects; how anxieties are handled—avoidance, repetition of feared situation, use of drugs or other activities for alleviation
- D. Past psychiatric and medical history: (1) Emotional or mental disturbances—extent of incapacity, type of treatment, names of hospitals, length of illness, effect of treatment; (2) psychosomatic disorders: hay fever, arthritis, colitis, rheumatoid arthritis, recurrent colds, skin conditions; (3) medical conditions: follow customary review of systems—sexually transmitted diseases, alcohol or other substance abuse, at risk for acquired immunodeficiency syndrome (AIDS); (4) neurological disorders: headache, craniocerebral trauma, loss of consciousness, seizures, or tumors
- E. Family history: Elicited from patient and from someone else, because quite different descriptions may be given of the same persons and events; ethnic, national, and religious traditions; other persons in the home, descriptions of them—personality and intelligence—and what has become of them since patient's childhood; descriptions of different households lived in; present relationships between patient and those who were in family; role of illness in the family; family history of mental illness; where does patient live—neighborhood and particular residence of the patient; is home crowded; privacy of family members from each other and from other families; sources of family income and difficulties in obtaining it; public assistance (if any) and attitude about it; will patient lose job or apartment by remaining in the hospital; who is caring for children
- F. Personal history (anamnesis): History of the patient's life from infancy to the present to the extent it can be recalled; gaps in history as spontaneously related by the patient; emotions associated with different life periods (painful, stressful, conflictual) or with phases of life cycle
 1. Early childhood (Birth through age 3)
 - a. Prenatal history and mother's pregnancy and delivery: Length of pregnancy, spontaneity and normality of delivery, birth trauma, whether patient was planned and wanted, birth defects
 - b. Feeding habits: Breast-fed or bottle-fed, eating problems
 - c. Early development: Maternal deprivation, language development, motor development, signs of unmet needs, sleep pattern, object constancy, stranger anxiety, separation anxiety
 - d. Toilet training: Age, attitude of parents, feelings about it
 - e. Symptoms of behavior problems: Thumb sucking, temper tantrums, tics, head bumping, rocking, night terrors, fears, bed-wetting or bed soiling, nail biting, masturbation
 - f. Personality and temperament as a child: Shy, restless, overactive, withdrawn, studious, outgoing, timid, athletic, friendly patterns of play, reactions to siblings
 2. Middle childhood (ages 3 to 11): Early school history—feelings about going to school, early adjustment, sex identification, conscience development, punishment; social relationships, attitudes toward siblings and playmates
 3. Later childhood (prepuberty through adolescence)
 - a. Peer relationships: Number and closeness of friends, leader or follower, social popularity, participation in group or gang activities, idealized figures; patterns of aggression, passivity, anxiety, antisocial behavior
 - b. School history: How far the patient went, adjustment to school, relationships with teachers—teacher's pet or rebellious—favorite studies or interests, particular abilities or assets, extracurricular activities, sports, hobbies, relationships of problems or symptoms to any school period
 - c. Cognitive and motor development: Learning to read and other intellectual and motor skills, minimal cerebral dysfunction, learning disabilities—their management and effects on the child
 - d. Particular adolescent emotional or physical problems: Nightmares, phobias, masturbation, bed-wetting, running away, delinquency, smoking, drug or alcohol use, weight problems, feeling of inferiority
 - e. Psychosexual history
 - i. Early curiosity, infantile masturbation, sex play
 - ii. Acquiring of sexual knowledge, attitude of parents toward sex, sexual abuse
 - iii. Onset of puberty, feelings about it, kind of preparation, feelings about menstruation, development of secondary sexual characteristics
 - iv. Adolescent sexual activity: Crushes, parties, dating, petting, masturbation, wet dreams and attitudes toward them
 - v. Attitudes toward same and opposite sex: Timid, shy, aggressive, need to impress, seductive, sexual conquests, anxiety
 - vi. Sexual practices: Sexual problems, homosexual and heterosexual experiences, paraphilias, promiscuity
 - f. Religious background: Strict, liberal, mixed (possible conflicts), relation of background to current religious practices
 4. Adulthood
 - a. Occupational history: Choice of occupation, training, ambitions, conflicts; relations with authority, peers, and subordinates; number of jobs and duration; changes in job status; current job and feelings about it
 - b. Social activity: Whether patient has friends or not; is patient withdrawn or socializing well; social, intellectual, and physical interests; relationships with same sex and opposite sex; depth, duration, and quality of human relations
 - c. Adult sexuality
 - i. Premarital sexual relationships, age of first coitus, sexual orientation
 - ii. Marital history: Common-law marriages, legal marriages, description of courtship and role played by each partner, age at marriage, family planning and contraception, names and ages of children, attitudes toward raising children, problems of any family members, housing difficulties if important to the marriage, sexual adjustment, extramarital affairs, areas of agreement and disagreement, management of money, role of in-laws

- iii. Sexual symptoms: Anorgasmia, impotence, premature ejaculation, lack of desire
- iv. Attitudes toward pregnancy and having children; contraceptive practices and feelings about them
- v. Sexual practices: Paraphilias such as sadism, fetishes, voyeurism; attitude toward fellation, cunnilingus; coital techniques, frequency
- d. Military history: General adjustment, combat, injuries, referral to psychiatrists, type of discharge, veteran status
- e. Value systems: Whether children are seen as a burden or a joy; whether work is seen as a necessary evil, an avoidable chore, or an opportunity; current attitude about religion; belief in heaven and hell

Summation of the examiner's observations and impressions derived from the initial interview

II. Mental Status

A. Appearance

1. Personal identification: May include a brief nontechnical description of the patient's appearance and behavior as a novelist might write it; attitude toward examiner can be described here—cooperative, attentive, interested, frank, seductive, defensive, hostile, playful, ingratiating, evasive, guarded
2. Behavior and psychomotor activity: Gait, mannerisms, tics, gestures, twitches, stereotypes, picking, touching examiner, echopraxia, clumsy, agile, limp, rigid, retarded, hyperactive, agitated, combative, waxy
3. General description: Posture, bearing, clothes, grooming, hair, nails; healthy, sickly, angry, frightened, apathetic, perplexed, contemptuous, ill at ease, poised, old looking, young looking, effeminate, masculine; signs of anxiety—moist hands, perspiring forehead, restlessness, tense posture, strained voice, wide eyes; shifts in level of anxiety during interview or with particular topic

- B. Speech: Rapid, slow, pressured, hesitant, emotional, monotonous, loud, whispered, slurred, mumbled, stuttering, echolalia, intensity, pitch, ease, spontaneity, productivity, manner, reaction time, vocabulary, prosody

C. Mood and affect

1. Mood (a pervasive and sustained emotion that colors the person's perception of the world): How does patient say he or she feels; depth, intensity, duration, and fluctuations of mood—depressed, despairing, irritable, anxious, terrified, angry, expansive, euphoric, empty, guilty, awed, futile, self-contemptuous, anhedonic, alexithymic
2. Affect (the outward expression of the patient's inner experiences): How examiner evaluates patient's affects—broad, restricted, blunted or flat, shallow, amount and range of expression; difficulty in initiating, sustaining, or terminating an emotional response; is the emotional expression appropriate to the thought content, culture, and setting of the examination; give examples if emotional expression is not appropriate

D. Thinking and perception

1. Form of thinking
 - a. Productivity: Overabundance of ideas, paucity of ideas, flight of ideas, rapid thinking, slow thinking, hesitant thinking; does patient speak spontaneously or only when questions are asked, stream of thought, quotations from patient
 - b. Continuity of thought: Whether patient's replies really answer questions and are goal directed, relevant, or irrelevant; loose associations; lack of causal relations in patient's explanations; illogical, tangential, circumstantial, rambling, evasive, perseverative statements, blocking or distractibility
 - c. Language impairments: Impairments that reflect disordered mentation, such as incoherent or incomprehensible speech (word salad), clang associations, neologisms
2. Content of thinking
 - a. Preoccupations: About the illness, environmental problems; obsessions, compulsions, phobias; obsessions or plans about suicide, homicide; hypochondriacal symptoms, specific antisocial urges or impulses
3. Thought disturbances
 - a. Delusions: Content of any delusional system, its organization, the patient's convictions as to its validity, how it affects his or her life; persecutory delusions—isolated or associated with pervasive suspiciousness; mood congruent or mood incongruent
 - b. Ideas of reference and ideas of influence: How ideas began, their content, and the meaning the patient attributes to them
4. Perceptual disturbances
 - a. Hallucinations and illusions: Whether patient hears voices or sees visions; content, sensory system involvement, circumstances of the occurrence; hypnagogic or hypnopompic hallucinations; thought broadcasting
 - b. Depersonalization and derealization: Extreme feelings of detachment from self or from the environment
5. Dreams and fantasies
 - a. Dreams: Prominent ones, if patient will tell them; nightmares
 - b. Fantasies: Recurrent, favorite, or unshakable daydreams

E. Sensorium

1. Alertness: Awareness of environment, attention span, clouding of consciousness, fluctuations in levels of awareness, somnolence, stupor, lethargy, fugue state, coma
2. Orientation
 - a. Time: Whether patient identifies the day correctly; or approximate date, time of day; if in a hospital, knows how long he or she has been there; behaves as though oriented to the present
 - b. Place: Whether patient knows where he or she is
 - c. Person: Whether patient knows who the examiner is and the roles or names of the persons with whom in contact
3. Concentration and calculation: Subtracting 7 from 100 and keep subtracting 7s; if patient cannot subtract 7s, can easier tasks be accomplished— 4×9 ; 5×4 ; how many nickels are in \$1.35; whether anxiety or some disturbance of mood or concentration seems to be responsible for difficulty
4. Memory: Impairment, efforts made to cope with impairment—denial, confabulation, catastrophic reaction, circumstantiality used to conceal deficit; whether the process of registration, retention, or recollection of material is involved
 - a. Remote memory: Childhood data, important events known to have occurred when the patient was younger or free of illness, personal matters, neutral material

- b. Recent past memory: Past few months
- c. Recent memory: Past few days, what did patient do yesterday, the day before, have for breakfast, lunch, dinner
- d. Immediate retention and recall: Ability to repeat six figures after examiner dictates them—first forward, then backward, then after a few minutes' interruption; other test questions; did same questions, if repeated, call forth different answers at different times
- e. Effect of defect on patient: Mechanisms patient has developed to cope with defect
- 5. Fund of knowledge: Level of formal education and self-education; estimate of the patient's intellectual capability and whether capable of functioning at the level of his or her basic endowment; counting, calculation, general knowledge; questions should have relevance to the patient's educational and cultural background
- 6. Abstract thinking: Disturbances in concept formation; manner in which the patient conceptualizes or handles his or her ideas; similarities (e.g., between apples and pears), differences, absurdities; meanings of simple proverbs (e.g., "A rolling stone gathers no moss") answers may be concrete (giving specific examples to illustrate the meaning) or overly abstract (giving generalized explanation); appropriateness of answers
- F. Insight: Degree of personal awareness and understanding of illness
 - 1. Complete denial of illness
 - 2. Slight awareness of being sick and needing help but denying it at the same time
 - 3. Awareness of being sick but blaming it on others, on external factors, on medical or unknown organic factors
 - 4. Intellectual insight: Admission of illness and recognition that symptoms or failures in social adjustment are due to irrational feelings or disturbances, without applying that knowledge to future experiences
 - 5. True emotional insight: Emotional awareness of the motives and feelings within, of the underlying meaning of symptoms; does the awareness lead to changes in personality and future behavior; openness to new ideas and concepts about self and the important persons in his or her life
- G. Judgment
 - 1. Social judgment: Subtle manifestations of behavior that are harmful to the patient and contrary to acceptable behavior in the culture; does the patient understand the likely outcome of personal behavior and is patient influenced by that understanding; examples of impairment
 - 2. Test judgment: Patient's prediction of what he or she would do in imaginary situations (e.g., what patient would do with a stamped addressed letter found in the street)
- III. Further Diagnostic Studies
 - A. Physical examination
 - B. Neurological examination
 - C. Additional psychiatric diagnostic studies
 - D. Interviews with family members, friends, or neighbors by a social worker
 - E. Psychological, neurological, or laboratory tests as indicated: Electroencephalogram, computed tomography scan, magnetic resonance imaging, tests of other medical conditions, reading comprehension and writing tests, test for aphasia, projective or objective psychological tests, dexamethasone-suppression test, 24-hour urine test for heavy metal intoxication, urine screen for drugs of abuse
- IV. Summary of Findings

Summarize mental symptoms, medical and laboratory findings, and psychological and neurological test results, if available; include medications patient has been taking, dosage, duration. Clarity of thinking is reflected in clarity of writing. When summarizing the mental status (e.g., the phrase "Patient denies hallucinations and delusions" is not as precise as "Patient denies hearing voices or thinking that he is being followed."). The latter indicates the specific question asked and the specific response given. Similarly, in the conclusion of the report one would write "Hallucinations and delusions were not elicited."
- V. Diagnosis

Diagnostic classification is made according to DSM-5. The diagnostic numerical code should be used from DSM-5 or ICD-10. It might be prudent to use both codes to cover current and future regulatory guidelines.
- VI. Prognosis

Opinion about the probable future course, extent, and outcome of the disorder; good and bad prognostic factors; specific goals of therapy
- VII. Psychodynamic Formulation

Causes of the patient's psychodynamic breakdown—influences in the patient's life that contributed to present disorder; environmental, genetic, and personality factors relevant to determining patient's symptoms; primary and secondary gains; outline of the major defense mechanism used by the patient
- VIII. Comprehensive Treatment Plan

Modalities of treatment recommended, role of medication, inpatient or outpatient treatment, frequency of sessions, probable duration of therapy; type of psychotherapy; individual, group, or family therapy; symptoms or problems to be treated. Initially, treatment must be directed toward any life-threatening situations such as suicidal risk or risk of danger to others that require psychiatric hospitalization. Danger to self or others is an acceptable reason (both legally and medically) for involuntary hospitalization. In the absence of the need for confinement, a variety of outpatient treatment alternatives are available: day hospitals, supervised residences, outpatient psychotherapy or pharmacotherapy, among others. In some cases, treatment planning must attend to vocational and psychosocial skills training and even legal or forensic issues.

Comprehensive treatment planning requires a therapeutic team approach using the skills of psychologists, social workers, nurses, activity and occupational therapists, and a variety of other mental health professionals, with referral to self-help groups (e.g., Alcoholics Anonymous [AA]) if needed. If either the patient or family members are unwilling to accept the recommendations of treatment and the clinician thinks that the refusal of the recommendations may have serious consequences, the patient, parent, or guardian should sign a statement to the effect that the recommended treatment was refused.

The psychiatric report covers both the psychiatric history and the mental status. The history, or anamnesis (from the Greek meaning "to remember"), describes life events within the framework of the life cycle, from infancy to old age, and the clinician should attempt to elicit the emotional reaction to each event as remembered by the patient. The mental status examination covers what the patient is thinking and feeling at the moment and how he or she responds to specific questions from the examiner. Sometimes it may be necessary to report, in detail, the questions asked and the answers received; but this should be kept to a minimum, so that the report does not read like a verbatim transcript. Nevertheless, the clinician should try to use the patient's own words as much as possible, especially when describing certain symptoms such as hallucinations or delusions.

Finally, the psychiatric report includes more than the psychiatric history and mental status. It also includes a summary of positive and negative findings and an interpretation of the data. It has more than descriptive value; it has meaning that helps provide an understanding of the case. The examiner addresses critical questions in the report: Are future diagnostic studies needed, and, if so, which ones? Is a consultant needed? Is a comprehensive neurological workup, including an electroencephalogram (EEG) or computed tomography (CT) scan, needed? Are psychological tests indicated? Are psychodynamic factors relevant? Has the cultural context of the patient's illness been considered? The report includes a diagnosis made according to the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). A prognosis is also discussed in the report, with good and bad prognostic factors listed. The report concludes with a discussion of a treatment plan and makes firm recommendations about management of the case.

MEDICAL RECORD

The psychiatric report is a part of the medical record; however, the medical record is more than the psychiatric report. It is a narrative that documents all events that occur during the course of treatment, most often referring to the patient's stay in the hospital. Progress notes record every interaction between doctor and patient; reports of all special studies, including laboratory tests; and prescriptions and orders for all medications. Nurses' notes help describe the patient's course: Is the patient beginning to respond to treatment? Are there times during the day or night when symptoms get worse or remit? Are there adverse effects or complaints by the patient about prescribed medication? Are there signs of agitation, violence, or mention of suicide? If the patient requires restraints or seclusion, are the proper supervisory procedures being followed? Taken as a whole, the medical record tells what happened to the patient since first making contact with the health care system. It concludes with a discharge summary that provides a concise overview of the patient's course with recommendations

for future treatment, if necessary. Evidence of contact with a referral agency should be documented in the medical record to establish continuity of care if further intervention is necessary.

Use of the Record

The medical record is not only used by physicians, but is also used by regulatory agencies and managed care companies to determine length of stay, quality of care, and reimbursement to doctors and hospitals. In theory, the inpatient medical record is accessible to authorized persons only and is safeguarded for confidentiality. In practice, however, absolute confidentiality cannot be guaranteed. Guidelines for what material needs to be incorporated into the medical record are provided in [Table 5.2-2](#).

 **Table 5.2-2**
Medical Record

There shall be an individual record for each person admitted to the psychiatric inpatient unit. Patient records shall be safeguarded for confidentiality and should be accessible only to authorized persons. Each case record shall include:

- Legal admission documents
 - Identifying information on the individual and family
 - Source of referral, date of commencement of service, and name of staff member carrying overall responsibility for treatment and care
 - Initial, intercurrent, and final diagnoses, including psychiatric or mental retardation diagnoses in official terminology
 - Reports of all diagnostic examinations and evaluations, including findings and conclusions
 - Reports of all special studies performed, including X-rays, clinical laboratory tests, clinical psychological testing, electroencephalograms, and psychometric tests
 - The individual written plan of care, treatment, and rehabilitation
 - Progress notes written and signed by all staff members having significant participation in the program of treatment and care
 - Summaries of case conferences and special consultations
 - Dated and signed prescriptions or orders for all medications, with notation of termination dates
 - Closing summary of the course of treatment and care
 - Documentation of any referrals to another agency
-

(Adapted from the 1995 guidelines of the New York State Office of Mental Health.)

The medical record is also crucial in malpractice litigation. Robert I. Simon summarized the liability issues as follows:

Properly kept medical records can be the psychiatrist's best ally in malpractice litigation. If no record is kept, numerous questions will be raised regarding the psychiatrist's competence and credibility. This failure to keep medical records may also violate state statutes or licensing provisions. Failure to keep medical records may arise out of the psychiatrist's concern that patient treatment information be totally protected. Although this is an admirable ideal, in real life the psychiatrist may be legally compelled under certain circumstances to testify directly about confidential treatment matters.

Outpatient records are also subject to scrutiny by third parties under certain circumstances, and psychiatrists in private practice are under the same obligation to maintain a record of the patient in treatment as the hospital psychiatrist. [Table 5.2-3](#) lists documentation issues of concern to third-party payers.

 **Table 5.2-3**
Documentation Issues

Are patient's areas of dysfunction described? From the biological, psychological, and social points of view?

Is alcohol or substance abuse addressed?

Do clinical activities happen at the expected time? If too late or never, why?

Are issues identified in the treatment plan and followed in progress notes?

When there is a variance in the patient's outcome, is there a note in the progress notes to that effect? Is there also a note in the progress notes reflecting the clinical strategies recommended to overcome the impediments to the patient's improvement?

If new clinical strategies are implemented, how is their impact evaluated? When?

Is there a sense of multidisciplinary input and coordination of treatment in the progress notes?

Do progress notes indicate the patient's functioning in the therapeutic community and its relationship to their discharge criteria?

Can one extrapolate from the patient's behavior in the therapeutic community how he or she will function in the community at large?

Are there notes depicting the patient's understanding of his or her discharge planning? Family participation in discharge planning must be entered in the progress notes with their reaction to the plan.

Do attending progress notes bridge the differences in thinking of other disciplines?

Are the patient's needs addressed in the treatment plan?

Are the patient's family's needs evaluated and implemented?

Is patient and family satisfaction evaluated in any way?

Is alcohol and substance abuse addressed as a possible contributor to readmission?

If the patient was readmitted, are there indications that previous records were reviewed, and, if the patient is on medication other than that prescribed on discharge, is there a rationale for this change?

Do the progress notes identify the type of medication used and the rationale for increase, decrease, discontinuation, or augmentation of medication?

Are medication effects documented, including dosages, response, and adverse or other side effects?

Note: Documentation issues are of concern to third-party payers, such as insurance companies and health maintenance organizations who examine patients' charts to see if the areas listed above are covered. In many cases, however, the review is conducted by persons with little or no background in psychiatry or psychology who do not recognize the complexities of psychiatric diagnosis and treatment. Payments to hospitals, doctors, and patients are often denied because of what such reviewers consider to be so-called inadequate documentation.

Personal Notes and Observations

According to laws relating to access to medical records, some jurisdictions (such as in the Public Health Law of New York State) have a provision that applies to a physician's personal notes and observations. *Personal notes* are defined as "a practitioner's speculations, impressions (other than tentative or actual diagnosis) and reminders." The data are maintained only by the clinician and cannot be disclosed to any other person, including the patient. Psychiatrists concerned about material that may prove damaging or otherwise hurtful to the patient if released to a third party may consider using this provision to maintain doctor-patient confidentiality.

Psychotherapy Notes

Psychotherapy notes include details of transference, fantasies, dreams, personal information about persons with whom the patient interacts, and other intimate details of the patient's life. They may also include the psychiatrist's comments on his or her countertransference and feelings toward the patient. Psychotherapy notes should be kept separate from the rest of the medical records.

Patient Access to Records

Patients have a legal right to access their medical records. This right represents society's belief that the responsibility for medical care has become a collaborative process between doctor and patient. Patients see many different physicians, and they can be more effective historians and coordinators of their own care with such information.

Psychiatrists must be careful in releasing their records to the patient if, in their judgment, the patient can be harmed emotionally as a result. Under these circumstances, the psychiatrist may choose to prepare a summary of the patient's course of treatment, holding back material that might be hurtful—especially if it were to get into the hands of third parties. In malpractice cases, however, it may not be possible to do so. When litigation occurs, the entire medical record is subject to discovery. Psychotherapy notes are usually protected, but not always. If psychotherapy notes are ordered to be produced, the judge would probably review them privately and select what is relevant to the case in question.

Blogs

Blogs or web logs are used by persons who wish to record their day-to-day experiences or to express their thoughts and feelings about events. Physicians should be especially cautious about such activities because they are subject to discovery in lawsuits. Pseudonyms and aliases offer no protection because they can be traced. Writing about patients on blogs is a breach in confidentiality. In one case a doctor detailed his thoughts about a lawsuit that included hostile comments about the plaintiff and his attorney. His blog was discovered inadvertently and was used against him in court. Physicians are advised not to use blogs to vent emotions and to write nothing that they would not write for attribution even if their identity were discovered.

E-Mail

E-mail is increasingly being used by physicians as a quick and efficient way to communicate not only with patients but also with other doctors about their patients; however, it is a public document and should be treated as such. The dictum of not diagnosing or prescribing medication over the telephone to a patient one has not examined should also apply to e-mail. It is not only dangerous but also unethical. All e-mail messages should be printed to include with the paper chart unless electronic archives are regularly backed up and secure.

Ethical Issues and the Medical Record

Psychiatrists continually make judgments about what is appropriate material to include in the psychiatric report, the medical record, the case report, and other written communications about a patient. Such judgments often involve ethical issues. In a case report, for example, the patient should not be identifiable, a position made clear in the American Psychiatric Association's (APA's) *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry*, which states that published case reports must be suitably disguised to safeguard patient confidentiality without altering material to provide a less-than-complete portrayal of the patient's actual condition. In some instances, obtaining a written release from the patient that allows the psychiatrist to publish the case may also be advisable, even if the patient is appropriately disguised.

Psychiatrists sometimes include material in the medical record that is specifically directed toward warding off future culpability if liability issues are ever raised. This may include having advised the patient about specific adverse effects of medication to be prescribed.

Health Insurance Portability and Accountability Act (HIPAA)

The Health Insurance Portability and Accountability Act (HIPAA) was passed in 1996 to address the medical delivery system's mounting complexity and its rising dependence on electronic communication. The act orders that the federal Department of Health and Human Services (HHS) develop rules protecting the transmission and confidentiality of patient information, and all units under HIPAA must comply with such rules.

Two rules were finalized in February 2003: the Transaction Rule and the Privacy Rule (see [Tables 5.2-4](#) and [5.2-5](#)). The Transaction Rule facilitates transferring health information effectively and efficiently by means of regulations created by the HHS that established a uniform set of formats, code sets, and data requirements. The Privacy Rule, administered by the Office of Civil Rights (OCR) at HHS, protects the confidentiality of patient information. This means that a patient's medical information belongs to the patient and that the patient has the right to access it, with the exception of psychotherapy notes, which are deemed as property of the psychotherapist who wrote them.

Table 5.2-4

Transaction Rule Code Sets

Health care information: The Transactions Rule defines standards and establishes code sets and forms to be used for electronic transaction that involve the following health care information:

- Claims or equivalent encounter information
- Eligibility inquiries
- Referral certification and authorization
- Claims status inquiries
- Enrollment and disenrollment information
- Payment and remittance advice
- Health plan premium payments
- Coordination of benefits

Code sets: Under the Transaction Rule, the following code sets are required for filing claims with Medicare:

- Procedure codes
 - American Medical Association Current Procedural Terminology codes
- Healthcare Common Procedure Coding System codes
- Diagnosis codes
 - International Classification of Disease*, 10th edition, clinical modification, codes
- Drugs and biologicals
 - National Drug Codes
- Dental codes
 - Code on dental procedures
 - Nomenclature for dental services

Adapted from Jaffe E. HIPAA basics for psychiatrists. *Psych Pract Manage Care*. 2002;8:15.

Table 5.2-5

Patient's Rights under the Privacy Rule

Physician must give the patient a written notice of his or her privacy rights, the privacy policies of the practice, and how patient information is used, kept, and disclosed. A written acknowledgment should be taken from the patient verifying that he or she seen such notice.

Patients should be able to obtain copies of their medical records and to request revisions to those records within a stated amount of time (usually 30 days). Patients do not have the right to see psychotherapy notes.

Physicians must provide the patient with a history of most disclosures of his or her medical history on request. There are some exceptions. The APA Committee on Confidentiality has developed a model document for this requirement.

Physicians must obtain authorization from the patient for disclosure of information other than for treatment, payment, and health care operations (these three are considered to be routine uses, for which consent is not required). The APA Committee on Confidentiality has developed a model document for this requirement.

Patients may request another means of communication of their protected information (i.e., request that the physician contact them at a specific phone number or address).

Physicians cannot generally limit treatment to obtaining patient authorization for disclosure of the patient's information for nonroutine uses.

Patients have the right to complain about Privacy Rule violations to the physician, their health plan, or to the secretary of HHS.

APA, American Psychiatric Association; HHS, Department of Health and Human Services.
(Adapted from Jaffe E. HIPAA basics for psychiatrists. *Psych Pract Manage Care*. 2002;8:15.)

In 2003, the Privacy Rule was executed. Under the Privacy Rule, there are certain guidelines by which every practice must abide:

1. Every practice must establish written privacy procedures. These include administrative, physical, and technical safeguards that establish who has access to the patient's information, how this information is used within the facility, and when the information will and will not be disclosed to others.
2. Every practice must take steps to make sure that its business associates protect the privacy of medical records and other health information.
3. Every practice must train employees to comply with the rule.
4. Every practice must have a designated person to serve as a privacy officer. If it is an individual practice or private practice, this person can be the physician.
5. Every practice must establish complaint procedures for patients who wish to ask or to complain about the privacy of their records.

The OCR at HHS is responsible for making sure that Privacy Rule is enforced; however, it is not clear as to how it will be done. One method expressed by the government is a complaint-driven system in which the OCR will respond to complaints made by patients concerning confidentiality violations or denied access to records, all of which are covered under HIPAA. In such cases, OCR may follow up and audit compliance.

The APA's Committee on Confidentiality, along with legal experts, has developed a set of sample forms. They are part of the APA's HIPAA educational packet, which can be obtained on the APA web site (www.psych.org/). On the web site, there are also recommendations for enabling physicians to comply with HIPAA.

5.3 Psychiatric Rating Scales

The term *psychiatric rating scales* encompasses a variety of questionnaires, interviews, checklists, outcome assessments, and other instruments that are available to inform psychiatric practice, research, and administration. Psychiatrists must keep up with major developments in rating scales for several reasons. Most critically, many such scales are useful in psychiatric practice for monitoring patients over time or for providing information that is more comprehensive than what is generally obtained in a routine clinical interview. In addition, health care administrators and payors are increasingly requiring standardized assessments to justify the need for services or to assess quality of care. Lastly, but equally important, rating scales are used in research that informs the practice of psychiatry, so familiarity with them provides a deeper understanding of the results of that research and the degree to which it applies to psychiatric practice.

POTENTIAL BENEFITS AND LIMITATIONS OF RATING SCALES IN PSYCHIATRY

The key role of rating scales in psychiatry and elsewhere is to standardize the information collected across time and by various observers. This standardization ensures a consistent, comprehensive evaluation that may aid treatment planning by establishing a diagnosis, ensuring a thorough description of symptoms, identifying comorbid conditions, and characterizing other factors affecting treatment response. In addition, the use of a rating scale can establish a baseline for follow up of the progression of an illness over time or in response to specific interventions. This is particularly useful when more than one clinician is involved—for instance, in a group practice or in the conduct of psychiatric research.

In addition to standardization, most rating scales also offer the user the advantages of a formal evaluation of the measure's performance characteristics. This allows the clinician to know to what extent a given scale produces reproducible results (reliability) and how it compares to more definitive or established ways of measuring the same thing (validity).

TYPES OF SCALES AND WHAT THEY MEASURE

Scales are used in psychiatric research and practice to achieve a variety of goals. They also cover a broad range of areas and use a broad range of procedures and formats.

Measurement Goals

Most psychiatric rating scales in common use fall into one or more of the following categories: making a diagnosis; measuring severity and tracking change in specific symptoms, in general functioning, or in overall outcome; and screening for conditions that may or may not be present.

Constructs Assessed

Psychiatric practitioners and investigators assess a broad range of areas, referred to as *constructs*, to underscore the fact that they are not simple, direct observations of nature. These include diagnoses, signs and symptoms, severity, functional impairment, quality of life, and many others. Some of these constructs are fairly complex and are divided into two or more domains (e.g., positive and negative symptoms in schizophrenia or mood and neurovegetative symptoms in major depression).

Categorical versus Continuous Classification. Some constructs are viewed as *categorical* or classifying, whereas others are seen as *continuous* or measuring. Categorical constructs describe the presence or absence of a given attribute (e.g., competency to stand trial) or the category best suited to a given individual among a finite set of options (e.g., assigning a diagnosis). Continuous measures provide a quantitative assessment along a continuum of intensity, frequency, or severity. In addition to symptom severity and functional status, multidimensional personality traits, cognitive status, social support, and many other attributes are generally measured continuously.

The distinction between categorical and continuous measures is by no means absolute. *Ordinal* classification, which uses a finite, ordered set of categories (e.g., unaffected, mild, moderate, or severe) stands between the two.

Measurement Procedures

Rating scales differ in measurement methods. Issues to be considered include format, raters, and sources of information.

Format. Rating scales are available in a variety of formats. Some are simply checklists or guides to observation that help the clinician achieve a standardized rating. Others are self-administered questionnaires or tests. Still others are formal interviews that may be *fully structured* (i.e., specifying the exact wording of questions to be asked) or *partly structured* (i.e., providing only some specific wording, along with suggestions for additional questions or probes).

Raters. Some instruments are designed to be administered by doctoral-level clinicians only, whereas others may be administered by psychiatric nurses or social workers with more limited clinical experience. Still other instruments are designed primarily for use by lay raters with little or no experience with psychopathology.

Source of Information. Instruments also vary in the source of information used to make the ratings. Information may be obtained solely from the patient, who generally knows the most about his or her condition. In some instruments, some or all of the information may be obtained from a knowledgeable informant. When the construct involves limited insight (e.g., cognitive disorders or mania) or significant social undesirability (e.g., antisocial personality or substance abuse), other informants may be preferable. Informants may also be helpful when the subject has limited ability to recall or report symptoms (e.g., delirium, dementia, or any disorder in young children). Some rating scales also allow or require information to be included from medical records or from patient observation.

ASSESSMENT OF RATING SCALES

In clinical research, rating scales are mandatory to ensure interpretable and potentially generalizable results and are selected based on coverage of the relevant constructs, expense (based on the nature of the raters, purchase price if any, and necessary training), length and administration time, comprehensibility to the intended audience, and quality of the ratings provided. In clinical practice, one considers these factors and, also, whether a scale would provide more or better information than what would be obtained in ordinary clinical practice or would contribute to the efficiency of obtaining that information. In either case, the assessment of quality is based on *psychometric*, or mind-measuring, properties.

Psychometric Properties

The two principal psychometric properties of a measure are *reliability* and *validity*. Although these words are used almost interchangeably in everyday speech, they are distinct in the context of evaluating rating scales. To be useful, scales should be *reliable*, or consistent and repeatable even if performed by different raters at different times or under different conditions, and they should be *valid*, or accurate in representing the true state of nature.

Reliability. *Reliability* refers to the consistency or repeatability of ratings and is largely empirical. An instrument is more likely to be reliable if the instructions and questions are clearly and simply worded and the format is easy to understand and score. There are three standard ways to assess reliability: *internal consistency*, *interrater*, and *test-retest*.

Internal Consistency. Internal consistency assesses agreement among the individual items in a measure. This provides information about reliability, because each item is viewed as a single measurement of the underlying construct. Thus, the coherence of the items suggests that each is measuring the same thing.

Interrater and Test-Retest Reliability. Interrater (also called *interjudge* or *joint*) reliability is a measure of agreement between two or more observers evaluating the same subjects using the same information. Estimates may vary with assessment conditions—for instance, estimates of interrater reliability based on videotaped interviews tend to be higher than those based on interviews conducted by one of the raters. Test-retest evaluations measure reliability only to the extent that the subject's true condition remains stable in the time interval.

Issues in Interpreting Reliability Data. When interpreting reliability data, it is important to bear in mind that reliability estimates published in the literature may not generalize to other settings. Factors to consider are the nature of the sample, the training and experience of the raters, and the test conditions. Issues regarding the sample are especially critical. In particular, reliability tends to be higher in samples with high variability in which it is easier to discriminate among individuals.

Validity. *Validity* refers to conformity with truth, or a gold standard that can stand for truth. In the categorical context, it refers to whether an instrument can make correct classifications. In the continuous context, it refers to accuracy, or whether the score assigned can be said to represent the true state of nature. Although reliability is an empirical question, validity is partly theoretical—for many constructs measured in psychiatry, there is no underlying absolute truth. Even so, some measures yield more useful and meaningful data than others do. Validity assessment is generally divided into face and content validity, criterion validity, and construct validity.

FACE AND CONTENT VALIDITY. *Face validity* refers to whether the items appear to assess the construct in question. Although a rating scale may purport to measure a construct of interest, a review of the items may reveal that it embodies a very different conceptualization of the construct. For instance, an insight scale may define *insight* in either psychoanalytic or neurological terms. However, items with a transparent relationship to the construct may be a disadvantage when measuring socially undesirable traits, such as substance abuse or malingering. *Content validity* is similar to face validity but describes whether the measure provides good balanced coverage of the construct and is less focused on whether the items give the appearance of validity. Content validity is often assessed with formal procedures such as expert consensus or factor analysis.

CRITERION VALIDITY. *Criterion validity* (sometimes called *predictive* or *concurrent validity*) refers to whether or not the measure agrees with a gold standard or criterion of accuracy. Suitable gold standards include the long form of an established instrument for a new, shorter version, a clinician-rated measure for a self-report form, and blood or urine tests for measures of drug use. For diagnostic interviews, the generally accepted gold standard is the Longitudinal, Expert, All Data (LEAD) standard, which incorporates expert clinical evaluation, longitudinal data, medical records, family history, and any other sources of information.

CONSTRUCT VALIDITY. When an adequate gold standard is not available—a frequent state of affairs in psychiatry—or when additional validity data are desired, construct validity must be assessed. To accomplish this, one can compare the measure to *external validators*, attributes that bear a well-characterized relationship to the construct under study but are not measured directly by the instrument. External validators used to validate psychiatric diagnostic criteria and the diagnostic instruments that aim to operationalize them include course of illness, family history, and treatment response. For example, when compared with schizophrenia measures, mania measures are expected to identify more individuals with a remitting course, a family history of major mood disorders, and a good response to lithium.

SELECTION OF PSYCHIATRIC RATING SCALES

The scales discussed below cover various areas such as diagnosis, functioning, and symptom severity, among others. Selections were made based on coverage of major areas and common use in clinical research or current (or potential) use in clinical practice. Only a few of the many scales available in each category are discussed here.

Disability Assessment

One of the most widely used scales to measure disability was developed by the World Health Association (WHO), known as the WHO Disability Assessment Schedule, now in its second iteration (WHODAS 2.0). It is self-administered and measures disability along a number of parameters such as cognition, interpersonal relations, work and social impairment, among many others. It can be taken at intervals along the course of a person's illness and is reliable in tracking changes that indicate a positive or negative response to therapeutic interventions or course of illness (Table 5.3-1).

 **Table 5.3-1**
WHODAS 2.0

World Health Organization Disability Assessment Schedule 2.0
36-item version, self-administered

Patient Name: _____ Age: _____ Sex: Male Female Date: _____

This questionnaire asks about difficulties due to health/mental health conditions. Health conditions include diseases or illnesses, other health problems that may be short or long lasting, injuries, mental or emotional problems, and problems with alcohol or drugs. Think back over the past 30 days and answer these questions thinking about how much difficulty you had doing the following activities. For each question, please circle only one response.

Numeric Scores Assigned to Each of the Items:		1	2	3	4	5	Clinician Use Only		
							Raw Item Score	Raw Domain Score	Average Domain Score
In the <u>last 30 days</u> , how much difficulty did you have in:									
Understanding and Communicating									
D1.1	<u>Concentrating on doing something for ten minutes?</u>	None	Mild	Moderate	Severe	Extreme or cannot do		30	5
D1.2	<u>Remembering to do important things?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D1.3	<u>Analyzing and finding solutions to problems in day-to-day life?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D1.4	<u>Learning a new task for example, learning how to get to a new place?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D1.5	<u>Generally understanding what people say?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D1.6	<u>Starting and maintaining a conversation?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
Getting Around									
D2.1	<u>Standing for long periods, such as 30 minutes?</u>	None	Mild	Moderate	Severe	Extreme or cannot do		25	5
D2.2	<u>Standing up from sitting down?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D2.3	<u>Moving around inside your home?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D2.4	<u>Getting out of your home?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D2.5	<u>Walking a long distance, such as a kilometer (or equivalent)?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
Self-Care									
D3.1	<u>Washing your whole body?</u>	None	Mild	Moderate	Severe	Extreme or cannot do		20	5
D3.2	<u>Getting dressed?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D3.3	<u>Eating?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D3.4	<u>Staying by yourself for a few days?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
Getting Along with People									
D4.1	<u>Dealing with people you do not know?</u>	None	Mild	Moderate	Severe	Extreme or cannot do		25	5
D4.2	<u>Maintaining a friendship?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D4.3	<u>Getting along with people who are close to you?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D4.4	<u>Making new friends?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			
D4.5	<u>Sexual activities?</u>	None	Mild	Moderate	Severe	Extreme or cannot do			

Life Activities–Household								
D5.1	Taking care of your <u>household responsibilities</u> ?	None	Mild	Moderate	Severe	Extreme or cannot do		
D5.2	Doing most important household tasks <u>well</u> ?	None	Mild	Moderate	Severe	Extreme or cannot do		
D5.3	Getting all of the household work <u>done</u> that you needed to do?	None	Mild	Moderate	Severe	Extreme or cannot do	20	5
D5.4	Getting your household work done as <u>quickly</u> as needed?	None	Mild	Moderate	Severe	Extreme or cannot do		
Life Activities–School/Work								
D5.5	Your day-to-day <u>work/school</u> ?	None	Mild	Moderate	Severe	Extreme or cannot do		
D5.6	Doing your most important work/school tasks <u>well</u> ?	None	Mild	Moderate	Severe	Extreme or cannot do		
D5.7	Getting all of the work <u>done</u> that you need to do?	None	Mild	Moderate	Severe	Extreme or cannot do	20	5
D5.8	Getting your work done as <u>quickly</u> as needed?	None	Mild	Moderate	Severe	Extreme or cannot do		
Participation in Society								
In the past 30 days:								
D6.1	How much of a problem did you have in <u>joining in community activities</u> (for example, festivities, religious, or other activities) in the same way as anyone else can?	None	Mild	Moderate	Severe	Extreme or cannot do		
D6.2	How much of a problem did you have because of <u>barriers or hindrances</u> around you?	None	Mild	Moderate	Severe	Extreme or cannot do		
D6.3	How much of a problem did you have <u>living with dignity</u> because of the attitudes and actions of others?	None	Mild	Moderate	Severe	Extreme or cannot do		
D6.4	How much <u>time</u> did you spend on your health condition or its consequences?	None	Mild	Moderate	Severe	Extreme or cannot do	40	5
D6.5	How much have you been <u>emotionally affected</u> by your health condition?	None	Mild	Moderate	Severe	Extreme or cannot do		
D6.6	How much has your health been a <u>drain on the financial resources</u> of you or your family?	None	Mild	Moderate	Severe	Extreme or cannot do		
D6.7	How much of a problem did your <u>family</u> have because of your health problems?	None	Mild	Moderate	Severe	Extreme or cannot do		
D6.8	How much of a problem did you have in doing things <u>by yourself</u> for relaxation or pleasure?	None	Mild	Moderate	Severe	Extreme or cannot do		
General Disability Score (Total):							180	5

©World Health Organization 2012. All rights reserved. Measuring health and disability: manual for WHO Disability Assessment Schedule (WHODAS 2.0). World Health Organization, 2010, Geneva.)

A number of assessment scales were developed for inclusion in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association, (DSM-5); however, they were developed by and intended for use by research psychiatrists and are not as well tested as the WHO scales. It is expected that, in time, they will eventually be better adapted for clinical use. Some clinicians may wish to use the scales known as *Cross-Cutting Symptom Measure Scales*, but at this time the WHO scale is recommended for general use.

Psychiatric Diagnosis

Instruments assessing psychiatric diagnosis are central to psychiatric research and may be useful in clinical practice as well. However, they tend to be rather long, especially with individuals reporting many symptoms, potentially requiring many follow-up questions. When such instruments are evaluated, it is important to ensure they implement the current diagnostic criteria and cover the diagnostic areas of interest.

Structured Clinical Interview for DSM (SCID). The SCID begins with a section on demographic information and clinical background. Then there are seven diagnostic modules focused on different diagnostic groups: mood, psychotic, substance abuse, anxiety, somatic, eating, and adjustment disorders; the modules can be administered separately. Both required and optional probes are provided, and skip outs are suggested where no further questioning is warranted. All available information, including that from hospital records, informants, and patient observation, should be used to rate the SCID. The SCID is designed to be administered by experienced clinicians and is generally not recommended for use by lay interviewers. In addition, formal training in the SCID is required, and training books and videos

are available to facilitate this. Although the primary focus is research with psychiatric patients, a nonpatient version (with no reference to a chief complaint) and a more clinical version (without as much detailed subtyping) are also available. Reliability data on the SCID suggest that it performs better on more severe disorders (e.g., bipolar disorder or alcohol dependence) than on milder ones (e.g., dysthymia). Validity data are limited, as the SCID is more often used as the gold standard to evaluate other instruments. It is considered the standard interview to verify diagnosis in clinical trials and is extensively used in other forms of psychiatric research. Although its length precludes its use in routine clinical practice, the SCID can sometimes be useful to ensure a systematic evaluation in psychiatric patients—for instance, on admission to an inpatient unit or at intake into an outpatient clinic. It is also used in forensic practice to ensure a formal and reproducible examination.

Psychotic Disorders

A variety of instruments are used for patients with psychotic disorders. Those discussed here are symptom severity measures. A developing consensus suggests that the distinction between positive and negative symptoms in schizophrenia is worthwhile, and more recently developed instruments implement this distinction.

Brief Psychiatric Rating Scale (BPRS). The BPRS (Table 5.3-2) was developed in the late 1960s as a short scale for measuring the severity of psychiatric symptomatology. It was developed primarily to assess change in psychotic inpatients and covers a broad range of areas, including thought disturbance, emotional withdrawal and retardation, anxiety and depression, and hostility and suspiciousness. Reliability of the BPRS is good to excellent when raters are experienced, but this is difficult to achieve without substantial training; a semistructured interview has been developed to increase reliability. Validity is also good as measured by correlations with other measures of symptom severity, especially those assessing schizophrenia symptomatology. The BPRS has been used extensively for decades as an outcome measure in treatment studies of schizophrenia; it functions well as a measure of change in this context and offers the advantage of comparability with earlier trials. However, it has been largely supplanted in more recent clinical trials by the newer measures described below. In addition, given its focus on psychosis and associated symptoms, it is only suitable for patients with fairly significant impairment. Its use in clinical practice is less well supported, in part because considerable training is required to achieve the necessary reliability.

PATIENT NAME

RATER NUMBER

RATER NUMBER - - -	EVALUATION TYPE (Circle)				
	1 Baseline	4 Start double-blind	7 Start open meds	10 Early termination	
	2	5 Major evaluation	8 During open meds	11 Study completion	
	3 4-week minor	6 Other	9 Stop open minds		

Introduce all questions with "During the past week have you..."

- *1. **SOMATIC CONCERN:** Degree of concern over present bodily health. Rate the degree to which physical health is perceived as a problem by the patient, whether complaints have a realistic basis or not. Do not rate mere reporting of somatic symptoms. Rate only concern for (or worrying about) physical problems (real or imagined). **Rate on the basis of reported (i.e., subjective) information pertaining to the past week.**

 - 1 = Not reported
 - 2 = Very Mild: occasionally is somewhat concerned about body, symptoms, or physical illness
 - 3 = Mild: occasionally is moderately concerned, or often is somewhat concerned
 - 4 = Moderate: occasionally is very concerned, or often is moderately concerned
 - 5 = Moderately Severe: often is very concerned
 - 6 = Severe: is very concerned most of the time
 - 7 = Very Severe: is very concerned nearly all of the time
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
2. **ANXIETY:** Worry, fear, or overconcern for present or future: Rate solely on the basis of verbal report of patient's own subjective experiences pertaining to the past week. Do not infer anxiety from physical signs or from neurotic defense mechanisms. Do not rate if restricted to somatic concern.

 - 1 = Not reported
 - 2 = Very Mild: occasionally feels somewhat anxious
 - 3 = Mild: occasionally feels moderately anxious, or often feels somewhat anxious
 - 4 = Moderate: occasionally feels very anxious, or often feels moderately anxious
 - 5 = Moderately Severe: often feels very anxious
 - 6 = Severe: feels very anxious most of the time
 - 7 = Very Severe: feels very anxious nearly all of the time
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
3. **EMOTIONAL WITHDRAWAL:** Deficiency in relating to the interviewer and to the interview situation. Overt manifestations of this deficiency include poor/absence of eye contact, failure to orient oneself physically toward the interviewer, and a general lack of involvement or engagement in the interview. Distinguish from BLUNTED AFFECT, in which deficits in facial expression, body gesture, and voice pattern are scored.

 - 1 = Not observed
 - 2 = Very Mild: e.g., occasionally exhibits poor eye contact
 - 3 = Mild: e.g., as above, but more frequent
 - 4 = Moderate: e.g., exhibits little eye contact, but still seems engaged in the interview and is appropriately responsive to all questions
 - 5 = Moderately Severe: e.g., stares at floor or orients self away from interviewer but still seems moderately engaged
 - 6 = Severe: e.g., as above, but more persistent or pervasive
 - 7 = Very Severe: e.g., appears "spacey" or "out of it" (total absence of emotional relatedness) and is disproportionately uninvolved or unengaged in the interview (DO NOT SCORE IF EXPLAINED BY DISORIENTATION)
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
4. **CONCEPTUAL DISORGANIZATION:** Degree of speech incomprehensibility. Include any type of formal thought disorder (e.g., loose associations, incoherence, flight of ideas, neologisms). DO NOT include mere circumstantiality or pressured speech, even if marked. DO NOT rate on the basis of the patient's subjective impressions (e.g., "my thoughts are racing. I can't hold a thought," "My thinking gets all mixed up"). Rate ONLY on the basis of observations made during the interview.

 - 1 = Not observed
 - 2 = Very Mild: e.g., somewhat vague, but of doubtful clinical significance
 - 3 = Mild: e.g., frequently vague, but the interview is able to progress smoothly; occasional loosening of associations
 - 4 = Moderate: e.g., occasional irrelevant statements, infrequent use of neologisms, or moderate loosening of associations
 - 5 = Moderately Severe: as above, but more frequent
 - 6 = Severe: formal thought disorder is present for most of the interview, and the interview is severely strained
 - 7 = Very Severe: e.g., appears "spacey" or "out of it" (total absence of emotional relatedness) and is disproportionately uninvolved or unengaged in the interview (DO NOT SCORE IF EXPLAINED BY DISORIENTATION)

5. **GUILT FEELINGS:** Overconcern or remorse for past behavior. Rate on the basis of the patient's subjective experiences of guilt as evidenced by verbal report pertaining to the past week. Do not infer guilt feelings from depression, anxiety, or neurotic defenses.
- 1 = Not reported
 - 2 = Very Mild: occasionally feels somewhat guilty
 - 3 = Mild: occasionally feels moderately guilty, or often feels somewhat guilty
 - 4 = Moderate: occasionally feels very guilty, or often feels moderately guilty
 - 5 = Moderately Severe: often feels very guilty
 - 6 = Severe: feels very guilty most of the time, or encapsulated delusion of guilt
 - 7 = Very Severe: agonizing constant feelings of guilt, or pervasive delusion(s) of guilt
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
6. **TENSION:** Rate motor restlessness (agitation) observed during the interview.
DO NOT rate on the basis of subjective experiences reported by the patient. Disregard suspected pathogenesis (e.g., tardive dyskinesia).
- 1 = Not reported
 - 2 = Very Mild: e.g., occasionally fidgets
 - 3 = Mild: e.g., frequently fidgets
 - 4 = Moderate: e.g., constantly fidgets, or frequently fidgets, wrings hands and pulls clothing
 - 5 = Moderately Severe: e.g., constantly fidgets, wrings hands and pulls clothing
 - 6 = Severe: e.g., cannot remain seated (i.e., must pace)
 - 7 = Very Severe: e.g., paces in a frantic manner
7. **MANNERISMS AND POSTURING:** Unusual and unnatural motor behavior.
Rate only abnormality of movements. Do not rate simple heightened motor activity here. Consider frequency, duration, and degree of bizarreness. Disregard suspected pathogenesis.
- 1 = Not observed
 - 2 = Very Mild: odd behavior but of doubtful clinical significance, e.g., occasional unprompted smiling, infrequent lip movements
 - 3 = Mild: strange behavior but not obviously bizarre, e.g., infrequent head-tilting (side to side) in a rhythmic fashion, intermittent abnormal finger movements
 - 4 = Moderate: e.g., assumes unnatural position for a brief period of time, infrequent tongue protrusions, rocking, facial grimacing
 - 5 = Moderately Severe: e.g., assumes and maintains unnatural position throughout interview, unusual movements in several body areas
 - 6 = Severe: as above, but more frequent, intense, or pervasive
 - 7 = Very Severe: e.g., bizarre posturing throughout most of the interview, continuous abnormal movements in several body areas
- *8. **GRANDIOSITY:** Inflated self-esteem (self-confidence), or inflated appraisal of one's talents, powers, abilities, accomplishments, knowledge, importance, or identity. Do not score mere grandiose quality of claims (e.g., "I'm the worst sinner in the world," "The entire country is trying to kill me") unless the guilt/persecution is related to some special, exaggerated attributes of the individual. Also, the patient must claim exaggerated attributes: e.g., if patient denies talents, powers, etc., even if he or she states that others indicate that he/she has these attributes, this item should not be scored. Rate on the basis of reported (i.e., subjective) information pertaining to the past week.
- 1 = Not reported
 - 2 = Very Mild: e.g., is more confident than most people, but of only possible clinical significance
 - 3 = Mild: e.g., definitely inflated self-esteem or exaggerates talents somewhat out of proportion to the circumstances
 - 4 = Moderate: e.g., inflated self-esteem clearly out of proportion to the circumstances or suspected grandiose delusion(s)
 - 5 = Moderately Severe: e.g., a single (definite) encapsulated grandiose delusion, or multiple (definite) encapsulated grandiose delusion, or multiple (definite) fragmentary grandiose delusions
 - 6 = Severe: e.g., a single (definite) grandiose delusion/delusional system, or multiple (definite) grandiose delusions that the patient seems preoccupied with
 - 7 = Very Severe: e.g., as above, but nearly all conversation is directed toward the patient's grandiose delusion(s)
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed

- ^a9. **DEPRESSIVE MOOD:** Subjective report of feeling depressed, blue, "down in the dumps," etc. Rate only degree of reported depression. Do not rate on the basis of inferences concerning depression based upon general retardation and somatic complaints. Rate on the basis of report (i.e., subjective) information pertaining to the past week.
- 1 = Not reported
 - 2 = Very Mild: occasionally feels somewhat depressed
 - 3 = Mild: occasionally feels moderately depressed, or often feels somewhat depressed
 - 4 = Moderate: occasionally feels very depressed, or often feels moderately depressed
 - 5 = Moderately Severe: often feels very depressed
 - 6 = Severe: feels very depressed most of the time
 - 7 = Very Severe: feels very depressed nearly all of the time
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
- ^a10. **HOSTILITY:** Animosity, contempt, belligerence, disdain for other people outside the interview situation. Rate solely on the basis of the verbal report of feelings and actions of the patient toward others during the past week. Do not infer hostility from neurotic defenses, anxiety, somatic complaints.
- 1 = Not reported
 - 2 = Very Mild: occasionally feels somewhat angry
 - 3 = Mild: often feels somewhat angry, or occasionally feels moderately angry
 - 4 = Moderate: occasionally feels very angry, or often feels moderately angry
 - 5 = Moderately Severe: often feels very angry
 - 6 = Severe: has acted on his anger by becoming verbally or physically abusive on one or two occasions
 - 7 = Very Severe: has acted on his anger on several occasions
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not Assessed
- ^a11. **SUSPICIOUSNESS:** Belief (delusional or otherwise) that others have now, or have had in the past, malicious or discriminatory intent toward the patient. On the basis of verbal report, rate only those suspicions which are currently held whether they concern past or present circumstances. Rate on the basis of reported (i.e., subjective) information pertaining to the past week.
- 1 = Not reported
 - 2 = Very Mild: rare instances of distrustfulness which may or may not be warranted by the situation
 - 3 = Mild: occasional instances of suspiciousness that are definitely not warranted by the situation
 - 4 = Moderate: more frequent suspiciousness, or transient ideas of reference
 - 5 = Moderately Severe: pervasive suspiciousness, frequent ideas of reference, or an encapsulated delusion
 - 6 = Severe: definite, delusion(s) of reference or persecution that is (are) not wholly pervasive (e.g., an encapsulated delusion)
 - 7 = Very Severe: as above, but more widespread, frequent, or intense
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
- ^a12. **HALLUCINATORY BEHAVIOR:** Perceptions (in any sensory modality) in the absence of an identifiable external stimulus. Rate only those experiences that have occurred during the last week. DO NOT rate "voices in my head," or "visions in my mind" unless the patient can differentiate between these experiences and his or her thoughts.
- 1 = Not reported
 - 2 = Very Mild: suspected hallucinations only
 - 3 = Mild: definite hallucinations, but insignificant, infrequent, or transient (e.g., occasional formless visual hallucinations, a voice calling the patient's name)
 - 4 = Moderate: as above, but more frequent or extensive (e.g., frequently sees the devil's face, two voices carry on lengthy conversations)
 - 5 = Moderately Severe: hallucinations are experienced nearly every day, or are a source of extreme distress
 - 6 = Severe: as above, and has had a moderate impact on the patient's behavior (e.g., concentration difficulties leading to impaired work functioning)
 - 7 = Very Severe: as above, and has had a severe impact (e.g., attempts suicide in response to command hallucinations)
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed

13. **MOTOR RETARDATION:** Reduction in energy level evidenced in slowed movements. Rate on the basis of observed behavior of the patient only. Do not rate on the basis of the patient's subjective impression of his or her own energy level.
- 1 = Not observed
 - 2 = Very Mild: Very Mild and of doubtful clinical significance
 - 3 = Mild: e.g., conversation is somewhat retarded, movements somewhat slowed
 - 4 = Moderate: e.g., conversation is noticeably retarded but not strained
 - 5 = Moderately Severe: e.g., conversation is strained, moves very slowly
 - 6 = Severe: e.g., conversation is difficult to maintain, hardly moves at all
 - 7 = Very Severe: e.g., conversation is almost impossible, does not move at all throughout interview
14. **UNCOOPERATIVENESS:** Evidence of resistance, unfriendliness, resentment, and lack of readiness to cooperate with the interviewer. Rate only on the basis of the patient's attitude and responses to the interviewer and the interview situation. Do not rate on the basis of reported resentment or uncooperativeness outside the interview situation.
- 1 = Not observed
 - 2 = Very Mild: e.g., does not seem motivated
 - 3 = Mild: e.g., seems evasive in certain areas
 - 4 = Moderate: e.g., monosyllabic, fails to elaborate spontaneously, somewhat unfriendly
 - 5 = Moderately Severe: e.g., expresses resentment and is unfriendly throughout the interview
 - 6 = Severe: e.g., refuses to answer a number of questions
 - 7 = Very Severe: e.g., refuses to answer most questions
15. **UNUSUAL THOUGHT CONTENT:** Severity of delusions of any type—consider conviction, and effect on actions. Assume full conviction if patient has acted on his or her beliefs. Rate on the basis of reported (i.e., subjective) information pertaining to past week.
- 1 = Not reported
 - 2 = Very Mild: delusion(s) suspected or likely
 - 3 = Mild: at times, patient questions his or her belief(s) (partial delusion)
 - 4 = Moderate: full delusional conviction, but delusion(s) has little or no influence on behavior
 - 5 = Moderately Severe: full delusional conviction, but delusion(s) has only occasional impact on behavior
 - 6 = Severe: delusion(s) has significant effect, e.g., neglects responsibilities because of preoccupation with belief that he/she is God
 - 7 = Very Severe: delusion(s) has major impact, e.g., stops eating because believes food is poisoned
16. **BLUNTED AFFECT:** Diminished affective responsiveness, as characterized by deficits in facial expression, body gesture, and voice pattern. Distinguish from EMOTIONAL WITHDRAWAL, in which the focus is on interpersonal impairment rather than affect. Consider degree and consistency of impairment. Rate based on observations made during interview.
- 1 = Not reported
 - 2 = Very Mild: e.g., occasionally seems indifferent to material that is usually accompanied by some show of emotion
 - 3 = Mild: e.g., somewhat diminished facial expression, or somewhat monotonous voice or somewhat restricted gestures
 - 4 = Moderate: e.g., as above, but more intense, prolonged, or frequent
 - 5 = Moderately Severe: e.g., flattening of affect, including at least two of the three features: severe lack of facial expression, monotonous voice or restricted body gestures
 - 6 = Severe: e.g., profound flattening of affect
 - 7 = Very Severe: e.g., totally monotonous voice, and total lack of expressive gestures throughout the evaluation
17. **EXCITEMENT:** Heightened emotional tone, including irritability and expansiveness (hypomanic affect). Do not infer affect from statements of grandiose delusions. Rate based on observations made during interview.
- 1 = Not reported
 - 2 = Very Mild and of doubtful clinical significance
 - 3 = Mild: e.g., irritable or expansive at times
 - 4 = Moderate: e.g., frequently irritable or expansive
 - 5 = Moderately Severe: e.g., constantly irritable or expansive; or, at times, enraged or euphoric
 - 6 = Severe: e.g., enraged or euphoric throughout most of the interview
 - 7 = Very Severe: e.g., as above, but to such a degree that the interview must be terminated prematurely

18. **DISORIENTATION:** Confusion or lack of proper association for person, place or time.
Rate based on observations made during interview
- 1 = Not reported
 - 2 = Very Mild: e.g., seems somewhat confused
 - 3 = Mild: e.g., indicated 1982 when, in fact, it is 1983
 - 4 = Moderate: e.g., indicates 1978
 - 5 = Moderately Severe: e.g., is unsure where he/she is
 - 6 = Severe: e.g., has no idea where he/she is
 - 7 = Very Severe: e.g., does not know who he/she is
 - 8 = Cannot be assessed adequately because of severe formal thought disorder, uncooperativeness, or marked evasiveness/guardedness; or Not assessed
19. **SEVERITY OF ILLNESS:** Considering your total clinical experience with this patient population, how mentally ill is the patient at this time?
- 1 = Normal, not at all ill
 - 2 = Borderline mentally ill
 - 3 = Mildly ill
 - 4 = Moderately ill
 - 5 = Markedly ill
 - 6 = Severely ill
 - 7 = Among the most severely ill patients
20. **GLOBAL IMPROVEMENT:** Rate total improvement whether or not, in your judgment, it is due to treatment. At baseline assessment, mark "Not assessed" for item 20. For assessments up to the start of double-blind medication, rate Global Improvement compared to baseline. For assessments following the start of double-blind medication, rate Global Improvement compared to the start of double-blind.
- 1 = Very much improved
 - 2 = Much improved
 - 3 = Minimally improved
 - 4 = No change
 - 5 = Minimally worse
 - 6 = Much worse
 - 7 = Very much worse
 - 8 = Not assessed

*Ratings based primarily on verbal report.

(From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009:1043, with permission.)

Positive and Negative Syndrome Scale (PANSS). The PANSS was developed in the late 1980s to remedy perceived deficits in the BPRS in the assessment of positive and negative symptoms of schizophrenia and other psychotic disorders by adding additional items and providing careful anchors for each. The PANSS requires a clinician rater because considerable probing and clinical judgment are required. A semistructured interview guide is available. Reliability for each scale has been shown to be fairly high, with excellent internal consistency and interrater reliability. Validity also appears good based on correlation with other symptom severity measures and factor analytic validation of the subscales. The PANSS has become the standard tool for assessing clinical outcome in treatment studies of schizophrenia and other psychotic disorders and has been shown to be easy to administer reliably and sensitive to change with treatment. Its high reliability and good coverage of both positive and negative symptoms make it excellent for this purpose. It may also be useful for tracking severity in clinical practice, and its clear anchors make it easy to use in this setting.

Scale for the Assessment of Positive Symptoms (SAPS) and Scale for the Assessment of Negative Symptoms

(SANS). The SAPS and SANS (Tables 5.3-3 and 5.3-4) were designed to provide a detailed assessment of positive and negative symptoms of schizophrenia and may be used separately or in tandem. SAPS assesses hallucinations, delusions, bizarre behavior, and thought disorder, and SANS assesses affective flattening, poverty of speech, apathy, anhedonia, and inattentiveness. The SAPS and SANS are mainly used to monitor treatment effects in clinical research.

 **Table 5.3-3**
Scale for the Assessment of Positive Symptoms (SAPS)

	0 = None	1 = Questionable	2 = Mild	3 = Moderate	4 = Marked	5 = Severe
Hallucinations						
1	<i>Auditory hallucinations</i> The patient reports voices, noises, or other sounds that no one else hears.					0 1 2 3 4 5
2	<i>Voices commenting</i> The patient reports a voice which makes a running commentary on his [her] behavior or thoughts.					0 1 2 3 4 5
3	<i>Voices conversing</i> The patient reports hearing two or more voices conversing.					0 1 2 3 4 5
4	<i>Somatic or tactile hallucinations</i> The patient reports experiencing peculiar physical sensations in the body.					0 1 2 3 4 5
5	<i>Olfactory hallucinations</i> The patient reports experiencing unusual smells which no one else notices.					0 1 2 3 4 5
6	<i>Visual hallucinations</i> The patient sees shapes or people that are not actually present.					0 1 2 3 4 5
7	<i>Global rating of hallucinations</i> This rating should be based on the duration and severity of the hallucinations and their effects on the patient's life.					0 1 2 3 4 5
Delusions						
8	<i>Persecutory delusions</i> The patient believes he [she] is being conspired against or persecuted in some way.					0 1 2 3 4 5
9	<i>Delusions of jealousy</i> The patient believes his [her] spouse is having an affair with someone.					0 1 2 3 4 5
10	<i>Delusions of guilt or sin</i> The patient believes that he [she] has committed some terrible sin or done something unforgivable.					0 1 2 3 4 5
11	<i>Grandiose delusions</i> The patient believes he [she] has special powers or abilities.					0 1 2 3 4 5
12	<i>Religious delusions</i> The patient is preoccupied with false beliefs of a religious nature.					0 1 2 3 4 5
13	<i>Somatic delusions</i> The patient believes that somehow his [her] body is diseased, abnormal, or changed.					0 1 2 3 4 5
14	<i>Delusions of reference</i> The patient believes that insignificant remarks or events refer to him [her] or have some special meaning.					0 1 2 3 4 5
15	<i>Delusions of being controlled</i> The patient feels that his [her] feelings or actions are controlled by some outside force.					0 1 2 3 4 5
16	<i>Delusions of mind reading</i> The patient feels that people can read his [her] mind or know his [her] thoughts.					0 1 2 3 4 5
17	<i>Thought broadcasting</i> The patient believes that his [her] thoughts are broadcast so that he himself [she herself] or others can hear them.					0 1 2 3 4 5
18	<i>Thought insertion</i> The patient believes that thoughts that are not his [her] own have been inserted into his [her] mind.					0 1 2 3 4 5
19	<i>Thought withdrawal</i> The patient believes that thoughts have been taken away from his [her] mind.					0 1 2 3 4 5
20	<i>Global rating of delusions</i> This rating should be based on the duration and persistence of the delusions and their effect on the patient's life.					0 1 2 3 4 5
Bizarre Behavior						
21	<i>Clothing and appearance</i> The patient dresses in an unusual manner or does other strange things to alter his [her] appearance.					0 1 2 3 4 5
22	<i>Social and sexual behavior</i> The patient may do things considered inappropriate according to usual social norms (e.g., masturbating in public).					0 1 2 3 4 5
23	<i>Aggressive and agitated behavior</i> The patient may behave in an aggressive, agitated manner, often unpredictably.					0 1 2 3 4 5
24	<i>Repetitive or stereotyped behavior</i> The patient develops a set of repetitive actions or rituals that he [she] must perform over and over.					0 1 2 3 4 5
25	<i>Global rating of bizarre behavior</i> This rating should reflect the type of behavior and the extent to which it deviates from social norms.					0 1 2 3 4 5
Positive Formal Thought Disorder						
26	<i>Derailment</i> A pattern of speech in which ideas slip off track onto ideas obliquely related or unrelated.					0 1 2 3 4 5
27	<i>Tangentiality</i> Replying to a question in an oblique or irrelevant manner.					0 1 2 3 4 5
28	<i>Incoherence</i> A pattern of speech which is essentially incomprehensible at times.					0 1 2 3 4 5
29	<i>Illogicality</i> A pattern of speech in which conclusions are reached which do not follow logically.					0 1 2 3 4 5
30	<i>Circumstantiality</i> A pattern of speech which is very indirect and delayed in reaching its goal idea.					0 1 2 3 4 5
31	<i>Pressure of speech</i> The patient's speech is rapid and difficult to interrupt; the amount of speech produced is greater than that considered normal.					0 1 2 3 4 5
32	<i>Distractible speech</i> The patient is distracted by nearby stimuli which interrupt his [her] flow of speech.					0 1 2 3 4 5
33	<i>Clanging</i> A pattern of speech in which sounds rather than meaningful relationships govern word choice.					0 1 2 3 4 5
34	<i>Global rating of positive formal thought disorder</i> This rating should reflect the frequency of abnormality and degree to which it affects the patient's ability to communicate.					0 1 2 3 4 5
Inappropriate Affect						
35	<i>Inappropriate affect</i> The patient's affect is inappropriate or incongruous, not simply flat or blunted.					0 1 2 3 4 5

 **Table 5.3-4**
Scale for the Assessment of Negative Symptoms (SANS)

0 = None 1 = Questionable 2 = Mild 3 = Moderate 4 = Marked 5 = Severe

Affective Flattening or Blunting

- 1 *Unchanging facial expression* The patient's face appears wooden, changes less than expected as emotional content of discourse changes. 0 1 2 3 4 5
- 2 *Decreased spontaneous movements* The patient shows few or no spontaneous movements, does not shift position, move extremities, etc. 0 1 2 3 4 5
- 3 *Faucity of expressive gestures* The patient does not use hand gestures, body position, etc., as an aid to expressing his ideas. 0 1 2 3 4 5
- 4 *Poor eye contact* The patient avoids eye contact or "stares through" interviewer even when speaking. 0 1 2 3 4 5
- 5 *Affective nonresponsivity* The patient fails to smile or laugh when prompted. 0 1 2 3 4 5
- 6 *Lack of vocal inflections* The patient fails to show normal vocal emphasis patterns, is often monotonic. 0 1 2 3 4 5
- 7 *Global rating of affective flattening* This rating should focus on overall severity of symptoms, especially unresponsiveness, eye contact, facial expression, and vocal inflections. 0 1 2 3 4 5

Alogia

- 8 *Poverty of speech* The patient's replies to questions are restricted in amount tend to be brief, concrete, and unelaborated. 0 1 2 3 4 5
- 9 *Poverty of content of speech* The patient's replies are adequate in amount but tend to be vague, overconcrete, or overgeneralized, and convey little information. 0 1 2 3 4 5
- 10 *Blocking* The patient indicates, either spontaneously or with prompting, that his [her] train of thought was interrupted. 0 1 2 3 4 5
- 11 *Increased latency of response* The patient takes a long time to reply to questions; prompting indicates the patient is aware of the question. 0 1 2 3 4 5
- 12 *Global rating of alogia* The core features of alogia are poverty of speech and poverty of content. 0 1 2 3 4 5

Avolition-Apathy

- 13 *Grooming and hygiene* The patient's clothes may be sloppy or soiled, and he [she] may have greasy hair, body odor, etc. 0 1 2 3 4 5
- 14 *Impersistence at work or school* The patient has difficulty seeking or maintaining employment, completing school work, keeping house, etc. If an inpatient, cannot persist at ward activities, such as occupational therapy, playing cards, etc. 0 1 2 3 4 5
- 15 *Physical anergia* The patient tends to be physically inert. He [she] may sit for hours and does not initiate spontaneous activity. 0 1 2 3 4 5
- 16 *Global rating of avolition-apathy* Strong weight may be given to one or two prominent symptoms if particularly striking. 0 1 2 3 4 5

Anhedonia-Asociality

- 17 *Recreational interests and activities* The patient may have few or no interests. Both the quality and quantity of interests should be taken into account. 0 1 2 3 4 5
- 18 *Sexual activity* The patient may show a decrease in sexual interest and activity, or enjoyment when active. 0 1 2 3 4 5
- 19 *Ability to feel intimacy and closeness* The patient may display an inability to form close or intimate relationships, especially with the opposite sex and family. 0 1 2 3 4 5
- 20 *Relationships with friends and peers* The patient may have few or no friends and may prefer to spend all of his [her] time isolated. 0 1 2 3 4 5
- 21 *Global rating of anhedonia-asociality* This rating should reflect overall severity, taking into account the patient's age, family status, etc. 0 1 2 3 4 5

Attention

- 22 *Social inattentiveness* The patient appears uninvolved or unengaged. He [she] may seem spacey. 0 1 2 3 4 5
- 23 *Inattentiveness during mental status testing* Tests of "serial 7s" (at least five subtractions) and spelling *world* backward: Score: 2 = 1 error; 3 = 2 errors; 4 = 3 errors. 0 1 2 3 4 5
- 24 *Global rating of attention* This rating should assess the patient's overall concentration, clinically and on tests. 0 1 2 3 4 5

Mood Disorders

The domain of mood disorders includes both unipolar and bipolar disorder, and the instruments described here assess depression and mania. For mania, the issues are similar to those for psychotic disorders in that limited insight and agitation may hinder accurate symptom reporting, so clinician ratings including observational data are generally required. Rating depression, on the other hand, depends, to a substantial extent, on subjective assessment of mood states, so interviews and self-report instruments are both common. Because depression is common in the general population and involves significant morbidity and even mortality, screening instruments—especially those using a self-report format—are potentially quite useful in primary care and community settings.

Hamilton Rating Scale for Depression (HAM-D). The HAM-D was developed in the early 1960s to monitor the severity of major depression, with a focus on somatic symptomatology. The 17-item version is the most commonly used version, although versions with different numbers of items, including the 24-item version in Table 5.3-5, have been used in many studies as well. The 17-item version does not include some of the symptoms for depression in DSM-III and its successors, most notably the so-called reverse neurovegetative signs (increased sleep, increased appetite, and psychomotor retardation). The HAM-D was designed for clinician raters but has been used by trained lay administrators as well. Ratings are completed by the examiner based on the patient interview and observations. A structured interview guide has been developed to improve reliability. The ratings can be completed in 15 to 20 minutes. Reliability is good to excellent, particularly when the structured interview version is used. Validity appears good based on correlation with other depression symptom measures. The HAM-D has been used extensively to evaluate change in response to pharmacological and other interventions and, thus, offers the advantage of comparability across a broad range of treatment trials. It is more problematic in the elderly and the medically ill, in whom the presence of somatic symptoms may not be indicative of major depression.

 **Table 5.3-5**
Hamilton Rating Scale for Depression

For each item select the "cue" which best characterizes the patient.

- 1: Depressed mood (Sadness, hopeless, helpless, worthless)
 0 Absent
 1 These feeling states indicated only on questioning
 2 These feeling states spontaneously reported verbally
 3 Communicates feeling states nonverbally—i.e., through facial expression, posture, voice, and tendency to weep
 4 Patient reports VIRTUALLY ONLY these feeling states in his spontaneous verbal and nonverbal communication
- 2: Feelings of guilt
 0 Absent
 1 Self-reproach, feels he has let people down
 2 Ideas of guilt or rumination over past errors or sinful deeds
 3 Present illness is a punishment. Delusions of guilt.
 4 Hears accusatory or denunciatory voices and/or experiences threatening visual hallucinations
- 3: Suicide
 0 Absent
 1 Feels life is not worth living
 2 Wishes he were dead or any thoughts of possible death to self
 3 Suicide ideas or gesture
 4 Attempts at suicide (any serious attempt rates 4)
- 4: Insomnia early
 0 No difficulty falling asleep
 1 Complains of occasional difficulty falling asleep—i.e., more than ¼ hour
 2 Complains of nightly difficulty falling asleep
- 5: Insomnia middle
 0 No difficulty
 1 Patient complains of being restless and disturbed during the night
 2 Waking during the night—any getting out of bed rates 2 (except for purpose of voiding)
- 6: Insomnia late
 0 No difficulty
 1 Waking in early hours of the morning but goes back to sleep
 2 Unable to fall asleep again if gets out of bed
- 7: Work and activities
 0 No difficulty
 1 Thoughts and feelings of incapacity, fatigue, or weakness related to activities, work, or hobbies
 2 Loss of interest in activity, hobbies, or work—either directly reported by patient, or indirect in listlessness, indecision, and vacillation (feels he has to push self to work or activities)
 3 Decrease in actual time spent in activities or decrease in productivity. In hospital, rate 3 if patient does not spend at least 3 hours a day in activities (hospital job or hobbies) exclusive of ward chores
 4 Stopped working because of present illness. In hospital, rate 4 if patient engages in no activities except ward chores, or if patient fails to perform ward chores unassisted
- 8: Retardation (Slowness of thought and speech; impaired ability to concentrate; decreased motor activity)
 0 Normal speech and thought
 1 Slight retardation at interview
 2 Obvious retardation at interview
 3 Interview difficult
 4 Complete stupor

- 9: Agitation
 0 None
 1 "Playing with" hands, hair, etc.
 2 Hand-wringing, nail biting, hair pulling, biting of lips
- 10: Anxiety psychic
 0 No difficulty
 1 Subjective tension and irritability
 2 Worrying about minor matters
 3 Apprehensive attitude apparent in face or speech
 4 Fears expressed without questioning
- 11: Anxiety somatic
 0 Absent Physiological concomitants of anxiety, such as:
 1 Mild Gastrointestinal—dry mouth, wind, indigestion, diarrhea, cramps, belching
 2 Moderate Cardiovascular—palpitations, headaches
 3 Severe Respiratory—hyperventilation, sighing
 4 Incapacitating Urinary frequency
 Sweating
- 12: Somatic symptoms gastrointestinal
 0 None
 1 Loss of appetite but eating without staff encouragement. Heavy feelings in abdomen
 2 Difficulty eating without staff urging; requests or requires laxatives or medication for bowels or medication for G.I. symptoms
- 13: Somatic symptoms general
 0 None
 1 Heaviness in limbs, back or head. Backaches, headache, muscle aches. Loss of energy and fatigability
 2 Any clear-cut symptom rates 2
- 14: Genital symptoms
 0 Absent Symptoms such as:
 1 Mild Loss of libido
 2 Severe Menstrual disturbances
- 15: Hypochondriasis
 0 Not present
 1 Self-absorption (bodily)
 2 Preoccupation with health
 3 Frequent complaints, requests for help, etc.
 4 Hypochondriacal delusions
- 16: Loss of weight
 A: When rating by history
 0 No weight loss
 1 Probable weight loss associated with present illness
 2 Definite (according to patient) weight loss
 B: On weekly ratings by ward psychiatrist, when actual weight changes are measured
 0 Less than 1 lb weight loss in week
 1 Greater than 1 lb weight loss in week
 2 Greater than 2 lb weight loss in week
- 17: Insight
 0 Acknowledges being depressed and ill
 1 Acknowledges illness but attributes cause to bad food, climate, overwork, virus, need for rest, etc.
 2 Denies being ill at all
- 18: Diurnal variation

AM	PM		
0	0	Absent	If symptoms are worse in the morning or evening, note which it is and rate severity of variation
1	1	Mild	
2	2	Severe	

- 19: Depersonalization and derealization
 0 Absent
 1 Mild Such as:
 2 Moderate Feeling of unreality
 3 Severe Nihilistic ideas
 4 Incapacitating
- 20: Paranoid symptoms
 0 None
 1
 Suspiciousness
 2
 3 Ideas of reference
 4 Delusions of reference and persecution
- 21: Obsessional and compulsive symptoms
 0 Absent
 1 Mild
 2 Severe
- 22: Helplessness
 0 Not present
 1 Subjective feelings which are elicited only by inquiry
 2 Patient volunteers his helpless feelings
 3 Requires urging, guidance, and reassurance to accomplish ward chores or personal hygiene
 4 Requires physical assistance for dress, grooming, eating, bedside tasks, or personal hygiene
- 23: Hopelessness
 0 Not present
 1 Intermittently doubts that "things will improve" but can be reassured
 2 Consistently feels "hopeless" but accepts reassurances
 3 Expresses feelings of discouragement, despair, pessimism about future, which cannot be dispelled
 4 Spontaneously and inappropriately perseverates: "I'll never get well" or its equivalent
- 24: Worthlessness (Ranges from mild loss of esteem, feelings of inferiority, self-deprecation to delusional notions of worthlessness)
 0 Not present
 1 Indicates feelings of worthlessness (loss of self-esteem) only on questioning
 2 Spontaneously indicates feelings of worthlessness (loss of self-esteem)
 3 Different from 2 by degree. Patient volunteers that he is "no good," "inferior," etc.
 4 Delusional notions of worthlessness—i.e., "I am a heap of garbage" or its equivalent

(From Hamilton M. A rating scale for depression. *J Neurol Neurosurg Psychiatry*. 1960;23:56, with permission.)

Beck Depression Inventory (BDI). The BDI was developed in the early 1960s to rate depression severity, with a focus on behavioral and cognitive dimensions of depression. The current version, the Beck-II, has added more coverage of somatic symptoms and covers the most recent 2 weeks. Earlier versions are focused on the past week or even shorter intervals, which may be preferable for monitoring treatment response. The scale can be completed in 5 to 10 minutes. Internal consistency has been high in numerous studies. Test–retest reliability is not consistently high, but this may reflect changes in underlying symptoms. Validity is supported by correlation with other depression measures. The principal use of the BDI is as an outcome measure in clinical trials of interventions for major depression, including psychotherapeutic interventions. Because it is a self-report instrument, it is sometimes used to screen for major depression.

Anxiety Disorders

The anxiety disorders addressed by the measures below include panic disorder, generalized anxiety disorder, posttraumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD). When anxiety measures are examined, it is important to be aware that there have been significant changes over time in how anxiety disorders are defined. Both panic and OCD are relatively recently recognized, and the conceptualization of generalized anxiety disorder has shifted over time. Thus, older measures have somewhat less relevance for diagnostic purposes, although they may identify symptoms causing considerable distress. Whether reported during an interview or on a self-report rating scale, virtually all measures in this domain, like the measures of depression discussed above, depend on subjective descriptions of inner states.

Hamilton Anxiety Rating Scale (HAM-A). The HAM-A (Table 5.3-6) was developed in the late 1950s to assess anxiety symptoms, both somatic and cognitive. Because the conceptualization of anxiety has changed considerably, the HAM-A provides limited coverage of the "worry" required for a diagnosis of generalized anxiety disorder and does not include the episodic anxiety found in panic disorder. A score of 14 has been suggested as the threshold for clinically significant anxiety, but scores of 5 or less are typical in individuals in the community. The scale is designed to be administered by a clinician, and formal training or the use of a structured interview guide is required to achieve high reliability. A computer-administered version is also available. Reliability is fairly good based on internal consistency, interrater, and test–retest studies. However, given the lack of specific anchors, reliability should not be assumed to be high across different users in the absence of formal training. Validity appears good based on correlation with other anxiety scales but is limited by the relative lack of coverage of domains critical to the modern understanding of anxiety disorders. Even so, the HAM-A has been used extensively to monitor treatment response in clinical trials of generalized anxiety disorder and may also be useful for this purpose in clinical settings.

 **Table 5.3-6**
Hamilton Anxiety Rating Scale

Instructions: This checklist is to assist the physician or psychiatrist in evaluating each patient as to his degree of anxiety and pathological condition. Please fill in the appropriate rating:

NONE = 0	MILD = 1	MODERATE = 2	SEVERE = 3	SEVERE, GROSSLY DISABLING = 4
Item	Rating			
Anxious Tension	Worries, anticipation of the worst, fearful anticipation, irritability			
Fears	Feelings of tension, fatigability, startle response, moved to tears easily, trembling, feelings of restlessness, inability to relax			
Insomnia	Of dark, of strangers, of being left alone, of animals, of traffic, of crowds			
Intellectual (cognitive)	Difficulty in falling asleep, broken sleep, unsatisfying sleep and fatigue on waking, dreams, nightmares, night-terrors			
Depressed mood	Difficulty in concentration, poor memory			
Somatic (muscular)	Loss of interest, lack of pleasure in hobbies, depression, early waking, diurnal swing			
Somatic (sensory)	Pains and aches, twitching, stiffness, myoclonic jerks, grinding of teeth, unsteady voice, increased muscular tone			
Cardiovascular symptoms	Tinnitus, blurring of vision, hot and cold flushes, feelings of weakness, picking sensation			
Respiratory symptoms	Tachycardia, palpitations, pain in chest, throbbing of vessels, fainting feelings, missing beat			
Gastrointestinal symptoms	Pressure or constriction in chest, choking feelings, sighing, dyspnea			
Genitourinary symptoms	Difficulty in swallowing, wind, abdominal pain, burning sensations, abdominal fullness, nausea, vomiting, borborygmi, looseness of bowels, loss of weight, constipation			
Autonomic symptoms	Frequency of micturition, urgency of micturition, amenorrhea, menorrhagia, development of frigidity, premature ejaculation, loss of libido, impotence			
Behavior at interview	Dry mouth, flushing, pallor, tendency to sweat, giddiness, tension headache, raising of hair			
	Fidgeting, restlessness or pacing, tremor of hands, furrowed brow, strained face, sighing or rapid respiration, facial pallor, swallowing, belching, brisk tendon jerks, dilated pupils, exophthalmos			
ADDITIONAL COMMENTS				
Investigator's signature:				

(From Hamilton M. The assessment of anxiety states by rating. *Br J Psychiatry*. 1959;32:50, with permission.)

Panic Disorder Severity Scale (PDSS). The PDSS was developed in the 1990s as a brief rating scale for the severity of panic disorder. It was based on the Yale-Brown Obsessive-Compulsive Scale and has seven items, each of which is rated on an item-specific, 5-point Likert scale. The seven items address frequency of attacks, distress associated with attacks, anticipatory anxiety, phobic avoidance, and impairment. Reliability is excellent based on interrater studies, but, in keeping with the small number of items and multiple dimensions, internal consistency is limited. Validity is supported by correlations with other anxiety measures, both at the total and item levels; lack of correlation with the HAM-D; and, more recently, by brain imaging studies. Growing experience with the PDSS suggests that it is sensitive to change with treatment and is useful as a change measure in clinical trials or other outcome studies for panic disorder, as well as for monitoring panic disorder in clinical practice.

Clinician-Administered PTSD Scale (CAPS). The CAPS includes 17 items required to make the diagnosis, covering all four criteria: (1) the event itself, (2) re-experiencing of the event, (3) avoidance, and (4) increased arousal. The diagnosis requires evidence of a traumatic event, one symptom of re-experiencing, three of avoidance, and two of arousal (typically, an item is counted if frequency is rated at least 1 and intensity is at least 2). The items can also be used to generate a total PTSD severity score obtained by summing the frequency and intensity scales for each item. The CAPS also includes several global rating scales for the impact of PTSD symptomatology on social and occupational functioning, for general severity, for recent changes, and for the validity of the patient's report. The CAPS must be administered by a trained clinician and requires 45 to 60 minutes to complete, with follow-up examinations somewhat briefer. It has demonstrated reliability and validity in multiple settings and multiple languages, although it has had more limited testing in the setting of sexual and criminal assault. It performs well in the research setting for diagnosis and severity assessment but is generally too lengthy for use in clinical practice.

Yale-Brown Obsessive-Compulsive Scale (YBOCS). The YBOCS was developed in the late 1980s to measure the severity of symptoms in OCD. It has ten items rated based on a semistructured interview. The first five items concern obsessions: the amount of time that they consume, the degree to which they interfere with normal functioning, the distress that they cause, the patient's attempts to resist them, and the patient's ability to control them. The remaining five items ask parallel questions about compulsions. The semistructured interview and ratings can be completed in 15 minutes or less. A self-administered version has recently been developed and can be completed in 10 to 15 minutes. Computerized and telephone use have also been found to provide acceptable ratings. Reliability studies of the YBOCS show good internal consistency, interrater reliability, and test-retest reliability over a 1-week interval. Validity appears good, although data are fairly limited in this developing field. The YBOCS has become the standard instrument for assessing OCD severity and is used in virtually every drug trial. It may also be used clinically to monitor treatment response.

Substance Use Disorders

Substance use disorders include abuse and dependence on both alcohol and drugs. These disorders, particularly those involving alcohol, are common and debilitating in the general population, so screening instruments are particularly helpful. Because these behaviors are socially undesirable, underreporting of symptoms is a significant problem; thus, the validity of all substance use measures is limited by the honesty of the patient. Validation against drug tests or other measures is of great value, particularly when working with patients who have known substance abuse.

CAGE. The CAGE was developed in the mid-1970s to serve as a very brief screen for significant alcohol problems in a variety of settings, which could then be followed up by clinical inquiry. CAGE is an acronym for the four questions that comprise the instrument: (1) Have you ever felt you should Cut down on your drinking? (2) Have people Annoyed you by criticizing your drinking? (3) Have you ever felt bad or Guilty about your drinking? (4) Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (Eye-opener)? Each "yes" answer is scored as 1, and these are summed to generate a total score. Scores of 1 or more warrant follow up, and scores of 2 or more strongly suggest significant alcohol problems. The instrument can be administered in a minute or less, either orally or on paper. Reliability has not been formally assessed. Validity has been assessed against a clinical diagnosis of alcohol abuse or dependence, and

these four questions perform surprisingly well. Using a threshold score of 1, the CAGE achieves excellent sensitivity and fair to good specificity. A threshold of 2 provides still greater specificity but at the cost of a drop in sensitivity. The CAGE performs well as an extremely brief screening instrument for use in primary care or in psychiatric practice focused on problems unrelated to alcohol. However, it has limited ability to pick up early indicators of problem drinking that might be the focus of preventive efforts.

Addiction Severity Index (ASI). The ASI was developed in the early 1980s to serve as a quantitative measure of symptoms and functional impairment due to alcohol or drug disorders. It covers demographics, alcohol use, drug use, psychiatric status, medical status, employment, legal status, and family and social issues. Frequency, duration, and severity are assessed. It includes both subjective and objective items reported by the patient and observations made by the interviewer.

Eating Disorders

Eating disorders include anorexia nervosa, bulimia, and binge-eating disorder. A wide variety of instruments, particularly self-report scales, are available. Because of the secrecy that may surround dieting, bingeing, purging, and other symptoms, validation against other indicators (e.g., body weight for anorexia or dental examination for bulimia) may be very helpful. Such validation is particularly critical for patients with anorexia, who may lack insight into their difficulties.

Eating Disorders Examination (EDE). The EDE was developed in 1987 as the first interviewer-based comprehensive assessment of eating disorders, including diagnosis, severity, and an assessment of subthreshold symptoms. A self-report version (the EDE-Q) as well as an interview for children have since been developed. The EDE focuses on symptoms during the preceding 4 weeks, although longer-term questions are included to assess diagnostic criteria for eating disorders. Each item on the EDE has a required probe with suggested follow-up questions to judge severity, frequency, or both, which are then rated on a 7-point Likert scale. For the self-report version, subjects are asked to make similar ratings of frequency or severity. The instrument provides both global severity ratings and ratings on four subscales: restraint, eating concern, weight concern, and shape concern. The interview, which must be administered by a trained clinician, requires 30 to 60 minutes to complete, whereas the self-report version can be completed more quickly. Reliability and validity data for both the EDE and EDE-Q are excellent, although the EDE-Q may have greater sensitivity for binge-eating disorder. The EDE performs well in both the diagnosis and the detailed assessment of eating disorders in the research context. It also has the sensitivity to change as is required for use in clinical trials or monitoring of individual therapy. Even in the research setting, however, the EDE is fairly lengthy for repeated use, and the EDE-Q may be preferable for some purposes. Although the EDE is too lengthy for routine clinical practice, the EDE or EDE-Q might be helpful in providing a comprehensive assessment of a patient with a suspected eating disorder, particularly during an evaluation visit or on entry into an inpatient facility.

Bulimia Test-Revised (BULIT-R). The BULIT-R was developed in the mid-1980s to provide both a categorical and a continuous assessment of bulimia. Patients with bulimia typically score above 110, whereas patients without disordered eating typically score below 60. The instrument can be completed in approximately 10 minutes. The BULIT-R shows high reliability based on studies of internal consistency and test-retest reliability in multiple studies. Validity is supported by high correlations with other bulimia assessments. The recommended cutoff of 104 suggested to identify probable cases of bulimia shows high sensitivity and specificity for a clinical diagnosis of bulimia nervosa. With cutoffs between 98 and 104, the BULIT-R has been used successfully to screen for cases of bulimia nervosa. As with any screening procedure, follow-up by clinical examination is indicated for individuals scoring positive; clinical follow-up is particularly critical because the BULIT-R does not distinguish clearly between different types of eating disorders. The BULIT-R may also be useful in clinical and research practice to track symptoms over time or in response to treatment, although more detailed measures of the frequency and severity of bingeing and purging may be preferable in research settings.

Cognitive Disorders

A wide variety of measures of dementia are available. Most involve cognitive testing and provide objective, quantifiable data. However, scores vary by educational level in subjects without dementia, so these instruments tend to be most useful when the patient's own baseline scores are known. Other measures focus on functional status, which can be assessed based on a comparison with a description of the subject's baseline function; these types of measures generally require a knowledgeable informant and, thus, may be more cumbersome to administer but tend to be less subject to educational biases. A third type of measure focuses on the associated behavioral symptoms that are frequently seen in demented patients.

Mini-Mental State Examination (MMSE). The MMSE is a 30-point cognitive test developed in the mid-1970s to provide a bedside assessment of a broad array of cognitive function, including orientation, attention, memory, construction, and language. It can be administered in less than 10 minutes by a busy doctor or a technician and scored rapidly by hand. The MMSE has been extensively studied and shows excellent reliability when raters refer to consistent scoring rules. Validity appears good based on correlations with a wide variety of more comprehensive measures of mental functioning and clinicopathological correlations.

Since its development in 1975, the MMSE was widely distributed in textbooks, pocket guides, and on web sites and has been used at the bedside. In 2001 the authors granted a worldwide exclusive license to Psychological Assessment Resources (PAR) to publish, distribute, and manage all intellectual property rights to the test. A licensed version of the MMSE must now be purchased from PAR per test. The MMSE form is gradually disappearing from textbooks, web sites, and clinical tool kits.

In an article in the *New England Journal of Medicine* (2011;365:2447-2449) John C. Newman and Robin Feldman concluded: "The restrictions on the MMSE's use present clinicians with difficult choices: increase practice costs and complexity, risk copyright infringement, or sacrifice 30 years of practical experience and validation to adopt new cognitive assessment tools."

Neuropsychiatric Inventory (NPI). The NPI was developed in the mid-1990s to assess a wide range of behavioral symptoms that are often seen in Alzheimer's disease and other dementing disorders. The current version rates 12 areas: delusions, hallucinations, dysphoria, anxiety, agitation/aggression, euphoria, disinhibition, irritability/lability, apathy, aberrant motor behavior, nocturnal disturbances, appetite and eating. The standard NPI is an interview with a caregiver or other informant that can be performed by a clinician or trained lay interviewer and requires 15 to 20 minutes to complete. There is also a nursing home interview version, the NPI-NH, and a self-report questionnaire, the NPI-Q. For each area, the NPI asks whether a symptom is present and, if so, assesses frequency, severity, and associated caregiver distress. The instrument has demonstrated reliability and validity and is useful to screen for problem behaviors in both clinical and research settings. Because of the detailed frequency and severity ratings, it is also useful to monitor change with treatment.

Scored General Intelligence Test (SGIT). This test was developed and validated by N. D. C. Lewis at the New York State Psychiatric Institute in the 1930s. It is one of the few tests that attempts to measure general intelligence that can be administered by the clinician during the psychiatric interview. A decline in general intelligence will be seen in cognitive disorders, and the SGIT can alert the clinician to begin a workup for disease states that interfere with cognition. This test deserves more widespread use (Table 5.3-7).

Table 5.3-7
Scored General Intelligence Test (SGIT)

Indications: When a cognitive disorder is suspected because of apparent intellectual defects, impairment in the ability to make generalizations, the ability to maintain a trend of thought, or to show good judgment, a scored test can be of value.

Directions: Ask the following questions as part of the mental status examination. A conversational manner should be used and the questions may be adapted to cultural differences.

Scoring: If the patient obtains a score of 25 or under (out of a maximum of 40), it is indicative of a cognitive problem and further examination should follow.

Questions: There are 13 questions that follow.

1. What are houses made of? (Any material you can think of)..... 1-4
One point for each item, up to four.
2. What is sand used for? 1, 2, or 4
Four points for manufacture of glass. Two points for mixing with concrete, road building, or other constructive use. One point for play or sandboxes. Credit not cumulative.
3. If the flag floats to the south, from what direction is the wind? 3
Three points for north, no partial credits. It is permissible to say: "Which way is the wind coming from?"
4. Tell me the names of some fish..... 1-4
One point for each, up to four. If the subject stops with one, encourage him or her to go on.
5. At what time of day is your shadow shortest? 3
Noon, three points. If correct response is suspected of being a guess, inquire why.
6. Give the names of some large cities. 1-4
One point for each, up to four. When any state is named as a city, no credit, that is, New York unless specified as New York City. No credit for hometown, except when it is an outstanding city.
7. Why does the moon look larger than the stars? 2, 3, or 4
Make it clear that the question refers to any particular star, and give assurance that the moon is actually smaller than any star.
Encourage the subject to guess. Two points for "Moon is lower down." Three points for nearer or closer. Four points for generalized statement that nearer objects look larger than more distant objects.
8. What metal is attracted by a magnet? 2 or 4
Four points for iron, two for steel.
9. If your shadow points to the northeast, where is the sun? 4
Four points for southwest, no partial credits.
10. How many stripes are in the American flag? 2
Thirteen, two points. A subject who responds 50 may be permitted to correct the mistake. Explain, if necessary, that the white stripes are included as well as the red ones.
11. What does ice become when it melts? 1
Water, one point.
12. How many minutes in an hour? 1
60, one point.
13. Why is it colder at night than in the daytime? 1-2
Two points for "sun goes down," or any recognition of direct rays of sun as source of heat. Question may be reversed: "What makes it warmer in the daytime than at night?" Only one point for answer to reverse question.

This test was developed and validated by N. D. C. Lewis, MD.

Personality Disorders and Personality Traits

Personality may be conceptualized categorically as personality disorders or dimensionally as personality traits, which may be viewed as normal or pathological. The focus here is on personality disorders and the maladaptive traits generally viewed as their milder forms. There are ten personality disorders that are divided into three clusters. Patients tend not to fall neatly into DSM personality categories; instead, most patients who meet the criteria for one personality disorder also meet the criteria for at least one other, particularly within the same cluster. This and other limitations in the validity of the constructs themselves make it difficult to achieve validity in personality measures. Personality measures include both interviews and self-report instruments. Self-report measures are appealing in that they require less time and may appear less threatening to the patient. However, they tend to overdiagnose personality disorders. Because many of the symptoms suggesting personality problems are socially undesirable and because patients' insight tends to be limited, clinician-administered instruments, which allow for probing and patient observation, may provide more accurate data.

Personality Disorder Questionnaire (PDQ). The PDQ was developed in the late 1980s as a simple self-report questionnaire designed to provide categorical and dimensional assessment of personality disorders. The PDQ includes 85 yes-no items designed primarily to assess the diagnostic criteria for personality disorders. Within the 85 items, two validity scales are embedded to identify underreporting, lying, and inattention. There is also a brief clinician-administered Clinical Significance Scale to address the impact of any personality disorder identified by the self-report PDQ. The PDQ can provide categorical diagnoses, a scaled score for each, or an overall index of personality disturbance based on the sum of all of the diagnostic criteria. Overall scores range from 0 to 79; normal controls tend to score below 20, personality disordered patients generally score above 30, and psychotherapy outpatients without such disorders tend to score in the 20 to 30 range.

Childhood Disorders

A wide variety of instruments are available to assess mental disorders in children. Despite this rich array of instruments, however, the evaluation of children remains difficult for several reasons. First, the child psychiatric nosology is at an earlier stage of development, and construct validity is often problematic. Second, because children change markedly with age, it is virtually impossible to design a measure that covers children of all ages. Lastly, because children, particularly young children, have limited ability to report their symptoms, other informants are necessary. This often creates problems because there are frequent disagreements among child, parent, and teacher reports of symptoms, and the optimal way to combine information is unclear.

Child Behavior Checklist (CBCL). The CBCL is a family of self-rated instruments that survey a broad range of difficulties

encountered in children from preschool through adolescence. One version of the CBCL is designed for completion by parents of children between 4 and 18 years of age. Another version is available for parents of children between 2 and 3 years of age. The Youth Self-Report is completed by children between 11 and 18 years of age, and the Teacher Report Form is completed by teachers of school-age children. The scale includes not only problem behaviors, but also academic and social strengths. Each version includes approximately 100 items scored on a 3-point Likert scale. Scoring can be done by hand or computer, and normative data are available for each of the three subscales: problem behaviors, academic functioning, and adaptive behaviors. A computerized version is also available. The CBCL does not generate diagnoses but, instead, suggests cutoff scores for problems in the “clinical range.” Parent, teacher, and child versions all show high reliability on the problem subscale, but the three informants frequently do not agree with one another. The CBCL may be useful in clinical settings as an adjunct to clinical evaluation, as it provides a good overall view of symptomatology and may also be used to track change over time. It is used frequently for similar purposes in research involving children and, thus, can be compared with clinical experience. The instrument does not, however, provide diagnostic information, and its length limits its efficiency for tracking purposes.

Diagnostic Interview Schedule for Children (DISC). The current DISC, the DISC-IV, covers a broad range of DSM diagnoses, both current and lifetime. It has nearly 3,000 questions but is structured with a series of stem questions that serve as gateways to each diagnostic area, with the remainder of each section skipped if the subject answers no. Subjects who enter each section have very few skips, so complete diagnostic and symptom scale information can be obtained. Child, parent, and teacher versions are available. Computer programs are available to implement diagnostic criteria and generate severity scales based on each version or to combine parent and child information. A typical DISC interview may take more than 1 hour for a child, plus an additional hour for a parent. However, because of the stem question structure, the actual time varies widely with the number of symptoms endorsed. The DISC was designed for lay interviewers. It is fairly complicated to administer, and formal training programs are highly recommended. Reliability of the DISC is only fair to good and generally better for the combined child and parent interview. Validity judged against a clinical interview by a child psychiatrist is also fair to good—better for some diagnoses and better for the combined interview. The DISC is well tolerated by parents and children and can be used to supplement a clinical interview to ensure comprehensive diagnostic coverage. Because of its inflexibility, some clinicians find it uncomfortable to use, and its length makes it less than optimal for use in clinical practice. However, it is used frequently in a variety of research settings.

Conners Rating Scales. The Conners Rating Scales are a family of instruments designed to measure a range of childhood and adolescent psychopathology but are most commonly used in the assessment of attention-deficit/hyperactivity disorder (ADHD). The main uses of the Conners Rating Scales are in screening for ADHD in school or clinic populations and following changes in symptom severity over time; sensitivity to change in response to specific therapies has been demonstrated for most versions of the Conners Rating Scales. There are teacher, parent, and self-report (for adolescents) versions and both short (as few as ten items) and long (as many as 80 items, with multiple subscales) forms. Reliability data are excellent for the Conners Rating Scales. However, the teacher and parent versions tend to show poor agreement. Validity data suggest that the Conners Rating Scales are excellent at discriminating between ADHD patients and normal controls.

Autism Diagnostic Interview–Revised (ADI-R). The Autism Diagnostic Interview (ADI) was developed in 1989 as a clinical assessment of autism and related disorders. The ADI-R was developed in 2003 with an aim to provide a shorter instrument with better ability to discriminate autism from other developmental disorders. The instrument has 93 items, is designed for individuals with a mental age greater than 18 months, and covers three broad areas, consistent with the diagnostic criteria for autism: language and communication; reciprocal social interactions; and restricted, repetitive, and stereotyped behaviors and interests. There are three versions: one for lifetime diagnosis, one for current diagnosis, and one for patients under age 4 focused on an initial diagnosis. It must be administered by a clinician trained in its use and takes about 90 minutes to complete. When clinicians are properly trained, it has good to excellent reliability and validity but performs poorly in the setting of severe developmental disabilities. It is generally intended for the research setting when a thorough assessment of autism is required but may have use in clinical practice as well.

5.4 Clinical Neuropsychology and Intellectual Assessment of Adults

Clinical neuropsychology is a specialty in psychology that examines the relationship between behavior and brain functioning in the realms of cognitive, motor, sensory, and emotional functioning. The clinical neuropsychologist integrates the medical and psychosocial history with the reported complaints and the pattern of performance on neuropsychological procedures in order to determine whether results are consistent with a particular area of brain damage or a particular diagnosis.

NEUROANATOMICAL CORRELATES

The early history of neuropsychology was driven in large part by the goal of linking behavioral deficits to specific neuroanatomical areas of dysfunction or damage. Although this early assessment method helped to validate neuropsychological tests that are commonly used today, the localizing function of neuropsychological assessment is now considered less important in light of recent advances in neuroimaging techniques. Increasing knowledge in the neurosciences has also led to a more sophisticated view of brain–behavior relationships, in which complex cognitive, perceptual, and motor activities are controlled by neural circuits rather than single structures within the brain. An understanding of these brain–behavior relationships is particularly helpful when evaluating patients with focal damage. It is crucial to ensure that the neuropsychological evaluation adequately assesses relevant behavior that is likely to be associated with that area and its

interconnecting pathways.

Hemispheric Dominance and Intrahemispheric Localization

Many functions are mediated by both the right and left hemispheres. However, important qualitative differences between the two hemispheres can be demonstrated in the presence of lateralized brain injury. Various cognitive skills that have been linked to the left or right hemisphere in right-handed individuals are listed in Table 5.4-1. Although language is the most obvious function that is largely controlled by the left hemisphere, especially among right-handed individuals, the left hemisphere is also generally considered to be dominant for limb praxis (i.e., performing complex movements, such as brushing teeth, to command, or imitation), and it has been associated with the cluster of deficits identified as Gerstmann syndrome (i.e., finger agnosia, dyscalculia, dysgraphia, and right-left disorientation). In contrast, the right hemisphere is thought to play a more important role in controlling visuospatial abilities and hemispatial attention, which are associated with the clinical presentations of constructional apraxia and neglect, respectively.

 **Table 5.4-1**
Selected Neuropsychological Deficits Associated with Left or Right Hemisphere Damage

Left Hemisphere	Right Hemisphere
Aphasia	Visuospatial deficits
Right-left disorientation	Impaired visual perception
Finger agnosia	Neglect
Dysgraphia (aphasic)	Dysgraphia (spatial, neglect)
Dyscalculia (number alexia)	Dyscalculia (spatial)
Constructional apraxia (details)	Constructional apraxia (Gestalt)
Limb apraxia	Dressing apraxia Anosognosia

(From Sadock BJ, Sadock VA, Ruiz P, Kaplan & Sadock's *Comprehensive Textbook of Psychiatry*, 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Although lateralized deficits such as these are typically characterized in terms of *damage* to the right or left hemisphere, it is important to keep in mind that the patient's performance can also be characterized in terms of *preserved* brain functions. In other words, it is the remaining intact brain tissue that drives many behavioral responses following injury to the brain and not only the absence of critical brain tissue.

Language Disorders. Appreciation for the special role of the left hemisphere in the control of language functions in most right-handed individuals has been validated in many studies. These include the results of sodium amytal testing in epilepsy surgery patients, as well as the incidence of aphasia following unilateral stroke to the left versus right hemisphere. Although it is rare for right-handed individuals to be right hemisphere dominant for language, it does occur in about 1 percent of the cases. Hemispheric dominance for language in left-handed individuals is less predictable. About two-thirds of left-handed individuals are actually left hemisphere dominant for language, while about 20 percent each are right hemisphere dominant or bilaterally dominant.

A number of classification systems have been developed over the years for describing various patterns of language breakdown. A common method takes into account the presence or absence of three key features: (1) fluency, (2) comprehension, and (3) repetition (i.e., intact ability to repeat verbally presented words or phrases).

BROCA'S APHASIA. *Broca's aphasia* (also called *nonfluent* or *expressive aphasia*) has traditionally been characterized by nonfluent speech but intact auditory comprehension and somewhat impaired repetition. It has long been thought to be associated with damage to Broca's area (i.e., left inferior frontal convolution) or Brodmann area 44 (Fig. 5.4-1). However, more recent neuroimaging data in stroke patients have shown that the full syndrome of Broca's aphasia, including *agrammatism* (telegraphic speech), is found only in the presence of more extensive damage, which encompasses the suprasylvian area from Broca's area to the posterior extent of the sylvian fissure.

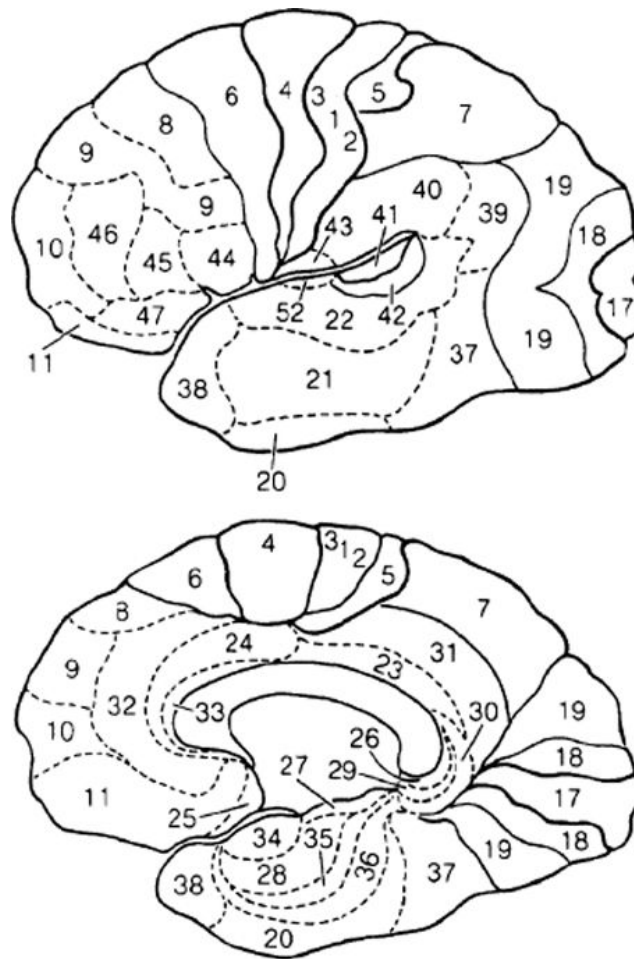

FIGURE 5.4-1

Brodman's areas of the human cortex, showing convex surface (*top*) and medial surface (*bottom*). (From Elliott HC. *Textbook of Neuroanatomy*. Philadelphia: Lippincott; 1969, with permission.)

WERNICKE'S APHASIA. *Wernicke's aphasia* (also called *fluent* or *receptive aphasia*) is characterized by fluent speech, impaired comprehension, and somewhat impaired repetition. It has been associated with damage to Wernicke's area in the region of the superior temporal gyrus. The impaired ability to comprehend language directly affects the individual's ability to self-monitor language output and may be related to a breakdown of the syntactic structure of language. Unlike patients with Broca's aphasia, who are usually painfully and obviously aware of their communication difficulty, patients with Wernicke's aphasia are typically not aware of their communication problems, because Wernicke's area is critical for comprehending their own speech as well as the language of others. This lack of insight is similar to the condition of *anosognosia*, in which patients fail to appreciate their own deficits, and presents a particularly frustrating condition for many family members and caregivers.

CONDUCTION APHASIA. Patients with *conduction aphasia* demonstrate relatively intact auditory comprehension and spontaneous speech, due to the preservation of Wernicke's and Broca's areas. However, the ability to repeat words and phrases is specifically impaired and has traditionally been attributed to damage to the arcuate fasciculus, which interconnects Wernicke's and Broca's areas. This type of aphasia is much more subtle and tends to have less negative impact on daily functioning.

GLOBAL APHASIA. Another common classification, *global aphasia*, is characterized by impairment in all three dimensions of fluency, comprehension, and repetition due to damage to the core language areas on the lateral surface of the left hemisphere. In reality many aphasic patients cannot be neatly classified within a specific system because the pattern of deficits does not exactly fit clear descriptive categories. In fact, detailed language assessment of most aphasic patients typically demonstrates deficits in all three areas, although the degree of deficit among the three areas varies.

Limb Apraxia. Limb apraxia and other cognitive-motor skills deficits are more commonly seen with left than with right hemisphere damage. However, Kathleen Haaland and Deborah Harrington reviewed data showing that the difference in the incidence of limb apraxia after left or right hemisphere damage is not as great as with language, suggesting that left hemisphere dominance for disorders of complex movement is not as strong as that for language. Although limb apraxia has not traditionally been considered to be of substantial functional importance, recent data reviewed by Leslie Rothi and Kenneth Heilman also suggest that limb apraxia significantly affects rehabilitation outcome. *Conceptual apraxia* might result in using the wrong object to perform a movement, such as attempting to use a toothbrush to eat. Finally, sequencing errors and ideational errors can lead to disrupted activities, such as trying to light a candle before striking the match.

Arithmetic. Arithmetic skills can be impaired after either left or right hemisphere damage. Left hemisphere damage, especially of the parietal lobe, produces difficulty in reading and appreciating the symbolic meaning of numbers (*number dyslexia*). Left hemisphere damage also can be associated with impaired conceptual understanding of the arithmetic problem (*anarithmetria*). In contrast, the deficits in arithmetic computation that can accompany right hemisphere damage are more likely to be observed in written problems. These emerge as problems with the spatial aspects of arithmetic, such as errors resulting from hemispatial visual neglect, poor alignment of columns, or visual misperceptions and rotations that can result in confusion of signs for addition and multiplication.

Spatial Disorders. Right hemisphere damage in right-handed individuals is frequently associated with deficits in visuospatial skills. Common assessment techniques include drawings and constructional or spatial assembly tasks.

VISUOSPATIAL IMPAIRMENT. Distinctive qualitative errors in constructing block designs and in drawing a complex geometric configuration (e.g., Rey-Osterrieth Complex Figure test) can be seen with either right or left hemisphere damage. In the presence of lateralized damage to the

right hemisphere, impaired performance often reflects the patient's inability to appreciate the "Gestalt" or global features of a design. In the example shown in Figure 5.4-2, this is seen in the patient's failure to maintain the 2×2 matrix of blocks and instead converting this matrix into a column of four blocks. In contrast, damage to the left hemisphere commonly results in inaccurate reproduction of internal details of the design, including improper orientation of individual blocks, but the 2×2 matrix (i.e., the Gestalt) is more likely to be preserved. Many neuropsychologists emphasize that a neuropsychological understanding of the impairment depends not just on a set of test scores but also on a qualitative description of the type of error. This often allows the impairment to be linked to a specific neuroanatomical region as well as enabling a better understanding of the mechanisms of the deficit for rehabilitation purposes. This qualitative focus on the type of error is similar to the *pathognomonic* approach that is often used by behavioral neurologists.

FIGURE 5.4-2

Examples of block design construction seen in a right hemisphere stroke patient and a left hemisphere stroke patient. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

In another example, damage to the right hemisphere tends to be associated with decreased appreciation of global features of visual stimuli, while left hemisphere damage tends to be associated with decreased analysis of local features and detail. This notion is illustrated in Figure 5.4-3, where a patient with left hemisphere damage focuses on the larger Gestalt of the triangle or letter M with no regard for the internal characters that actually make up the designs. In contrast, the "local" approach of a patient with right hemisphere damage emphasizes the internal details (small rectangles or letter Z) without appreciation of the Gestalt that is formed by the internal details. This example also illustrates the important point that behavioral responses (including errors) are driven as much by preserved regions of intact brain functioning as by the loss of other regions of brain functioning.

FIGURE 5.4-3

Global local target stimuli with drawings from memory by a patient with right hemisphere cerebrovascular accident (CVA) and by a patient with left hemisphere CVA. (From Robertson LC, Lamb MR. Neuropsychological contributions to theories of part/whole organization. *Cognit Psychol*. 1991;23:325, with permission from Elsevier Science.)

NEGLECT. *Neglect syndromes* are characterized by failure to detect visual or tactile stimuli or to move the limb in the contralateral hemisphere. They are most commonly associated with right hemisphere damage in the parietal region, but damage to other areas within the cerebral cortex and subcortical areas can also produce this problem. Although neglect syndromes have a similar incidence and may co-occur with visual field cuts or somatosensory deficits, the neglect syndrome is distinct and not explained by any motor or sensory problems that may be present. Visual neglect can be assessed with line cancellation and line bisection tasks, in which the paper is placed at the patient's midline, and the patient is asked to either cross out all of the lines on the page or to bisect the single line presented. The method of double simultaneous stimulation or visual extinction is another standard procedure for demonstrating the deficit. Neglect syndromes can have devastating functional effects on safety and the ability to live independently and should be taken into account as a standard consideration in the evaluation process.

DRESSING APRAXIA. The syndrome of *dressing apraxia* tends to arise in association with spatial deficits following right hemisphere damage. The resulting difficulty in coordinating the spatial and tactual demands of dressing can be seen in the patient's difficulty in identifying the top or bottom of a garment, as well as right-left confusion in inserting his or her limbs into the garment. As a result, dressing time can be painfully protracted, and the patient may actually present with a greater level of functional dependence than might otherwise be expected from assessment of simple motor or spatial skills alone.

Memory Disorders. Memory complaints constitute the most common referral to neuropsychology. Thorough neuropsychological examination of memory considers the modality (e.g., verbal vs. spatial) in which the material is presented, as well as presentation formats that systematically assess different aspects of the information-processing and storage system that forms the basis for memory. Accumulated

research indicates that specialized processing of verbal and spatial memory material tends to be differentially mediated by the left and right hemispheres, respectively. In addition to interhemispheric differences in functional localization, specific memory problems can be associated with breakdown at any stage in the information-processing model of memory. These stages include (1) registration of the material through *attention*, (2) initial processing and encoding of the material within *short-term memory*, also known as *working memory*, (3) consolidation and storage of material in *long-term memory*, and (4) *retrieval* processes, in which material moves from long-term memory storage back into consciousness. A great advantage of neuropsychological assessment is that these various types of memory problems can be readily isolated and described in the course of the examination procedures. Once identified, the specific nature of the deficit can then have important implications for diagnosis, treatment, and prognosis.

ENCODING. The initial encoding of new material can be influenced by a variety of factors, including deficits in attention, language, and spatial processing abilities. It is usually measured by immediate recall of newly learned information (e.g., narrative stories or designs) or by demonstrating the ability to learn new material that has been presented across multiple “learning trials” (e.g., word lists). Attention itself is a relatively fragile cognitive function that can be affected by many factors, including neurologically based disorders (e.g., head injury or acute confusional state) and psychiatric disorders (e.g., depression or anxiety), so it is a crucial aspect of a proper assessment of memory.

STORAGE AND RETRIEVAL. Deficits in recall can be associated with impaired storage of information, or it can be due to impaired retrieval, in which case the material is still present but not readily accessible. The best way of differentiating these problems is to examine *recognition memory*, in which a patient is typically asked to choose from a set of multiple-choice alternatives or to discriminate target words from *false-positive* foils. If the patient demonstrates accurate recognition but poor recall, then the problem most likely lies in poor retrieval. However, if recognition is impaired, then the problem is more likely to be related to impaired storage of new information. This distinction is important because the functions of retrieval and storage are subserved by different neuroanatomical structures. Impaired storage is more often associated with dysfunction of the medial temporal lobe–diencephalic systems, whereas impaired retrieval can be associated with a variety of structures, including the frontal lobes.

Executive Function. The prefrontal lobes and their interconnections to the rest of the brain are known to play an important role in *executive functions*, which are essential in planning and organizing, self-monitoring, and controlling complex problem-solving responses. Damage to the frontal lobes also has been associated with significant personality changes. This was historically exemplified by the famous 19th-century case of Phineas Gage, who became irresponsible, socially inappropriate, and unable to carry out plans after a tamping iron was blown through his frontal lobes. As conceptualized by Muriel Lezak, the executive functions include volition (i.e., formulation of a goal, motivation to achieve the goal, and awareness of one’s own ability to achieve the goal), planning, purposive action (response selection and initiation, maintenance, switching, and stopping), and execution, which involves self-monitoring and self-correction as well as control of the spatiotemporal aspects of the response. Hemispheric differences in the control of executive functions by the frontal lobes have not been as well documented as in the parietal and temporal lobes.

Motor Skills. The neuropsychological evaluation commonly includes formal tests of motor skills, such as measures of finger tapping speed, grip strength, and fine motor dexterity. These tests, which have demonstrated validity and reliability, are useful for assessing lateralized motor impairment and have implications for functioning in daily life as well as vocational planning.

GENERAL REFERRAL ISSUES

Referents turn to neuropsychology for many reasons that include differential diagnosis, baseline measurement, and treatment planning, as well as opinions regarding causality and decisional capacity. Because many referents have limited experience and knowledge of the scope of neuropsychology, it is both reasonable and important for the neuropsychologist to take an active role in refining the specific questions that are asked and providing realistic information about the limitations of the consultation.

Level of Functioning

A common referral issue involves documentation of level of functioning for a variety of purposes, including assessment of change or capacity to make decisions, especially in the presence of diagnoses such as dementia, stroke, and head injury.

Differential Diagnosis

Like any other diagnostic procedure, the results of a neuropsychological examination must be interpreted in light of all available information, including the history and any associated medical factors that are documented or reported for the individual. Many neurological and psychiatric disorders have similar clusters of symptoms in common, with complaints of concentration or memory problems being among the most frequently reported problems.

Age- or Stress-Related Cognitive Change. Many middle-aged and older adults have concerns about everyday concentration and memory failures, and with heightened public awareness about conditions such as Alzheimer’s disease, an increasing number of these individuals seek evaluations for these concerns. Neuropsychological testing provides a detailed, objective picture of different aspects of memory and attention, which can be helpful in reassuring healthy persons about their abilities. It also provides an opportunity for assessing undetected mood or anxiety disorders that may be reflected in cognitive concerns and for offering suggestions about mnemonic strategies that can sharpen everyday function.

A 77-year-old, left-handed man with a high school education was referred for neuropsychological assessment by his primary care physician after the patient mentioned a recent episode of getting turned around while driving. Results of neuropsychological assessment indicated variable performance on tests of attention and concentration. His performance was excellent on tests of memory, language, and executive problem-solving abilities, but visual-spatial and constructional abilities were moderately impaired.

Mild Traumatic Brain Injury. Traumatic brain injury (TBI) is usually classified as mild, moderate, or severe. However, the vast majority of TBI cases referred for neuropsychological consultation involve mild TBI. A significant proportion of persons who have suffered a mild TBI complain of problems with attention and inefficient information processing, memory, and mood, in addition to headache or other forms of pain, for many months after the injury. Neuropsychological testing plays a crucial role in determining the extent of objective cognitive deficit and examining the possible role of psychological factors in perpetuating cognitive problems.

The neuropsychologist should bear in mind that many patients with mild TBI are involved in litigation, which can complicate the neuropsychologist’s ability to identify the causes for impairment. Although outright malingering is probably relatively infrequent, subtle presentations of chronic illness behavior should be a prominent consideration when potential legal settlements or disability benefits are in question. This is a particularly important factor in the case of mild head injury, when subjective complaints may be disproportionate to the objectively reported circumstances of the injury, especially because most follow-up studies of mild head injury indicate return to

neuropsychological baseline with no objective evidence of significant cognitive sequelae after 3 to 12 months following injury.

Poststroke Syndromes. After the acute phase of recovery from stroke, patients may be left with residual deficits, which can affect memory, language, sensory/motor skills, reasoning, or mood. Neuropsychological testing can help to identify areas of strength, which can be used in planning additional rehabilitation and can provide feedback on the functional implications of residual deficits for work or complex activities of daily living. Assessment of functional skills can also be helpful to a psychiatrist who is managing mood and behavioral symptoms or dealing with family caregivers.

Detecting Early Dementia. Conditions that particularly warrant neuropsychological assessment for early detection and potential treatment include HIV-related cognitive deficits and normal pressure hydrocephalus. When concerns about a person's memory functioning are expressed by relatives instead of the patient, there is a higher probability of a neurological basis for the functional problems. Neuropsychological testing, combined with a good clinical history and other medical screening tests, can be highly effective in distinguishing early dementia from the mild changes in memory and executive functioning that can be seen with normal aging. Neuropsychological evaluation is particularly helpful in documenting cognitive deterioration and differentiating among different forms of dementia. An additional incentive for early diagnosis of dementia now lies in the fact that a portion of patients with early dementia may be candidates for memory-enhancing therapies (e.g., acetylcholinesterase inhibitors), and testing can provide an objective means of monitoring treatment efficacy.

Distinguishing Dementia and Depression. A substantial minority of patients with severe depression exhibit serious generalized impairment of cognitive functioning. In addition to problems with attention and slowing of thought and action, there may be significant forgetfulness and problems with reasoning. By examining the pattern of cognitive impairment, neuropsychological testing can help to identify a dementia syndrome that is associated with depression, usually known as *pseudodementia*. Mixed presentations are also common, in which symptoms of depression coexist with various forms of cognitive decline and exacerbate the effects of cognitive dysfunction beyond what would be expected from the neurological impairment alone. Neuropsychological testing in this case can be very helpful by providing a baseline for measuring the effect of antidepressant or other therapy in alleviating cognitive and mood symptoms.

A 75-year-old man with a Ph.D. in the social sciences sought neuropsychological re-examination for ongoing memory complaints, stating that "several of my friends have Alzheimer's." In an initial examination 1 year prior, he had performed in the expect range (above average) for most procedures, despite variable performance on measures of attention and concentration. Results of the follow-up examination again clustered in the expected above average range with variable performance on measures of attention. On list learning tests of memory, his initial learning of a word list was lower than expected, but delayed retention of the material was above average, with excellent discrimination of target items on a recognition subtest. He also endorsed a large number of symptoms of depression on a self-report inventory.

Change in Functioning Over Time

Because many neurological diagnoses carry clear expectations regarding normal rates of recovery and decline over time, it is frequently important to re-examine a given patient with follow-up neuropsychological assessment after 6 months to a year. For example, it might be important to monitor declines in independent functioning that could be associated with a progressive dementia or to identify improvement following a stroke or tumor resection. Follow-up examinations also provide an opportunity to objectively examine complaints of long-standing or worsening cognitive sequelae following mild head trauma, even though the current literature indicates that the greatest proportion of recovery of function is likely to occur over the initial 6 months to 1 year postinjury. Although continuing subtle signs of recovery can continue after that period, failure to improve following the injury—or worsening of complaints—would suggest the possibility of contributing psychological factors or the existence of a preexisting or coexisting condition, such as substance abuse, dementia, or outright malingering.

Assessment of Decision-Making Capacity

Neuropsychologists are often asked to assist in determining an individual's capacity to make decisions or to manage personal affairs. Neuropsychological testing can be useful in these cases by documenting areas of significant impairment and by identifying areas of strength and well-preserved skills. Opinions about decision-making capacity are seldom based on test findings alone and usually rely heavily on information gleaned from clinical interview, collateral interviews with family or caregivers, and direct observations (e.g., in-home assessment) of everyday function. In fact, appraisal of an individual's level of insight and capacity to appreciate his or her own limitations is typically the single most important aspect of the assessment. Standards for decision-making capacity are generally defined by state statutes, and, of course, the ultimate determination of competence rests in the authority of the presiding judge. However, the neuropsychologist or other health care professional can play a significant role in shaping the judge's ruling by providing a professional opinion that is supported by compelling behavioral data that have strong face validity. As a general rule of thumb, consideration of decision-making capacity is usually best approached in the narrowest possible sense so as to infringe as little as possible on the individual's freedom to represent his or her own interests. Therefore, consultation requests for assessment of decision-making capacity should identify specific areas of decision making and behavior that are of concern. Frequent concerns having to do with decision-making capacity involve the areas of (1) financial and legal matters, (2) health care and medical treatment, and (3) ability to live independently. Some capacity issues involve higher standards, such as ability to drive, ability to work, or practice in a given profession (e.g., air traffic controller, surgeon, or financial advisor). In such cases, it is particularly important for the neuropsychologist to rely on normative expectations that are appropriate for the type of activity, as well as the patient's demographics.

Forensic Evaluation

Neuropsychological evaluation of individuals in matters pertaining to criminal or civil law usually requires specialized knowledge beyond expertise in neuropsychology. Neuropsychologists are frequently called upon as experts in matters involving head injury, especially in the case of mild head injury associated with a motor vehicle accident. As a distinct subspecialty, this area of practice requires integration of knowledge of statutes, laws, precedents, and legal procedures as well as expertise in identifying and describing the impact of an injury or event on cognitive, emotional, and behavioral functioning.

APPROACHES TO NEUROPSYCHOLOGICAL ASSESSMENT

The neuropsychological examination systematically assesses functioning in the realms of attention and concentration, memory, language, spatial skills, sensory and motor abilities, as well as executive functioning and emotional status. Because deficits in cognitive performance can only be interpreted in comparison to a person's long-standing or *premorbid level of functioning*, overall intellectual abilities are typically

examined in order to measure the current level of overall functioning and to identify any changes in intellectual functioning. Psychological contributions to performance are also considered with regard to personality and coping style, emotional lability, presence of thought disorder, developmental history, and significant past or current stressors. The expertise of the neuropsychologist lies in integrating findings that are obtained from many diverse sources, including the history, clinical presentation, and several dozen discrete performance scores that make up the neuropsychological data.

Battery Approach

The battery approach, exemplified by the Halstead-Reitan Neuropsychological Test Battery (HRNTB) or the Neuropsychological Assessment Battery (NAB), grew directly out of the psychometric tradition in psychology. This approach typically includes a large variety of tests that measure most cognitive domains as well as sensory and motor skills. Traditionally, all parts of the test battery are administered regardless of the patient's presenting problem, although the NAB has a screening exam that covers all appropriate domains. The battery approach has the advantage of identifying problems that the patient might not have mentioned and that the medical history may not necessarily predict. However, it has the disadvantage of being very time-consuming (i.e., 6- to 8-hour examination for the HRNTB).

Hypothesis Testing Approach

The qualitative hypothesis testing approach is historically best exemplified by the work of Alexander Luria and more recently developed as the Boston Process Approach by Edith Kaplan and her colleagues. It is characterized by detailed evaluation of areas of functioning that are related to the patient's complaints and predicted areas of impairment, with relatively less emphasis on aspects of functioning that are less likely to be impaired. The hypothesis testing approach has been particularly helpful in illuminating the differential roles of the two hemispheres, as discussed above. This approach has the advantage of efficiently honing in on areas of impairment and producing a detailed description of the deficits from a cognitive processing standpoint, but it has the shortcoming of potentially overlooking unexpected areas of deficits.

Screening Approaches

Many practitioners have moved away from strict battery or hypothesis testing approaches since the 1990s and developed more flexible and efficient screening approaches. In this model, the neuropsychologist utilizes a core set of screening procedures as a first step in determining whether a diagnosis can be made with less information or whether additional testing is necessary in order to identify more subtle problems. Therefore, a screening protocol that efficiently assesses the major areas of neuropsychological functioning may or may not be followed by more detailed testing in selected areas that might provide better understanding of the reasons for the deficits demonstrated on the screening evaluation.

Mental Status Examinations

In some cases, usually involving very acute or severe cognitive impairment, it is simply not feasible to administer extensive cognitive examination procedures, so the neuropsychologist might appropriately rely on bedside mental status examination or very brief cognitive screening procedures to address the referral issues. However, research has shown that, even with brief screening procedures, the systematic use of a structured examination format can greatly increase the accuracy of detecting cognitive impairment.

One of the most widely used screening instruments for documenting gross changes in mental status is the Mini-Mental State Examination (MMSE). However, it is important to note that the MMSE does have distinct limitations. Other than serial seven counting, the MMSE does not really assess executive functions, which are often impaired in dementing patients. In addition, the MMSE is likely to underestimate the prevalence of cognitive deficits in well-educated older persons with early Alzheimer's disease or in younger adults with focal brain injury, but it is more likely to overestimate the presence of cognitive deficits in persons with little education. Therefore, cutoff scores should be adjusted for age and education before concluding that impairment is present. Although mental status examinations can be very useful in screening for gross signs of cognitive impairment, they do not provide a sufficient foundation for diagnosing specific etiologies of cognitive impairment, and they are not interchangeable with neuropsychological testing.

DOMAINS OF FORMAL NEUROPSYCHOLOGICAL ASSESSMENT

The past decade has seen a virtual explosion in the growth of more sophisticated and better standardized tests and procedures for neuropsychological evaluation. A list of examples of common neuropsychological tests and techniques is provided in [Table 5.4-2](#).

Table 5.4-2
Selected Tests of Neuropsychological Functioning

Area of Function	Comment
INTELLECTUAL FUNCTIONING	
Wechsler Intelligence Scales	Age-stratified normative references; appropriate for adults up to age 89, adolescents, and young children
Shipley Scale	Scale Brief (20-minute) paper-and-pencil measure of multiple-choice vocabulary and open-ended verbal abstraction
ATTENTION AND CONCENTRATION	
Digit Span	Auditory-verbal measure of simple span of attention (<i>digits forward</i>) and cognitive manipulation of increasingly longer strings of digits (<i>digits backward</i>)
Visual Memory Span	Visual-spatial measure of ability to reproduce a spatial sequence in forward and reverse order
Paced Auditory Serial Addition Test (PASAT)	Requires double tracking to add pairs of digits at increasing rates; particularly sensitive to subtle simultaneous processing deficits, especially in head injury
Digit Vigilance Test	Timed measure of speed and accuracy in cancelling a specific digit on a page of random digits; directly examines an individual's tendency to sacrifice either speed or accuracy in favor of the other.
MEMORY	
Wechsler Memory Scale III	Comprehensive set of subtests measuring attention and encoding, retrieval, and recognition of various types of verbal and visual material with both immediate recall and delayed retention; excellent age-stratified normative comparisons for adults up to age 89 with intellectual data for direct comparison
California Verbal Learning Test II	Documents encoding, recognition, and both immediate and 30-minute recall; affords examination of possible learning strategies as well as susceptibility to semantic interference with alternate and short forms available
Fuld Object Memory Evaluation	Selective reminding format requires patient to identify objects tactually, then assesses consistency of retrieval and storage as well as ability to benefit from cues; normative reference group is designed for use with older individuals
Benton Visual Retention Test	Assesses memory for ten geometric designs after 10-second exposures; requires graphomotor response
Brief Visuospatial Memory Test—Revised	Serial learning approach used to assess recall and recognition memory for an array of six geometric figures; six alternate forms
LANGUAGE	
Boston Diagnostic Aphasia Examination	Comprehensive assessment of expressive and receptive language functions
Boston Naming Test—Revised	Documents word finding difficulty in a visual confrontation format
Verbal Fluency	Measures ability to fluently generate words within semantic categories (e.g., animals) or phonetic categories (e.g., words beginning with "S")
Token Test	Systematically assesses comprehension of complex commands using standard token stimuli that vary in size, shape, and color

VISUOSPATIAL-CONSTRUCTIONAL	
Judgment of Line Orientation	Ability to judge angles of lines on a page presented in a match-to-sample format
Facial Recognition	Assesses matching and discrimination of unfamiliar faces
Clock Drawing	Useful screening technique is sensitive to organization and planning as well as constructional ability
Rey-Osterrieth Complex Figure Test	Ability to draw and later recall a complex geometric configuration; sensitive visual memory as well as executive deficits in development of strategies and planning
MOTOR	
Finger Tapping	Standard measure of simple motor speed; particularly useful for documenting lateralized motor impairment
Grooved Pegboard	Ability to rapidly place notched pegs in slotted holes; measures fine finger dexterity as well as eye-hand coordination
Grip Strength	Standard measure of lateralizing differences in strength
EXECUTIVE FUNCTIONS	
Wisconsin Card Sorting Test	Measure of problem-solving efficiency is particularly sensitive to executive deficits of perseveration and impaired ability to flexibly generate alternative strategies in response to feedback
Category Test	This measure of problem-solving ability also examines ability to benefit from feedback while flexibly generating alternative response strategies; regarded as one of the most sensitive measures of general brain dysfunction in the Halstead-Reitan Battery
Trail-Making Test	Requires rapid and efficient integration of attention, visual scanning, and cognitive sequencing
Delis-Kaplan Executive Function System (D-KEFS)	Battery of measures that are sensitive to executive functions
PSYCHOLOGICAL FACTORS	
Beck Depression Inventory	Brief (5 to 10 minutes) self-report measure that is sensitive to symptoms of depression; best for screening depression in adults up to late middle age, who can be expected to frankly report symptoms; available in standard (21 four-choice items) or short (13-item) form
Geriatric Depression Scale	30-item self-report screen for symptoms of depression; the yes-no format is less cognitively demanding than other scales
Minnesota Multiphasic Personality Inventory 2	This psychometrically developed self-report instrument remains highly useful for documenting quantitative levels of self-reported symptoms that can be objectively compared with known populations; drawbacks include administration time (567 true-false questions, requires about 1 to 1.5 hours or more) for frail individuals, and the emphasis on pathological features for persons who are generally psychologically healthy; advantages include well-developed validity scales and availability of many symptom-specific subscales that have been identified over the years

(From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Interview

The clinical interview provides the single best opportunity for identifying the patient's concerns and questions, eliciting a direct description of current complaints from the patient, and understanding the context of the patient's history and current circumstances. Although the patient typically serves as the primary interview source, it is important to seek corroborating information for the patient's account from interviews with caregivers or family members as well as thorough review of relevant records, such as medical and mental health treatment, educational, and employment experiences.

Intellectual Functioning

Assessment of intellectual functioning serves as the cornerstone of the neuropsychological examination. The Wechsler Intelligence Scales have represented the traditional gold standard in intellectual assessment for many years, based on carefully developed normative standards. The scope and variety of subtests on which the summary IQ values are based also provide useful benchmarks against which to compare performance on other tests of specific abilities. The latest revision of this instrument, the Wechsler Adult Intelligence Scale III (WAIS-III), offers the additional advantage of greatly extended age norms (ages 16 to 89) that are directly related to normative performances on the Wechsler Memory Scale III (WMS-III). The Wechsler Intelligence Scales utilize a broad set of complex verbal and visuospatial tasks that have traditionally been summarized as a verbal IQ, a performance IQ, and full-scale IQ. In the context of a neuropsychological examination, the patient's performance across the procedures provides useful information regarding long-standing abilities as well as current functioning. Most neuropsychologists recognize that the summary IQ values provide only a ballpark range for characterizing an individual's general level of functioning. Therefore, it is usually more appropriate and meaningful to characterize an individual's intellectual functioning in terms of the range of functioning (e.g., borderline, low average, average, high average, or superior) that is represented by the IQ value rather than the specific value itself.

Careful examination of the individual's performance across the various verbal and performance subtests can provide information regarding the patient's pattern of strengths and weaknesses as well as the degree to which these performance characteristics are consistent with the history and performance on other aspects of the neuropsychological examination. Tests of long-standing knowledge, such as for vocabulary or general information, provide a basis for estimating an individual's long-standing (or premorbid) level of intellectual abilities, which in turn can help to gauge the degree to which an individual may have deteriorated.

The verbal IQ and performance IQ (VIQ and PIQ) have historically been reported to be associated with left and right hemisphere functioning, respectively. However, more recent research indicates that, in addition to language and spatial skills, the subtests of the Wechsler Intelligence Scales reflect other contributions such as speed, sustained concentration, and novel experience. Therefore, experienced neuropsychologists do not simply assume that a discrepancy between VIQ and PIQ is due to unilateral hemispheric damage. Important clues to the nature of the contributing problem can often be gleaned by considering the pattern of performance across other aspects of the examination and by carefully analyzing the types of errors that are observed.

Attention

Attention underlies performance in virtually all other areas of functioning and should always be considered a potential contributor to impairment on any tests that require sustained concentration and vigilance or rapid integration of new information. Measures of attention and concentration have traditionally been included in the Wechsler Intelligence and Wechsler Memory Scales in order to assess orientation and “freedom from distractibility.” These procedures also provide a useful basis for “previewing” the individual’s ability to comprehend, process information, and otherwise engage in the assessment process. *Digit span* requires patients to repeat increasingly longer strings of digits as a way of assessing ability to process relatively simple information, while *digit span backward* reflects more complex simultaneous processing and cognitive manipulation demands or working memory.

Memory

Complaints of memory problems constitute one of the most common reasons for referral to neuropsychology. As described above, the neuropsychologist utilizes an information-processing approach to assess memory problems that might involve difficulty with encoding, retrieval, or storage of new information. The WMS-III is the latest revision of a widely used battery of subtests that utilizes several measures of attention, memory, and new learning ability.

Language

Assessment of language examines both expressive abilities and comprehension. However, most neuropsychologists screen for language impairment rather than administer an extensive formal language assessment battery, such as the Boston Diagnostic Aphasia Examination. Expressive language is commonly assessed by measures of *verbal fluency*, which require the patient to rapidly generate words within semantic (e.g., names of animals) and phonetic categories (e.g., words beginning with specified letters of the alphabet).

Visuospatial Functions

Complex visuospatial abilities can be assessed through procedures that were developed in Arthur Benton’s laboratory, such as *facial recognition* and *judgment of line orientation*. Measures of visual constructional ability examine the person’s ability to draw spatial designs or assemble two- or three-dimensional figures (see Fig. 5.4-3). In addition to the significant visuospatial component, these tasks reflect contributions of executive planning and organizational abilities. More impaired individuals can be asked to copy simple geometric forms, such as a Greek cross or intersecting pentagons, in order to examine visuospatial abilities that are less influenced by planning and organization.

The widely used technique of *clock drawing* provides a surprisingly sensitive measure of planning and organization, especially for older individuals who are at risk for dementia. Although problems involving poor organization, perseveration, and possible neglect are obvious in the drawing that is illustrated in Figure 5.4-4, more subtle difficulties can also be detected, especially when a patient’s performance is evaluated in light of premorbid expectations.

FIGURE 5.4-4

Clock drawing by a patient with vascular dementia, showing poor planning and organization, perseveration, and possible neglect. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock’s Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Sensory and Motor Functions

Double simultaneous stimulation in the visual, tactile, and auditory modalities is a standard component of the HRNTB and can be useful for assessing the integrity of basic sensory functions as well as neglect if deficits are present on one side only on the bilateral simultaneous trials and not when stimulation is unilateral. *Grip strength* and rapid *finger tapping* are commonly used measures of motor strength and speed that are sensitive to lateralized brain dysfunction.

Executive Functions

One of the most important aspects of the neuropsychological examination lies in the assessment of higher *executive* functions, which play an important role in the planning and initiation of independent activities, self-monitoring of performance, inhibition of inappropriate responses, switching between tasks, and planning and control of complex motor and problem-solving responses. Although the prefrontal lobes have long been regarded as an important component in mediating these functions, more recent developments in the neurosciences have also led to an increased appreciation for the essential role that is played by extensive cerebral interconnections between subcortical and cortical regions of the brain.

Psychological Factors

A key component of any neuropsychological examination involves consideration of the degree to which long-standing personality or other psychological factors (including current stressors) might contribute to the patient's presentation. Common techniques for assessing personality and psychological factors include the Minnesota Multiphasic Personality Inventory 2 (MMPI-2) and paper and pencil techniques, such as the Beck Depression Inventory II.

Assessment of Effort and Motivation

Because the results of neuropsychological examinations may eventually be introduced as evidence in litigation or other forensic proceedings or be used for determining disability compensation, it is important for the neuropsychologist to address any possible concerns about effort and motivation as a routine matter. Several instruments have been developed recently that directly assess a patient's level of effort and motivation to perform at his or her best. Normative research indicates that patients with histories of bona fide brain injury or even dementia perform close to perfect levels on many such instruments, so poor performance suggests poor effort or tendencies to exaggerate symptoms. Many other indicators of effort are based on the pattern of an individual's performance on standard procedures in a neuropsychological examination.

A 32-year-old woman with 13 years' education was seen for disability evaluation, claiming current "trouble remembering things." Her account of personal history was vague, and she "forgot" information, such as her own birth date and mother's maiden name. Response latencies were extremely long, even for highly familiar information (e.g., count from 1 to 20), she could not repeat more than three digits forward consistently, and on a word list learning procedure, she was not able to correctly recognize more items (only five) than she could freely recall (also five). Despite otherwise fluent language, she was only able to generate five examples of animals in 1 minute. When asked to recall 15 items on a procedure (Rey's Memory Test) that is presented as a challenging task, but in reality is fairly simple, her performance demonstrated exaggerated errors of commission (Fig. 5.4-5). The evaluation concluded that current levels of cognitive functioning could not be conclusively established, due to overt symptoms exaggeration.

FIGURE 5.4-5

Rey's Memory Test with example of a response that is typical of exaggerated "memory" problems. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

THERAPEUTIC DISCUSSION OF RESULTS

A key component of the neuropsychological examination process is found in the opportunity to discuss results of the examination with the patient and family or other caregivers. This meeting can represent a powerful therapeutic opportunity to educate and clarify individual and relationship issues, which can impact the identified patient's functioning. If the patient's active cooperation in the initial examination has been appropriately enlisted, then the patient will be prepared to invest value and confidence in the findings of the examination. At the time of the results discussion, it is useful to review the goals of the examination with the patient and supportive family or caregivers and to clarify the expectations of those who are present. Typically, these sessions will include information about the patient's diagnosis, with emphasis on the natural course and prognosis as well as compensation and coping strategies for the patient and family. Given the impact of chronic neurological disease on the family system as well as the patient, explicit discussion of these issues is critical in maximizing adjustment to brain injury. It is equally important to relate the impact of the results to the patient's current living circumstances, future goals, and course of adjustment. It is not unusual for strong emotions and underlying tensions within family relationships to come to light in the context of honest discussion, so the results discussion can represent an important therapeutic opportunity to model effective communication and problem-solving techniques.

▲ 5.5 Personality Assessment: Adults and Children

Personality is defined as an individual's enduring and pervasive motivations, emotions, interpersonal styles, attitudes, and traits. Personality assessment is the systematic measurement of these personality characteristics. Personality tests measure such difficult-to-define concepts as depression, anger, and anxiety. Even more challenging personality concepts such as somatization, ability to delay gratification, or suicide potential can be quantified by the means of personality assessment. Personality assessment can be of utmost importance in the scientific study of psychology and psychiatry.

PURPOSES OF PSYCHOLOGICAL TESTING

Personality testing can be an expensive undertaking. A considerable amount of time is required to administer, score, and interpret psychological test results. Personality testing should not be routinely obtained from all psychiatric patients. Personality testing can be helpful with selective patients from both a clinical and a cost-benefit analysis perspective.

Assisting in Differential Diagnosis

Psychiatric diagnosis can be a difficult and, at times, confusing exercise. However, knowing a patient's diagnosis is essential to treatment, as a proper diagnosis can assist in understanding the etiology of the presenting psychiatric problem and the prognosis of the disorder.

A 49-year-old man had abruptly resigned his position as an accountant and decided he was going to start an oil exploration business. He had never worked in the oil business and knew nothing about the profession. The patient had received a revelation from an unknown entity through an auditory hallucination. This voice told him he would become quite wealthy in the business if he would simply follow the directions given to him. Around this time, the patient had a marked change in personality. Although his grooming was formally very neat and appropriate, he became disheveled. He began sleeping about 3 hours a night. He became somewhat agitated and talked loudly to those around him.

The differential diagnosis in this case includes schizophrenia and bipolar disorder. Psychological testing might be helpful in assisting in this differential diagnosis, as well as in formulation of a treatment plan.

Aiding in Psychotherapy

Psychological tests can be useful in psychotherapy. The usefulness of these tests can be even more important for short-term, problem-centered therapy, where understanding the patient and his or her problem must be accomplished quickly. Psychological assessment can be used in pretreatment planning, assessing progress once therapy begins, and in evaluating the effectiveness of therapy. Patients need to have objective information about themselves at the time of therapy if they are to go about changing themselves productively. Personality tests, particularly objective tests, allow patients to compare themselves to objective norms and evaluate the extent and magnitude of their problem. Testing also can reveal areas of the patient's life that may be problematic but for which the patient may not have a full appreciation. Information about patients' willingness to reveal information about themselves can also be helpful. Psychological tests may reveal considerable information concerning the patient's inner life, feelings, and images, which may make therapy progress faster. Psychological testing can provide baseline information at the beginning of therapy, and repeat testing can then be used to assess change that occurred during the course of therapy.

Providing Narrow-Band Assessment

Narrow-band personality tests measure a single personality characteristic or a few related characteristics. *Broad-bank personality tests*, on the other hand, are designed to measure a wide spectrum of personality characteristics. A psychiatrist may need answers to specific questions, such as those that arise when assessing the degree of clinical depression, measuring the intensity of the state or trait anxiety, or, possibly, quantifying the amount of a patient's anger. Such quantification can be helpful in measuring severity or in providing a baseline for future assessment.

PSYCHOMETRIC PROPERTIES OF PERSONALITY ASSESSMENT INSTRUMENTS

The quality of personality tests varies widely. On the one hand, there are well-constructed, empirically validated instruments, and, on the other hand, there are "psychological tests" that one can find in the Sunday supplement of the newspaper or on the Internet. Evaluating the usefulness of particular psychological instruments can be challenging, even to the well informed.

Normative Sample

To construct a personality test, a representative sample of subjects (normative sample) should be administered the test to establish expected performance. Basic issues, such as the size and representativeness of the sample used to construct the test, must be evaluated. To illustrate this point, the Minnesota Multiphasic Personality Inventory 2 (MMPI-2), a well-constructed instrument, initially tested approximately 2,900 subjects. However, approximately 300 subjects were eliminated because of test invalidity or incompleteness of needed information.

Test Characteristics

To be useful, any psychological test must be completed, in its entirety, by the intended test taker. If the questions are offensive or are difficult to understand, then the individual taking the test may not complete all items. These omissions can create problems, especially when normative tables are used to interpret results.

Validity Issues

Perhaps the most important characteristic in evaluating the scientific merit of a given personality test is the validity of the instrument. Does the test measure what it purports to measure? If a test is designed to measure depression, does it indeed measure depression? Although validity may seem like a simple issue to address, it can become complex, especially when attempting to measure such characteristics as self-esteem, assertiveness, hostility, or self-control.

Face Validity. *Face validity* refers to the content of the test items themselves. In other words, do the items appear to measure what they purport to measure? One problem with face validity is that professionals differ in their subjective appraisal of individual items.

Criteria and Construct Validity. Although face validity refers to the degree that test items appear on the surface to measure what the instrument, as a whole, purports to measure, *criterion validity* uses data outside the test itself to measure validity. For example, if a test

were designed to measure hypochondria, one would expect that a patient with high scores would have more visits to the physician's office, complain of more physical symptoms, and use prescribed and over-the-counter medications more extensively.

Concurrent and Predictive Validity. To determine test *concurrent validity*, external measures are obtained at the same time that the test is given to the sample of subjects. Thus, the concurrent validity of the test reveals that, at a given point of time, high scorers on a test may be more likely than low scorers on a test to manifest the behavior reflected in the criteria (e.g., more physician visits or more medication for a hypochondriac patient). Occasionally, however, a test developer is interested in predicting future events. The *discriminant validity* of a test tells whether the test is able to discriminate between known groups of patients at a given time. Is a measure of depression able to statistically discriminate among mild, moderate, and severe major depression disorder?

Factor Validity. Factor validity utilizes a multivariate statistical technique known as *factor analysis* to determine if certain major groups of items on a given test empirically cluster together. For example, on a personality test measuring depression, do items concerning vegetative symptoms tend to covary together?

Reliability

Reliability refers to the degree that a test measures what it purports to measure, consistently. The key word here is *consistently*. There are several means of checking reliability, including test–retest reliability, internal consistency reliability, and parallel form reliability.

Test–Retest Reliability. *Test–retest reliability* is obtained by simply administering the same test on two occasions to a group of subjects and statistically correlating the results. To be useful, the correlation coefficient should be at least 0.80 if the two tests were administered within 2 weeks of each other and if the trait in question is stable.

Internal Consistency Reliability. Another approach to determine *internal consistency reliability* is to divide a given test into two equal parts and statistically correlate the two halves for the test with each other. This technique determines the *split-half reliability* of a test. The first half of the test should be highly correlated with the second half of the test if the test is consistently measuring what it purportedly measures. Alternatively, the odd-numbered items could be correlated with the even-numbered items (*odd–even consistent reliability*). A reliability coefficient of 0.80 to 0.85 is needed to demonstrate usefulness in most circumstances. However, the higher the reliability as measured by the correlation coefficient, the better the test instrument.

Parallel Form Reliability. Sometimes, two separate forms of the same test are needed. For example, if the process of taking a test at one point in time would by itself influence a patient's score the second time he or she took the same test, then parallel forms of the tests are needed. *Parallel forms* of a test measure the same construct but use different items to do so. To ensure that the test does, in fact, measure the same construct, the correlation coefficient between the two parallel forms of the same test is computed. Such parallel form reliability should be at least 0.90 or higher.

Use of Standard Error of Measurement to Assess Reliability. Another way to assess the usefulness of a given test is to examine the test's standard error of measurement (SEM), which should be included in the test's manual. The SEM is a single statistic that is used to estimate what the score of a given patient would be on the test if the patient took the same test again within a short period of time.

ADULT PSYCHOLOGICAL TESTS

Objective Personality Tests

Objective personality tests are rather straightforward in approach. Patients are usually asked specific and standard questions in a structured written or oral format. Each patient is typically asked the same question. The data obtained from a given patient are compared to similar data obtained from the normative group. The degree to which the patient deviates from the norm is noted and is used in the interpretive process. The patient's responses are scored according to certain agreed-upon criteria. The obtained scores are then compared with normative tables and often converted to standardized scores or percentiles, or both. The MMPI-2 is an example of an objective personality test. [Table 5.5-1](#) lists a sample of objective personality test along with a brief description and brief list of strengths and weaknesses.

Table 5.5-1
Objective Measures of Personality

Name	Description	Strengths	Weaknesses
Minnesota Multiphasic Personality Inventory-2 (MMPI-2)	567 Items; true-false; self-report format; 20 primary scales	Current revision of MMPI that has updated the response booklet; revised scaling methods and new validity scores; new normative data	Preliminary data indicate that the MMPI-2 and the MMPI can provide discrepant results; normative sample biased toward upper socioeconomic status; no normative data for adolescents
Million Clinical Multiaxial Inventory (MCMI)	175 Items; true-false; self-report format; 20 primary scales	Brief administration time; corresponds well with diagnostic classifications	In need of more validation research; no information on disorder severity; needs revision for DSM-5
Million Clinical Multiaxial Inventory-II (MCMI-II)	175 Items; true-false; self-report format; 25 primary scales	Brief administration time	High degree of item overlap in various scales; no information on disorder or trait severity
16 Personality Factor Questionnaire (16 PF)	True-false; self-report format; 16 personality dimensions	Sophisticated psychometric instrument with considerable research conducted on nonclinical populations	Limited usefulness with clinical populations
Personality Assessment Inventory (PAI)	344 Items; Likert-type format; self-report; 22 scales	Includes measures of psychopathology, personality dimensions, validity scales, and specific concerns to psychotherapeutic treatment	The inventory is new and has not yet generated a supportive research base
California Personality Inventory (CPI)	True-false; self-report format; 17 scales	Well-accepted method of assessing patients who do not present with major psychopathology	Limited usefulness with clinical populations
Jackson Personality Inventory (JPI)	True-false; self-report format; 15 personality scales	Constructed in accord with sophisticated psychometric techniques; controls for response sets	Unproved usefulness in clinical settings
Edwards Personal Preference Schedule (EPPS)	Forced choice; self-report format	Follows Murray's theory of personality; accounts for social desirability	Not widely used clinically because of restricted nature of information obtained
Psychological Screening Inventory (PSI)	103 Items; true-false; self-report format	Yields four scores, which can be used as screening measures on the possibility of a need for psychological help	The scales are short and have correspondingly low reliability
Eysenck Personality Questionnaire (EPQ)	True-false; self-report format	Useful as a screening device; test has a theoretical basis with research support	Scales are short, and items are transparent as to purpose; not recommended for other than a screening device
Adjective Checklist (ACL)	True-false; self-report or informant report	Can be used for self-rating or other rating	Scores rarely correlate highly with conventional personality inventories
Comrey Personality Scales (CPS)	True-false; self-report format; eight scales	Factor analytic techniques used with a high degree of sophistication in test constructed	Not widely used; factor analytic interpretation problems
Tennessee Self-Concept Scale (TSCS)	100 Items; true-false; self-report format; 14 scales	Brief administration time yields considerable information	Brevity is also a disadvantage, lowering reliability and validity; useful as a screening device only

(Courtesy of Robert W. Butler, Ph.D., and Paul Satz, Ph.D.)

Minnesota Multiphasic Personality Inventory. The MMPI-2 is relatively easy to administer and score and takes approximately 1.5 hours for most patients to complete. It consists of 567 true or false questions concerning a wide variety of issues and requires only an eighth-grade reading comprehension. Scoring of the MMPI-2 involves adding up the number of responses on numerous scales and comparing the results to certain normative information. Interpretation of the MMPI-2 is more straightforward than with many other tests.

When a patient takes the MMPI-2, questions are not grouped in any particular order to aid in interpretation. Various items in the MMPI-2 can be selected, sorted, and analyzed according to various criteria.

A new version of the MMPI-2 was developed in 2008, the MMPI-2 Restructured Form (MMPI-2 RF). It contains 338 questions and allows less time to administer. The MMPI-2 RF is meant to be an alternative to the MMPI-2, not a replacement.

Personality Assessment Inventory (PAI). Another increasingly popular objective personality test is the Personality Assessment Inventory (PAI). This test consists of 344 items that are written at a fourth-grade reading level. This reading level ensures that most patients can complete it without experiencing any reading problems. The PAI takes about 45 to 50 minutes to complete for most patients. The PAI was normed on 1,000 community-dwelling individuals stratified according to sex, race, and age. There are no separate norms for male and female as there are in the MMPI. In addition, data were gathered on 1,246 clinical subjects and 1,051 college students in the normative process. The clinical subjects were drawn from a variety of different clinical settings, including inpatient psychiatric facilities (25 percent), outpatient psychiatric facilities (35 percent), correctional institutions (12 percent), medical settings (2 percent), and substance abuse treatment programs (15 percent).

The PAI has 11 clinical scales. These main clinical scales are similar to the MMPI-2 clinical scales and measure such personality issues as somatic concerns, depression, paranoia, borderline features, or alcohol or drug problems. The PAI also has five treatment-related scales that are designed to address such issues as treatment rejection, suicide ideation, or aggression.

Projective Personality Test

Projective personality tests, in contrast to objective personality instruments, are more indirect and unstructured. Unlike objective tests in which the patient may simply mark true or false to given questions, the variety of responses to projective personality tests are almost unlimited. Instructions are usually very general in nature, allowing the patient's fantasies to be expressed. The patient generally does not know how his or her responses will be scored or analyzed. Consequently, trying to feign the test becomes difficult. Projective tests typically do not measure one particular personality characteristic such as "type A personality" (e.g., narrow-band measurement) but instead are designed to assess one's personality as a whole (e.g., broad-band measurement).

Projective tests often focus on "latent" or unconscious aspects of personality. Obviously, psychologists and others differ in the degree to which they rely on "unconscious" information. In many projective techniques, the patient is simply shown a picture of something and asked to tell what the picture reminds him or her of. An underlying assumption of projective techniques (projective hypothesis) is that, when presented with an ambiguous stimulus, such as an inkblot, for which there are an almost unlimited number of responses, the patient's responses will reflect fundamental aspects of his or her personality. The ambiguous stimulus is a sort of screen on which the individual projects his or her own needs, thoughts, or conflicts. Different persons have different thoughts, needs, and conflicts and, hence, have widely different responses. A schizophrenic's responses often reflect a rather bizarre, idiosyncratic view of the world.

Table 5.5-2 lists the common projective tests together with a description and strengths and weaknesses for each test.

 **Table 5.5-2**
Projective Measures of Personality

Name	Description	Strengths	Weaknesses
Rorschach test	Ten stimulus cards of inkblots, some colored, others achromatic	Most widely used projective device and certainly the best researched; considerable interpretative data available	Some Rorschach interpretive systems have unimproved validity
Thematic Apperception Test (TAT)	20 Stimulus cards depicting a number of scenes of varying ambiguity	A widely used method that, in the hands of a well-trained person, provides valuable information	No generally accepted scoring system results in poor consistency in interpretation; time-consuming administration
Sentence completion test	A number of different devices available, all sharing the same format with more similarities than differences	Brief administration time; can be a useful adjunct to clinical interviews if supplied beforehand	Stimuli are obvious as to intent and subject to easy falsification
Holtzman Inkblot Technique (HIT)	Two parallel forms of inkblot cards with 45 cards per form	Only one response is allowed per card, making research less troublesome	Not widely accepted and rarely used; not directly comparable to Rorschach interpretive strategies
Figure drawing	Typically human forms but can involve houses or other forms	Quick administration	Interpretive strategies have typically been unsupported by research
Make-a-Picture Story (MAPS)	Similar to TAT; however, stimuli can be manipulated by the patient	Provides idiographic personality information through thematic analysis	Minimal research support; not widely used

(Courtesy of Robert W. Butler, Ph.D., and Paul Satz, Ph.D.)

Rorschach Test. Herman Rorschach, a Swiss psychiatrist, developed the first major use of projective techniques around 1910. The Rorschach test is the most frequently used projective personality instrument (Fig. 5.5-1). The test consists of ten ambiguous symmetrical inkblots. The inkblot card appears as if a blot of ink were poured onto a piece of paper and folded over—hence, the symmetrical appearance.

FIGURE 5.5-1

Card I of the Rorschach test. (From Hermann Rorschach, *Rorschach®-Test*. Copyright © Verlag Hans Huber AG, Bern, Switzerland, 1921, 1948, 1994, with permission.)

Minimal interaction between the examiner and the patient occurs while the Rorschach is administered, which ensures standardization procedures are upheld. The examiner writes down verbatim what the patient says during the above-described “free association” or “response proper” phase. If the patient rotates the card during his or her response, then the examiner makes the appropriate notation on the test protocol. After the patient has given responses to all ten cards, an inquiry phase of administration begins. The examiner asks the patient to go through the cards again and help the examiner see the responses he or she gave. The examiner reads the patient’s initial response and asks the patient to point out what he or she saw and explain what made it look like that to him or her. An almost unlimited range of responses is possible with the Rorschach test and most projective tests.

Thematic Apperception Test. Although the Rorschach test is clearly the most frequently used projective personality test, the Thematic Apperception Test (TAT) is probably in second place. Many clinicians will include both the TAT and the Rorschach test in a battery of tests for personality assessment. The TAT consists of a series of ten black-and-white pictures that depict individuals of both sexes and of different age groups, who are involved in a variety of different activities. An example of a TAT card is presented in Figure 5.5-2.

FIGURE 5.5-2

Card 12F of the Thematic Apperception Test. (Reprinted from Henry A. Murray, *Thematic Apperception Test*, Harvard University Press, Cambridge, MA. Copyright © 1943 President and Fellows of Harvard College, © 1971 Henry A. Murray, with permission.)

Henry Murray developed the TAT in 1943 at the Harvard Psychological Clinic. The stories that the patient makes up concerning the pictures, according to the projective hypothesis, reflect the patient's own needs, thoughts, feelings, stresses, wishes, desires, and view of the future. According to the theory underlying the test, a patient identifies with a particular individual in the picture. This individual is called the *hero*. The hero is usually close to the age of the patient and frequently of the same sex, although not necessarily so. Theoretically, the patient would attribute his or her own needs, thoughts, and feelings to this hero. The forces present in the hero's environment represent the *press* of the story, and the *outcome* is the resolution of the interaction between the hero's needs and desires and the press of the environment.

Sentence Completion Test. Although a projective instrument, the sentence completion test is much more direct in soliciting responses from the patient. He or she is simply presented with a series of incomplete sentences and is asked to complete the sentence with the first response that comes to mind. The following are examples of possible incomplete sentences:

- My father seldom...
- Most people don't know that I'm afraid of...
- When I was a child, I...
- When encountering frustration, I usually...

The purpose of the test is to elicit, in a somewhat indirect manner, information about the patient that cannot be elicited from other measures. Because the patient responds in writing, the examiner's time is limited. The length of time it takes to complete the sentence completion varies greatly depending on the number of incomplete sentences. Tests can range from less than ten sentences to greater than 75.

Behavioral Assessment

Behavioral assessment involves the direct measurement of a given behavior. Rather than focus primarily on human characteristics, such as repression, ego strength, or self-esteem (vague terms to a behaviorist), strict behavioral measurement concentrates on the direct measurement that can be observed, such as a number of temper tantrums per unit of time, duration and intensity and number of hyperventilation episodes, or the number of cigarettes smoked per 24-hour period.

Although early strict behaviorists would count only behaviors that were observable, a broader definition of behavior has emerged, under which just about anything people do—whether it is overt such as crying, swearing, or hand-washing or covert such as feeling and thinking—is considered behavior.

Direct Counting of Behavior. Measuring overt behavior is direct and can be done by the patient himself or herself, a family member, or an impartial observer.

Cognitive behavior therapists use these measurements to establish baselines of a given undesirable behavior (i.e., violent thoughts that the patient may wish to reduce). Similarly, therapists can measure behavior that the patient wants to increase (time studying, time out of bed, or distance walked on a treadmill). Follow-up measures of the same behavior monitor progress and quantify improvement.

ASSESSMENT OF PERSONALITY IN CHILDREN AND ADOLESCENTS

Assessment of emotional and interpersonal characteristics in children presents many challenges to the clinician because of the discontinuities in development that exist throughout childhood, adolescence, and adulthood. Many clinicians are reluctant to assign the diagnosis of a personality disorder before the ages of 16 to 18 years due to rapid changes that occur during childhood. However, assessment of children and adolescents can often reveal antecedent symptoms, behaviors, or traits associated with emotional disorders at an age when these problems are very amenable to intervention. For this reason, facility in assessment of emotional disorders in children and adolescents is important for mental health professionals.

Special Considerations in Assessment of Children

Assessment of children with symptoms of emotional or behavioral disorders is best accomplished within developmental and ecological contexts—both of which help one interpret the child's symptoms from the perspective of developmental influences on behavior and also with consideration of the risk and protective factors in the child's social environment. Indeed, the balance of risk and protective factors may often provide important clues as to the etiology of the child's current problems and the prognosis for effective intervention.

The Developmental Context. Knowledge about the normal sequence and transitions of development forms a fundamental backdrop

from which to view children's suspected psychopathology. The major developmental transition of infancy related to formation of a secure attachment relationship with significant caregivers gives way to the movement from dependence to greater self-reliance in the toddler years. The developmental tasks most salient during the preschool years involve development of a growing capacity for empathy and self-control, while showing a desire for mastery of developmental tasks. Within the early to middle elementary years, youngsters strive for greater mastery of knowledge and intellectual and academic skills, leading to feelings of productivity and competence. The developmental tasks of adolescence center around separation-individuation, resolving conflicts with authority figures, peer group identification, and realistic appraisal and evaluation of self-qualities. Although development does not occur in a linear stage, familiarity with the primary developmental themes and transitions of each age period provides an important context from which to view current symptoms.

Decisions about appropriate assessment methods are also based on developmental factors. Before children participate in projective testing procedures, such as storytelling tasks, clinicians must have developmental information about their expressive language, receptive language, and conceptualization ability. Knowledge of a child's reading proficiency is critical when presenting self-report measures. If children are asked to complete projective drawings, information about their level of visual-motor development is important for interpretation. Young children often do not have the motor or language abilities to provide meaningful responses to projective testing procedures, but they may reveal much about their socialization abilities, fears, anxieties, and significant relationships through play. Therefore, play observation techniques can be a useful alternative to more formal projective measures. Likewise, some adolescents may resist providing responses on projective measures that require verbal disclosure to a clinician but may willingly complete objective paper-and-pencil personality measures that require a less direct response. Choosing an approach to assessment with the developmental context in mind will enhance the validity of the information obtained.

Ecological Context. The broad social-ecological context of children's family, peer group and social relationships, and the culture in which they live can influence the interpretation of assessment information. From a developmental psychopathology perspective, most psychopathology is expressed as an interaction among various factors that are operating at the levels of the individual (including developmental and personality attributes), the family (e.g., parenting skill, the security of primary attachment relationships, marital stability, and extended family support), the community (e.g., including the influences of work, school, informal social networks, socioeconomic factors, and degree of family social isolation), and the larger cultural context of society (e.g., cultural values and beliefs that govern behavior).

Two 4-year-olds were referred by their Head Start teacher due to concerns about a recent onset of regressive behavior (e.g., enuresis during the school day and immature speech patterns). Both girls were interviewed separately but were reluctant to talk with the clinician. A play interview was set up with each girl, using dolls and a dollhouse with a variety of furniture. The first girl assumed the role of "mother" and played out the scenario of feeding and diapering the baby doll in a nurturing manner. The second girl was aggressive in her play, with enactment of the "adult" dolls hitting the "child" dolls and making them "die." The child dolls were described as having blood on them. The family context for the first girl revealed that a new baby sibling had been born just prior to the onset of regressive symptoms; the infant was born prematurely and the mother spent much time with the infant in the hospital. Both the arrival of the new sibling and the mother's separation from her 4-year-old daughter created the social context for the emergence of the child's regressive behavior. In the second case, the girl's mother was interviewed. After the clinician provided a description of the girl's play, the mother revealed that she had a new boyfriend who just moved into the house. She said she had noted her daughter's fear of the boyfriend and her frequent tearfulness at home. She reported suspicion that her boyfriend might be sexually molesting her daughter and agreed to call Protective Services in the presence of the clinician to make a report.

There can be vastly different explanations for similar presenting symptoms, and often, the projective assessment procedures only suggest concerns without providing enough specific information about the nature and etiology of the problems. The social context can reveal both risk and protective factors that are important in conceptualizing the child's problems. The ecological approach allows one to examine the possible multiple determinants of emotional psychopathology in children and to better understand the interaction between risk and protective factors that are present in the child's life.

Use of Informant Information. Children and adolescents usually are referred for assessment due to concerns of their parents or caregivers. Teachers also may be the source of specific concerns. For this reason, information relevant to the diagnosis is typically obtained from these significant adults who can provide important information regarding the child's behavior in various settings. Reliance on persons other than the client as reporters of the primary symptoms represents a fundamental difference in the process of diagnosis compared with adult assessment.

Therefore, the validity of the information presented about children's symptoms is often a concern for clinicians. During intake, parents often express feelings of anxiety or frustration regarding their child's problems, and their descriptions of the child may be exaggerated or vague (e.g., "She *never* minds" or "He *always* acts like a monster"). It is not uncommon for depressed parents to report an increased number and severity level of symptoms in their children. In cases where one suspects that the informant's perceptions may be distorted, it is critical to obtain collateral information from teachers or others who are familiar with the child's current problems. A primary task is to help informants translate imprecise complaints to specific descriptions of behaviors of concern, using methods that help the clinician ascertain the nature, frequency, and severity of symptoms. The behavioral assessment procedures described later are very useful in providing age- and gender-referenced ratings of symptom characteristics.

Specialized Training. Clinicians who conduct personality assessment of children need training not only in clinical assessment methods but also in developmental psychology and child psychopathology. Presentation of many emotional disorders in prelatency years differs from postlatency presentation. Training and experience in how to assist the child with the demands of the testing situation are also critical. Children's ability to participate in testing depends on their attention and concentration ability, anxiety regarding separation from significant others during the testing, fatigue or hunger states, motivation and persistence, and the relatively greater influence of familial, cultural, and environmental variables on their ability to participate effectively in the testing. A clinician with specialized training to work with children will have both the understanding of these influences on child test-taking behavior and the skills to work with the challenges of testing children so as to achieve more valid results.

ASSESSMENT FOR CHILDREN AND ADOLESCENTS

Like assessment of adults, personality assessment of children can be accomplished via three primary methods: projective, objective, and behavioral tests and procedures. The projective methods involve direct interaction with the child and adolescent, whereas the objective and behavioral methods often involve obtaining information from significant adults in the child's life as well as direct interaction with the child. With the evolution of more sophisticated statistical methodology and psychometric science in recent years has come the development of new objective and behavioral measures of personality. Improved validity indices and psychometric procedures that take into account informant reporting are now routinely included. Many of the projective procedures have changed less, although improvements in developmental norms for interpretation have increased the diagnostic validity of measures such as the Rorschach.

Projective Assessment Procedures

As stated in the adult subsection, objective tests of personality present the patient with a structured set of questions and a finite range of answers. Projective tests, on the other hand, present more ambiguous stimuli and ask the adult or child to make up something (i.e., story, percept, or drawing) related to the stimulus. The most common projective assessment procedures for children and adolescents are the Rorschach test, various projective storytelling measures (i.e., Roberts Apperception Test for Children—2nd edition, or Children's Apperception Test), projective drawings (such as human figure and kinetic family drawings), and incomplete sentence procedures (Table 5.5-3).

Table 5.5-3
Projective Assessment Procedures for Children

Name	Age Range	Description
Rorschach Inkblot Test	5 years—Adulthood	Consists of ten inkblots, some colored and others achromatic, used as basis for eliciting associations that are revealing of disrupted personality development.
Children's Apperception Test (CAT)	3–10 years	Two versions of the CAT—animal and human—depict characters in various social situations and are used to elicit stories from children. Younger children are felt to identify more readily with the animal figures, while older children are usually presented the human figures. Scoring and interpretation is based on psychodynamic theory.
Adolescent Apperception Cards	12–19 years	11 picture cards focus on parent-, peer-, and sibling-adolescent interaction, pulling for themes of physical and sexual abuse, neglect, peer acceptance, loneliness, depression, drug use, and domestic violence. Two versions are available—one depicting white teenagers and the other black teenagers.
Roberts Apperception Test for Children—2 nd edition (RATC-2)	6–18 years	16 picture cards—with parallel male and female versions depicting Caucasian, black, or Hispanic characters—are designed to elicit information about two independent dimensions: adaptive social perception (which is a developmental measure) and the presence of maladaptive or atypical social perception (which is a clinical measure). The responses indicate where a child is on a continuum of social understanding. The revision has an expanded age range (from 6 to 18 years) and a standardized scoring system based on updated, stratified normative data to aid interpretation.
Tell-Me-A-Story (TEMAS)	5–18 years	Multicultural apperception test with 23 color picture cards (11 of which are sex specific) depicting minority (Hispanic or black) or nonminority characters. Measures ten personality functions (e.g., aggression, interpersonal relations, and self-concept), 18 cognitive functions (e.g., reaction time, fluency, sequencing, and imagination), and seven affective functions (e.g., happy, sad, angry, and fearful). Has an objective scoring system and normative data based on a diverse cultural and ethnic sample.
Projective Drawings	3 or 4 years through adolescence	Various versions exist, from individual drawings of human figures, a house, and tree to kinetic drawings of family. These are simple, cost-effective measures that provide information on children's perceptions of self and relationships with others. Especially useful with children who have difficulty with verbal expression. Objective scoring available for some drawings (e.g., human figures), but interpretation of other types of projective drawings is often subjective.
Sentence and Story Completion Tasks	4 or 5 years through adolescence	A number of different formats available, each providing a sentence stem or initiating a story, after which the child is asked to complete the sentence or story. Provides information on such factors as interpersonal relationships and dynamics, self perception, wishes, and worries.

Rorschach Test. Projective instruments such as the Rorschach test allow the clinician to explore dynamics of the child's personality by gathering information on both the child's perceptual-cognitive world and inner fantasy world. The Rorschach test ideally is used as part of a more comprehensive battery that includes an interview with the child and significant adults, expressive (play) techniques, and perhaps storytelling techniques to allow the child the maximum freedom and spontaneity of expression.

The Rorschach test with children has a long research and clinical history of examining developmental norms and symbolic interpretations. Clinicians using the Rorschach test for the evaluation of children and adolescents must take care to analyze the structural summary within the context of appropriate age norms, as a given result may be interpreted as normal for a young child but could be of concern in an adolescent. Children's Rorschach responses have been examined as a function of their cognitive functioning, academic performance, and behavioral problems within the school setting. The underlying conceptual framework for this work hypothesizes that there is a direct relationship between the degree of secondary process development and school achievement.

As with adults, there are numerous systems for administering and scoring the Rorschach with children, but all ask children to say what they see on the inkblot (i.e., the percept), followed by an inquiry referring back to each response. Whether the inquiry should be done following the child's free association responses to all ten inkblots or best accomplished after each individual blot is controversial. Proponents of the latter approach suggest that young children may have difficulty remembering the reasoning behind the original free associations or may become fatigued by the end of the test, thus limiting their cooperation and responsiveness to the inquiry. Clinicians must also be aware of state anxiety as a potential confounding variable in children's responses to the Rorschach test. Care in building rapport and an explanation of the purpose and process of testing can ease the situational anxiety.

As with adults, scoring is done on the basis of response characteristics, or determinants, such as form, color, shading, texture, and dimensionality. The content and form quality of the child's responses are also used in scoring and interpretation.

Projective Storytelling Procedures. In projective storytelling approaches, the child is presented with a picture stimulus of human or animal figures in rather ambiguous situations. The child is asked to make up a story about the figures—a story that has a beginning and end and includes the thinking and feeling of the persons represented in the pictures. A fantasy response is evoked, and the resulting projective information is a combination of the perceptual and the imaginative. Stories are typically analyzed for repetitive, unique, intense, or problematic themes, beliefs, or affects. This procedure is very similar to the TAT approach used with adults.

Children's Apperception Test. The initial Children's Apperception Test (CAT), developed in 1949, used animal figures and was developed for children ages 3 to 10 years. Animal figures were thought to be more culture-free than human characters. In 1965, the human figures version (CAT-H) was produced, showing human figures in situations as analogous as possible to those pictured in the animal version. During administration, the cards are presented individually in the numbered order of the card (because certain cards were designed for sequential impact). The child is asked to tell a story about each picture (e.g., what is going on, what happened before, and what will happen next). There is some debate about the use of prompts with young children and whether such prompts (e.g., "How did the story end?") may contaminate important projective information. Generally, prompts are often necessary to help the young child understand what

is expected. Young children have a tendency to merely label or describe portions of the picture and may not understand the concept of telling a story with a beginning, middle, and conclusion. However, the clinician must always guard against overly intrusive or helpful prompts that guide the child's responses in a particular direction or suggest a specific format for the story. The various scoring protocols for the CAT have focused on the analysis of ego functions and evaluation of the relative use of various defense mechanisms. However, qualitative interpretation is also made based on recurrent or sequential themes and determination of identification figures, while taking into consideration the child's family and case history information.

Roberts Apperception Test for Children—2nd Edition. The original Roberts Apperception Test for Children (RATC) was developed specifically for children and provided a standardized system for scoring the thematic content and structural characteristics of the child's responses. The 2nd edition of the RATC is now available, and it provides normative data (stratified by geographic region, sex, ethnicity, and parental education) on a sample of 1,000 children and adolescents, ages 6 to 18 years, to aid in clinical interpretation. The RATC-2 asks the child or adolescent to tell a story in response to each of 16 test pictures that represent important interpersonal themes. The RATC-2 assesses two independent dimensions: adaptive social perception (which is a developmental measure) and the presence of maladaptive or atypical social perception (which is a clinical measure). The responses indicate where a child is on a continuum of social understanding. Interpretation of the RATC-2, like that of other projective measures, is based on the assumption that children presented with ambiguous drawings of children and adults in everyday interaction will project their typical thoughts, concerns, conflicts, and coping styles into the stories that they create.

The RATC-2 has three parallel versions of the test pictures—one for Caucasian children, one featuring African American children, and the other depicting Hispanic children.

Objective Personality Measures

Objective approaches to child personality assessment typically have straightforward test stimuli and clear instructions regarding completion of the tests, as opposed to projective approaches, which typically use more unstructured, ambiguous test stimuli. Objective tests typically have good standardization, reliability, and validity, and they often are norm referenced so as to provide comparisons with a particular criterion group.

The advantages of using objective measures with children are similar to those previously discussed with adults. Disadvantages include the length of the measures (some have several hundred questions to which the informant must respond), the reading level required for completion (which could place children and adolescents at a disadvantage), and the initial outlay of expense to purchase either computer administration or computer scoring software. Despite the disadvantages, objective personality measures remain an important part of a comprehensive personality assessment by providing a broad survey of major areas of psychopathology at the initial stages of the evaluation. [Table 5.5-4](#) list some of the major objective personality measures for children.

Table 5.5-4
Objective Personality Measures for Children

Name	Age Range	Description
Children's Personality Questionnaire (CPQ)	8–13 years	140-item questionnaire that measures 14 basic personality traits useful in predicting school achievement, delinquency, leadership, and potential emotional problems. Can be individually or group administered.
High School Personality Questionnaire (HSPQ)	13–18 years	An upward extension of CPQ, this scale can be individually or group administered to junior and senior high school students. Has 142 items measuring 14 personality traits. Useful in predicting school achievement, vocational fitness, delinquency, and leadership, as well as those who need clinical assistance.
Millon Adolescent Personality Inventory (MAPI)	Adolescents (13–18 years)	An objective, 150-item, true–false, self-report inventory that identifies eight personality styles (introversive, inhibited, cooperative, sociable, confident, forceful, respectful, and sensitive); eight concerns frequently expressed by adolescents (self-concept, personal esteem, body comfort, sexual acceptance, peer security, social tolerance, family rapport, and academic confidence); and four scales that are typically of interest to clinicians (impulse control, social conformity, scholastic achievement, and attendance consistency). Reliability and validity indices help identify poor test-taking attitudes and confused or random responding.
Millon Adolescent Clinical Inventory (MACI)	Adolescents (13–19 years)	Designed to expand the clinical utility of the MAPI, the MACI stresses maladaptive levels of the original eight personality styles on the MAPI. The MACI also uses DSM-IV disorders. Includes Clinical Indices Scales that tap eating dysfunctions, substance abuse proneness, delinquent predisposition, impulsive propensity, anxious feelings, depression affect, and suicidal tendency. It is helpful in confirming diagnostic hypotheses, developing individual treatment plans, and measuring progress before, during, and after treatment.
Millon Pre-Adolescent Clinical Inventory (M-PACI)	9–12 years	Written at a third-grade reading level, the M-PACI is designed to provide an integrated view of the child's emerging personality patterns and current clinical signs, which may help to detect early signs of Axis I and Axis II disorders. The scales tap into emerging personality patterns (i.e., confident, outgoing, conforming, submissive, inhibited, unruly, and unstable) and current clinical signs (i.e., anxiety/fears, attention deficits, obsessions/compulsions, conduct disorder, disruptive behaviors, depressive moods, and reality distortions). Paper-and-pencil, CD, and computer administration formats are available. The Interpretive Report provides an integrated analysis of results with regard to the child's personality patterns and clinical signs.
Minnesota Multiphasic Personality Inventory–Adolescent (MMPI-A)	14–18 years	This 478-item, true–false objective measure of psychopathology is specifically designed for use with adolescents. It contains the basic clinical scales of the original MMPI along with four new validity scales, 15 content scales and six supplementary scales, and 28 Harris and Lingoes and three Si subscales. Both hand-scoring and computer-scoring programs are available, as well as an MMPI-A Interpretive System.
Personality Inventory for Children–2 nd edition (PIC-2)	Preschool–Adolescence (5–19 years)	An objective, multidimensional parent-report measure of the emotional, behavioral, cognitive, and interpersonal adjustment of children and adolescents. The total scale has 275 items (reduced from 420 in the 1 st edition) that provide scores on several key areas: cognitive impairment, family dysfunction, psychological discomfort, social withdrawal, impulsivity and distractibility, delinquency, reality distortion, somatic concern, and social skills deficit. Two normative groups are available for the PIC-2. One includes boys and girls in kindergarten through 12 th grade and is representative of the U.S. population in regard to socioeconomic levels and ethnicity. The second sample includes parents of children that had been referred for educational or clinical intervention.

DSM, *Diagnostic and Statistical Manual of Mental Disorders*.

Personality Measures for Specific Disorders in Children. In contrast to the multidimensional personality measures already discussed, several measures address more specific disorders in children, such as depressive and anxiety disorders. Examples of several of these measures are found in [Table 5.5-5](#).

 **Table 5.5-5**
Personality Measures for Specific Disorders in Children

Name	Age Range	Description
Children's Depression Inventory (CDI)	7–17 years	Self-report inventory that assesses symptoms of depression. The long form contains 27 multiple-choice items that assess five key areas: negative mood, ineffectiveness, anhedonia, negative self-esteem, and interpersonal problems. Cutoff scores are provided for various levels of severity. Discriminant validity between depressive disorders and other disorders on the CDI has been questionable in some studies. The CDI short version consists of ten key items from the long version. Both parent and teacher versions are also available. They rate children's behavior on the Emotional Problems and Functional Problems scales.
Reynolds Child Depression Scale (RCDS)	Grades 3–6	Brief, self-report measure of depressive symptomatology in children. Contains 30 items written at a second-grade reading level. May be administered individually or in groups. A cutoff score is provided to designate a clinically relevant level of depressive symptoms. Normative groups are stratified by grade and sex.
Reynolds Adolescent Depression Scale–2 nd edition (RADS-2)	11–20 years	Brief, self-report measure that identifies adolescents who exhibit significant depressive symptoms. Contains 30 items that measure four key areas: dysphoric mood, anhedonia/negative affect, negative self-evaluation, and somatic complaints. The RADS-2 has an expanded age range and updated normative data divided into three age groups: 11–13 years, 14–16 years, and 17–20 years. May be administered individually or in groups. RADS Total Score and Cutoff Score can be used to judge severity of depressive symptoms.
Revised Children's Manifest Anxiety Scale–2 nd edition (RCMAS-2)	6–19 years	Brief self-report measure of anxiety symptoms in children and adolescents. The scale contains 49 items at a second-grade reading level, answered in a yes–no format. It assesses four key areas: physiological anxiety, social anxiety, worry, and defensiveness. The RCMAS-2 also assesses for the presence of academic stress, test anxiety, peer and family conflicts, and drug problems. A Spanish translation is available, as is an audio CD recording of the test items, designed for poor readers.
Multidimensional Anxiety Scale for Children (MASC)	8–19 years	Brief self-report measure that assesses the presence of anxiety disorders in youth. The 39-item long version taps seven key areas: harm avoidance, social anxiety, physical symptoms, anxiety disorders, separation/panic, Total Anxiety Index, Inconsistence Index (validity). The short version (MASC-10) combines the basic anxiety scales from the long version to produce one score that indicates the severity of anxiety problems. Written at a fourth-grade reading level, it is useful in planning focused treatment and monitoring progress.
Social Phobia and Anxiety Inventory for Children (SPAI-C)	8–14 years	Self-report inventory with 26 items written at a third-grade reading level. The SPAI-C evaluates the somatic, cognitive, and behavior aspects of social phobia in children to help determine the most appropriate treatment plan.
State-Trait Anxiety Inventory for Children (STAIC)	8–14 years	Developed to assess both enduring tendencies to experience anxiety and also temporal and situational variations in levels of perceived anxiety. The STAIC consists of two 20-item scales that measure state and trait anxiety in children and determines which type of anxiety is dominant. Reliability studies for internal consistency are strong, but validity studies have not strongly supported the state-trait distinction in children.
Fear Survey Schedule For Children (FSSC) and Fear Survey Schedule for Children–Revised (FSSC-R)	7–12 years	The FSSC is an 80-item scale developed to assess specific fears in children. Categories of items include school, home, social, physical, animal, travel, classical phobia, and miscellaneous. Few data are available regarding psychometric properties of the FSSC. A revised version of the scale (FSSC-R) has shown good internal consistency, and total scores have discriminated between normal and school-phobic children.

Often, clinicians will use the multidimensional personality measures to obtain a broad overview of risk for psychopathology and then use the more narrow-band, specific measures to explore a particular set of symptoms in greater detail. Neither type of personality inventory is used to confirm a diagnosis, but both provide valuable information about the nature and severity of symptoms that can be combined with other approaches to arrive at a diagnosis.

Advantages of the specific personality inventories include their brevity, low cost in terms of time to administer, and ease in scoring and interpreting. However, as with similar adult measures, caution should be taken in reviewing the psychometric qualities of these personality measures, particularly with regard to discriminant validity for the disorder under study versus other disorders versus children without disorders.

Behavioral Assessment Procedures

Behavioral assessment procedures offer a highly structured method of obtaining information about behavioral or emotional functioning and social competencies of children and adolescents. These procedures include direct observations and informant ratings on normed age and sex scales. The popularity of these measures has grown in recent years, in part due to their improved psychometric properties, their cost-effectiveness, and their utility in multitrait–multimethod diagnostic procedures (Table 5.5-6 presents examples of these measures).

 **Table 5.5-6**
Behavioral Assessment Procedures for Children

Test Name	Age Range	Description
Beck Youth Inventories—2 nd edition (BYI-II)	7–18 years	The BYI consists of five inventories of 20 questions each: depression, anxiety, anger, disruptive behavior, and self-concept. The five self-report inventories can be administered separately or in combination, with administration time only 5 minutes per inventory. The normative group is well stratified for age, sex, ethnicity, and socioeconomic status. Results provide clinical ranges for symptom severity, profile analysis for general understanding, and items or item clusters as probes for deeper understanding.
Behavior Assessment System for Children—2 nd edition (BASC-2)	Preschool: 2–5 years School age: 6–11 years Adolescent: 12–21 years	Multidimensional scale, normed by age and sex, which measures behavior, emotions, and self-perceptions. Includes parent and teacher rating scales, a self-report of personality scale, a student observation system, and a structured developmental history. It is available in Spanish as well as English, and it provides an audio CD recording for individuals with reading problems. Assesses internalizing, externalizing, and school problems, atypical behavior, and adaptive skills. Both computer- and hand-scored versions are available.
Child Behavior Checklist (CBCL), Teacher's Report Form (TRF), and Youth Self Report (YSR)	CBCL 1.5–5 years TRF 1.5–5 years CBCL 6–18 years TRF 6–18 years YSR 11–18 years	Multiaxial, empirically based scales, normed by age and sex that assess social competencies as well as behavioral/emotional problems. The CBCL 6–18, TRF 6–18, and YSR 11–18 were designed to obtain similar types of data in a similar format from parents, teachers, and youth. The behavior problem items on these scales cluster into eight subscales: anxious/depressed, withdrawn/depressed, somatic complaints, social problems, thought problems, attention problems, rule-breaking behavior, and aggressive behavior. The analogous CBCL 1.5–5 extends the empirically based assessment to younger children. It includes an Emotionally Reactive subscale, but excludes the Social, Thought, and Rule-Breaking subscales. On the YSR, youths rate themselves for how true each item is within the past 6 months. A new scoring module (2007) displays problem-scale profiles and cross-informant bar graphs in relation to multicultural norms.
Semistructured Clinical Interview for Children (SCIC)	6–11 years	Developed to accompany the CBCL 4–18 and TRF, this interview format was adapted to the cognitive levels and interactive style of 6- to 11-year-old children. It provides open-ended questions designed to elicit children's reports on various important areas of their lives, including family, friends, school, activities, concerns, and fantasies. Also includes a kinetic family drawing, brief achievement tests, a screen for fine and gross motor abnormalities, and probe questions about problems attributed to the child by others.
Conners' Rating Scales—Revised (CRS-R) and Conners-Wells' Adolescent Self-Report Scale	Parent Rating Scales: 3–17 years Teacher Rating Scales: 5–17 years Adolescent Self-Report: 13–17 years	Factor-analytically derived, age and sex normed, behavioral rating scales for parents, teachers, and adolescent self-report. Both long and short forms available.
Symptom Checklist—90 Revised (SCL-90-R)	13+ years	A 90-item self-report scale that asks respondents to rate the subjective severity of psychological symptoms in nine areas: somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism. It yields three general indices: a Global Severity Index of overall psychological distress; a Positive Symptom Distress Index (designed to measure intensity of symptoms), and a Positive Symptom Total Index, which reports the number of self-reported symptoms.
Piers-Harris Children's Self-Concept Scale—2 nd edition (PHCSSC-2)	7–18 years	An 80-item self-report scale of self-concept and self-esteem in children. It yields a Total Self-Concept Score, along with subscale scores (Behavioral Adjustment, Freedom from Anxiety, Happiness and Satisfaction, Intellectual and School Status, Physical Appearance and Attributes, and Popularity) that permit more detailed interpretation. It is used in clinical settings to determine specific areas of conflict, typical coping and defense mechanisms, and appropriate intervention techniques.

DSM, *Diagnostic and Statistical Manual of Mental Disorders*.

Validity of Informant Reports. Use of behavioral rating scales raises questions about the validity of informant information. The research regarding agreement among various raters of child behaviors is consistent in showing greater agreement between raters who interact with a child in similar situations (e.g., between mothers and fathers) than between raters who interact with the child in different situations (e.g., between parents and teachers or parents and children).

Advantages and Disadvantages of Behavioral Approaches. There are several advantages of the behavioral approaches to assessment of behavior and emotional functioning in children and youth. These procedures are cost-effective in that they maximize the amount of information obtained with little clinician time. They often have convenient hand-score or computer scoring methodology, another cost-effective aspect. Use of behavioral assessment increases the likelihood of obtaining information from multiple sources (e.g., teachers and parents) across multiple settings (e.g., school, home, and day care). These sources of information are necessary for some diagnoses, such as attention-deficit/hyperactivity disorder (ADHD), and likely increase the validity of other diagnoses. Many of the scales are empirically derived, factor-analytic scales that are normed for age and sex and generally possess good psychometric properties.

Disadvantages of behavioral rating methods in children include questions about the validity of informants' reports and concerns about informant reading level. The behavioral ratings are filtered through the perceptions of the informant, and the degree of frustration, emotional pathology (e.g., depression), and intellectual and academic skills of the informant are critical to understanding the report. There is much debate about how to handle discrepant ratings across informants. Although perfect correlation is not expected, the issue of how to weigh one person's observations against those of another is an important issue that is as yet unresolved.

Achenbach Child Behavior Checklists. The checklists developed by Thomas Achenbach have been perhaps the most widely used behavioral rating scales in child and adolescent clinics in recent years. Similar to the Behavior Assessment System for Children, 2nd edition (BASC-2), the Achenbach scales include a parent rating (the Child Behavior Checklist [CBCL]), a teacher rating (Teacher Report Form [TRF]), and a self-report (Youth Self-Report [YSR]). The CBCL is appropriate for children from the ages of 6 to 18 years, the TRF is used for children from the ages of 6 to 18 years, and the YSR is appropriate for those from the ages of 11 to 18 years. Each scale is interpreted in comparison to a large normative sample stratified by age and sex. A cross-informant computerized scoring paradigm is provided to assist with comparisons of the CBCL, TRF, and YSR measures regarding a given client.

A version of the CBCL and TRF for toddlers (CBCL 1.5–5 and Caregiver-Teacher Report Form for Ages 1.5–5) is also available. The Internalizing, Externalizing, and Total Problems scales are scored from both forms. The CBCL 1.5–5 also includes the Language Development Survey and a Sleep Problems syndrome scale. The C-TRF asks teachers and caregivers to

provide descriptions of problems, disabilities, issues that concern the respondent most about the child, and things that the respondent views to be best about the child. A separate computerized scoring system is available for the toddler versions of the CBCL.

Other Behavioral Personality Approaches. Many other behavioral approaches to assessment are available in addition to behavior rating scales, as discussed in the earlier part of this section. Direct observations of child and adolescent behavior can be a useful adjunct to other assessment procedures, whether the observation is unstructured or structured according to a specific format.

5.6 Neuropsychological and Cognitive Assessment of Children

Although cognitive and neuropsychological assessments might overlap, these approaches analyze behavior according to two different paradigms. *Cognitive assessment* is undertaken without reference to the possible neurobiological underpinnings of overt behavior, and it describes the patient very much as others might observe him or her in the world. *Neuropsychological assessment* is undertaken in the context of growing knowledge about brain–behavior relationships, and it has the additional possibility of describing the child in terms of unseen neural pathways. These approaches provide ways of conceptualizing how children integrate information (and their thinking, learning, and responding) at different levels. General cognitive assessment focuses on understanding behavior at a cognitive level and in descriptive terms. Focused neuropsychological assessment introduces the additional possibility of understanding behavior at neural levels and in neurobiological terms. However, regardless of the theoretical differences among the psychologists undertaking these evaluations, in a practical way it is the patient's referral issues that shape the assessment process and focus the interpretation of results.

BASICS OF PSYCHOLOGICAL ASSESSMENT

Psychological assessment involves more than testing. Although measurements are useful, testing involves more than scores.

The Testing Process

In addition to testing, assessment procedures include examining past records (medical examinations, prior testing, report cards), interviewing the client and his or her family (in structured and unstructured formats), obtaining information from home and school (and, sometimes, onsite observations), and obtaining rating scales that have been filled out by the child's parents and teachers (regarding developmental, behavioral, emotional, and diagnostic issues). The diagnostic aspect of the process involves an attempt to determine the psychiatric and educational categories for which the client meets the criteria. Cognitive and neuropsychological testings are only two aspects of an attempt to get a broad view of the way a child solves problems in the world, to understand his or her unique interaction with any diagnostic category, and to provide recommendations for interventions.

Measurements in Testing

Although many techniques might be used to help understand a child client and his or her referral question, the emphasis here is on standardized testing (based on regularized procedures as well as normative data). The point of testing is to create a way of comparing one individual to a population of such individuals, as well as the strengths and weaknesses within one individual. The psychologist will select an instrument that is valid (it measures what is intended) and reliable (it measures it consistently). The testing involves establishing a basal level (the level at which all items are passed) and a ceiling (the level at which no items are passed). The testing process involves converting a raw score to a standard score that can be compared with other scores along what is thought of as a normal distribution with predictable statistical properties. The standard deviation (SD) is a measure of dispersion around the mean; the farther scores are from the mean and each other in terms of the SD, the more meaningful is the discrepancy. It is accepted that a measurement is an approximation and not exact. This approximation is recognized by the concept of standard error of measurement (SEM), which is the naturally occurring (random) error that takes place in the real world as one attempts to measure anything. The fact that measurements are not exact is also recognized by the concepts of confidence intervals (the probability that the true score falls within a range of scores) and statistical significance (the probability of finding a result by chance).

Beyond Scores and Tests

It should be noted that the testing process involves more than scores. Although scores are important, how the patient goes about solving cognitive problems is also carefully observed. The examiner is interested not only in test performance, but also in the patient's reaction. It is important to the psychologist to note how the patient arrives at right as well as wrong answers and to explore the patient's cognitive strategies on tasks. In general, it is important to note whether the patient responds in a deliberate or impulsive way.

The testing process is not separate from the therapeutic process. If well handled, the testing can become an extension of the treatment. Feedback about results and their relationship to the presenting problems can be presented as the evaluation unfolds.

COGNITIVE AND NEUROPSYCHOLOGICAL ASSESSMENT

The general cognitive assessment tends to be a descriptive and practical event with an eye to the policies and possibilities in the outside world. As a result, the cognitive tests tend to be “comprehensive” instruments. The very factors that make them useful for general assessment limit them when it comes to understanding neurobiological functioning. The neuropsychological instruments tend to be more “precision” tests that attempt to assess very specific behaviors that represent neural constructs in an inner world. Even when the results are explored at more descriptive levels, functioning within the domains is not seen as separate or independent of their neurobiological underpinnings. [Tables 5.6-1](#) and [5.6-2](#) list the current cognitive and neuropsychological tests.

Table 5.6-1
Cognitive Tests

Test	Age Range	Description
Intellectual Tests		
Omnibus Intellectual and Ability Tests		
Wechsler Preschool and Primary Scale of Intelligence—3 rd edition (WPPSI-III)	2.6 yrs–7.3 yrs	The tests consist of several subtests that can be combined in different ways to understand basic intellectual functioning. The Wechsler tests yield a full-scale intelligence quotient (IQ) score, as well as overall scores within the verbal and nonverbal areas. There are ways of grouping subtests of the WISC and WAIS to distinguish between more pure verbal and perceptual reasoning, as well as to measure working memory and processing speed. Because of its age range, the WISC (now with an integrated supplement to evaluate more processing issues related to instructional recommendations) is probably the most familiar of the Wechsler tests to child clinicians. The SB also provides full-scale as well as verbal and nonverbal IQ scores. In addition, it provides factor indexes in fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing, and working memory. The KABC scales and their subtests (which minimize verbal instructions and responses) include measures of sequential and simultaneous processing, fluid reasoning and crystallized ability, and long-term retrieval. Many, if not most, cognitive tests (including intellectual, achievement, and processing) are structured in the same way (mean is 100, standard deviation is 15), so results can be compared across instruments. This is particularly important in identifying learning problems.
Wechsler Intelligence Scale for Children—4 th edition (WISC-IV)	6 yrs–16.11 yrs	
Wechsler Adult Intelligence Scale—4 th edition (WAIS-III)	16 yrs–90.11 yrs	
Stanford-Binet Intelligence Scales—5 th edition (SB5)	2 yrs–89 yrs	
Kaufman Assessment Battery for Children—2 nd edition (KABC-II)	3 yrs–18 yrs	
Infant and Child Tests		
Revised Gesell Development Schedules	1–36 mos	The Gesell is an old test that is still administered by medical professionals, as well as psychologists. Along with the BSID, the Gesell is as useful for its opportunities for observations as it is for its scores. Both can be helpful in the identification of children at risk for developmental delay. The MSEL, with its five scales (Gross Motor, Visual Reception, Fine Motor, Expressive and Receptive Language), is often valued in assessing readiness for school, as well as in identifying specific interventions for children with developmental disabilities. The MSCA consists of six scales (Verbal, Perceptual-Performance, Quantitative, General Cognitive, Memory, and Motor). It is a good instrument for assessing general strengths and weaknesses in young children.
Bayley Scales of Infant Development—3 rd edition (BSID-III)	1–42 mos	
Mullen Scales of Early Learning (MSEL)	0–68 mos	
McCarthy Scales of Children's Abilities (MSCA)	2.6 yrs–8.6 yrs	
Nonverbal and Language-Free Tests		
Leiter International Performance Scale—Revised (Leiter-R)	2 yrs–20.11 yrs	Although the nonverbal tests are often seen as language or culture free, strictly speaking, this is not always true because of representational content or language demands. However, some nonverbal tests (such as the TONI-3) depend more on abstract pattern recognition and can make fewer demands on language systems. The WNV provides batteries for younger (4 to 7:11) and older clients (8 to 21:11) and claims to be a general ability measure using nonverbal tests. Tests like Raven's Progressive Matrices (which actually come in several forms) are based on pattern recognition and thought of as "culturally reduced," if not unbiased or unloaded. Nonverbal tests can be useful in assessing individuals whose experience falls outside the cultural norm.
Test of Nonverbal Intelligence—3 rd edition (TONI-3)	6 yrs–89.11 yrs	
Comprehensive Test of Nonverbal Intelligence (CTONI)	6 yrs–89.11 yrs	
Wechsler Nonverbal Scale of Ability (WNV)	4 yrs–21.11 yrs	
Raven's Progressive Matrices	5 yrs–17+ yrs	
Quick Tests		
Kaufman Brief Intelligence Test—2 nd edition (KBIT-2)	4 yrs–90 yrs	Although the KBIT and WASI include verbal and nonverbal scores, they do not include as much information as more comprehensive intellectual tests. However, they provide an estimate of intellectual level in a fraction of the time.
Wechsler Abbreviated Scale of Intelligence (WASI)	6 yrs–89 yrs	
Achievement Tests		
Wechsler Individual Achievement Test—3 rd edition (WIAT-II)	4 yrs–85 yrs	The WRAT has traditionally been seen as a screening instrument. The WRAT4 includes subtests on sentence comprehension, word reading, spelling, and math calculation. An expanded version (WRAT-E) provides achievement and intellectual information (nonverbal reasoning). The PIAT assesses general information, reading recognition and comprehension, written expression, spelling, and mathematics. The KTEA assesses reading (decoding and comprehension), mathematics (applications and calculations), spelling, written expression, and oral language (listening comprehension and oral expression). The WIAT and WJ-ACH also systematically address the basic areas that have been identified as relevant for learning disability.
Woodcock-Johnson—III Test of Achievement (WJ III ACH)	2 yrs–90+ yrs	
Kaufman Test of Educational Achievement—2 nd edition (KTEA-II)	4.5 yrs–25 yrs	
Peabody Individual Achievement Test—Revised (PIAT-R)	5 yrs–22.11 yrs	
Wide Range Achievement Test—4 th edition (WRAT4) and WRAT—Expanded (WRAT-E)	5 yrs–94 yrs 4–24 yrs (Indiv.)	

Reading Tests		
Gray-Oral Reading Tests—4 th edition (GORT-4)	6 yrs–18.11 yrs	The WRMT (which includes a measure of sound–symbol association) and GORT (which includes a measure of fluency) involve systematic approaches to assess different aspects of reading skills. Because of the importance of phonological awareness in the development of reading skills, tests of phonological processing (such as the CTOPP) are often included in assessments in which reading problems are identified.
Woodcock Reading Mastery Tests—Revised (WRMT-R)	5 yrs–75+ yrs	
Comprehensive Test of Phonological Processing (CTOPP)	5 yrs–24.11 yrs	
Processing Tests		
General Processing Tests		
Woodcock-Johnson-III Test of Cognitive Abilities (WJ III COG)	2 yrs–90+ yrs	The WJ-COG scores provide information about intellectual ability as well as a variety of cognitive and clinical areas. A Diagnostic Supplement (for kindergarten through graduate school) allows for more assessment of processing issues.
Differential Ability Scales–II (DAS-II)	2.6 yrs–17.11 yrs	The DAS provides a measure of general conceptual ability and a profile of cognitive strengths and weaknesses.
Specialized Tests		
A Developmental Neuropsychological Assessment (NEPSY-II)	3 yrs–16.11 yrs	Scored across six domains, the NEPSY provides scores in executive functioning/attention, language, sensorimotor, visuospatial, and memory/learning, and as social perception. As a test of executive functions, nine stand-alone subtests assess cognitive flexibility, response inhibition, problem solving, and concept formation.
Delis-Kaplan Executive Function System (D-KEFS)	8 yrs–89 yrs	
Visual–Motor Tests		
Bender Visual–Motor Gestalt Test—2 nd edition (Bender Gestalt II)	4 yrs–85+ yrs	Both the Bender and VMI involve copying geometric figures. Because the Bender allows the student to organize the items on the page and the VMI asks the student to copy each figure in its own space, the two can be used together to assess organizational issues, as well as visual–motor integration. Both the current versions of the Bender and VMI provide ways of assessing perceptual separate from motor skills. The TVPS is motor free and involves making judgments about visual information—for example, a client might be asked to identify an item from a fragmented presentation.
Beery Developmental Test of Visual–Motor Integration—5 th edition, Revised (VMI-5)	2 yrs–18 yrs	
Test of Visual–Perceptual Skills—3 rd edition (TVPS-3)	4 yrs–18.11 yrs	
Auditory–Vocal Tests		
Test of Auditory–Perceptual Skills—Revised (TAPS-3)	4 yrs–18.11 yrs	The TAPS involves making judgments about auditory information. For example, the student might be asked to discriminate sounds or remember words or numbers under different constraints. The TARPS measures the “quality” and “quantity” of the client’s auditory thinking and reasoning.
Test of Auditory Reasoning and Processing Skills (TARPS)	5 yrs–13.11 yrs	
Memory Tests		
Wide Range Assessment of Memory and Learning—2 nd edition (WRAML2)	5 yrs–90 yrs	Memory scales attempt systematically to assess memory skills within different spheres. The WRAML core battery consists of Verbal, Visual, and Attention/Concentration subtests. The CMS allows for the assessment of attention and working memory, verbal and visual memory, short-delay and long-delay memory, recall and recognition, and learning characteristics.
Children’s Memory Scale (CMS)	5 yrs–16 yrs	
Social Cognition		
Test of Problem Solving TOPS-3 referential	6 yrs–12 yrs	Elementary and adolescent clients are asked to answer questions about pictures or scenarios to reveal social reasoning. A test of language used to achieve goals, with information about six areas (setting, audience, topic, purpose, cues, and abstraction).
TOPS-2 Adolescent	12 yrs–17 yrs	
Test of Pragmatic Language (TOPL)	5 yrs–13.11 yrs	

Publishers are constantly updating their tests, and these editions will be superseded by newer and better tests. Even now, there are variations on some instruments that are supplanted, expanded, integrated or newly normed.

 **Table 5.6-2**
Neuropsychological Tests

Memory and Learning	Language
Verbal California Verbal Learning Test for Children (CVLT-C) Children's Auditory Verbal Learning Test Children's Memory Scale (CMS): stories, word pairs, word lists A Developmental Neuropsychological Assessment (NEPSY): memory for names, narrative memory, list learning Wide Range Assessment of Memory and Learning (WRAML): story memory, sentence memory, verbal learning Nonverbal/Visual Benton Visual Recognition Test CMS: dot locations, faces, family pictures NEPSY: memory for faces, memory for designs Rey-Osterrieth Complex Figure, delayed conditions WRAML: design memory picture memory, visual learning Attention Sustained attention/vigilance Continuous Performance Tests (CPT): AX version of the CPT; Connors Continuous Performance Test (CCPT), Tests of Variables of Attention (TOVA) NEPSY: Auditory Attention and Response Set, Visual Attention Paced Auditory Serial Addition Test (PASAT) Working Memory Auditory Consonant Trigrams (ACT) CMS: numbers, sequences Wechsler Intelligence Scale for Children (WISC): digit span, letter/number sequencing, arithmetic, spatial span WRAML: finger windows, number/letter memory, sentence memory Inhibition/impulse control Delis-Kaplan Executive Functions System (DKEFS): color word interference (inhibition) Go/No Go Test NEPSY: auditory attention and response set, inhibition, knock and tap Executive Functioning Organization/problem solving/planning Children's Category Test DKEFS: sorting, 20 questions, tower NEPSY: animal sorting, clocks Rey-Osterrieth Complex Figure: copy condition Cognitive flexibility/set shifting Children's Color Trails DKEFS: trails (number/letter switching), verbal fluency (category switching), design fluency (switching), color-word interference (inhibition/switching) Matching Familiar Figures Test NEPSY: inhibition (shifting) Trail-making Test A and B Wisconsin Card Sorting Test Fluency Controlled Word Association Test DKEFS: verbal fluency, design fluency NEPSY: word generation, design fluency	Expressive Boston Naming Test Clinical Evaluation of Language Fundamentals (CELF): word structure, recalling sentences, formulated sentences, word classes-expressive, expressive vocabulary, sentence assembly Expressive One Word Picture Vocabulary Test NEPSY: sentence repetition, speeded naming Test of Language Competence (TOLC): ambiguous sentences, oral expression Woodcock Johnson-III (WJ-III): picture vocabulary, rapid picture naming Receptive CELF: sentence structure, concepts and following directions, word classes-receptive, semantic relationships, understanding spoken paragraphs NEPSY: comprehension of instructions Peabody Picture Vocabulary Test Token Test TOLC: listening comprehension, figurative language WJ-III: story memory, understanding directions, oral comprehension, auditory attention Visuoperceptual/Visuomotor Functioning Visuoperceptual Benton Facial Recognition Benton Judgment of Line Orientation Hooper Visual Organization Test Motor-Free Test of Visual Perception NEPSY: Arrows, Geometric Designs, Picture Puzzles, Route Finding Test of Visual Perceptual Skills Wide Range Assessment of Visual Motor Abilities (WRAVMA): matching Visuomotor functioning Beery Developmental Test of Visual-Motor Integration NEPSY: block construction, design copying Rey-Osterrieth Complex Figure: copy WRAVMA: drawing WISC: block design Sensorimotor Functions Sensory perceptual Dean-Woodcock Sensory Motor Battery (DWSMB) (all sensory subtests) NEPSY: finger discrimination Reitan-Klove Sensory Perceptual Exam Motor DWSMB: all motor subtests Grip Strength (hand dynamometer) Grooved Pegboard NEPSY: fingertip tapping, imitating hand positions, manual motor sequences, visuomotor precision WRAVMA: pegboard

Description of Cognitive Tests

Although psychologists use diverse tests, three kinds of cognitive testing are described in this subsection: intellectual, achievement, and processing instruments. Generally, intellectual tests measure overall mental ability, achievement tests assess past learning, and processing tests measure discrete cognitive functions.

Intellectual Testing. Intelligence is defined as the ability to learn from and adapt to the environment and the ability to think abstractly. Intelligence tests are used to determine the patient's general intellectual functioning. The intelligence quotient (IQ) is a measure of present intellectual functioning. Although intelligence tests yield one IQ score (or several IQ or index scores), they are, in fact, devices for "sampling" many tasks in a variety of verbal and nonverbal areas. Intelligence testing is often part of a variety of psychological assessment batteries, including psychoeducational and neuropsychological evaluation, along with more general developmental and clinical evaluations. Although there is some disagreement, IQ scores tend to be relatively stable starting as young as 5 to 7 years of age. In general, the older the child is when tested and the smaller the interval between test administrations, the greater is the correlation between two IQ scores. Although using an IQ score can be useful as a way of assessing the client's basic trajectory through life, the prudent practitioner must be aware that there are a number of factors that can affect intellectual functioning and, thus, IQ scores. Factors associated with a disorder and illness can suppress scores, particularly in psychiatric practice. These can include situational factors, such as lack of motivation, as well as transient factors, including inattention, depression, and psychosis.

Despite conceptual and practical complications, high intelligence is associated with better prognosis in a wide range of psychiatric conditions; lower rates for behavior, conduct, and emotional problems in children; and lower rates of referral for psychiatric problems in adults. In the case of any kind of brain damage (neuronal death), intellectual level accounts for a great deal of variance in predicting outcome, with lower IQs associated with poorer outcomes and higher IQs associated with better outcomes.

ASSESSMENT. Although IQ is what is obtained with an IQ test, there are a variety of intellectual tests, as well as other ways of calculating intellectual level. There are a number of instruments from which to choose, and psychologists must make their selection based on the specific characteristics of each test (e.g., normative sample and construction of the instrument) as they relate to the characteristics of the client (e.g., age and referral question). Once the test has been administered, the clinician must make interpretations based on the analysis of overall and subtest scores and their pattern in the context of the diagnostic process.

Comprehensive Intellectual Tests. The two best-known intellectual tests are the Wechsler Intelligence Scales and the Stanford-Binet Intelligence Scales (SB). The current editions of both are divided into separate subtests, and the data are analyzed in separate spheres. There are three separate instruments within the Wechsler tests that are designed for three different age groups over the life span: Wechsler

Preschool and Primary Scale of Intelligence (WPPSI), Wechsler Intelligence Scale for Children (WISC), and Wechsler Adult Intelligence Scale (WAIS). One SB instrument covers a lifetime. Both instruments have made attempts to assist in decision making regarding attentional problems. The WISC has made particular attempts to link its findings to memory, adaptive, and giftedness scales. The SB includes a routing system so that the examiner can “adapt” the administration to the functioning level of the examinee. Table 5.6-3 provides the intellectual classifications systems for the SB and the Wechsler tests. These categories are also relevant to the cognitive results of other psychometrically similar tests.

Table 5.6-3
Comparison of Wechsler Intelligence Scales and Stanford-Binet Intelligence Scales—5th Edition (SB5) Intellectual Ranges^a

Wechsler Intellectual Ranges ^b		SB5 Intellectual Ranges	
IQ/Index Score	Range	IQ/Index Score	Range
		145–160	Very gifted or highly advanced
≥130	Very superior	130–144	Gifted or very advanced
120–129	Superior	120–129	Superior
110–119	High average	110–119	High average
90–109	Average	90–109	Average
80–89	Low average	80–89	Low average
70–79	Borderline	70–79	Borderline impaired or delayed
≤69	Extremely low	55–69	Mildly impaired or delayed
		40–54	Moderately impaired or delayed

IQ, intelligence quotient.

^aBoth instruments have a mean of 100 and standard deviation of 15.

^bThese ranges apply to the composite scores of all current Wechsler IQ tests (WPPSI-III, WISC-IV, WAIS-III).

Achievement Testing. Achievement testing is used to determine a student’s level of functioning in basic academic areas (i.e., reading, mathematics, and writing). The purpose of the assessment is to identify learning problems and usually to rule out other psychological factors that might be complicating learning. Unlike intellectual testing, achievement testing is not necessarily expected to be stable over time because it measures the child’s success in formal learning and is highly dependent on the home environment and the school curriculum. Learning disability is commonly defined in terms of “unexpected underachievement”—that is, the child has the potential and opportunities to have learned more. When achievement testing is undertaken along with intellectual and processing testing, the overall evaluation is commonly referred to as a psychoeducational assessment.

ASSESSMENT. Psychologists commonly begin an assessment of academic achievement by giving a comprehensive test in order to get a sense of a client’s areas of weakness in contrast to his or her strengths in reading, math, and writing. These findings are compared with school records. Because reading problems are a relatively common reason for referral and their causes are increasingly understood, where indicated, this comprehensive test is commonly followed by other tests of reading skills that separate out accuracy, fluency, and comprehension.

Comprehensive Achievement Tests. Each of the tests assesses a range of academic areas, so that they can be compared with each other for any individual or to academic achievement according to more external standards (age/grade expectations). The Wechsler Individual Achievement Tests (WIAT) and the Woodcock-Johnson Tests of Achievement (WJ-ACH) allow for the systematic assessment of reading (basic word recognition/decoding and comprehension), mathematics (calculation and reasoning), and writing (brief to extensive composition), as well as spelling and other academic spheres.

FOCUSED NEUROPSYCHOLOGICAL ASSESSMENT

Neuropsychology is dedicated to the study of brain-behavior relations and has matured into a clinical discipline for the diagnosis and characterization of brain function and dysfunction.

Assessment of Functioning

Neuropsychological assessment was originally developed for the assessment of *adult* patients and was not generally applied to child assessment until later. This functional assessment was important because the effect of trauma to the brain is highly variable across individuals, even when the precise location and size of the lesion is known. In these situations, neuropsychological tests could provide specific functional information that take the child’s age and developmental status into account. This continues to be a prominent point of referral for pediatric neuropsychology because it discusses not just the existence of the brain disruption but also its *meaning* in terms of the child’s ability to function. This use of neuropsychological assessment is important with gross injury to the brain, but it is also valuable in situations in which sequelae are subtle and at risk of being attributed to psychological factors such as grief or poor motivation.

Technical Advances

Recent advances in neuroimaging have added to the use of neuropsychology in child assessment. One reason that neuropsychology was later in being applied to children was that technology for learning about *children’s normal brain development* was not available. Given that neuropsychology studies the relationship between *behavior and the brain*, this gap in knowledge meant that inferences about brain function could not be applied to children. Because techniques such as positron emission tomography (PET) were prohibited in research with children, it was not until the introduction of functional magnetic resonance imaging (fMRI) in the early 1990s that full-scale research of child brain development could begin. Since that time, there has been an unprecedented explosion of knowledge that has expanded the scientific understanding of child brain development exponentially every year up to the present.

Developments in Test Instruments

Other advances in pediatric neuropsychology include the introduction of tests specifically designed for use with children. These instruments assess similar behaviors as do their adult counterparts but use paradigms that are more engaging to children and better measure developmental transitions throughout childhood. These instruments are used in clinical assessments but are now also part of many research protocols examining childhood diseases and genetic conditions. Given its precision in measuring behavior, neuropsychological assessment is now involved, not just in the assessment of function after an injury but also in the initial *diagnostic* processes. Another example of this

specificity is the now-routine use of neuropsychological testing in genetic research of developmental disorders of childhood, given the precision that it adds to questions of endophenotype expression.

Neuropsychology's Application to Diagnosis and Treatment Planning

These new technologies have greatly enlarged our understanding of both normal and atypical brain development in children, affecting our knowledge of childhood brain-behavior relationships, as well as diagnosis and treatment planning in pediatric groups. This increased understanding of typical as well as atypical brain development has made neuropsychological assessment useful, not just for children with acquired disorders but also in cases of developmental disorders. In this context, the term *developmental disorders* is used in reference to a child who is not developing in step with peers but who for unknown reasons struggles greatly or fails to develop specific abilities. Examples are difficulty in learning to read in an otherwise intact child (referred to as the developmental disorder of dyslexia) and problems with developing social or self-regulatory skills (seen in, respectively, autism spectrum and attention-deficit disorders). These disorders stand in contrast to "acquired" disorders, in which a known event, such as injury or illness, has affected the child's developmental trajectory.

Integration of Neuropsychological, Educational, and Psychological Paradigms in Testing

The effect on testing that these breakthroughs have made has also been significant. Most of this subsection focuses on test instruments that are foundational when assessing developmental differences in children. These measures (including tests of IQ or academic achievement) are central when youngsters are not keeping up with their peers in one regard or another and are the backbone of testing, regardless of whether the assessor is trained as a psychologist or a neuropsychologist or has a background in education. These instruments are pivotal because they measure the major paradigms of both education and psychology, paradigms that govern both diagnosis and the provision of services.

More recently, however, these established paradigms have been joined and affected by new information emerging from cognitive and neuropsychology in concert with the aforementioned breakthroughs in neuroimaging. The integration of these findings has led to relatively rapid changes in educational law and in the instruments used to test children for learning disabilities.

Applications of Neuropsychological Assessment

The functional and diagnostic assessment of children and adolescents often begins (and ends) with the kinds of evaluations described in the "General Cognitive Assessment" subsection. There are situations, however, in which the use of educational or psychological or cognitive testing alone is not able to clarify the diagnosis and determine the most appropriate treatment plan. In those cases, the psychiatrist should consider additional neuropsychological testing.

Descriptions and Assessment of Typical Neuropsychological Domains

Typically, in addition to assessing IQ, academic achievement, and social and emotional functioning, neuropsychologists assess domains of memory, attention, executive functioning, language, visual perception, and sensory-motor development. Tests have been developed to examine specific aspects of these domains in isolation so as to increase diagnostic clarity. Although these domains are discussed as different constructs in this subsection, in truth they overlap with one another in many different ways. For example, the term *working memory* is often conceptualized as being an aspect of attention as well as a necessary component of good planning (which is part of executive functioning). It is also a component of memory in that, when it is not well developed, it leads to the phenomenon of forgetfulness.

Memory. *Memory* is defined as the ability to reproduce or recall what has been learned or retained through activities or experiences. The process of memorizing includes two steps: encoding and retrieving. One metaphor for this two-step memory process is a filing cabinet. *Encoding*, then, is when a person puts information into the "filing cabinet drawer." Someone with a true amnesic disorder (such as Alzheimer's disease) never gets the information into the drawer. No amount of cueing or reminders later on will help the person to recall the information because it never "got into the drawer" in the first place. This type of impairment can be seen in some children, most often those with seizure disorders that adversely affect the temporal lobes. For most children, however, the problem described as "poor memory" is actually a difficulty with retrieval. *Retrieval* is the ability to get information out of the "file cabinet drawer" once it has been put in. Poor retrieval is associated with problems of organization (the folders are missing labels) and is more often the issue when children are described as being forgetful.

To differentiate between encoding and retrieval, children are asked to memorize material and then, 20 to 30 minutes later, to recall it. If they are unable to remember it spontaneously, the examiner does not know whether they have not encoded it or are having problems with retrieval. If the child can remember the material with cueing (e.g., "In the story I read you, was the boy's name Johnny or Sam?"), retrieval is implicated. For the child who cannot encode, however, cueing will not help.

ASSESSMENT. In assessing memory, several guidelines should be followed. Both visual and verbal memory tasks should be given. Visual memory tasks (such as learning the location of dots or memorizing faces) are usually aided by the right hemisphere. In most people, verbal memory tasks (such as memorizing a shopping list or a story) are supported by the left hemisphere. In addition, material to be memorized should include rote tasks (such as word lists) as well as material that is presented in context (such as stories). Some memory tasks assess learning, or the child's ability to benefit from several presentations of the material. It is expected that, after three exposures to a picture of dots, the child's memory of it will be stronger than it was after the first exposure. If not, encoding may be implicated. A 20- to 30-minute delay should also be part of the memory assessment, and cues should be available to differentiate between encoding and retrieval difficulties.

Other terms in the neuropsychological literature appear to describe memory but are actually probably better classified as part of the attention system. These include *short-term memory* and *working memory*. These terms are discussed in the following subsection on attention.

Attention. The attention literature is large and includes many different conceptualizations. The following illustration demonstrates some elements of good attention.

Suppose you arrive at a lecture hall, open your notebook, and rather than scanning the room indiscriminately, turn your attention to the instructor, who is just beginning to speak (*selective attention*). The lecture is mildly interesting, and you are able to pay attention for the full 20-minute presentation (*sustained attention* or *vigilance*). At the same time that you are listening to the instructor, you are taking handwritten notes incorporating headings and subheadings. It appears that you are able simultaneously to listen, write, and organize rather effortlessly, although you are probably shifting your attention among these competing tasks (*divided attention*). A fire engine goes by the lecture hall and you look up (*distraction*) but are then able to ignore the dimming noise of the siren (*inhibition*) and continue to listen to the lecture (again, *sustained attention*). Suddenly, the fire alarm rings, and you smell smoke. These distracters capture your full attention (*disengagement* from lecture), and their importance causes you to change your attention and behavior (*set shifting*) as you hurriedly head for the door. A breakdown in any one of these areas can lead to a breakdown in attention.

ASSESSMENT. Assessment of attention requires a number of approaches. Children with attention problems exhibit them at home and at school whenever a task becomes less interesting to them. They function better when working one-on-one with a person or when working on a new activity because it is more stimulating. For this reason, the testing environment may not elicit the inattentive behavior (especially on

the first day). To assess the child's attention "in real life" and across settings, attention questionnaires should be completed by both parents and teachers. Many researchers consider this aspect of the assessment of attention to be the most important. Some neuropsychological measures have been found to be sensitive to attention as well. Computerized measures of sustained attention that are designed to be long and boring can capture the loss of attention described here. In addition, specific kinds of performance patterns on these measures have been shown to differentiate different types of attention problems.

Assessment of *verbal* short-term memory might include the repetition of digits or of short sentences. Assessment of *visual* short-term memory can be achieved by having the child point to dots or circles on the page in the same order in which the examiner has just pointed to them. Working memory is usually assessed as the second part of a short-term memory test. It requires that the material that has been stored in short-term memory be manipulated in some way. Verbal working memory can be assessed by having the child repeat digits backward or by doing mathematics in his or her head. Saying the months of the year backward can also assess verbal working memory (as long as the child is able to give them in their usual order without difficulty). Having the child point to the dots on the page in the reverse order in which they are shown can assess visual-spatial working memory.

Executive Functioning. Executive functioning could be considered to be the mature product of good attention. Although not developed in earnest until children reach adolescence, many aspects of executive functioning begin to appear when children are younger and, thus, can be measured. *Executive functioning* refers to the person's ability to organize his or her behaviors to perform a specific goal. Good executive functioning allows a person to identify problems, generate solutions, choose among them, follow through on the chosen strategy, and evaluate its effectiveness as the work progresses. Without good executive functioning, children who are bright have difficulty demonstrating their abilities. Their parents often report school underachievement that cannot be explained by learning problems. The issue is not about "knowledge" but rather the application of that knowledge to everyday functioning.

ASSESSMENT. Assessment of executive functioning requires several tests, given its many facets. Good attention and working memory, already discussed, are crucial to goal-directed behavior. Inhibition can be tested by giving the child a task in which he or she must control an automatic response.

Fluency can be assessed by having the child generate category words under a time limit. For example, a child might be asked to name as many kinds of toys as he or she can in 1 minute. A variant of this task requires the child to create as many designs as he or she can in a 1-minute period, according to strict guidelines.

Cognitive flexibility is often tested with the Wisconsin Card Sorting Test (WCST), a measure of problem solving. On this test, the child is not told how to solve the puzzles; rather, he or she must use feedback that his or her attempts are "right" or "wrong" and is then expected to use this information to generate strategies. During the course of this test, the rules often change without warning, requiring that the child "regroup" and develop a new strategy. This measure generates information about the child's ability to initially figure out the task, his or her tendency to perseverate on wrong responses, and his or her ability to use feedback to generate new responses.

Planning is another aspect of executive functioning. Variants of a "tower" test are often used to assess this ability. On a tower test, the child is shown a picture with colored balls or disks stacked on top of one another on wooden pegs in a specific configuration. The child is told to move the balls or disks on the pegs for an actual model on the table to match the configuration shown in the picture. The child is instructed to move only one ball or disk at a time and to use as few moves as possible. To perform the task well, the child must first "hold back" and not make impulsive moves that may get him or her "cornered." The child must also visualize the first few steps of the problem. Thus, both impulse control and visual working memory are required to exhibit good planning on this rather entertaining test.

Language. Human language organizes, supports, and communicates knowledge, memories, and ideas. Beyond just allowing us to communicate with others, language organizes both thoughts and emotions, as well as helping us sequence our actions. Although traditionally discussed in terms of left hemisphere functioning, much of the human cortex is involved in various aspects of language. Communication includes both *speech*, the rapid and complex motor movements involved in talking, and *language*, the code used to express thoughts and ideas.

Linguists conceptualize language as being composed of four separate parts: *phonemes*, defined as the smallest units of sound in a language; *morphemes*, the smallest units of meaning; *syntax* at the level of the sentence (e.g., use of direct or indirect pronouns); and *discourse*, the stringing together of sentences to create a narrative.

In considering language, perhaps the most common distinction made is between expressive and receptive language. *Expressive language* requires the production of language, including articulating clearly, finding the right word, and applying grammar and syntax to one's ideas, in addition to vocal fluency and voice tone (prosody). *Receptive language* involves the ability to comprehend and remember what is said.

Children with expressive language problems may appear to have little to say and considered to be shy. In fact, however, their difficulty may be with self-expression. Some children who are very talkative (fluent) may also have difficulty with finding the word they want or organizing their sentences to make them clear. The paradox of a fluent child with an expressive language disorder may cause his or her problems to be overlooked.

Receptive language, or the ability to understand what is being said, represents another aspect of the language system. Children with poor receptive language have difficulty in processing information that is spoken to them and may have difficulty learning in the classroom or appear to be inattentive. Sometimes they appear to be oppositional because of their difficulty with understanding (and therefore *doing*) what they are told.

Secondary problems of children with language disorders include difficulties with social interactions and processing of emotions. Language is what humans use to interact and communicate their ideas to one another. When this ability is compromised, children may isolate or try to find less language-intense activities to occupy their time. Emotional problems may ensue from the child's difficulty with using language to express and, therefore, process his or her inner world.

ASSESSMENT. Assessment of language should include several measures meant to identify the child's specific language profile. Tests should assess all levels of language, including phonemes, single words, simple phrases, complex sentences, and conversation. Measures of both expressive and receptive language should be included. In the assessment of receptive language, children are asked to distinguish between similar sounds and words, remember and repeat word lists and related strings of words, point to a picture that depicts a vocabulary word, and follow increasingly complex directions presented only once. In the assessment of expressive language, children are asked to perform tasks such as listing as many round objects as they can within a time limit, naming a depicted or described item, defining words or concepts, or creating a syntactically complex sentence according to strict guidelines.

In addition, the psychologist might explore *pragmatics*, which is the child's ability to participate in conversation and use social language. This involves interpreting nonverbal aspects of communication, as well as observing basic social rules, such as turn-taking in conversation. Although neuropsychologists often evaluate pragmatics in addition to receptive and expressive language, they also work in concert with speech and language specialists when additional assessment is indicated.

Visuoperceptual Functioning. There are several associated constructs in neuropsychology that reflect people's ability to make sense of what they see, to organize it, or to copy it. These abilities are referred to as *visuoperceptual-visuoconstructive abilities*.

Problems with visuoperception are distinct from problems with vision. A person with acute eyesight can struggle with perceptual difficulties, such as identifying which of several figures are exactly alike. Some children have difficulty seeing exactly where something is, and these children may have trouble localizing a point in space or judging the direction of

a line. *Visuoconstruction* abilities allow a child to join parts to make a whole. These skills require the integration of the motor system with the visual system. Examples include the ability to put together blocks to form a design or to draw three lines to form a triangle.

Problems with visuo-perceptual development have academic, as well as social, ramifications. Academic areas, such as mathematics, that are less reliant on verbal support are at risk. In addition, concepts such as time and monetary values may not be clearly understood. Students with these difficulties often exhibit a poor sense of direction, and problems with integrating complex visual arrays may lead to feelings of being overwhelmed. They may also have difficulty “reading between the lines,” thereby making comprehension of less tangible reading concepts (such as theme) more elusive.

Social problems are also often seen in students with these delays. Many elements of good social interactions are nonverbal, including the ability to notice and interpret gestures, facial expression, body posture, and tone of voice. Students with visuo-perceptual delays may be overreliant on verbal information and may not understand when people are being sarcastic or when something is said in jest.

ASSESSMENT. Assessment of visual processing must address each of the specific elements of this system. The visuo-perceptual abilities should be tested using tasks that do not require the child to use his or her hands to produce the response—for example, activities that require the child to identify designs that match or differ from the target, as well as measures of mental rotation (determining which design is the same as the target, only rotated). Visuoconstruction tasks add the demand of integrating the hands and eyes in producing the response—for example, having the child draw copies of designs or use blocks to create a replica of a model.

Sensory/Motor Functioning. The sensory/motor system is also assessed as part of the neuropsychological examination. Lateralized sensory or motor problems suggest neurological problems on the opposite side of the brain and are often correlated with cognitive processes localized to the right or left hemisphere. Tasks requiring the perception of visual or auditory fields or specific actions with right or left sides of the body are part of this domain. In addition, integration of perceptions or movements is also assessed.

Motor assessment is further categorized into the assessment of handedness and tests of large versus fine motor development, as well as the ability to plan motor responses (praxis).

ASSESSMENT. The sensory exam usually includes assessment of visual fields using clinical methods, such as having the child look at the examiner’s nose and then determine whether the assessor is moving the right or left extended hand. Similarly, assessment of bilateral auditory perception might include the assessor standing behind the child and rubbing his or her fingers near the child’s right or left ear. Other perceptual tests might assess the ability to name unseen objects placed in the child’s right or left hand. Finger agnosia is tested by touching a finger when the child’s hand is hidden behind a screen and then having him or her indicate which finger was touched. Integration of perception might include having the child follow directions involving a picture that is shown. Age-based normative data are available for all of these tasks.

Both fine and large motor tests are usually assessed on both the right and left sides of the body. Lateralized fine motor tasks include quickly placing pegs in holes with each hand or squeezing a hand dynamometer with each hand to assess grip strength. Fingertip tapping is one way of testing motor sequencing, as are activities that require the child to repeat sequences of movements from memory. Handedness is best assessed by having the child do a number of tasks with one hand (e.g., “Show me how you use this spoon,” “Hand me the dime,” and “Throw me the ball.”) in random order. Assessment of difficulties with motor planning can be done using pantomime.

Large motor testing involves having the child demonstrate gait while walking forward and backward, running, skipping, walking a straight line, and balancing on one foot. In cases in which the findings of motor screening are significant, the neuropsychologist might refer the child to an occupational or physical therapist for further, more specific, evaluation.

Neuropsychological testing is commonly undertaken according to several discrete domains that reflect areas of brain functioning. Typically, these include attention and executive functioning, memory, and language as well as visuo-perceptual and sensory/motor functioning. In considering neuropsychological issues, the following factors should be kept in mind:

- ▶ After early brain injury, language and motor functioning are the most likely to benefit from “plasticity.” Some research suggests that, with this process of reorganization, other functions (most notably, visuo-perceptual abilities) may be “crowded out,” yielding scores that are lower than expected.
- ▶ Interventions for neurologically driven developmental delays have their most profound effect on younger children. Recent studies have shown that, in children with reading disabilities, bilateral representation of language identified with fMRI before intervention shifted to the left hemisphere by several orders of magnitude in every subject after only 80 hours of reading intervention. These changes in the brain were accompanied by improved reading skills. Thus, the philosophy of delaying intervention until a deficit is fully expressed may keep children from receiving the full benefit that early intervention provides.
- ▶ Risk factors for reading disabilities include family history, early language delays, poor articulation, chronic ear infections, poor early rhyming abilities, inability to recite (not sing) the alphabet by the end of kindergarten, and early brain injury.
- ▶ Ambidexterity (consistently using the right hand for some specific tasks and the left hand for other specific tasks) often runs in families in which several members are left handed. In contrast, ambiguous handedness (or the use of either hand for the same task; sometimes writing with the right hand, sometimes writing with the left hand) can be a pathognomonic sign suggesting poor cerebral organization for specific behaviors.
- ▶ Attention-deficit/hyperactivity disorder (ADHD) more adversely affects abilities typically associated with right hemisphere functioning (such as fine motor skills and visuo-perceptual abilities) and affects attention and executive functioning. Psychostimulant medication has been shown to improve functioning in all of these domains in children with ADHD.

5.7 Medical Assessment and Laboratory Testing in Psychiatry

Two recent issues have pushed medical assessment and laboratory testing in psychiatric patients to the forefront of attention for most clinicians: the widespread recognition of the pervasive problem of metabolic syndrome in clinical psychiatry and the shorter life expectancy of psychiatric patients compared with that of the general population. Factors that may contribute to medical comorbidity include abuse of tobacco, alcohol and drugs, poor dietary habits, and obesity. Further, many psychotropic medications are associated with health risks that include obesity, metabolic syndrome, and hyperprolactinemia. Consequently, monitoring the physical health of psychiatric patients has become a more prominent issue.

A logical and systematic approach to the use of medical assessment and laboratory testing by the psychiatrist is vital to achieving the goals of arriving at accurate diagnoses, identifying medical comorbidities, implementing appropriate treatment, and delivering cost-effective care. With respect to the diagnosis or management of medical disease, consultation with colleagues in other specialties is important. Good clinicians recognize the limits of their expertise and the need for consultation with their nonpsychiatric colleagues.

PHYSICAL HEALTH MONITORING

Monitoring the physical health of psychiatric patients has two goals: to provide appropriate care for existing illnesses and to protect the patient's current health from possible future impairment. Disease prevention should begin with a clear concept of the condition to be avoided. Ideally, in psychiatry this would be a focus on commonly found conditions that could be a significant source of morbidity or mortality. It is clear that in psychiatry a small number of clinical problems underlie a significant number of impairments and premature deaths.

ROLE OF HISTORY AND PHYSICAL EXAMINATION

A thorough history, including a review of systems, is the basis for a comprehensive patient assessment. The history guides the clinician in the selection of laboratory studies that are relevant for a specific patient. Many psychiatric patients, owing to their illnesses, are not capable of providing sufficiently detailed information. Collateral sources of information, including family members and prior clinicians and their medical records, may be particularly helpful in the assessment of such patients.

The patient's medical history is an important component of the history. It should include notation of prior injuries and, in particular, head injuries that resulted in loss of consciousness and other causes of unconsciousness. The patient's medical history also should note pain conditions, ongoing medical problems, prior hospitalizations, prior surgeries, and a list of the patient's current medications. Toxic exposures are another important component of the medical history. Such exposures are often workplace related.

The social history contains many of the details relevant to the assessment of character pathology, including risk factors for personality disorders as well as information relevant to the assessment of major disorders. Commonly, the social history includes a legal history, information about family and other significant relationships, and an occupational history.

In evaluating patients who appear demented, the role of the physical examination is to elucidate possible causative factors such as the cogwheel rigidity and tremor associated with Parkinson's disease or neurological deficits suggestive of prior strokes. Standard laboratory studies commonly assessed in dementia patients include a complete blood count (CBC), serum electrolytes, liver function tests, blood urea nitrogen (BUN), creatinine (Cr), thyroid function tests, serum B₁₂ and folate levels, Venereal Disease Research Laboratory (VDRL) test, and a urinalysis. Currently, there is no clear clinical indication for testing for the apolipoprotein E epsilon 4 allele. Often, a computed tomography (CT) scan is performed if there are focal neurological findings, and an electroencephalogram (EEG) may be performed if there is delirium. When patients are delirious, the neurological examination may be complicated by inattention due to altered levels of consciousness. Delirium workup often includes the same laboratory workup described above for dementia. Urine or blood cultures, chest radiograph, neuroimaging studies, or EEG also may be appropriate.

IMAGING OF THE CENTRAL NERVOUS SYSTEM

Imaging of the central nervous system (CNS) can be broadly divided into two domains: structural and functional. Structural imaging provides detailed, noninvasive visualization of the morphology of the brain. Functional imaging provides a visualization of the spatial distribution of specific biochemical processes. Structural imaging includes X-ray CT and magnetic resonance imaging (MRI). Functional imaging includes positron emission tomography (PET), single photon emission computed tomography (SPECT), functional MRI (fMRI), and magnetic resonance spectroscopy (MRS). With the limited exception of PET scanning, functional imaging techniques are still considered research tools that are not yet ready for routine clinical use.

Magnetic Resonance Imaging

MRI scans are used to distinguish structural brain abnormalities that may be associated with a patient's behavioral changes. These studies provide the clinician with images of anatomical structures viewed from cross-sectional, coronal, or oblique perspectives. MRI scans can detect a large variety of structural abnormalities. The MRI is particularly useful in examining the temporal lobes, the cerebellum, and the deep subcortical structures. It is unique in its ability to identify periventricular white matter hyperintensities. MRI scans are useful in examining the patient for particular diseases, such as nonmeningeal neoplasms, vascular malformations, seizure foci, demyelinating disorders, neurodegenerative disorders, and infarctions. Advantages of MRI include the absence of ionizing radiation and the absence of iodine-based contrast agents. MRI scans are contraindicated when the patient has a pacemaker, aneurysm clips, or ferromagnetic foreign bodies.

Computed Tomography

CT scans are used to identify structural brain abnormalities that may contribute to a patient's behavioral abnormalities. These studies provide the clinician with cross-sectional X-ray images of the brain. CT scans can detect a large variety of structural abnormalities in the cortical and subcortical regions of the brain. CT scans are useful when a clinician is looking for evidence of a stroke, subdural hematoma, tumor, or abscess. These studies also permit visualization of skull fractures. CT scans are the preferred modality when there is suspicion of a meningeal tumor, calcified lesions, acute subarachnoid or parenchymal hemorrhage, or acute parenchymal infarction.

CT scans may be performed with or without contrast. The purpose of contrast is to enhance the visualization of diseases that alter the blood-brain barrier, such as tumors, strokes, abscesses, and other infections.

Positron Emission Tomography

PET scans are performed predominantly at university medical centers. PET scans require a positron emission tomograph (the scanner) and a cyclotron to create the relevant isotopes. This type of scan involves the detection and measurement of emitted positron radiation after the injection of a compound that has been tagged with a positron-emitting isotope. Typically, PET scans use fluorodeoxyglucose (FDG) to measure regional brain glucose metabolism. Glucose is the principal energy source for the brain. These scans can provide information about the relative activation of brain regions because regional glucose metabolism is directly proportionate to neuronal activity. Brain FDG scans are useful in the differential diagnosis of dementing disease. The most consistent finding in the PET literature is the pattern of temporal-parietal glucose hypometabolism in patients with Alzheimer's type dementia.

PET scanning using FDDNP (2-(1-{6-[(2-[fluorine-18]fluoroethyl)(methyl)amino]-2-naphthyl}-ethylidene) malononitrile) has the ability to differentiate between normal aging, mild cognitive impairment, and Alzheimer's disease by determining regional cerebral patterns of plaques and tangles associated with Alzheimer's disease. FDDNP binds to the amyloid senile plaques and tau neurofibrillary tangles. FDDNP appears to be superior to FDG PET in differentiating Alzheimer's patients from those with mild cognitive impairment and subjects with normal aging and no cognitive impairment.

Single Photon Emission Computed Tomography

SPECT is available in most hospitals but is rarely used to study the brain. SPECT is more commonly used to study other organs, such as the heart, liver, and spleen. Some recent work, however, attempts to correlate SPECT brain imaging with mental disorders.

Functional Magnetic Resonance Imaging

fMRI is a research scan used to measure regional cerebral blood flow. Often, fMRI data are superimposed on conventional MRI images, resulting in detailed brain maps of brain structure and function. The measurement of blood flow involves the use of the heme molecule as an endogenous contrast agent. The rate of flow of heme molecules can be measured, resulting in an assessment of regional cerebral metabolism.

Magnetic Resonance Spectroscopy

MRS is another research method to measure regional brain metabolism. MRS scans are performed on conventional MRI devices that have had specific upgrades to their hardware and software. The upgrades permit the signal from protons to be suppressed and other compounds to be measured. (Conventional MRI images are, in reality, a map of the spatial distribution of protons found in water and fat.)

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is a method for creating three-dimensional maps of cerebral blood flow. Neurologists and neurosurgeons more commonly use this test. It is rarely used by psychiatrists.

TOXICOLOGY STUDIES

Urine drugs of abuse screens are immunoassays that detect barbiturates, benzodiazepines, cocaine metabolites, opiates, phencyclidine, tetrahydrocannabinol, and tricyclic antidepressants. These rapid tests provide results within an hour. However, they are screening tests; additional testing is required to confirm the results of this screening.

Testing to determine blood concentrations of certain psychotropic medications enables the clinician to ascertain whether blood levels of medications are at therapeutic, subtherapeutic, or toxic levels. Psychiatric symptoms are not uncommon when prescribed medications are at toxic levels. In the debilitated and the elderly, pathological symptoms may occur at therapeutic concentrations. The normal reference range varies between laboratories. It is important to check with the laboratory performing the test to obtain the normal reference range for that laboratory.

Testing for drugs of abuse is usually performed on urine specimens. It also may be performed on specimens of blood, breath (alcohol), hair, saliva, and sweat. Urine screens provide information about recent use of frequently abused drugs such as alcohol, amphetamines, cocaine, marijuana, opioids, and phencyclidine along with 3,4-methylenedioxymethamphetamine (MDMA) (ecstasy). Many substances may produce false positives with urine drug screening tests. When a false positive is suspected, a confirmatory test may be requested.

Comprehensive qualitative toxicology screening is usually performed by liquid and gas chromatography. This may require many hours to perform and is rarely done in routine clinical situations. It is usually performed in patients with unexplained toxicity and an atypical clinical picture.

Qualitative toxicology assessments may be useful in managing patients who have overdosed, when combined with clinical assessment and knowledge of when the ingestion occurred.

Drug Abuse

Patients are frequently unreliable when reporting their drug abuse history. Drug-induced mental disorders often resemble primary psychiatric disorders. Furthermore, substance abuse can exacerbate preexisting mental illness. Indications for ordering a drug abuse screen include unexplained behavioral symptoms, a history of illicit drug use or dependence in a new patient evaluation, or a high-risk background (e.g., criminal record, adolescents, and prostitutes). A drug abuse screen is also frequently used to monitor patient abstinence during treatment of substance abuse. Such tests can be ordered on a scheduled or random basis. Many clinicians believe random testing may be more accurate in the assessment of abstinence. The tests also may help to motivate the patient.

Other laboratory data may suggest a problem with substance abuse. An increase in the mean corpuscular volume is associated with alcohol abuse. Liver enzymes may be increased with alcohol abuse or from hepatitis B or C acquired from intravenous (IV) drug abuse. Serological testing for hepatitis B or C can confirm that diagnosis. IV drug abusers are at risk for bacterial endocarditis. If bacterial endocarditis is suspected, further medical workup is indicated.

Tested Substances. Routine tests are available for phencyclidine (PCP), cocaine, tetrahydrocannabinol (THC; also known as *marijuana*), benzodiazepines, methamphetamine and its metabolite amphetamine, morphine (Duramorph), codeine, methadone (Dolophine), propoxyphene (Darvon), barbiturates, lysergic acid diethylamide (LSD), and MDMA.

Drug screening tests may have high false-positive rates. This is often due to the interaction of prescribed medication with the test, resulting in false-positive results and lack of confirmatory testing. False-negative tests are common as well. False-negative results may be due to problems with specimen collection and storage.

Testing is most commonly performed on urine, although serum testing is also possible for most agents. Hair and saliva testing are also available in some laboratories. Alcohol can also be detected in the breath (breathalyzer). With the exception of alcohol, drug levels are not usually determined. Instead, only the presence or absence of the drug is determined. There is usually not a meaningful or useful correlation between the level of the drug and clinical behavior. The length of time that a substance can be detected in the urine is listed in [Table 5.7-1](#).

Table 5.7-1
Drugs of Abuse that Can Be Detected in Urine

Drug	Length of Time Detected in Urine
Alcohol	7–12 hrs
Amphetamine	48–72 hrs
Barbiturate	24 hrs (short acting); 3 wks (long acting)
Benzodiazepine	3 days
Cocaine	6–8 hrs (metabolites 2–4 days)
Codeine	48 hrs
Heroin	36–72 hrs
Marijuana	2–7 days
Methadone	3 days
Methaqualone	7 days
Morphine	48–72 hrs

Alcohol

There is no single test or finding on physical examination that is diagnostic for alcohol abuse. The history of the pattern of alcohol ingestion is most important in making the diagnosis. Laboratory test results and findings on physical examination may help to confirm the diagnosis. In patients with acute alcohol intoxication, a blood alcohol level (BAL) may be useful. A high BAL in a patient who clinically does not show significant intoxication is consistent with tolerance. Significant clinical evidence of intoxication with a low BAL should suggest intoxication with additional agents. Intoxication is commonly found with levels between 100 and 300 mg/dL. The degree of alcohol intoxication can also be assessed using the concentration of alcohol in expired respirations (breathalyzer). Chronic alcohol use is commonly associated with other laboratory abnormalities, including elevation in liver enzymes, such as aspartate aminotransferase (AST), which is usually greater than serum alanine aminotransferase (ALT). Bilirubin also is often elevated. Total protein and albumin may be low, and prothrombin time (PT) may be increased. A macrocytic anemia may be present.

Alcohol abuse may be associated with rhinophyma, telangiectasias, hepatomegaly, and evidence of trauma on physical examination. In withdrawal, patients may have hypertension, tremulousness, and tachycardia.

Laboratory studies in patients who abuse alcohol may reveal macrocytosis. This occurs in most patients who consume four or more drinks per day. Alcoholic liver disease is characterized by elevations in AST and ALT, typically in a ratio of AST to ALT of 2:1 or greater. The γ -glutamyl transpeptidase (GGT) level may be elevated. Carbohydrate-deficient transferrin (CDT) may be helpful in the identification of chronic heavy alcohol use. It has a sensitivity of 60 to 70 percent and a specificity of 80 to 90 percent.

BAL is used to legally define intoxication in the determination of whether an individual is driving under the influence. The legal limit in many states is 80 mg/dL. However, clinical manifestations of intoxication vary with an individual's degree of alcohol tolerance. At the same BAL, an individual who chronically abuses alcohol may exhibit less impairment than an alcohol-naïve individual. Generally a BAL in the range of 50 to 100 mg/dL is associated with impaired judgment and coordination, and levels greater than 100 mg/dL produce ataxia.

Environmental Toxins

Specific toxins are associated with a variety of behavioral abnormalities. Exposure to toxins commonly occurs through occupation or hobbies.

Aluminum intoxication can cause a dementia-like condition. Aluminum can be detected in the urine or blood.

Arsenic intoxication may cause fatigue, loss of consciousness, anemia, and hair loss. Arsenic can be detected in urine, blood, and hair.

Manganese intoxication may present with delirium, confusion, and a parkinsonian syndrome. Manganese may be detected in urine, blood, and hair.

Symptoms of mercury intoxication include apathy, poor memory, lability, headache, and fatigue. Mercury can be detected in urine, blood, and hair.

Manifestations of lead intoxication include encephalopathy, irritability, apathy, and anorexia. Lead can be detected in blood or urine.

Lead levels typically are assessed by collecting a 24-hour urine sample. The free erythrocyte protoporphyrin test is a screening test for chronic lead intoxication. This test is commonly coupled with a blood lead level. The Centers for Disease Control and Prevention specify that a lead level greater than 25 $\mu\text{g}/\text{dL}$ is significant for children. The incidence of lead toxicity in children has been falling recently.

Significant exposure to organic compounds, such as insecticides, may produce behavioral abnormalities. Many insecticides have strong anticholinergic effects. There are no readily available laboratory tests to detect these compounds. Poison control centers may assist in the identification of appropriate testing facilities.

Volatile Solvent Inhalation

Volatile substances produce vapors that are inhaled for their psychoactive effect. The most commonly abused volatile solvents include gasoline, glue, paint thinner, and correction fluid (white-out). The aerosol propellants from cleaning sprays, deodorant sprays, and whipped cream containers may be abused. Nitrites, such as amyl nitrite ("poppers") and butyl nitrite vials ("rush"), and anesthetic gases, such as chloroform, ether, and nitrous oxide, are also abused.

Chronic abuse of volatile solvents is associated with damage to the brain, liver, kidneys, lung, heart, bone marrow, and blood. Abuse may produce hypoxia or anoxia. Signs of abuse include short-term memory loss, cognitive impairment, slurred and "scanning" speech, and tremor. Cardiac arrhythmias may occur. Exposure to toluene, which is present in many cleaning solutions, paints, and glues, has been associated with loss of clear gray-white matter differentiation and with brain atrophy on MRI scans. Methemoglobinemia has occurred with butyl nitrite abuse. Chronic use of volatile solvents is associated with the production of panic attacks and an organic personality disorder. Chronic use may also produce impairment in working memory and executive cognitive function.

SERUM MEDICATION CONCENTRATIONS

Serum concentrations of psychotropic medications are assessed to minimize the risk of toxicity to patients receiving these medications and to ensure the administration of amounts sufficient to produce therapeutic response. This is particularly true for medications with therapeutic blood levels. Medication levels are often influenced by hepatic metabolism. This metabolism occurs via the action of enzymes in the liver.

Acetaminophen

Acetaminophen may produce hepatic necrosis, which in some cases may be fatal. Acetaminophen is one of the most frequently used agents in intentional drug overdoses and is a common cause of overdose-related deaths. Toxicity is associated with levels greater than 5 mg/dL.

(>330 µmol/L) in patients without preexisting liver disease. Chronic abusers of alcohol are particularly vulnerable to the effects of overdose. Acetylcysteine (Mucomyst) treatment must occur promptly after overdose to prevent hepatotoxicity.

Salicylate Toxicity

Aspirin is frequently ingested in overdose. Consequently, serum salicylate levels often are obtained in overdose cases. Some rheumatic patients may chronically ingest large amounts of salicylate for therapeutic reasons. Ingestion of 10 to 30 g of aspirin may be fatal. Most patients will develop symptoms of toxicity when salicylate levels are greater than 40 mg/dL (2.9 mmol/L). Common symptoms of toxicity include acid-base abnormalities, tachypnea, tinnitus, nausea, and vomiting. In cases of severe toxicity, symptoms may include hyperthermia, altered mental status, pulmonary edema, and death.

Antipsychotic Agents

Clozapine. Clozapine (Clozaril) levels are trough levels determined in the morning before administration of the morning dose of medication. A therapeutic range for clozapine has not been established; however, a level of 100 mg/mL is widely considered to be the minimum therapeutic threshold. At least 350 mg/mL of clozapine is considered to be necessary to achieve therapeutic response in patients with refractory schizophrenia. The likelihood of seizures and other side effects increases with clozapine levels greater than 1,200 mg/mL or doses greater than 600 mg per day or both. Clozapine is a common cause of a leukopenia in psychiatry. When moderate to severe leukopenia develops, clozapine treatment must be interrupted, but patients may be retreated with clozapine in the future.

Mood Stabilizers

Carbamazepine. Carbamazepine (Tegretol) may produce changes in the levels of white blood cells, platelets, and, under rare circumstances, red blood cells. Anemia, aplastic anemia, leukopenia, and thrombocytopenia may all occur but are rare. Pretreatment evaluations typically include CBC.

Carbamazepine may produce hyponatremia. This hyponatremia is usually mild and does not produce clinical symptoms. However, carbamazepine may cause the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Carbamazepine may produce a variety of congenital abnormalities, including spina bifida and anomalies of the fingers. Manifestations of toxicity may include nausea, vomiting, urinary retention, ataxia, confusion, drowsiness, agitation, or nystagmus. At very high levels, symptoms may also include cardiac dysrhythmias, seizures, and respiratory depression.

Lithium. Lithium (Eskalith) has a narrow therapeutic index. Consequently, blood levels of lithium must be monitored to achieve therapeutic dosing and avoid toxicity. Side effects are dose dependent. Symptoms of toxicity include tremors, sedation, and confusion. At higher levels delirium, seizures, and coma may occur. Symptoms of toxicity may begin to manifest with serum levels of greater than 1.2 mEq/L and are common with levels greater than 1.4 mEq/L. Elderly or debilitated patients may show signs of toxicity with levels less than 1.2 mEq/L.

Valproate. Because of the risk of hepatotoxicity, ranging from mild dysfunction to hepatic necrosis, pretreatment liver function tests are usually obtained. More commonly valproate (valproic acid [Depakene] and divalproex [Depakote]) may cause a sustained elevation in liver transaminase levels of as much as three times the upper limit of normal.

Valproate may increase the risk of birth defects. A pretreatment urine pregnancy test is usually obtained in women of childbearing years. Women should be cautioned to use adequate contraception.

Hematological abnormalities are also possible and include leukopenia and thrombocytopenia. Treatment with valproate may increase serum ammonia levels. It is prudent to obtain an ammonia level in a patient undergoing valproate treatment who presents with altered mental status or lethargy. Acute pancreatitis may also occur.

Antidepressants

Monoamine Oxidase Inhibitors. Treatment with monoamine oxidase inhibitors (MAOIs) can cause orthostasis and, rarely, hypertensive crisis. Baseline blood pressure measurement should be obtained before the initiation of treatment, and blood pressure should be monitored during treatment.

There are no meaningful blood levels for MAOIs, and direct monitoring of MAOI blood levels is not clinically indicated. Treatment with MAOIs is occasionally associated with hepatotoxicity. For this reason, liver function tests usually are obtained at the initiation of treatment and periodically after.

Tricyclic and Tetracyclic Antidepressants. Routine laboratory studies obtained before initiation of tricyclic or tetracyclic antidepressants (TCAs) typically include CBC, serum electrolytes, and liver function tests. Because TCAs affect cardiac conduction, clinicians also may obtain an electrocardiogram (ECG) to assess for the presence of abnormal cardiac rhythms and prolonged PR, QRS, and QTc complexes before initiation of these medication.

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome (NMS) is a rare, potentially fatal, consequence of neuroleptic administration. The syndrome consists of autonomic instability, hyperpyrexia, severe extrapyramidal symptoms (i.e., rigidity), and delirium. Sustained muscle contraction results in peripheral heat generation and muscle breakdown. Muscle breakdown contributes to elevated levels of creatine kinase (CK). Peripheral heat generation with impaired central mechanisms of thermoregulation results in hyperpyrexia. Myoglobinuria and leukocytosis are common. Hepatic and renal failure may occur. Liver enzymes become elevated with liver failure. Patients may die from hyperpyrexia, aspiration pneumonia, renal failure, hepatic failure, respiratory arrest, or cardiovascular collapse. Treatment includes discontinuation of the neuroleptic, hydration, administration of muscle relaxants, and general supportive nursing care.

A typical laboratory workup for NMS includes a CBC, serum electrolytes, BUN, Cr, and CK. A urinalysis, including an assessment of urine myoglobin, is also usually performed. As part of the differential diagnosis, blood and urine cultures are performed as part of a fever workup. Pronounced elevations in the white blood cell (WBC) count may occur in NMS. White blood cell counts are typically in the range from 10,000 to 40,000 per mm³.

Muscle Injury

Serum CK levels may rise in response to repeated intramuscular (IM) injections, prolonged or agitated periods in restraint, or NMS. Dystonic reactions from neuroleptic administration may also result in elevated levels of CK.

ELECTROCONVULSIVE THERAPY

Electroconvulsive therapy (ECT) is usually reserved for patients with the most treatment-resistant depression. Typical laboratory tests obtained before the administration of ECT include a CBC, serum electrolytes, urinalysis, and liver function tests. However, no specific laboratory tests are required in the pre-ECT evaluation. Usually, an ECG is also obtained. A spinal X-ray series is no longer considered routinely indicated because of the low risk of spinal injury associated with modern administration techniques that use paralyzing agents. A comprehensive medical history and physical examination are useful screening tools to identify possible conditions that could complicate treatment.

ENDOCRINE EVALUATIONS

Endocrine disease is of great relevance to psychiatry. Management of psychiatric illness is complicated by comorbid endocrine disease. Endocrine illness frequently has psychiatric manifestations. For these reasons, screening for endocrine disease is often of relevance to the psychiatrist.

Adrenal Disease

Adrenal disease may have psychiatric manifestations, including depression, anxiety, mania, dementia, psychosis, and delirium. However, patients with adrenal disease rarely come to the attention of psychiatrists. Assessment and management of these patients are best done in conjunction with specialists.

Low plasma levels of cortisol are found in Addison's disease. These patients may have symptoms that are also common in psychiatric conditions including fatigue, anorexia, weight loss, and malaise. Patients may also have memory impairment, confusion, or delirium. Depression or psychosis with hallucinations and delusions may occur.

Elevated levels of cortisol are seen in Cushing's syndrome. About half of all patients with Cushing's syndrome develop psychiatric symptoms. These symptoms may include lability, irritability, anxiety, panic attacks, depressed mood, euphoria, mania, or paranoia. Cognitive dysfunctions may include cognitive slowing and poor short-term memory. Symptoms usually improve when cortisol normalizes. If not, or if symptoms are severe, psychiatric treatment may be necessary.

Cortisol levels have not been found to be useful in the assessment or management of primary psychiatric disease. In particular, the dexamethasone-suppression test (DST) remains a research tool in psychiatry that is not used in routine clinical care.

Anabolic Steroid Use

Use of anabolic steroids has been associated with irritability, aggression, depression, and psychosis. Athletes and bodybuilders are common abusers of anabolic steroids. Urine specimens can be used to screen for these agents. Because so many compounds have been synthesized, a variety of tests may be required to confirm the diagnosis, depending on the compound that has been used. Consultation with a specialist is advised. Generally, androgens other than testosterone can be detected by gas chromatography and mass spectroscopy.

Antidiuretic Hormone

Arginine vasopressin (AVP), also called antidiuretic hormone (ADH), is decreased in central diabetes insipidus (DI). DI may be central (due to the pituitary or hypothalamus) or nephrogenic. Nephrogenic DI may be acquired or due to an inherited X-linked condition. Lithium-induced DI is an example of an acquired form of DI. Lithium has been shown to decrease the sensitivity of renal tubules to AVP. Patients with central DI respond to the administration of vasopressin with a decrease in urine output. Secondary central DI may develop in response to head trauma that produces damage in the pituitary or hypothalamus.

About one-fifth of patients taking lithium develop polyuria, and a larger amount may have some degree of impairment in concentrating urine. Chronic treatment with lithium is a common cause of nephrogenic DI. However, there are other causes of polyuria in lithium-treated patients in addition to nephrogenic DI. Primary polydipsia is common and is often associated with the dry mouth associated with many psychiatric medications. Central diabetes has also been associated with lithium treatment.

Excessive secretion of AVP results in increased retention of fluid in the body. This condition is called SIADH. Water retention in SIADH causes hyponatremia. SIADH may develop in response to injury to the brain or from medication administration (including phenothiazines, butyrophenones, carbamazepine, and oxcarbazepine). The hyponatremia associated with this condition may produce delirium.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) can be assessed in the urine and blood. The urine test for hCG is the basis for the commonly used urine pregnancy test. This immunometric test is able to detect pregnancy approximately 2 weeks after an expected menstrual period has passed. Routine tests are most accurate when performed 1 to 2 weeks after a missed period and are not reliably accurate until the 2-week period has passed. However, there are ultrasensitive urine hCG tests that can accurately detect pregnancy 7 days after fertilization. Pregnancy tests often are obtained before initiating certain psychotropic medications, such as lithium, carbamazepine, and valproate, which are associated with congenital anomalies.

Parathormone

Parathormone (parathyroid hormone) modulates serum concentrations of calcium and phosphorus. Dysregulation in this hormone and the resulting production of abnormalities in calcium and phosphorus may produce depression or delirium.

Prolactin

Prolactin levels may become elevated in response to the administration of antipsychotic agents. Elevations in serum prolactin result from the blockade of dopamine receptors in the pituitary. This blockade produces an increase in prolactin synthesis and release.

Cerebral MRI is not usually performed if the patient is taking an antipsychotic drug known to cause hyperprolactinemia, and the magnitude of the prolactin elevation is consistent with drug-induced causes.

Prolactin levels may briefly rise after a seizure. For this reason, prompt measurement of a prolactin level after possible seizure activity may assist in differentiating a seizure from a pseudoseizure.

Thyroid Hormone

Disease of the thyroid is associated with many psychiatric manifestations. Thyroid disease is most commonly associated with depression and anxiety but may also give rise to symptoms of panic, dementia, and psychosis. Thyroid disease may mimic depression. It is difficult to achieve euthymia if a patient is not euthyroid.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disorder. Tests for SLE are based on the detection of antibodies formed as part of the disease. Antinuclear antibodies are found in virtually all patients with SLE. Antibody levels also are used to monitor the severity of the

illness. A fluorescent test is used to detect the antinuclear antibodies. This test can be positive in a variety of rheumatic diseases. For this reason, a positive result usually is followed by additional tests, including a test to detect anti-deoxyribonucleic acid (DNA) antibodies. Anti-DNA antibodies, when associated with antinuclear antibodies, are strongly suggestive of a diagnosis of lupus. Anti-DNA antibodies are followed to monitor the response to treatment.

Psychiatric manifestations of lupus include depression, dementia, delirium, mania, and psychosis. About 5 percent of patients with lupus present with symptoms of psychosis including hallucinations and delusions.

Pancreatic Function

Measurement of serum amylase is used to monitor pancreatic function. Elevations in amylase levels may occur in alcohol-abusing patients who develop pancreatitis. Serum amylase levels also may be fractionated into salivary and pancreatic components.

CLINICAL CHEMISTRY

Serum Electrolytes

Serum electrolyte levels may be useful in the initial evaluation of a psychiatric patient. Levels of serum electrolytes often are abnormal in patients with delirium. Abnormalities also may occur in response to the administration of psychotropic medications. Low serum chloride levels may occur in eating disorder patients who purge by self-induced vomiting. Serum bicarbonate levels may be elevated in patients who purge or who abuse laxatives. Bicarbonate levels are commonly low in patients who hyperventilate in response to anxiety.

Hypokalemia may be present in eating disorder patients who purge or abuse laxatives and in psychogenic vomiting. Diuretic abuse by eating disorder patients also may produce hypokalemia. Low levels of potassium are associated with weakness and fatigue. Characteristic ECG changes occur with hypokalemia and consist of cardiac arrhythmias, U waves, flattened T waves, and ST-segment depression.

Eating disorder patients with anorexia nervosa or bulimia nervosa usually receive a fairly standard set of laboratory studies, including serum electrolytes (particularly potassium and phosphorus), blood glucose, thyroid function tests, liver enzymes, total protein, serum albumin, BUN, Cr, CBC, and ECG. Serum amylase is often assessed in bulimic patients.

Magnesium levels may be low in alcohol-abusing patients. Low magnesium levels are associated with agitation, confusion, and delirium. If untreated, convulsions and coma may follow.

Low levels of serum phosphorus may be present in eating disorder patients with purging behavior. Phosphorus levels may also be low in anxiety patients who hyperventilate. Hyperparathyroidism may produce low serum phosphorus levels. Elevated serum phosphorus levels are seen in hypoparathyroidism.

Hyponatremia is seen in psychogenic polydipsia and SIADH and in response to certain medications, such as carbamazepine. Low sodium levels are associated with delirium.

Serum calcium abnormalities are associated with a variety of behavioral abnormalities. Low serum calcium levels are associated with depression, delirium, and irritability. Elevated levels are associated with depression, psychosis, and weakness. Laxative abuse, common in eating disorder patients, can be associated with hypocalcemia. Hypocalcemia secondary to hypoparathyroidism may occur in patients who have undergone surgery for thyroid disease.

Serum copper levels are low in Wilson's disease, a rare abnormality in copper metabolism. Copper is deposited in the brain and liver, resulting in decreased intellectual functioning, personality changes, psychosis, and a movement disorder. Symptoms are usually present in the second and third decades of life. Laboratory assessment for Wilson's disease includes the measurement of serum ceruloplasmin, the transport protein for copper, which is low, and urine copper, measured in a 24-hour specimen, which is elevated.

Renal Function

Tests of renal function include BUN and Cr. Other relevant laboratory studies include the routine urinalysis and Cr clearance. An elevated BUN often results in lethargy or delirium. BUN commonly is elevated with dehydration. Elevations in BUN often are associated with impaired clearance of lithium. A less sensitive index of renal function is Cr. Elevations in Cr may indicate extensive renal impairment. Elevated levels occur when approximately 50 percent of the nephrons are damaged.

Cr clearance is often assessed in patients taking lithium. It is a sensitive measurement of renal function. The test is performed in a well-hydrated patient by collecting all of the patient's urine for 24 hours. During the midpoint of the 24-hour collection period, a serum Cr level also is obtained. The resulting data are used to calculate the patient's Cr clearance. Usually, the laboratory performs the calculation.

Elevated levels of porphobilinogen are found in the urine of symptomatic patients with acute intermittent porphyria. Symptoms of this disease include psychosis, apathy, or depression, along with intermittent abdominal pain, neuropathy, and autonomic dysfunction. If urine porphobilinogen levels are elevated when the patient is symptomatic, collection of a 24-hour urine specimen for quantitative assessment of porphobilinogen and aminolevulinic acid is indicated.

Liver Function

Liver function tests (LFTs) commonly include the serum aminotransferases, alkaline phosphatase, γ -glutamyl transpeptidase and tests of synthetic function, usually the serum albumin concentration and prothrombin time, and the serum bilirubin, which reflects hepatic transport capability.

Elevations in AST may occur with diseases of the liver, heart, lungs, kidneys, and skeletal muscle. In patients with alcohol-induced liver disease, AST typically is more elevated than ALT. In viral- and drug-induced liver disease, ALT is often elevated. Serum GGT is elevated in hepatobiliary disease, including alcohol-induced liver disease and cirrhosis.

Alkaline phosphatase elevations occur in many diseases, including diseases of the liver, bone, kidney, and thyroid. Levels of alkaline phosphatase may be elevated in response to some psychiatric medications, most notably the phenothiazines.

Serum ammonia levels are often elevated in patients with hepatic encephalopathy. High levels are associated with the delirium of hepatic encephalopathy. Serum ammonia levels also may be elevated in patients undergoing treatment with valproate.

Serum bilirubin is an index of hepatic and bile duct function. Prehepatic, unconjugated, or indirect bilirubin and posthepatic, conjugated, or direct bilirubin are often assessed to help elucidate the origin of the elevation in bilirubin.

Lactate dehydrogenase (LDH) may be elevated in diseases of the liver, skeletal muscle, heart, and kidney. It is also elevated in pernicious anemia.

Vitamins

Folate and B₁₂. Folate and B₁₂ deficiencies are common in patients who abuse alcohol. Folate and B₁₂ deficiencies are associated with dementia; delirium; psychosis, including paranoia; fatigue; and personality change. Folate and B₁₂ can be directly measured. Low folate levels may be found in patients who use contraceptive pills or other forms of estrogen, who drink alcohol, or who take phenytoin (Dilantin).

INFECTIOUS DISEASE TESTING

Testing for sexually transmitted diseases (STDs) has become common, given the current frequency of these diseases. Some psychiatric illnesses, such as mania and substance abuse, are associated with a higher risk of contracting STDs. STDs include herpes simplex virus types 1 and 2, chlamydia, hepatitis viruses, gonorrhea, syphilis, and human immunodeficiency virus (HIV). Risk factors for STD include contact with sex workers, drug abuse, prior history of STDs, meeting partners on the Internet, multiple sex partners, a new sex partner, and being young or unmarried. Other diseases to think about are Epstein-Barr virus and gonorrhea.

Intravenous Drug Use

The IV route is used for many substances of abuse. Most commonly, heroin, amphetamines, and cocaine are used alone or in combination via the IV route. Because needles often are contaminated, IV drug users are at risk for bacterial endocarditis, hepatitis B and C, HIV infection, and acquired immunodeficiency syndrome (AIDS) from HIV infection. It has been estimated that over 60 percent of new cases of hepatitis C occur in individuals with a history of injecting illicit drugs.

CBC and Serum Blood Cultures. The use of contaminated needles or nonsterile injection sites places IV drug users at risk for bacterial infections, including abscesses, bacteremia, and bacterial endocarditis. Findings on physical examination suggestive of endocarditis, possible bacteremia, or abscess necessitate obtaining a CBC to rule out an elevated WBC count. Blood cultures should be obtained from at least two different sites if the patient is febrile or if findings are suggestive of bacteremia or endocarditis, and internal medicine consultation should be obtained.

Syphilis

The fluorescent treponemal antibody absorption (FTA-ABS) test detects antibody against *Treponema pallidum* spirochetes and is more sensitive and specific than nontreponemal tests for syphilis. The test is used to confirm positive screening tests for syphilis, such as the rapid plasma reagin (RPR) test and the VDRL test. The FTA-ABS test is also used when neurosyphilis is suspected. Once positive, a patient usually remains so for life. False-positive results may occur in patients with SLE.

Viral Hepatitis

Several types of viruses can cause viral hepatitis. Viral hepatitis produces abnormalities in LFTs including elevation of liver enzymes, especially ALT. Symptoms range from mild flu-like manifestations to rapidly progressive and fatal liver failure. Psychiatric manifestations include depression, anxiety, weakness, and psychosis. Viral hepatitis can also impair the metabolism of psychotropic medications that are metabolized by the liver. Impaired liver metabolism requires an adjustment of the dose of medications metabolized by the liver or consideration of agents that are less affected by alterations in liver metabolism. Viruses causing hepatitis include: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis D virus (HDV) (delta agent).

The WBC is normal to low in patients with hepatitis, especially in the preicteric phase. Large atypical lymphocytes occasionally are present. Rarely, aplastic anemia follows an episode of acute hepatitis not caused by any of the known hepatitis viruses. Mild proteinuria is common, and bilirubinuria often precedes the appearance of jaundice. Acholic stools frequently are present during the icteric phase. Strikingly elevated AST or ALT occurs early, followed by elevations of bilirubin and alkaline phosphatase. In a minority of patients, elevations of bilirubin and alkaline phosphatase persist after aminotransferase levels have normalized. Cholestasis may be substantial in acute hepatitis A. Marked prolongation of the PT in severe hepatitis correlates with increased mortality.

Chronic hepatitis, characterized by elevated aminotransferase levels for more than 6 months, develops in 1 to 2 percent of immunocompetent adults with acute hepatitis B. More than 80 percent of all persons with acute hepatitis C develop chronic hepatitis, which, in many cases, progresses slowly. Ultimately, cirrhosis develops in as many as 30 percent of those with chronic hepatitis C and 40 percent of those with chronic hepatitis B; the risk of cirrhosis is even higher in patients coinfecting with both viruses or with HIV. Patients with cirrhosis are at risk, with a rate of 3 to 5 percent per year, of hepatocellular carcinoma. Even in the absence of cirrhosis, patients with chronic hepatitis B—particularly those with active viral replication—are at an increased risk.

ELECTROENCEPHALOGRAM

The EEG assesses regional cerebral electrical activity. Clinical neuroscience has a long history of using the EEG. The EEG can be used in different ways to study specific brain states or activities by modifications to the technique of data collection or to the data themselves. EEG data can be displayed on paper tracings in the manner of conventional EEG recordings. Alternatively, the data can be digitized, and the digitized data can be transformed, often using a Fourier transformation, to yield color-coded topographic brain maps of regional activity. The collection periods can be prolonged, and the data can be electronically displayed along with video monitoring of the patient to provide telemetry assessments of patients with epilepsy. Telemetry assessments are typically performed in an effort to correlate behavioral abnormalities with brain electrical activity as part of the workup of seizure disorders. Prolonged periods of EEG recording during sleep, when coupled with recording of a limited lead ECG and facial muscle activity, result in the sleep EEG or polysomnography. Many clinicians also use the EEG to monitor ECT administration.

Clinicians use the EEG to localize seizure foci and to evaluate delirium. The EEG and its topographical descendants have not found a clear role in the diagnostic assessment of psychiatric patients. The EEG is usually used in psychiatry to rule out nonpsychiatric disease, such as seizure disorders or delirium, as a cause of psychiatric symptoms. When the differential diagnosis includes strokes, tumors, subdural hematomas, or dementia, the yield is usually higher with imaging tests. Not surprisingly, the yield is the highest in patients with a history of a seizure disorder or a clinical history that is strongly suggestive of a recent seizure or other organic illness. Such clinical features would include a history of altered consciousness, atypical hallucinations (e.g., olfactory), head injury, and automatism. In addition, the EEG is commonly obtained when there is an abnormal CT or MRI. It is important to remember that seizures are a clinical diagnosis; a normal EEG does not rule out the possibility of a seizure disorder.

Evoked Potential

Evoked potential (EP) testing is the measurement of the EEG response to specific sensory stimulation. The stimulation may be visual, auditory, or somatosensory. During visual EPs, the patient is exposed to flashing lights or a checkerboard pattern. With auditory EP, the patient hears a specific tone. In somatosensory EP, the patient experiences an electrical stimulation to an extremity. These stimuli occur repeatedly while the patient undergoes a routine EEG. Using a computer, the responses to these stimuli are recorded and averaged. The time frame is measured in milliseconds. These tests are useful in neurology and neurosurgery. For example, they assist in the assessment of demyelinating disorders such as multiple sclerosis (MS). In psychiatry, EP testing may help in the differentiation of organic from functional impairments. A classical example is the use of EP testing to evaluate possible hysterical blindness. The usefulness of these tests in psychiatry is still under investigation.

Polysomnography

Polysomnography is used to assess disorders of sleep by concurrently assessing the EEG, ECG, blood oxygen saturation, respirations, body temperature, electromyogram, and electro-oculogram. Polysomnography has demonstrated an increase in the overall amount of rapid eye movement (REM) sleep and a shortened period before the onset of REM sleep (decreased REM latency) in patients with major depression. These studies may assist in differentiating depression from other conditions that mimic depression. For example, patients who appear depressed from dementia do not have a decreased REM latency or an increase in the amount of REM sleep.

ELECTROCARDIOGRAM

The ECG is a graphical representation of the electrical activity of the heart. Abnormalities in this activity correlate with cardiac pathology. The ECG is most commonly used in psychiatry to assess side effects of psychotropic medications.

Ziprasidone (Geodon) has been associated with a dose-related prolongation of the QTc interval. There is a known association of fatal arrhythmias (e.g., torsades de pointes) with QTc prolongation from some other medications. For this reason, clinicians usually obtain an ECG before initiation of treatment with ziprasidone. Ziprasidone is contraindicated in patients with a known history of QTc prolongation (including congenital long QT syndrome), with recent acute myocardial infarction, or with uncompensated heart failure. Bradycardia, hypokalemia or hypomagnesemia, or the concurrent use of other drugs that prolong the QTc interval all increase the risk for serious arrhythmias. Ziprasidone should be discontinued in patients who have persistent QTc measurements greater than 500 milliseconds.

Like ziprasidone, thioridazine (Mellaril) has been associated with prolongation of the QTc interval in a dose-related manner. Prolongation of the QTc interval has been associated with torsades de pointes arrhythmias and sudden death. An ECG should be obtained before initiating treatment with thioridazine to rule out QTc prolongation.

TCA's are, at times, associated with ECG changes. Anticholinergic effects may increase heart rate. Prolongation of the PR, QT, and QRS intervals, along with ST-segment and T-wave abnormalities, may occur. The TCAs can cause or increase preexisting atrioventricular or bundle branch block. When the QTc exceeds 0.440 second, a patient is at an increased risk for sudden death due to cardiac arrhythmias. Many clinicians obtain an ECG before beginning a TCA in a patient older than 40 years of age and in any patient with known cardiovascular disease.

Lithium therapy can cause benign reversible T-wave changes, can impair sinoatrial (SA) node function, and can cause heart block. ECGs are often obtained before initiation of treatment with lithium and in cases of lithium toxicity or overdose.

Psychiatrists, when treating patients with certain psychiatric diagnoses, also use the ECG. Eating disorder patients commonly have low potassium levels that may result in abnormal ECG recordings. As the serum potassium drops below normal, T waves become flat (or inverted), and U waves may appear.

Holter Monitoring

Holter monitoring is the continuous recording of a patient's ECG activity for a sustained time period (e.g., 24 hours). Patients are ambulatory during this time. It is useful for the evaluation of dizziness, palpitations, and syncope. It is commonly used in the evaluation of patients with panic disorder who manifest cardiac symptoms.

Cardiac Ultrasound

Cardiac ultrasound is the visualization of cardiac anatomy by the use of computer-transformed echoes of ultrasound. It is commonly used in the evaluation of mitral valve prolapse. There is an unclear association between mitral valve prolapse and panic attacks and anxiety disorders.

5.8 Neuroimaging

Primary observation of structural and functional brain imaging in neuropsychiatric disorders such as dementia, movement disorders, demyelinating disorders, and epilepsy has contributed to a greater understanding of the pathophysiology of neurological and psychiatric illnesses and helps practicing clinicians in difficult diagnostic situations.

Neuroimaging methodologies allow measurement of the structure, function, and chemistry of the living human brain. Over the past decade, studies using these methods have provided new information about the pathophysiology of psychiatric disorders that may prove to be useful for diagnosing illness and for developing new treatments. Computer tomographic (CT) scanners, the first widely used neuroimaging devices, allowed assessment of structural brain lesions such as tumors or strokes. Magnetic resonance imaging (MRI) scans, developed next, distinguish gray and white matter better than CT scans do and allow visualizations of smaller brain lesions as well as white matter abnormalities. In addition to structural neuroimaging with CT and MRI, a revolution in functional neuroimaging has enabled clinical scientists to obtain unprecedented insight into the diseased human brain. The foremost techniques for functional neuroimaging include positron emission tomography (PET) and single photon emission computed tomography (SPECT).

USES OF NEUROIMAGING

Indications for Ordering Neuroimaging in Clinical Practice

Neurological Deficits. In a neurological examination, any change that can be localized to the brain or spinal cord requires neuroimaging. Neurological examination includes mental status, cranial nerves, motor system, coordination, sensory system, and reflex components. The mental status examination assesses arousal, attention, and motivation; memory; language; visuospatial function; complex cognition; and mood and affect. Consultant psychiatrists should consider a workup including neuroimaging for patients with new-onset psychosis and acute changes in mental status. The clinical examination always assumes priority, and neuroimaging is ordered on the basis of clinical suspicion of a central nervous system (CNS) disorder.

Dementia. Loss of memory and cognitive abilities affects more than 10 million persons in the United States and will affect an increasing number as the population ages. Reduced mortality from cancer and heart disease has increased life expectancy and has allowed persons to survive to the age of onset of degenerative brain disorders, which have proved more difficult to treat. Depression, anxiety, and psychosis are common in patients with dementia. The most common cause of dementia is Alzheimer's disease, which does not have a characteristic appearance on routine neuroimaging but, rather, is associated with diffuse loss of brain volume.

One treatable cause of dementia that requires neuroimaging for diagnosis is *normal pressure hydrocephalus*, a disorder of the drainage of cerebrospinal fluid (CSF). This condition does not progress to the point of acutely increased intracranial pressure but stabilizes at a pressure at the upper end of the normal range. The dilated ventricles, which may be readily visualized with CT or MRI, exert pressure on the frontal lobes. A gait disorder is almost uniformly present; dementia, which may be indistinguishable from Alzheimer's disease, appears less consistently. Relief of the increased CSF pressure may completely restore gait and mental function.

Infarction of the cortical or subcortical areas, or stroke, can produce focal neurological deficits, including cognitive and emotional changes. Strokes are easily seen on MRI scans. Depression is common among stroke patients, either because of direct damage to the emotional centers of the brain or because of the patient's reaction to the disability. Depression, in turn, can cause pseudodementia. In addition to major strokes, extensive atherosclerosis in brain capillaries can cause countless tiny infarctions of brain tissue; patients with this phenomenon may develop dementia as fewer and fewer neural pathways participate in cognition. This state, called *vascular dementia*, is characterized on MRI scans by patches of increased signal in the white matter.

Certain degenerative disorders of basal ganglia structures, associated with dementia, may have a characteristic appearance on MRI scans. Huntington's disease typically produces atrophy of the caudate nucleus; thalamic degeneration can interrupt the neural links to the cortex (Fig. 5.8-1).

FIGURE 5.8-1

Brain slices. **Top:** Huntington disease. Atrophy of caudate nucleus and lentiform nuclei with dilatation of lateral ventricle. **Bottom:** Normal brain. (From Fahn S. Huntington disease. In: Rowland LP, ed. *Merritt's Textbook of Neurology*. 10th ed. Philadelphia: Lippincott Williams & Wilkins; 2000:659, with permission.)

Space-occupying lesions can cause dementia. Chronic subdural hematomas and cerebral contusions, caused by head trauma, can produce focal neurological deficits or may only produce dementia. Brain tumors can affect cognition in several ways. Skull-based meningiomas can compress the underlying cortex and impair its processing. Infiltrative glial cell tumors, such as astrocytoma or glioblastoma multiforme, can cut off communication between brain centers by interrupting white matter tracts. Tumors located near the ventricular system can obstruct the flow of CSF and gradually increase the intracranial pressure.

Chronic infections, including neurosyphilis, cryptococcosis, tuberculosis, and Lyme disease, can cause symptoms of dementia and may produce a characteristic enhancement of the meninges, especially at the base of the brain. Serological studies are needed to complete the diagnosis. Human immunodeficiency virus (HIV) infection can cause dementia directly, in which case is seen a diffuse loss of brain volume, or it can allow proliferation of Creutzfeldt-Jakob virus to yield progressive multifocal leukoencephalopathy, which affects white matter tracts and appears as increased white matter signal on MRI scans.

Chronic demyelinating diseases, such as multiple sclerosis, can affect cognition because of white matter disruption. Multiple sclerosis plaques are easily seen on MRI scans as periventricular patches of increased signal intensity.

Any evaluation of dementia should consider medication effects, metabolic derangements, infections, and nutritional causes that may not

produce abnormalities on neuroimaging.

Indications for Neuroimaging in Clinical Research

Analysis of Clinically Defined Groups of Patients. Psychiatric research aims to categorize patients with psychiatric disorders to facilitate the discovery of neuroanatomical and neurochemical bases of mental illness. Researchers have used functional neuroimaging to study groups of patients with such psychiatric conditions as schizophrenia, affective disorders, and anxiety disorders, among others. In schizophrenia, for example, neuropathological volumetric analyses have suggested a loss of brain weight, specifically of gray matter. A paucity of axons and dendrites appears present in the cortex, and CT and MRI may show compensatory enlargement of the lateral and third ventricles. Specifically, the temporal lobes of persons with schizophrenia appear to lose the most volume relative to healthy persons. Recent studies have found that the left temporal lobe is generally more affected than the right. The frontal lobe may also have abnormalities, not in the volume of the lobe, but in the level of activity detected by functional neuroimaging. Persons with schizophrenia consistently exhibit decreased metabolic activity in the frontal lobes, especially during tasks that require the prefrontal cortex. As a group, patients with schizophrenia are also more likely to have an increase in ventricular size than are healthy controls.

Disorders of mood and affect can also be associated with loss of brain volume and decreased metabolic activity in the frontal lobes. Inactivation of the left prefrontal cortex appears to depress mood; inactivation of the right prefrontal cortex elevates it. Among anxiety disorders, studies of obsessive-compulsive disorder with conventional CT and MRI have shown either no specific abnormalities or a smaller caudate nucleus. Functional PET and SPECT studies suggest abnormalities in the corticolimbic, basal ganglial, and thalamic structures in the disorder. When patients are experiencing obsessive-compulsive disorder symptoms, the orbital prefrontal cortex shows abnormal activity. A partial normalization of caudate glucose metabolism appears in patients taking medications such as fluoxetine (Prozac) or clomipramine (Anafranil) or undergoing behavior modification.

Functional neuroimaging studies of persons with attention-deficit/hyperactivity disorder (ADHD) either have shown no abnormalities or have shown decreased volume of the right prefrontal cortex and the right globus pallidus. In addition, whereas normally the right caudate nucleus is larger than the left caudate nucleus, persons with ADHD may have caudate nuclei of equal size. These findings suggest dysfunction of the right prefrontal-striatal pathway for control of attention.

Analysis of Brain Activity during Performance of Specific Tasks. Many original conceptions of different brain region functions emerged from observing deficits caused by local injuries, tumors, or strokes. Functional neuroimaging allows researchers to review and reassess classic teachings in the intact brain. Most work, to date, has been aimed at language and vision. Although many technical peculiarities and limitations of SPECT, PET, and functional MRI (fMRI) have been overcome, none of these techniques has demonstrated clear superiority. Studies require carefully controlled conditions, which subjects may find arduous. Nonetheless, functional neuroimaging has contributed major conceptual advances, and the methods are now limited mainly by the creativity of the investigative protocols.

Studies have been designed to reveal the functional neuroanatomy of all sensory modalities, gross and fine motor skills, language, memory, calculations, learning, and disorders of thought, mood, and anxiety. Unconscious sensations transmitted by the autonomic nervous system have been localized to specific brain regions. These analyses provide a basis for comparison with results of studies of clinically defined patient groups and may lead to improved therapies for mental illnesses.

SPECIFIC TECHNIQUES

CT Scans

In 1972, CT scanning revolutionized diagnostic neuroradiology by allowing imaging of the brain tissue in live patients. CT scanners are currently the most widely available and convenient imaging tools available in clinical practice; practically every hospital emergency room has immediate access to a CT scanner at all times. CT scanners effectively take a series of head X-ray pictures from all vantage points, 360 degrees around a patient's head. The amount of radiation that passes through, or is not absorbed from, each angle is digitized and entered into a computer. The computer uses matrix algebra calculations to assign a specific density to each point within the head and displays these data as a set of two-dimensional images. When viewed in sequence, the images allow mental reconstruction of the shape of the brain.

The CT image is determined only by the degree to which tissues absorb X-irradiation. The bony structures absorb high amounts of irradiation and tend to obscure details of neighboring structures, an especially troublesome problem in the brainstem, which is surrounded by a thick skull base. Within the brain itself, there is relatively little difference in the attenuation between gray matter and white matter in X-ray images. Although the gray-white border is usually distinguishable, details of the gyral pattern may be difficult to appreciate in CT scans. Certain tumors may be invisible on CT because they absorb as much irradiation as the surrounding normal brain.

Appreciation of tumors and areas of inflammation, which can cause changes in behavior, can be increased by intravenous infusion of iodine-containing contrast agents. Iodinated compounds, which absorb much more irradiation than the brain, appear white. The intact brain is separated from the bloodstream by the blood-brain barrier, which normally prevents the passage of the highly charged contrast agents. The blood-brain barrier, however, breaks down in the presence of inflammation or fails to form within tumors and thus allows accumulation of contrast agents. These sites appear whiter than the surrounding brain. Iodinated contrast agents must be used with caution in patients who are allergic to these agents or to shellfish.

With the introduction of MRI scanning, CT scans have been supplanted as the nonemergency neuroimaging study of choice (Fig. 5.8-2). The increased resolution and delineation of detail afforded by MRI scanning is often required for diagnosis in psychiatry. In addition, performing the most detailed study available inspires the most confidence in the analysis. The only component of the brain better seen on CT scanning is calcification, which may be invisible on MRI.

FIGURE 5.8-2

Comparison of computed tomography (CT) and magnetic resonance imaging (MRI). **A.** CT scan in the axial plane at the level of the third ventricle. The cerebrospinal fluid (CSF) within the ventricles appears black, the brain tissue appears gray, and the skull appears white. There is very poor discrimination between the gray and white matter of the brain. The *arrow* indicates a small calcified lesion in a tumor of the pineal gland. Detection of calcification is one role in which CT is superior to MRI. **B.** T2-weighted image of the same patient at roughly the same level. With T2, the CSF appears white, the gray matter appears gray, the white matter is clearly distinguished from the gray matter; the skull and indicated calcification appear black. Much more detail of the brain is visible than with CT. **C.** T1-weighted image of the same patient at roughly the same level. With T1, the CSF appears dark, the brain appears more uniformly gray, and the skull and indicated calcification appear black. T1 MRI images are the most similar to CT images. (Reprinted from Grossman CB. *Magnetic Resonance Imaging and Computed Tomography of the Head and Spine*. 2nd ed. Baltimore: Williams & Wilkins; 1996:101, with permission.)

MRI Scans

MRI scanning entered clinical practice in 1982 and soon became the test of choice for clinical psychiatrists and neurologists. The technique does not rely on the absorption of X-rays but is based on nuclear magnetic resonance (NMR). The principle of NMR is that the nuclei of all atoms are thought to spin about an axis, which is randomly oriented in space. When atoms are placed in a magnetic field, the axes of all odd-numbered nuclei align with the magnetic field. The axis of a nucleus deviates away from the magnetic field when exposed to a pulse of radiofrequency electromagnetic radiation oriented at 90 or 180 degrees to the magnetic field. When the pulse terminates, the axis of the spinning nucleus realigns itself with the magnetic field, and during this realignment, it emits its own radiofrequency signal. MRI scanners collect the emissions of individual, realigning nuclei and use computer analysis to generate a series of two-dimensional images that represent the brain. The images can be in the axial, coronal, or sagittal planes.

By far the most abundant odd-numbered nucleus in the brain belongs to hydrogen. The rate of realignment of the hydrogen axis is determined by its immediate environment, a combination of both the nature of the molecule of which it is a part and the degree to which it is surrounded by water. Hydrogen nuclei within fat realign rapidly, and hydrogen nuclei within water realign slowly. Hydrogen nuclei in proteins and carbohydrates realign at intermediate rates.

Routine MRI studies use three different radiofrequency pulse sequences. The two parameters that are varied are the duration of the radiofrequency excitation pulse and the length of the time that data are collected from the realigning nuclei. Because T1 pulses are brief and data collection is brief, hydrogen nuclei in hydrophobic environments are emphasized. Thus, fat is bright on T1, and CSF is dark. The T1 image most closely resembles that of CT scans and is most useful for assessing overall brain structure. T1 is also the only sequence that allows contrast enhancement with the contrast agent gadolinium-diethylenetriamine pentaacetic acid (gadolinium-DTPA). As with the iodinated contrast agents used in CT scanning, gadolinium remains excluded from the brain by the blood-brain barrier, except in areas where this barrier breaks down, such as inflammation or tumor. On T1 images, gadolinium-enhanced structures appear white.

T2 pulses last four times as long as T1 pulses, and the collection times are also extended to emphasize the signal from hydrogen nuclei surrounded by water. Thus, brain tissue is dark, and CSF is white on T2 images. Areas within the brain tissue that have abnormally high water content, such as tumors, inflammation, or strokes, appear brighter on T2 images. T2 images reveal brain pathology most clearly. The third routine pulse sequence is the proton density, or balanced, sequence. In this sequence, a short radio pulse is followed by a prolonged period of data collection, which equalizes the density of the CSF and the brain and allows distinction of tissue changes immediately adjacent to the ventricles.

An additional technique, sometimes used in clinical practice for specific indications, is fluid-attenuated inversion recovery (FLAIR). In this method, the T1 image is inverted and added to the T2 image to double the contrast between gray matter and white matter. Inversion recovery imaging is useful for detecting sclerosis of the hippocampus caused by temporal lobe epilepsy and for localizing areas of abnormal metabolism in degenerative neurological disorders.

MRI magnets are rated in teslas (T), units of magnetic field strength. MRI scanners in clinical use range from 0.3 to 2.0 T. Higher field-strength scanners produce images of markedly higher resolution. In research settings for humans, magnets as powerful as 4.7 T are used; for animals, magnets up to 12 T are used. Unlike the well-known hazards of X-irradiation, exposure to electromagnetic fields of the strength used in MRI machines has not been shown to damage biological tissues.

MRI scans cannot be used for patients with pacemakers or implants of ferromagnetic metals. MRI involves enclosing a patient in a narrow tube, in which the patient must remain motionless for up to 20 minutes. The radiofrequency pulses create a loud banging noise that may be obscured by music played in headphones. A significant number of patients cannot tolerate the claustrophobic conditions of routine MRI scanners and may need an open MRI scanner, which has less power and thus produces images of lower resolution. The resolution of brain tissue of even the lowest power MRI scan, however, exceeds that of CT scanning. [Figure 5.8-3](#) reveals that a brain tumor is the cause of a patient's depression.

FIGURE 5.8-3

Three axial images from a 46-year-old woman who was hospitalized for the first time for depression and suicidality following the end of a long-standing relationship. A malignant neoplasm extending into the posterior aspect of the left lateral ventricle is clearly seen in all three images. Images A and B are T1 and T2 weighted, respectively. Image C demonstrates the effects of postcontrast enhancement. (Courtesy of Craig N. Carson, M.D., and Perry F. Renshaw, M.D.)

MRI Applications to Dementia. Several MRI changes, including increased number of subcortical hyperintensities, generalized atrophy, and ventricular enlargement, are associated with normal aging. However, it is well established that some changes seem more specific to the diagnosis of Alzheimer's disease and may be clinically useful in formulating the diagnosis and prognosis of the disorder. MRI evidence of medial temporal lobe (MTL) atrophy appears to be most closely associated with the disorder. One approach that may help to improve the clinical utility of MRI in the diagnosis and prognosis of Alzheimer's disease and other forms of dementia is to follow the rate of change in brain structure over time. Longitudinal follow-up studies have shown the rates of volume loss to be significantly greater in subjects with prodromal Alzheimer's disease (up to 5 percent brain volume per year) compared with those experiencing normal age-related reductions (0.1 percent brain volume per year).

MRI Applications to Alcohol Dependence. MRI studies have been the principal tool to describe in vivo the many sources of neurotoxicity associated with alcoholism, including (1) the direct neurotoxic and gliotoxic effect of ethanol, (2) the neurotoxic effects of poor nutrition that often accompany the abuse of alcohol, (3) the excitotoxicity associated with the ethanol withdrawal state, and (4) the possible disruption in adult-neurogenesis-associated ethanol intoxication and withdrawal. These studies documented a striking age dependence of the overall neurotoxicity associated with alcoholism.

Magnetic Resonance Spectroscopy

Whereas routine MRI detects hydrogen nuclei to determine brain structure, magnetic resonance spectroscopy (MRS) can detect several odd-numbered nuclei (Table 5.8-1). The ability of MRS to detect a wide range of biologically important nuclei allows the use of the technique to study many metabolic processes. Although the resolution and sensitivity of MRS machines are poor compared with those of currently available PET and SPECT devices, the use of stronger magnetic fields will improve this feature to some extent in the future. MRS can image nuclei with an odd number of protons and neutrons. The unpaired protons and neutrons (nucleons) appear naturally and are nonradioactive. As in MRI, the nuclei align themselves in the strong magnetic field produced by an MRS device. A radiofrequency pulse causes the nuclei of interest to absorb and then emit energy. The readout of an MRS device is usually in the form of a spectrum, such as those for phosphorus-31 and hydrogen-1 nuclei, although the spectrum can also be converted into a pictorial image of the brain. The multiple peaks for each nucleus reflect that the same nucleus is exposed to different electron environments (electron clouds) in different molecules. The hydrogen-1 nuclei in a molecule of creatine, therefore, have a different chemical shift (position in the spectrum) than the hydrogen-1 nuclei in a choline molecule, for example. Thus, the position in the spectrum (the chemical shift) indicates the identity of the molecule in which the nuclei are present. The height of the peak with respect to a reference standard of the molecule indicates the amount of the molecule present.

Table 5.8-1
Nuclei Available for In Vivo Magnetic Resonance Spectroscopy^a

Nucleus	Natural Abundance	Sensitivity	Relative Potential Clinical Uses
¹ H	99.99	1.00	Magnetic resonance imaging (MRI) Analysis of metabolism Identification of unusual metabolites Characterization of hypoxia
¹⁹ F	100.00	0.83	Measurement of pO ₂ Analysis of glucose metabolism Measurement of pH Noninvasive pharmacokinetics
⁷ Li	92.58	0.27	Pharmacokinetics
²³ Na	100.00	0.09	MRI
³¹ P	100.00	0.07	Analysis of bioenergetics Identification of unusual metabolites Characterization of hypoxia Measurement of pH
¹⁴ N	93.08	0.001	Measurement of glutamate, urea, ammonia
³⁹ K	93.08	0.0005	?
¹³ C	1.11	0.0002	Analysis of metabolite turnover rate Pharmacokinetics of labeled drugs
¹⁷ O	0.04	0.00001	Measurement of metabolic rate
² H	0.02	0.000002	Measurement of perfusion

^aNatural abundance is given as percentage abundance of the isotope of interest. Nuclei are tabulated in order of decreasing relative sensitivity; relative sensitivity is calculated by multiplying the relative sensitivity for equal numbers of nuclei (at a given field strength) by the natural abundance of that nucleus. A considerable gain in relative sensitivity can be obtained by isotopic enrichment of the nucleus of choice or by the use of novel pulse sequences. (Reprinted from Dager SR, Steen RG. Applications of magnetic resonance spectroscopy to the investigation of neuropsychiatric disorders. *Neuropsychopharmacology*. 1992;6:249, with permission.)

The MRS of the hydrogen-1 nuclei is best at measuring *N*-acetylaspartate (NAA), creatine, and choline-containing molecules; but MRS can also detect glutamate, glutamine, lactate, and myo-inositol. Although glutamate and γ -aminobutyric acid (GABA), the major amino acid neurotransmitters, can be detected by MRS, the biogenic amine neurotransmitters (e.g., dopamine) are present in concentrations too low to be detected with the technique. MRS of phosphorus-31 can be used to determine the pH of brain regions and the concentrations of phosphorus-containing compounds (e.g., adenosine triphosphate [ATP] and guanosine triphosphate [GTP]), which are important in the energy metabolism of the brain.

MRS has revealed decreased concentrations of NAA in the temporal lobes and increased concentrations of inositol in the occipital lobes of persons with dementia of the Alzheimer's type. In a series of subjects with schizophrenia, decreased NAA concentrations were found in the temporal and frontal lobes. MRS has been used to trace the levels of ethanol in various brain regions. In panic disorder, MRS has been used to record the levels of lactate, whose intravenous infusion can precipitate panic episodes in about three-fourths of patients with either panic disorder or major depression. Brain lactate concentrations were found to be elevated during panic attacks, even without provocative infusion.

Additional indications include the use of MRS to measure concentrations of psychotherapeutic drugs in the brain. One study used MRS to measure lithium (Eskalith) concentrations in the brains of patients with bipolar disorder and found that lithium concentrations in the brain were half those in the plasma during depressed and euthymic periods but exceeded those in the plasma during manic episodes. Some compounds, such as fluoxetine and trifluoperazine (Stelazine), contain fluorine-19, which can also be detected in the brain and measured by MRS. For example, MRS has demonstrated that it takes 6 months of steady use for fluoxetine to reach maximal concentrations in the brain, which equilibrate at about 20 times the serum concentrations.

MRS in Dementia. MRS presents the opportunity to noninvasively obtain measures of several neurochemicals related to neurotransmission, energy metabolism, and cellular function. Studies using MRS have shown a trend for a general reduction in NAA measures with increasing age in MTL and frontal cortical brain regions. The studies in MCI and Alzheimer's disease report patients with these disorders have decreased levels of NAA and increased levels of myo-inositol (a form of inositol normally found in the brain that contributes to osmotic regulation) compared with those of age-matched comparison subjects.

MRS in Schizophrenia. MRS has been applied widely in studies of cortical chemistry in schizophrenia. These studies documented reductions in NAA levels in many cortical and limbic brain regions in schizophrenic individuals and smaller reductions in family members of people diagnosed with schizophrenia. Other metabolites have been measured in MRS studies of schizophrenic patients. The most interesting finding may be the description of normal or low levels of glutamate and increased levels of glutamine in medication-free patients with schizophrenia. One preliminary study suggested that glutamine elevations were not present in medication-free patients who were receiving benzodiazepines, drugs that would be predicted to suppress excitatory neurotransmission.

MRS in Alcohol Dependence. MRS studies evaluating NAA and choline have provided neurochemical evidence that complements the MRI findings related to the emergence and recovery from alcohol-related neurotoxicity. MRS studies of GABA have provided insights into alterations in cortical inhibitory neurotransmissions associated with the recovery from alcohol dependence. During acute withdrawal, cortical GABA levels appear to be normal. With recovery from alcohol dependence, cortical GABA levels appear to decline and may be significantly below the level seen in healthy subjects with extended sobriety.

Functional MRI

Recent advances in data collection and computer data processing have reduced the acquisition time for an MRI image to less than 1 second. A new sequence of particular interest to psychiatrists is the T2 or blood oxygen level-dependent (BOLD) sequence, which detects levels of oxygenated hemoglobin in the blood. Neuronal activity within the brain causes a local increase in blood flow, which in turn increases the local hemoglobin concentration. Although neuronal metabolism extracts more oxygen in active areas of the brain, the net effect of neuronal activity is to increase the local amount of oxygenated hemoglobin. This change can be detected essentially in real time with the T2 sequence, which thus detects the functionally active brain regions. This process is the basis for the technique of fMRI.

What fMRI detects is not brain activity per se, but blood flow. The volume of brain in which blood flow increases exceeds the volume of activated neurons by about 1 to 2 cm and limits the resolution of the technique. Sensitivity and resolution can be improved with the use of nontoxic, ultrasmall iron oxide particles. Thus, two tasks that activate clusters of neurons 5 mm apart, such as recognizing two different faces, yield overlapping signals on fMRI and so are usually indistinguishable by this technique. fMRI is useful to localize neuronal activity to a particular lobe or subcortical nucleus and has even been able to localize activity to a single gyrus. The method detects tissue perfusion, not neuronal metabolism. In contrast, PET scanning may give information specifically about neuronal metabolism.

No radioactive isotopes are administered in fMRI, a great advantage over PET and SPECT. A subject can perform a variety of tasks, both experimental and control, in the same imaging session. First, a routine T1 MRI image is obtained; then the T2 images are superimposed to allow more precise localization. Acquisition of sufficient images for study can require 20 minutes to 3 hours, during which time the subject's

head must remain in exactly the same position. Several methods, including a frame around the head and a special mouthpiece, have been used. Although realignments of images can correct for some head movement, small changes in head position may lead to erroneous interpretations of brain activation.

fMRI has recently revealed unexpected details about the organization of language within the brain. Using a series of language tasks requiring semantic, phonemic, and rhyming discrimination, one study found that rhyming (but not other types of language processing) produced a different pattern of activation in men and women. Rhyming activated the inferior frontal gyrus bilaterally in women, but only on the left in men. In another study, fMRI revealed a previously suspected, but unproved, neural circuit for lexical categories, interpolated between the representations for concepts and those for phonemes. This novel circuit was located in the left anterior temporal lobe. Data from patients with dyslexia (reading disorder) doing simple rhyming tasks demonstrated a failure to activate Wernicke's area and the insula, which were active in normal subjects doing the same task (see [Color Plate 5.8-4](#)).

Sensory functions have also been mapped in detail with fMRI. The activation of the visual and auditory cortices has been visualized in real time. In a recent intriguing study, the areas that were activated while a subject with schizophrenia listened to speech were also activated during auditory hallucinations. These areas included the primary auditory cortex as well as higher-order auditory processing regions. fMRI is the imaging technique most widely used to study brain abnormality related to cognitive dysfunction.

fMRI of Dementia. fMRI methods provide information that can potentially be used in the study, diagnosis, and prognosis of Alzheimer's disease and other forms of dementia as well as proving insights into normal age-related changes in cognitive processing. Evidence that aging is associated with weaker and more diffused activations as well as decreased hemispheric lateralization suggests either a compensation for lost regional intensity or a dedifferentiation of processing. The weaker activation, especially prefrontal, suggests potential encoding-stage dysfunctions associated with aging. fMRI studies have consistently demonstrated that patients with Alzheimer's disease have decreased fMRI activation in the hippocampus and related structures within the MTL during the encoding of new memories compared with cognitively intact older subjects. More recently, fMRI studies of subjects at risk for Alzheimer's disease, by virtue of their genetics or evidence of minimal cognitive impairment, have yielded variable results with some studies suggesting there may be a phase of paradoxically increased activation early in the course of prodromal Alzheimer's disease.

fMRI of Alcohol Dependence. fMRI studies have provided insights into the functional consequences of alcoholism-related neurotoxicity. Studies suggest that recovering alcohol-dependent patients show abnormal activation patterns in frontal cortex, thalamus, striatum, cerebellum, and hippocampus related to impairments in attention, learning and memory, motor coordination, and inhibitory control of behavior. Studies have begun to explore pharmacological modulation of resting circuit activity to probe mechanisms underlying circuit dysfunction in alcoholism, illustrated by blunted responses to benzodiazepines.

SPECT Scanning

Manufactured radioactive compounds are used in SPECT to study regional differences in cerebral blood flow within the brain. This high-resolution imaging technique records the pattern of photon emission from the bloodstream according to the level of perfusion in different regions of the brain. As with fMRI, it provides information on the cerebral blood flow, which is highly correlated with the rate of glucose metabolism, but does not measure neuronal metabolism directly.

SPECT uses compounds labeled with single photon-emitting isotopes: iodine-123, technetium-99m, and xenon-133. Xenon-133 is a noble gas that is inhaled directly. The xenon quickly enters the blood and is distributed to areas of the brain as a function of regional blood flow. Xenon-SPECT is thus referred to as the *regional cerebral blood flow (rCBF) technique*. For technical reasons, xenon-SPECT can measure blood flow only on the surface of the brain, which is an important limitation. Many mental tasks require communication between the cortex and subcortical structures, and this activity is poorly measured by xenon-SPECT.

Assessment of blood flow over the whole brain with SPECT requires the injectable tracers, technetium-99m-D,L-hexamethylpropyleneamine oxime (HMPAO [Ceretec]) or iodoamphetamine [Spectamine]). These isotopes are attached to molecules that are highly lipophilic and rapidly cross the blood-brain barrier and enter cells. Once inside the cell, the ligands are enzymatically converted to charged ions, which remain trapped in the cell. Thus, over time, the tracers are concentrated in areas of relatively higher blood flow. Although blood flow is usually assumed to be the major variable tested in HMPAO SPECT, local variations in the permeability of the blood-brain barrier and in the enzymatic conversion of the ligands within cells also contribute to regional differences in signal levels.

In addition to these compounds used for measuring blood flow, iodine-123-labeled ligands for the muscarinic, dopaminergic, and serotonergic receptors, for example, can be used to study these receptors by SPECT technology. Once photon-emitting compounds reach the brain, detectors surrounding the patient's head pick up their light emissions. This information is relayed to a computer, which constructs a two-dimensional image of the isotope's distribution within a slice of the brain. A key difference between SPECT and PET is that in SPECT a single particle is emitted, whereas in PET two particles are emitted; the latter reaction gives a more precise location for the event and better resolution of the image. Increasingly, for both SPECT and PET studies, investigators are performing prestudy MRI or CT studies, then superimposing the SPECT or PET image on the MRI or CT image to obtain a more accurate anatomical location for the functional information (see [Color Plate 5.8-5](#)). SPECT is useful in diagnosing decreased or blocked cerebral blood flow in stroke victims. Some have described abnormal flow patterns in the early stages of Alzheimer's disease that may aid in early diagnosis.

PET Scanning

The isotopes used in PET decay by emitting positrons, antimatter particles that bind with and annihilate electrons, thereby giving off photons that travel in 180-degree opposite directions. Because detectors have twice as much signal from which to generate an image as SPECT scanners have, the resolution of the PET image is higher. A wide range of compounds can be used in PET studies, and the resolution of PET continues to be refined closer to its theoretical minimum of 3 mm, which is the distance positrons move before colliding with an electron. Relatively few PET scanners are available because they require an onsite cyclotron to make the isotopes.

The most commonly used isotopes in PET are fluorine-18 (^{18}F), nitrogen-13, and oxygen-15. These isotopes are usually linked to another molecule, except in the case of oxygen-15 (^{15}O). The most commonly reported ligand has been [^{18}F]fluorodeoxyglucose (FDG), an analogue of glucose that the brain cannot metabolize. Thus, the brain regions with the highest metabolic rate and the highest blood flow take up the most FDG but cannot metabolize and excrete the usual metabolic products. The concentration of ^{18}F builds up in these neurons and is detected by the PET camera. Water-15 (H_2^{15}O) and nitrogen-13 are used to measure blood flow, and ^{15}O can be used to determine the metabolic rate. Glucose is by far the predominant energy source available to brain cells, and its use is thus a highly sensitive indicator of the rate of brain metabolism. ^{18}F -labeled 3,4-dihydroxyphenylalanine (DOPA), the fluorinated precursor to dopamine, has been used to localize dopaminergic neurons.

PET has been used increasingly to study normal brain development and function as well as to study neuropsychiatric disorders. With regard to brain development, PET studies have found that glucose use is greatest in the sensorimotor cortex, thalamus, brainstem, and cerebellar vermis when an infant is 5 weeks of age or younger. By 3 months of age, most areas of the cortex show increased use, except for the frontal and association cortices, which do not begin to exhibit an increase until the infant is 8 months of age. An adult pattern of glucose metabolism is achieved by the age of 1 year, but use in the cortex continues to rise above adult levels until the child is about 9 years of age,

when use in the cortex begins to decrease and reaches its final adult level in the late teen years.

In another study, subjects listened to a rapidly presented list of thematically related words. When asked to recall words in the thematic category that may or may not have been on the list, some subjects falsely recalled that they had heard words that actually were not on the list. By PET scanning, the hippocampus was active during both true and false recollections, whereas the auditory cortex was only active during recollection of words that were actually heard. When pressed to determine whether memories were true or false, subjects activated the frontal lobes. FDG studies have also investigated pathology in neurological disorders and psychiatric disorders. Two other types of studies used precursor molecules and receptor ligands. The dopamine precursor dopa has been used to visualize pathology in patients with Parkinson's disease, and radiolabeled ligands for receptors have been useful in determining the occupancy of receptors by specific psychotherapeutic drugs. Neurochemical findings from PET radiotracer scan are listed in [Table 5.8-2](#).

Table 5.8-2
Neurochemical Findings from Positron Emission Tomography Radiotracer Scans

Dopamine	Decreased uptake of dopamine in striatum in parkinsonian patients Dopamine release higher in patients with schizophrenia than in controls High dopamine release associated with positive symptoms in schizophrenia
Receptors	
▶ D ₁ receptor	Lower D ₁ receptor binding in prefrontal cortex of patients with schizophrenia compared with controls; correlates with negative symptoms
▶ D ₂ receptor	Schizophrenia associated with small elevations of binding at D ₂ receptor
▶ Serotonin type 1A (5-HT _{1A})	Reduction in receptor binding in patients with unipolar major depression
Transporters	
▶ Dopamine	Amphetamine and cocaine cause an increase in dopamine Tourette disorder shows increase in dopamine transporter system (may account for success of dopamine blocking therapies)
▶ Serotonin	Serotonin binding is low in depression, alcoholism, cocaineism, binge eating, and impulse control
Metabolism	
▶ Nicotine	Cigarette smoking inhibits monoamine oxidase activity in brain
▶ Amyloid-β Deposits	Can be visualized in vivo with positron emission tomography
Pharmacology	Plasma levels of cocaine peak at 2 min D ₂ receptor occupancy lasts for several weeks after discontinuation of antipsychotic medication D ₂ receptor occupancy is lower for atypical antipsychotics than typical antipsychotics (may account for decrease in extrapyramidal side effects) Low doses (10–20 mg) of selective serotonin reuptake inhibitors cause occupancy of up to 90 percent of serotonin receptors

For example, dopamine receptor antagonists such as haloperidol (Haldol) block almost 100 percent of D₂ receptors. The atypical antipsychotic drugs block serotonin 5-HT₂ receptors in addition to D₂ receptors; hence, they are referred to as *serotonin-dopamine receptor antagonists*. The case study presented illustrates the potential diagnostic value of three-dimensional PET imaging.

Patient A is a 70-year-old man who had gotten more forgetful, to the point that his family was worried about him. The patient's family was interested in getting a diagnostic workup to evaluate the possible causes for his memory disorder. His PET scan showed that he had functional parietotemporal decrease, which corroborated other neurological evaluations, suggesting that he had Alzheimer's disease. The patient was treated with tacrine (Cognex) and benefited from some stabilization of his symptoms. (Courtesy of Joseph C. Wu, M.D., Daniel G. Amen, M.D., and H. Stefan Bracha, M.D.)

Pharmacological and Neuropsychological Probes

With both PET and SPECT and eventually with MRS, more studies and possibly more diagnostic procedures will use pharmacological and neuropsychological probes. The purpose of such probes is to stimulate particular regions of brain activity, so that, when compared with a baseline, workers can reach conclusions about the functional correspondence to particular brain regions. One example of the approach is the use of PET to detect regions of the brain involved in the processing of shape, color, and velocity in the visual system. Another example is the use of cognitive activation tasks (e.g., the Wisconsin Card Sorting Test) to study frontal blood flow in patients with schizophrenia. A key consideration in the evaluation of reports that measure blood flow is the establishment of a true baseline value in the study design. Typically, the reports use an awake, resting state, but there is variability in whether the patients have their eyes closed or their ears blocked; both conditions can affect brain function. There is also variability in such baseline brain function factors as sex, age, anxiety about the test, nonpsychiatric drug treatment, vasoactive medications, and time of day.

5.9 Physical Examination of the Psychiatric Patient

Confronted with a patient who has a mental disorder, the psychiatrist must decide whether a medical, surgical, or neurological condition may be the cause. Once satisfied that no disease process can be held accountable, then the diagnosis of mental disorder not attributable to a medical illness can be made. Although psychiatrists do not perform routine physical examinations of their patients, a knowledge and understanding of physical signs and symptoms is part of their training, which enables them to recognize signs and symptoms that may indicate possible medical or surgical illness. For example, palpitations can be associated with mitral valve prolapse, which is diagnosed by cardiac auscultation. Psychiatrists are also able to recognize and treat the adverse effects of psychotropic medications, which are used by an increasing number of patients seen by psychiatrists and nonpsychiatric physicians.

Some psychiatrists insist that every patient have a complete medical workup; others may not. Whatever their policy, psychiatrists should consider patients' medical status at the outset of a psychiatric evaluation. Psychiatrists must often decide whether a patient needs a medical examination and, if so, what it should include—most commonly, a thorough medical history, including a review of systems, a physical examination, and relevant diagnostic laboratory studies. A recent study of 1,000 medical patients found that in 75 percent of cases no cause of symptoms (i.e., subjective complaints) could be found, and a psychological basis was assumed in 10 percent of those cases.

HISTORY OF MEDICAL ILLNESS

In the course of conducting a psychiatric evaluation, information should be gathered about known bodily diseases or dysfunctions, hospitalizations and operative procedures, medications taken recently or at present, personal habits and occupational history, family history of illnesses, and specific physical complaints. Information about medical illnesses should be gathered from the patient, the referring physician, and the family, if necessary.

Information about previous episodes of illness may provide valuable clues about the nature of the present disorder. For example, a distinctly delusional disorder in a patient with a history of several similar episodes that responded promptly to diverse forms of treatment strongly suggests the possibility of substance-induced psychotic disorder. To pursue this lead, the psychiatrist should order a drug screen. The history of a surgical procedure may also be useful; for instance, a thyroidectomy suggests hypothyroidism as the cause of depression.

Depression is an adverse effect of several medications prescribed for hypertension. Medication taken in a therapeutic dosage occasionally reaches high concentrations in the blood. Digitalis intoxication, for example, can occur under such circumstances and result in impaired mental functioning. Proprietary drugs can cause or contribute to an anticholinergic delirium. The psychiatrist, therefore, must inquire about over-the-counter remedies as well as prescribed medications. A history of herbal intake and alternative therapy is essential in view of their increased use.

An occupational history may also provide essential information. Exposure to mercury can result in complaints suggesting a psychosis, and exposure to lead, as in smelting, can produce a cognitive disorder. The latter clinical picture can also result from imbibing moonshine whiskey with a high lead content.

In eliciting information about specific symptoms, the psychiatrist brings medical and psychological knowledge into full play. For example, the psychiatrist should elicit sufficient information from the patient complaining of headache to predict whether the pain results from intracranial disease that requires neurological testing. Also, the psychiatrist should be able to recognize that the pain in the right shoulder of a hypochondriacal patient with abdominal discomfort may be the classic referred pain of gallbladder disease.

REVIEW OF SYSTEMS

An inventory by systems should follow the open-ended inquiry. The review can be organized according to organ systems (e.g., liver, pancreas), functional systems (e.g., gastrointestinal), or a combination of the two, as in the outline presented in the following subsections. In all cases, the review should be comprehensive and thorough. Even if a psychiatric component is suspected, a complete workup is still indicated.

Head

Many patients give a history of headache; its duration, frequency, character, location, and severity should be ascertained. Headaches often result from substance abuse, including alcohol, nicotine, and caffeine. Vascular (migraine) headaches are precipitated by stress. Temporal arteritis causes unilateral throbbing headaches and can lead to blindness. Brain tumors are associated with headaches as a result of increased intracranial pressure; but some may be silent, the first signs being a change in personality or cognition.

A 63-year-old woman in treatment for depression began to complain of difficulties in concentration. The psychiatrist attributed the complaint to the depressive disorder; however, when the patient began to complain of balance difficulties, a magnetic resonance imaging was obtained, which revealed the presence of meningioma.

A head injury can result in subdural hematoma and, in boxers, can cause progressive dementia with extrapyramidal symptoms. The headache of subarachnoid hemorrhage is sudden, severe, and associated with changes in the sensorium. Normal pressure hydrocephalus can follow a head injury or encephalitis and be associated with dementia, shuffling gait, and urinary incontinence. Dizziness occurs in up to 30 percent of persons, and determining its cause is challenging and often difficult. A change in the size or shape of the head may be indicative of Paget's disease.

Eye, Ear, Nose, and Throat

Visual acuity, diplopia, hearing problems, tinnitus, glossitis, and bad taste are covered in this area. A patient taking antipsychotics who gives a history of twitching about the mouth or disturbing movements of the tongue may be in the early and potentially reversible stage of tardive dyskinesia. Impaired vision can occur with thioridazine (Mellaril) in high doses (over 800 mg a day). A history of glaucoma contraindicates drugs with anticholinergic effects. Complaints of bad odors may be a symptom of temporal lobe epilepsy rather than schizophrenia. Aphonia may be hysterical in nature. The late stage of cocaine abuse can result in perforations of the nasal septum and difficulty breathing.

A transitory episode of diplopia may herald multiple sclerosis. Delusional disorder is more common in hearing-impaired persons than in those with normal hearing. Blue-tinged vision can occur transiently when using sildenafil (Viagra) or similar drugs.

Respiratory System

Cough, asthma, pleurisy, hemoptysis, dyspnea, and orthopnea are considered in this subsection. Hyperventilation is suggested if the patient's symptoms include all or a few of the following: onset at rest, sighing respirations, apprehension, anxiety, depersonalization, palpitations, inability to swallow, numbness of the feet and hands, and carpopedal spasm. Dyspnea and breathlessness can occur in depression. In pulmonary or obstructive airway disease, the onset of symptoms is usually insidious, whereas in depression, it is sudden. In depression, breathlessness is experienced at rest, shows little change with exertion, and can fluctuate within a matter of minutes; the onset of breathlessness coincides with the onset of a mood disorder and is often accompanied by attacks of dizziness, sweating, palpitations, and paresthesias.

In obstructive airway disease, patients with the most advanced respiratory incapacity experience breathlessness at rest. Most striking and of greatest assistance in making a differential diagnosis is the emphasis placed on the difficulty in inspiration experienced by patients with depression and on the difficulty in expiration experienced by patients with pulmonary disease. Bronchial asthma has sometimes been associated with a childhood history of extreme dependence on the mother. Patients with bronchospasm should not receive propranolol (Inderal) because it can block catecholamine-induced bronchodilation; propranolol is specifically contraindicated for patients with bronchial asthma because epinephrine given to such patients in an emergency will not be effective. Patients taking angiotensin-converting enzyme (ACE) inhibitors can develop a dry cough as an adverse effect of the drug.

Cardiovascular System

Tachycardia, palpitations, and cardiac arrhythmia are among the most common signs of anxiety about which the patient may complain. Pheochromocytoma usually produces symptoms that mimic anxiety disorders, such as rapid heartbeat, tremors, and pallor. Increased urinary catecholamines are diagnostic of pheochromocytoma. Patients taking guanethidine (Ismelin) for hypertension should not receive tricyclic drugs, which reduce or eliminate the antihypertensive effect of guanethidine. A history of hypertension can preclude the use of monoamine oxidase inhibitors (MAOIs) because of the risk of a hypertensive crisis if such patients with hypertension inadvertently ingest foods high in tyramine. Patients with suspected cardiac disease should have an electrocardiogram before tricyclics or lithium (Eskalith) is prescribed. A history of substernal pain should be evaluated, and the clinician should keep in mind that psychological stress can precipitate angina-type chest pain in the presence of normal coronary arteries. Patients taking opioids should never receive MAOIs; the combination can cause cardiovascular collapse.

Gastrointestinal System

Such topics as appetite, distress before or after meals, food preferences, diarrhea, vomiting, constipation, laxative use, and abdominal pain relate to the gastrointestinal system. A history of weight loss is common in depressive disorders, but depression can accompany the weight loss caused by ulcerative colitis, regional enteritis, and cancer. Atypical depression is accompanied by hyperphagia and weight gain. Anorexia nervosa is accompanied by severe weight loss in the presence of normal appetite. Avoidance of certain foods may be a phobic phenomenon or part of an obsessive ritual. Laxative abuse and induced vomiting are common in bulimia nervosa. Constipation can be caused by opioid dependence and by psychotropic drugs with anticholinergic side effects. Cocaine or amphetamine abuse causes a loss of appetite and weight loss. Weight gain can occur under stress or in association with atypical depression. Polyphagia, polyuria, and polydipsia are the triad of diabetes mellitus. Polyuria, polydipsia, and diarrhea are signs of lithium toxicity. Some patients take enemas routinely as part of paraphilic behavior, and anal fissures or recurrent hemorrhoids may indicate anal penetration by foreign objects. Some patients may ingest foreign objects that produce symptoms that can be diagnosed only by X-ray (Fig. 5.9-1).

FIGURE 5.9-1

A mentally ill patient who is a habitual swallower of foreign objects. Included in his colonic lumen are 13 thermometers and 8 pennies. The dense, round, almost punctate densities are globules of liberated liquid mercury. (Courtesy of Stephen R. Baker, M.D., and Kyunghye C. Cho, M.D.)

Genitourinary System

Urinary frequency, nocturia, pain or burning on urination, and changes in the size and the force of the stream are some of the signs and symptoms emanating from the genitourinary system. Anticholinergic adverse effects associated with antipsychotics and tricyclic drugs can cause urinary retention in men with prostate hypertrophy. Erectile difficulty and retarded ejaculation are also common adverse effects of these drugs, and retrograde ejaculation occurs with thioridazine. A baseline level of sexual responsiveness before using pharmacological agents should be obtained. A history of sexually transmitted diseases—for example, gonorrheal discharge, chancre, herpes, and pubic lice—may indicate sexual promiscuity or unsafe sexual practices. In some cases, the first symptom of acquired immune deficiency syndrome (AIDS) is the gradual onset of mental confusion leading to dementia. Incontinence should be evaluated carefully, and if it persists, further investigation for more extensive disease should include a workup for human immunodeficiency virus (HIV) infection. Drugs with anticholinergic adverse effects should be avoided in men with prostatism. Urethral eroticism, in which catheters or other objects are inserted into the urethra, can cause infection or laceration (Fig. 5.9-2).

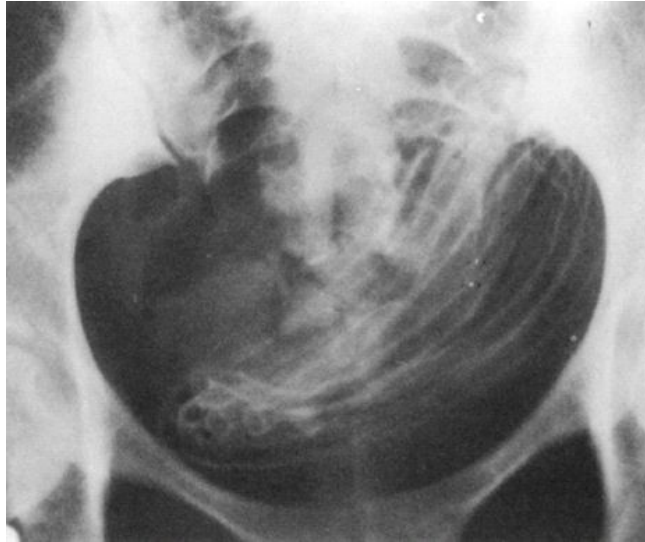

FIGURE 5.9-2

A patient brought to the emergency room with lower abdominal pain. X-ray shows a nasogastric tube folded into the bladder. The patient would insert the tube into his urethra as part of a masturbatory ritual (urethral eroticism). (Courtesy of Stephen R. Baker, M.D., and Kyunghee C. Cho, M.D.)

Orgasm causes prostatic contractions, which may artificially raise prostate-specific antigen (PSA) and give a false-positive result for prostatic cancer. Men scheduled to have a PSA test should avoid masturbation or coitus for 7 to 10 days prior to the test.

Menstrual History

A menstrual history should include the age of the onset of menarche (and menopause, if applicable); the interval, regularity, duration, and amount of flow of periods; irregular bleeding; dysmenorrhea; and abortions. Amenorrhea is characteristic of anorexia nervosa and also occurs in women who are psychologically stressed. Women who are afraid of becoming pregnant or who have a wish to be pregnant may have delayed periods. *Pseudocyesis* is false pregnancy with complete cessation of the menses. Perimenstrual mood changes (e.g., irritability, depression, and dysphoria) should be noted. Painful menstruation can result from uterine disease (e.g., myomata), from psychological conflicts about the menses, or from a combination of the two. Some women report a perimenstrual increase in sexual desire. The emotional reaction associated with abortion should be explored, because it can be mild or severe.

GENERAL OBSERVATION

An important part of the medical examination is subsumed under the broad heading of general observation—visual, auditory, and olfactory. Such nonverbal clues as posture, facial expression, and mannerisms should also be noted.

Visual Inspection

Scrutiny of the patient begins at the first encounter. When the patient goes from the waiting room to the interview room, the psychiatrist should observe the patient's gait. Is the patient unsteady? Ataxia suggests diffuse brain disease, alcohol or other substance intoxication, chorea, spinocerebellar degeneration, weakness based on a debilitating process, and an underlying disorder, such as myotonic dystrophy. Does the patient walk without the usual associated arm movements and turn in a rigid fashion, such as a toy soldier, as is seen in early Parkinson's disease? Does the patient have asymmetry of gait, such as turning one foot outward, dragging a leg, or not swinging one arm, suggesting a focal brain lesion?

As soon as the patient is seated, the psychiatrist should direct attention to grooming. Is the patient's hair combed, are the nails clean, and are the teeth brushed? Has clothing been chosen with care and is it appropriate? Although inattention to dress and hygiene is common in mental disorders—in particular, depressive disorders—it is also a hallmark of cognitive disorders. Lapses, such as mismatching socks, stockings, or shoes, may suggest a cognitive disorder.

The patient's posture and automatic movements or the lack of them should be noted. A stooped, flexed posture with a paucity of automatic movements may be caused by Parkinson's disease or diffuse cerebral hemispheric disease or be an adverse effect of antipsychotics. An unusual tilt of the head may be adopted to avoid eye contact, but it can also result from diplopia, a visual field defect, or focal cerebellar dysfunction. Frequent quick, purposeless movements are characteristic of anxiety disorders, but they are equally characteristic of chorea and hyperthyroidism. Tremors, although commonly seen in anxiety disorders, may point to Parkinson's disease, essential tremor, or adverse effects of psychotropic medication. Patients with essential tremor sometimes seek psychiatric treatment because they believe the tremor must be caused by unrecognized fear or anxiety, as others often suggest. Unilateral paucity or excess of movement suggests focal brain disease.

The patient's appearance is then scrutinized to assess general health. Does the patient appear to be robust or is there a sense of ill health? Does looseness of clothing indicate recent weight loss? Is the patient short of breath or coughing? Does the patient's general physiognomy suggest a specific disease? Men with Klinefelter's syndrome have a feminine fat distribution and lack the development of secondary male sex characteristics. Acromegaly is usually immediately recognizable by the large head and jaw.

What is the patient's nutritional status? Recent weight loss, although often seen in depressive disorders and schizophrenia, may be caused

by gastrointestinal disease, diffuse carcinomatosis, Addison's disease, hyperthyroidism, and many other somatic disorders. Obesity can result from either emotional distress or organic disease. Moon facies, truncal obesity, and buffalo hump are striking findings in Cushing's syndrome. The puffy, bloated appearance seen in hypothyroidism and the massive obesity and periodic respiration seen in Pickwickian syndrome are easily recognized in patients referred for psychiatric help. Hyperthyroidism is indicated by exophthalmos.

The skin frequently provides valuable information. The yellow discoloration of hepatic dysfunction and the pallor of anemia are reasonably distinctive. Intense reddening may be caused by carbon monoxide poisoning or by photosensitivity resulting from porphyria or phenothiazines. Eruptions can be manifestations of such disorders as systemic lupus erythematosus (e.g., the butterfly on the face), tuberous sclerosis with adenoma sebaceum, and sensitivity to drugs. A dusky purplish cast to the face, plus telangiectasia, is almost pathognomonic of alcohol abuse.

Careful observation may reveal clues that lead to the correct diagnosis in patients who create their own skin lesions. For example, the location and shape of the lesions and the time of their appearance may be characteristic of dermatitis factitia.

The patient's face and head should be scanned for evidence of disease. Premature whitening of the hair occurs in pernicious anemia, and thinning and coarseness of the hair occur in myxedema. In alopecia areata, patches of hair are lost, leaving bald spots; hair pulling disorder (trichotillomania) presents a similar picture. Pupillary changes are produced by various drugs—constriction by opioids and dilation by anticholinergic agents and hallucinogens. The combination of dilated and fixed pupils and dry skin and mucous membranes should immediately suggest the likelihood of atropine use or atropine-like toxicity. Diffusion of the conjunctiva suggests alcohol abuse, cannabis abuse, or obstruction of the superior vena cava. Flattening of the nasolabial fold on one side or weakness of one side of the face—as manifested in speaking, smiling, and grimacing—may be the result of focal dysfunction of the contralateral cerebral hemisphere or of Bell's palsy. A drooping eyelid may be an early sign of myasthenia gravis.

The patient's state of alertness and responsiveness should be evaluated carefully. Drowsiness and inattentiveness may be caused by a psychological problem, but they are more likely to result from organic brain dysfunction, whether secondary to an intrinsic brain disease or to an exogenous factor, such as substance intoxication.

Listening

Listening intently is just as important as looking intently for evidence of somatic disorders. Slowed speech is characteristic not only of depression but also of diffuse brain dysfunction and subcortical dysfunction; unusually rapid speech is characteristic of manic episodes and anxiety disorders and also of hyperthyroidism. A weak voice with monotonous tone may be a clue to Parkinson's disease in patients who complain mainly of depression. A slow, low-pitched, hoarse voice should suggest the possibility of hypothyroidism; this voice quality has been described as sounding like a drowsy, slightly intoxicated person with a bad cold and a plum in the mouth. A soft or tremulous voice accompanies anxiety.

Difficulty initiating speech may be owing to anxiety or stuttering or may indicate Parkinson's disease or aphasia. Easy fatigability of speech is sometimes a manifestation of an emotional problem, but it is also characteristic of myasthenia gravis. Patients with these complaints are likely to be seen by a psychiatrist before the correct diagnosis is made.

Word production, as well as the quality of speech, is important. Mispronounced or incorrectly used words suggests a possibility of aphasia caused by a lesion of the dominant hemisphere. The same possibility exists when the patient perseverates, has trouble finding a name or a word, or describes an object or an event in an indirect fashion (paraphasia). When not consonant with patients' socioeconomic and educational levels, coarseness, profanity, or inappropriate disclosures may indicate loss of inhibition caused by dementia.

Smell

Smell may also provide useful information. The unpleasant odor of a patient who fails to bathe suggests a cognitive or a depressive disorder. The odor of alcohol or of substances used to hide it is revealing in a patient who attempts to conceal a drinking problem. Occasionally, a uriferous odor calls attention to bladder dysfunction secondary to a nervous system disease. Characteristic odors are also noted in patients with diabetic acidosis, flatulence, uremia, and hepatic coma. Precocious puberty can be associated with the smell of adult sweat produced by mature apocrine glands.

A 23-year-old woman was referred to a psychiatrist for a second opinion. She had been diagnosed 6 months earlier with schizophrenia after complaining of smelling bad odors that were considered to be hallucinatory. She had been placed on an antipsychotic medication (perphenazine) and was compliant in spite of side effects of tremor and lethargy. Although there was some improvement in her symptoms, they did not remit entirely. The consulting psychiatrist obtained an electroencephalogram, which showed abnormal wave forms consistent with a diagnosis of temporal lobe epilepsy. The antipsychotic medication was replaced with an anticonvulsant (phenytoin) after which she no longer experienced olfactory hallucination, nor did she have to endure the unpleasant side effects of the previous medication.

PHYSICAL EXAMINATION

Patient Selection

The nature of the patient's complaints is critical in determining whether a complete physical examination is required. Complaints fall into the three categories of body, mind, and social interactions. Bodily symptoms (e.g., headaches and palpitations) call for a thorough medical examination to determine what part, if any, somatic processes play in causing the distress. The same can be said for mental symptoms such as depression, anxiety, hallucinations, and persecutory delusions, which can be expressions of somatic processes. If the problem is clearly limited to the social sphere (e.g., long-standing difficulties in interactions with teachers, employers, parents, or a spouse), there may be no special indication for a physical examination. Personality changes, however, can result from a medical disorder (e.g., early Alzheimer's disease) and cause interpersonal conflicts.

Psychological Factors

Even a routine physical examination may evoke adverse reactions; instruments, procedures, and the examining room may be frightening. A simple running account of what is being done can prevent much needless anxiety. Moreover, if the patient is consistently forewarned of what will be done, the dread of being suddenly and painfully surprised recedes. Comments such as "There's nothing to this" and "You don't have to be afraid because this won't hurt" leave the patient in the dark and are much less reassuring than a few words about what actually will be done.

Although the physical examination is likely to engender or intensify a reaction of anxiety, it can also stir up sexual feelings. Some women with fears or fantasies of being seduced may misinterpret an ordinary movement in the physical examination as a sexual advance. Similarly, a delusional man with homosexual fears may perceive a rectal examination as a sexual attack. Lingering over the examination of a particular organ because an unusual but normal variation has aroused the physician's scientific curiosity is likely to raise concern in the patient that a serious pathological process has been discovered. Such a reaction may be profound in an anxious or hypochondriacal patient.

The physical examination occasionally serves a psychotherapeutic function. Anxious patients may be relieved to learn that, despite troublesome symptoms, no evidence is found of the serious illness that they fear. The young person who complains of chest pain and is certain that the pain heralds a heart attack can usually be reassured by the report of normal findings after a physical examination and electrocardiogram. The reassurance relieves only the worry occasioned by the immediate episode, however. Unless psychiatric treatment succeeds in dealing with the determinants of the reaction, recurrent episodes are likely.

Sending a patient who has a deeply rooted fear of malignancy for still another test that is intended to be reassuring is usually unrewarding. Some patients may have a false fixed belief that a disorder is present.

During the performance of the physical examination, an observant physician may note indications of emotional distress. For instance, during genital examinations, a patient's behavior may reveal information about sexual attitudes and problems, and these reactions can be used later to open this area for exploration.

Timing of the Physical Examination

Circumstances occasionally make it desirable or necessary to defer a complete medical assessment. For example, a delusional or manic patient may be combative, resistive, or both. In this instance, a medical history should be elicited from a family member, if possible, but unless a pressing reason exists to proceed with the examination, it should be deferred until the patient is tractable.

For psychological reasons, it may be ill advised to recommend a medical assessment at the time of an initial office visit. In view of today's increased sensitivity and openness about sexual matters and a tendency to turn quickly to psychiatric help, young men may complain about their failure to consummate their first coital attempt. After taking a detailed history, the psychiatrist may conclude that the failure was because of situational anxiety. If so, neither a physical examination nor psychotherapy should be recommended; they would have the undesirable effect of reinforcing the notion of pathology. Should the problem be recurrent, further evaluation would be warranted.

Neurological Examination

If the psychiatrist suspects that the patient has an underlying somatic disorder, such as diabetes mellitus or Cushing's syndrome, referral is usually made for diagnosis and treatment. The situation is different when a cognitive disorder is suspected. The psychiatrist often chooses to assume responsibility in these cases. At some point, however, a thorough neurological evaluation may be indicated.

During the history-taking process in such cases, the patient's level of awareness, attentiveness to the details of the examination, understanding, facial expression, speech, posture, and gait are noted. It is also assumed that a thorough mental status examination will be performed. The neurological examination is carried out with two objectives in mind: to elicit (1) signs pointing to focal, circumscribed cerebral dysfunction and (2) signs suggesting diffuse, bilateral cerebral disease. The first objective is met by the routine neurological examination, which is designed primarily to reveal asymmetries in the motor, perceptual, and reflex functions of the two sides of the body, caused by focal hemispheric disease. The second objective is met by seeking to elicit signs that have been attributed to diffuse brain dysfunction and to frontal lobe disease. These signs include the sucking, snout, palmomental, and grasp reflexes and the persistence of the glabella tap response. Regrettably, with the exception of the grasp reflex, such signs do not correlate strongly with the presence of underlying brain pathology.

Other Findings

Psychiatrists should be able to evaluate the significance of findings uncovered by consultants. With a patient who complains of a lump in the throat (globus hystericus) and who is found on examination to have hypertrophied lymphoid tissue, it is tempting to wonder about a causal relation. How can a clinician be sure that the finding is not incidental? Has the patient been known to have hypertrophied lymphoid tissue at a time when no complaint was made? Do many persons with hypertrophied lymphoid tissue never experience the sensation of a lump in the throat?

With a patient with multiple sclerosis who complains of an inability to walk but, on neurological examination, has only mild spasticity and a unilateral Babinski sign, it is tempting to ascribe the symptom to the neurological disorder; but the complaint may be aggravated by emotional distress. The same holds true for a patient with profound dementia in whom a small frontal meningioma is seen on a computed tomography (CT) scan. Dementia is not always correlated with the findings. Significant brain atrophy could cause very mild dementia, and minimal brain atrophy could cause significant dementia.

A lesion is often found that can account for a symptom, but the psychiatrist should make every effort to separate an incidental finding from a causative one and to distinguish a lesion merely found in the area of the symptom from a lesion producing the symptom.

PATIENTS UNDERGOING PSYCHIATRIC TREATMENT

While patients are being treated for psychiatric disorders, psychiatrists should be alert to the possibility of intercurrent illnesses that call for diagnostic studies. Patients in psychotherapy, particularly those in psychoanalysis, may be all too willing to ascribe their new symptoms to emotional causes. Attention should be given to the possible use of denial, especially if the symptoms seem to be unrelated to the conflicts currently in focus.

Not only may patients in psychotherapy be likely to attribute new symptoms to emotional causes, but sometimes their therapists do so as well. The danger of providing psychodynamic explanations for physical symptoms is ever present.

Symptoms such as drowsiness and dizziness and signs such as a skin eruption and a gait disturbance, common adverse effects of psychotropic medication, call for a medical reevaluation if the patient fails to respond in a reasonable time to changes in the dose or the kind of medication prescribed. If patients who are receiving tricyclic or antipsychotic drugs complain of blurred vision (usually an anticholinergic adverse effect) and the condition does not recede with a reduction in dose or a change in medication, they should be evaluated to rule out other causes. In one case, the diagnosis proved to be toxoplasma chorioretinitis. The absence of other anticholinergic adverse effects, such as a dry mouth and constipation, is an additional clue alerting the psychiatrist to the possibility of a concomitant medical illness.

Early in an illness, there may be few if any positive physical or laboratory results. In such instances, especially if the evidence of psychic trauma or emotional conflicts is glaring, all symptoms are likely to be regarded as psychosocial in origin, and new symptoms are also seen in this light. Indications for repeating portions of the medical workup may be missed unless the psychiatrist is alert to clues suggesting that some symptoms do not fit the original diagnosis and, instead, point to a medical illness. Occasionally, a patient with an acute illness, such as encephalitis, is hospitalized with the diagnosis of schizophrenia, or a patient with a subacute illness, such as carcinoma of the pancreas, is treated in a private office or clinic with the diagnosis of a depressive disorder. Although it may not be possible to make the correct diagnosis at the time of the initial psychiatric evaluation, continued surveillance and attention to clinical details usually provide clues leading to the recognition of the cause.

The likelihood of intercurrent illness is greater with some psychiatric disorders than with others. Substance abusers, for example, because of their life patterns, are susceptible to infection and are likely to suffer from the adverse effects of trauma, dietary deficiencies, and poor hygiene. Depression decreases the immune response.

When somatic and psychological dysfunctions are known to coexist, the psychiatrist should be thoroughly conversant with the patient's medical status. In cases of cardiac decompensation, peripheral neuropathy, and other disabling disorders, the nature and degree of

impairment that can be attributed to the physical disorder should be assessed. It is important to answer the question: Does the patient exploit a disability, or is it ignored or denied with resultant overexertion? To answer this question, the psychiatrist must assess the patient's capabilities and limitations, rather than make sweeping judgments based on a diagnostic label.

Special vigilance about medical status is required for some patients in treatment for somatoform and eating disorders. Such is the case for patients with ulcerative colitis who are bleeding profusely and for patients with anorexia nervosa who are losing appreciable weight. These disorders can become life-threatening.

Importance of Medical Screening

Numerous articles have called attention to the need for thorough medical screening of patients seen in psychiatric inpatient services and clinics. (A similar need has been demonstrated for the psychiatric evaluation of patients seen in medical inpatient services and clinics.) The concept of *medical clearance* remains ambiguous and has meaning in the context of psychiatric admission or clearance for transfers from different settings or institutions. It implies that no medical condition exists to account for the patient's condition.

Among identified psychiatric patients, from 24 to 60 percent have been shown to suffer from associated physical disorders. In a survey of 2,090 psychiatric clinic patients, 43 percent were found to have associated physical disorders; of these, almost half the physical disorders had not been diagnosed by the referring sources. (In this study, 69 patients were found to have diabetes mellitus, but only 12 of these cases had been diagnosed before referral.)

Expecting psychiatrists to be experts in internal medicine is unrealistic, but they should be able to recognize or have high suspicion of physical disorders when they are present. Moreover, they should make appropriate referrals and collaborate in treating patients who have both physical and mental disorders.

Psychiatric symptoms are nonspecific; they can herald medical as well as psychiatric illness. They often precede the appearance of definitive medical symptoms. Some psychiatric symptoms (e.g., visual hallucinations, distortions, and illusions) should evoke a high level of suspicion of a medical toxicity.

The medical literature abounds with case reports of patients whose disorders were initially considered emotional but ultimately proved to be secondary to medical conditions. The data in most of the reports revealed features pointing toward organicity. Diagnostic errors arose because such features were accorded too little weight.

Classification in Psychiatry

Classification is the process by which the complexity of phenomena is reduced by arranging them into categories according to some established criteria for one or more purposes. At present, the classification of mental disorders consists of specific mental disorders that are grouped into various classes on the basis of some shared phenomenological characteristics. The ultimate purpose of classification is to improve treatment and prevention efforts. Ideally, a classification of disorders is based on knowledge of etiology or pathophysiology because this increases the likelihood of improving treatment and prevention efforts. But neuroscientists have not yet produced sufficient data to design a diagnostic system that relies on biomarkers that enable psychiatric diagnoses to be based on causes rather than symptoms. Instead, the diagnosis of mental disorders is based on clinical observations of clusters of signs and symptoms that are grouped together into disorders or syndromes which are then agreed upon by a consensus of psychiatrists and other mental health professionals.

Systems of classification for psychiatric diagnoses have several purposes: to distinguish one psychiatric diagnosis from another, so that clinicians can offer the most effective treatment; to provide a common language among health care professionals; and to explore the still unknown causes of many mental disorders. The two most important psychiatric classifications are the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) developed by the American Psychiatric Association in collaboration with other groups of mental health professionals, and the *International Classification of Diseases* (ICD), developed by the World Health Organization.

HISTORY

The various classification systems used in psychiatry date back to Hippocrates, who introduced the terms *mania* and *hysteria* as forms of mental illness in the fifth century BC. Since then, each era has introduced its own psychiatric classification. The first US classification was introduced in 1869 at the annual meeting of the American Medico-Psychological Association, which later became the American Psychiatric Association. In 1952, the American Psychiatric Association's Committee on Nomenclature and Statistics published the first edition of the DSM (DSM-I). Six editions (Table 6-1) have been published since then: DSM-II (1968); DSM-III (1980); a revised DSM-III, DSM-III-R (1987); DSM-IV (1994); DSM-IV-TR (TR stands for text revision) (2000); and DSM-5 published in 2013 (the roman numerals are no longer used).

 **Table 6-1**
DSM Editions*

DSM-I	1952
DSM-II	1968
DSM-III	1980
DSM-IV	1994
DSM-IV-TR	2000
DSM-5†	2013

R—revision, TR—text revision.
*There are plans to publish periodic revisions of DSM to be called 5.1, 5.2, and so on.
†Roman numerals discarded.

RELATION TO ICD-10

ICD-10 is the official classification system used in Europe and many other parts of the world. DSM-5 was designed to correspond to the 10th revision of ICD (ICD-10), first developed in 1992. This was done to ensure uniform reporting of national and international health statistics. In addition, Medicare requires that billing codes for reimbursement follow ICD. All categories used in DSM-5 are found in ICD-10, but not all ICD-10 categories are in DSM-5.

The DSM-5 is the official psychiatric coding system used in the United States. Although some psychiatrists have been critical of the many versions of DSM that have appeared since 1952, including the current edition, DSM-5 is the official US nomenclature. All terminology used in this textbook conforms to DSM-5 nomenclature. Either DSM or ICD codes may be used for insurance purposes and medical reporting. On October 1, 2014 all US health care providers and systems, as recommended by the Centers for Disease Control and Prevention's National Center for Health Statistics (CDC-NCHS) and the Centers for Medicare and Medicaid Services (CMS), were expected to use the ICD-10 codes for mental disorders, the DSM-5 codes no longer being required for coding purposes. That date was postponed to October 1, 2015.

Basic Features

Descriptive Approach. The approach to DSM-5 is atheoretical with regard to causes. Thus, DSM-5 attempts to describe the manifestations of the mental disorders and only rarely attempts to account for how the disturbances come about. The definitions of the disorders usually consist of descriptions of clinical features.

Diagnostic Criteria. Specified diagnostic criteria are provided for each specific mental disorder. These criteria include a list of features that must be present for the diagnosis to be made. Such criteria increase the reliability of the diagnostic process.

Systematic Description. DSM-5 systematically describes each disorder in terms of its associated features: specific age-, culture-, and gender-related features; prevalence, incidence, and risk; course; complications; predisposing factors; familial pattern; and differential diagnosis. In some instances, when many specific disorders share common features, this information is included in the introduction to the entire section. Laboratory findings and associated physical examination signs and symptoms are described when relevant.

DSM-5 is a diagnostic manual, not a textbook. It makes no mention of theories of causes, management, or treatment or the controversial issues, of which there are many, that surround a particular diagnostic category. For that, one requires a textbook such as *Comprehensive Textbook of Psychiatry*, which is free to discuss controversy and alternative points of view.

DSM-5 CLASSIFICATION

The DSM-5 lists 22 major categories of mental disorders, comprising more than 150 discrete illnesses. All of the disorders listed in DSM-5 are described in detail in the sections of the book that follow and cover epidemiology, etiology, diagnosis, differential diagnoses, clinical features, and treatment of each disorder. In this section, only a brief description of the disorders is provided to give the reader an overview

of psychiatric classification, including some of the changes made from DSM-IV to DSM-5.

The organization of the disorders in DSM-5 attempts to follow the lifespan. Thus, neurodevelopmental disorders that occur early in life are listed first in the classification system, and neurocognitive disorders that occur toward the end of life are listed last. Some disorders, however, such as encopresis and enuresis, which are associated with childhood, are assigned to the middle of the classification system, which presumably refers to adulthood. The justification for this organization is explained in the introduction to DSM-5 as a way to assist the diagnostic decision-making process; but whether or not this organizational schema is of any heuristic value is open to question.

Neurodevelopmental Disorders

These disorders are usually first diagnosed in infancy, childhood, or adolescence.

Intellectual Disability or Intellectual Developmental Disorder (previously called mental retardation in DSM-IV).

Intellectual disability (ID) is characterized by significant, below average intelligence and impairment in adaptive functioning. Adaptive functioning refers to how effective individuals are in achieving age-appropriate common demands of life in areas such as communication, self-care, and interpersonal skills. In DSM-5, ID is classified as mild, moderate, severe, or profound based on overall functioning; in DSM-IV, it was classified according to intelligence quotient (IQ) as mild (50–55 to 70), moderate (35–40 to 50–55), severe (20–25 to 35–40), or profound (below 20–25). A variation of ID called *global developmental delay* is for children younger than 5 years with severe defects exceeding those above. *Borderline intellectual functioning* is used in DSM-5 but is not clearly differentiated from mild ID. In DSM-IV, it meant an IQ of about 70, but in DSM-5, it is categorized as a condition that may be the focus of clinical attention, but no criteria are given.

Communication Disorders. There are four types of communication disorders that are diagnosed when problems in communication cause significant impairment in functioning: (1) *language disorder* is characterized by a developmental impairment in vocabulary resulting in difficulty producing age-appropriate sentences; (2) *speech sound disorder* is marked by difficulty in articulation; (3) *childhood-onset fluency disorder* or *stuttering* is characterized by difficulty in fluency, rate, and rhythm of speech; and (4) *social or pragmatic communication disorder* is profound difficulty in social interaction and communication with peers.

Autism Spectrum Disorder. The autistic spectrum includes a range of behaviors characterized by severe difficulties in multiple developmental areas, including social relatedness; communication; and range of activity and repetitive and stereotypical patterns of behavior, including speech. They are divided into 3 levels: Level 1 is characterized by the ability to speak with reduced social interaction (this level resembles Asperger's disorder, which is no longer part of DSM-5); Level 2, which is characterized by minimal speech and minimal social interaction (diagnosed as Rett's disorder in DSM-IV but not part of DSM-5); and Level 3, marked by a total lack of speech and no social interaction.

Attention-Deficit/Hyperactivity Disorder (ADHD). Since the 1990s, ADHD has been one of the most frequently discussed psychiatric disorders in the lay media because of the sometimes unclear line between age-appropriate normal and disordered behavior and because of the concern that children without the disorder are being misdiagnosed and treated with medication. The central features of the disorder are persistent inattention, hyperactivity and impulsivity, or both that cause clinically significant impairment in functioning.

Specific Learning Disorders. These are maturational deficits in development that are associated with difficulty in acquiring specific skills in *reading* (also known as dyslexia), in *written expression*, or in *mathematics* (also known as dyscalculia).

Motor Disorders. Analogous to learning disorders, motor disorders are diagnosed when motor coordination is substantially below expectations based on age and intelligence and when coordination problems significantly interfere with functioning. There are three major types of motor disorders: (1) *developmental coordination disorder* is an impairment in the development of motor coordination (e.g., delays in crawling or walking, dropping things, or poor sports performance); (2) *stereotypic movement disorder* consists of repetitive motion activity (e.g., head banging and body rocking); and (3) *tic disorder* is characterized by sudden involuntary, recurrent, and stereotyped movement or vocal sounds. There are two types of tic disorders; The first is *Tourette's disorder*, characterized by motor and vocal tics, including coprolalia, and the second is *persistent chronic motor or vocal tic disorders* marked by a single motor or vocal tic.

Schizophrenia Spectrum and Other Psychotic Disorders

The section on schizophrenia and other psychotic disorders includes eight specific disorders (schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, brief psychotic disorder, substance/medication-induced psychotic disorder, psychotic disorder due to another medical condition, and catatonia) in which psychotic symptoms are prominent features of the clinical picture. The grouping of disorders in DSM-5 under this heading includes schizotypal personality disorder, which is not a psychotic disorder but that sometimes precedes full-blown schizophrenia. In *Synopsis*, this is discussed under personality disorders (see [Chapter 22](#)).

Schizophrenia. Schizophrenia is a chronic disorder in which prominent hallucinations or delusions are usually present. The individual must be ill for at least 6 months, although he or she need not be actively psychotic during all of that time. Three phases of the disorder are recognized by clinicians, although they are not included in DSM-5 as discrete phases. The *prodrome phase* refers to deterioration in function before the onset of the active psychotic phase. The *active phase* symptoms (delusions, hallucinations, disorganized speech, grossly disorganized behavior, or negative symptoms such as flat affect, avolition, and alogia) must be present for at least 1 month. The *residual phase* follows the active phase. The features of the residual and prodromal phases include functional impairment and abnormalities of affect, cognition, and communication. In DSM-IV, schizophrenia was subtyped according to the most prominent symptoms present at the time of the evaluation (paranoid, disorganized, catatonic, undifferentiated, and residual types); however, those subtypes are no longer part of the official DSM-5 nomenclature. Nevertheless, they are phenomenologically accurate, and the authors of *Synopsis* believe they remain useful descriptions that clinicians will still find helpful when communicating with one another.

Delusional Disorder. Delusional disorder is characterized by persistent delusions (e.g., erotomanic, grandiose, jealous, persecutory, somatic, mixed, unspecified). In general, the delusions are about situations that could occur in real life such as infidelity, being followed, or having an illness, which are categorized as nonbizarre beliefs. Within this category one finds what was termed in DSM-IV, *Shared Delusional Disorder* (also known as *folie à deux*) but which has been renamed *delusional symptoms in partner with delusional disorder* in DSM-5 and is characterized by a delusional belief that develops in a person who has a close relationship with another person with the delusion, the content of which is similar. *Paranoia* (a term not included in DSM-5) is a rare condition characterized by the gradual development of an elaborate delusional system, usually with grandiose ideas; it has a chronic course, and the rest of the personality remains intact.

Brief Psychotic Disorder. Brief psychotic disorder requires the presence of delusions, hallucinations, disorganized speech, grossly disorganized behavior, or catatonic behavior for at least 1 day but less than 1 month. It may be precipitated by an external life stress. After the episodes, the individual returns to his or her usual level of functioning.

Schizophreniform Disorder. Schizophreniform disorder is characterized by the same active phase symptoms of schizophrenia (delusions, hallucinations, disorganized speech, grossly disorganized behavior, or negative symptoms), but it lasts between 1 and 6 months and has no prodromal or residual phase features of social or occupational impairment.

Schizoaffective Disorder. Schizoaffective disorder is also characterized by the same active phase symptoms of schizophrenia (delusions, hallucinations, disorganized speech, grossly disorganized behavior, or negative symptoms), as well as the presence of a manic or depressive syndrome that is not brief relative to the duration of the psychosis. Individuals with schizoaffective disorder, in contrast to a mood disorder with psychotic features, have delusions or hallucinations for at least 2 weeks without coexisting prominent mood symptoms.

Substance/Medication-Induced Psychotic Disorder. These are disorders with symptoms of psychosis caused by psychoactive or other substances (e.g., hallucinogens, cocaine).

Psychotic Disorder Due to Another Medical Condition. This disorder is characterized by hallucinations or delusions that result from a medical illness (e.g., temporal lobe epilepsy, avitaminosis, meningitis).

Catatonia. Catatonia is characterized by motor abnormalities such as catalepsy (waxy flexibility), mutism, posturing, and negativism. It can be associated with *another mental disorder* (e.g., schizophrenia or bipolar disorder) or *due to another medical condition* (e.g., neoplasm, head trauma, hepatic encephalopathy).

Bipolar and Related Disorders

Bipolar disorder is characterized by severe mood swings between depression and elation and by remission and recurrence. There are four variants: bipolar I disorder, bipolar II disorder, cyclothymic disorder, and bipolar disorder due to substance/medication or another medical condition.

Bipolar I Disorder. The necessary feature of bipolar I disorder is a history of a manic or mixed manic and depressive episode. Bipolar I disorder is subtyped in many ways, including type of current episode (manic, hypomanic depressed, or mixed), severity and remission status (mild, moderate, severe without psychosis, severe with psychotic features, partial remission, or full remission), and whether the recent course is characterized by rapid cycling (at least four episodes in 12 months).

Bipolar II Disorder. Bipolar II disorder is characterized by a history of hypomanic and major depressive episodes. The symptom criteria for a hypomanic episode are the same as those for a manic episode, although hypomania only requires a minimal duration of 4 days. The major difference between mania and hypomania is the severity of the impairment associated with the syndrome.

Cyclothymic Disorder. This is the bipolar equivalent of dysthymic disorder (see later discussion). Cyclothymic disorder is a mild, chronic mood disorder with numerous depressive and hypomanic episodes over the course of at least 2 years.

Bipolar Disorder Due to Another Medical Condition. Bipolar disorder caused by a general medical condition is diagnosed when evidence indicates that a significant mood disturbance is the direct consequence of a general medical condition (e.g., frontal lobe tumor).

Substance/Medication-Induced Bipolar Disorder. Substance-induced mood disorder is diagnosed when the cause of the mood disturbance is substance intoxication, withdrawal, or medication (e.g., amphetamine).

Depressive Disorders

Depressive disorders are characterized by depression; sadness; irritability; psychomotor retardation; and, in severe cases, suicidal ideation. They include a number of conditions described below.

Major Depressive Disorder

The necessary feature of major depressive disorder is depressed mood or loss of interest or pleasure in usual activities. All symptoms must be present nearly every day, except suicidal ideation or thoughts of death, which need only be recurrent. The diagnosis is excluded if the symptoms are the result of a normal bereavement and if psychotic symptoms are present in the absence of mood symptoms.

Persistent Depressive Disorder or Dysthymia

Dysthymia is a mild, chronic form of depression that lasts at least 2 years, during which, on most days, the individual experiences depressed mood for most of the day and at least two other symptoms of depression.

Premenstrual Dysphoric Disorder. Premenstrual dysphoric disorder occurs about 1 week before the menses and is characterized by irritability, emotional lability, headache, and anxiety or depression that remits after the menstrual cycle is over.

Substance/Medication-Induced Depressive Disorder. This disorder is characterized by a depressed mood that is due to a substance (e.g., alcohol) or medication (e.g., barbiturate).

Depressive Disorder Due to Another Medical Condition. This condition is a state of depression secondary to a medical disorder (e.g., hypothyroidism, Cushing's syndrome).

Other Specified Depressive Disorder. This diagnostic category includes two subtypes: (1) *recurrent depressive episode*, which is a depression that lasts between 2 to 13 days and that occurs at least once a month, and (2) *short-duration depressive episode*, which is a depressed mood lasting from 4 to 14 days and which is nonrecurrent.

Unspecified Depressive Disorder. This diagnostic category includes four major subtypes: (1) *melancholia*, which is a severe form of major depression characterized by hopelessness, anhedonia, and psychomotor retardation, and which also carries with it a high risk of suicide; (2) *atypical depression*, which is marked by a depressed mood that is associated with weight gain instead of weight loss and with hypersomnia instead of insomnia; (3) *peripartum depression*, which is a depression that occurs around parturition or within 1 month after giving birth (called post-partum depression in DSM-IV); and (4) *seasonal pattern*, which is a depressed mood that occurs at a particular time of the year, usually winter (also known as seasonal affective disorder [SAD]).

Disruptive Mood Dysregulation Disorder. This is a new diagnosis listed as a depressive disorder, which is diagnosed in children

older than age 6 years and younger than age 18 years and is characterized by severe temper tantrums, chronic irritability, and angry mood.

Anxiety Disorders

The section on anxiety disorders includes nine specific disorders (panic disorder, agoraphobia, specific phobia, social anxiety disorder or social phobia, generalized anxiety disorder, anxiety disorder caused by a general medical condition, and substance-induced anxiety disorder) in which anxious symptoms are a prominent feature of the clinical picture. Because separation anxiety disorder and selective mutism occur in childhood, they are discussed in the childhood disorders section of this book.

Panic Disorder. A panic attack is characterized by feelings of intense fear or terror that come on suddenly in situations when there is nothing to fear. It is accompanied by heart racing or pounding, chest pain, shortness of breath or choking, dizziness, trembling or shaking, feeling faint or lightheaded, sweating, and nausea.

Agoraphobia. Agoraphobia is a frequent consequence of panic disorder, although it can occur in the absence of panic attacks. Persons with agoraphobia avoid (or try to avoid) situations that they think might trigger a panic attack (or panic-like symptoms) or situations from which they think escape might be difficult if they have a panic attack.

Specific Phobia. Specific phobia is characterized by an excessive, unreasonable fear of specific objects or situations that almost always occurs on exposure to the feared stimulus. The phobic stimulus is avoided, or, when not avoided, the individual feels severely anxious or uncomfortable.

Social Anxiety Disorder or Social Phobia. Social phobia is characterized by the fear of being embarrassed or humiliated in front of others. Similar to specific phobia, the phobic stimuli are avoided, or, when not avoided, the individual feels severely anxious and uncomfortable. When the phobic stimuli include most social situations, then it is specified as *generalized social phobia*.

Generalized Anxiety Disorder. Generalized anxiety disorder is characterized by chronic excessive worry that occurs more days than not and is difficult to control. The worry is associated with symptoms, such as concentration problems, insomnia, muscle tension, irritability, and physical restlessness, and causes clinically significant distress or impairment.

Anxiety Disorder Due to Another Medical Condition. Anxiety disorder caused by a general medical condition is diagnosed when evidence indicates that significant anxiety is the direct consequence of a general medical condition (e.g., hyperthyroidism).

Substance/Medication-Induced Anxiety Disorder. Substance-induced anxiety disorder is diagnosed when the cause of the anxiety is a substance (e.g., cocaine) or is the result of a medication (e.g., cortisol).

Separation Anxiety Disorder. Separation anxiety disorder occurs in children and is characterized by excessive anxiety about separating from home or attachment figures beyond that expected for the child's developmental level.

Selective Mutism. Selective mutism is characterized by a persistent refusal to speak in specific situations despite the demonstration of speaking ability in other situations.

Obsessive-Compulsive and Related Disorders

There are eight categories of disorders listed in this section, all of which have associated obsessions (repeated thoughts) or compulsions (repeated activities).

Obsessive-Compulsive Disorder (OCD). OCD is characterized by repetitive and intrusive thoughts or images that are unwelcome (obsessions) or repetitive behaviors that the person feels compelled to do (compulsions) or both. Most often, the compulsions are done to reduce the anxiety associated with the obsessive thought.

Body Dysmorphic Disorder. Body dysmorphic disorder is characterized by a distressing and impairing preoccupation with an imagined or slight defect in appearance. If the belief is held with delusional intensity, then delusional disorder, somatic type, might be diagnosed.

Hoarding Disorder. Hoarding disorder is a behavioral pattern of accumulating items in a compulsive manner that may or may not have any utility to the person. The person is unable to get rid of those items even though they may create hazardous situations in the home such as risk of fire.

Trichotillomania or Hair-Pulling Disorder. Trichotillomania is characterized by repeated hair pulling causing noticeable hair loss. It may occur anywhere on the body (e.g., head, eyebrows, pubic area).

Excoriation or Skin-Picking Disorder. Skin-picking disorder is marked by the compulsive need to pick at one's skin to the point of doing physical damage.

Substance/Medication-Induced Obsessive-Compulsive Disorder. This disorder is characterized by obsessive or compulsive behavior that is secondary to the use of a medication or a substance such as abuse of cocaine that can cause compulsive skin picking (called formication).

Obsessive-Compulsive Disorder Due to Another Medical Condition. The cause of either obsessive or compulsive behavior is due to a medical condition, as sometimes may occur after a streptococcal infection.

Other Specified Obsessive-Compulsive and Related Disorder. This category includes a group of disorders such as *obsessional jealousy* in which one person has repeated thoughts about infidelity in the spouse or partner. It must be distinguished from a delusional belief such as *Koro*, which is a disorder found in South and East Asia in which the person believes the genitalia are shrinking and disappearing into the body; and *body-focused repetitive behavior disorder* in which the person engages in a compulsive behavioral pattern such as nail biting or lip chewing.

Trauma- or Stressor-Related Disorder

This group of disorders is caused by exposure to a natural or human-made disaster or to a significant life stressor such as experiencing abuse. There are six conditions that fall under this category in DSM-5.

Reactive Attachment Disorder. This disorder appears in infancy or early childhood and is characterized by a severe impairment in the ability to relate because of grossly pathological caregiving.

Disinhibited Social Engagement Disorder. This is a condition in which the child or adolescent has a deep-seated fear of interacting with strangers, especially adults, usually as a result of a traumatic upbringing.

Posttraumatic Stress Disorder (PTSD). PTSD occurs after a traumatic event in which the individual believes that he or she is in physical danger or that his or her life is in jeopardy. PTSD can also occur after witnessing a violent or life-threatening event happening to someone else. The symptoms of PTSD usually occur soon after the traumatic event, although, in some cases, the symptoms develop months or even years after the trauma. PTSD is diagnosed when a person reacts to the traumatic event with fear and re-experiences symptoms over time or has symptoms of avoidance and hyperarousal. The symptoms persist for at least 1 month and cause clinically significant impairment in functioning or distress.

Acute Stress Disorder. Acute stress disorder occurs after the same type of stressors that precipitate PTSD; however, acute stress disorder is not diagnosed if the symptoms last beyond 1 month.

Adjustment Disorders. Adjustment disorders are maladaptive reactions to clearly defined life stress. They are divided into subtypes depending on symptoms—with *anxiety*, with *depressed mood*, with *mixed anxiety and depressed mood*, *disturbance of conduct*, and *mixed disturbance of emotions and conduct*.

Persistent Complex Bereavement Disorder. Chronic and persistent grief that is characterized by bitterness, anger, or ambivalent feelings toward the dead accompanied by intense and prolonged withdrawal characterizes persistent complex bereavement disorder (also known as complicated grief or complicated bereavement). This must be distinguished from normal grief or bereavement.

Dissociative Disorders

The section on dissociative disorders includes four specific disorders (dissociative amnesia, dissociative fugue, dissociative identity disorder, and depersonalization/derealization disorder) characterized by a disruption in the usually integrated functions of consciousness, memory, identity, or perception.

Dissociative Amnesia. Dissociative amnesia is characterized by memory loss of important personal information that is usually traumatic in nature.

Dissociative Fugue. Dissociative fugue is characterized by sudden travel away from home associated with partial or complete memory loss about one's identity.

Dissociative Identity Disorder. Formerly called multiple personality disorder, the essential feature of dissociative identity disorder is the presence of two or more distinct identities that assume control of the individual's behavior.

Depersonalization/Derealization Disorder. The essential feature of depersonalization/derealization disorder is persistent or recurrent episodes of depersonalization (an altered sense of one's physical being, including feeling that one is outside of one's body, physically cut off or distanced from people, floating, observing oneself from a distance, as though in a dream) or derealization (experiencing the environment as unreal or distorted).

Somatic Symptom and Related Disorders

This group of disorders (previously called somatoform disorders in DSM-IV) is characterized by marked preoccupation with the body and fears of disease or consequences of disease (e.g., death).

Somatic Symptom Disorder. Somatic symptom disorder is characterized by high levels of anxiety and persistent worry about somatic signs and symptoms that are misinterpreted as having a known medical disorder. It is also known as hypochondriasis.

Illness Anxiety Disorder. Illness anxiety disorder is the fear of being sick with few or no somatic symptoms. It is a new diagnosis in DSM-5.

Functional Neurological Symptom Disorder. Formerly known as conversion disorder in DSM-IV, this condition is characterized by unexplained voluntary or motor sensory deficits that suggest the presence of a neurological or other general medical condition. Psychological conflict is determined to be responsible for the symptoms.

Psychological Factors Affecting Other Medical Conditions. This category is for psychological problems that negatively affect a medical condition by increasing the risk of an adverse outcome.

Factitious Disorder. Factitious disorder, also called Munchausen syndrome, refers to the deliberate feigning of physical or psychological symptoms to assume the sick role. *Factitious disorder imposed on another* (previously called factitious disorder by proxy) is when one person presents the other person as ill, most often mother and child. Factitious disorder is distinguished from malingering in which symptoms are also falsely reported; however, the motivation in malingering is external incentives, such as avoidance of responsibility, obtaining financial compensation, or obtaining substances.

Other Specified Somatic Symptom and Related Disorder. This category is for disorders that are not classified above. One such disorder is *pseudocyesis*, in which a person believes falsely that she (or he in rare instances) is pregnant.

Feeding and Eating Disorders

Feeding and eating disorders are characterized by a marked disturbance in eating behavior.

Anorexia Nervosa. Anorexia nervosa is an eating disorder characterized by loss of body weight and refusal to eat. Appetite is usually intact.

Bulimia Nervosa. Bulimia nervosa is an eating disorder characterized by recurrent and frequent binge eating with or without vomiting.

Binge Eating Disorder. Binge eating disorder is a variant of bulimia nervosa with occasional, once a week, binge eating.

Pica. Pica is the eating of non-nutritional substances (e.g., starch).

Rumination Disorder. The essential feature of rumination disorder is the repeated regurgitation of food, usually beginning in infancy or childhood.

Avoidant/Restrictive Food Intake Disorder. Previously called feeding disorder of infancy or childhood in DSM-IV, the main feature of this disorder is a lack of interest in food or eating, resulting in failure to thrive.

Elimination Disorders

These are disorders of elimination caused by physiological or psychological factors. There are two: *encopresis*, which is the inability to maintain bowel control, and *enuresis*, which is the inability to maintain bladder control.

Sleep-Wake Disorders

Sleep-wake disorders involve disruptions in sleep quality, timing, and amount that result in daytime impairment and distress. They include the following disorders or disorder groups in DSM-5.

Insomnia Disorder. Difficulty falling asleep or staying asleep is characteristic of insomnia disorder. Insomnia can be an independent condition, or it can be comorbid with another mental disorder, another sleep disorder, or another medical condition.

Hypersomnolence Disorder. Hypersomnolence disorder, or hypersomnia, occurs when a person sleeps too much and feels excessively tired despite normal or because of prolonged quantity of sleep.

Parasomnias. Parasomnias are marked by unusual behavior, experiences, or physiological events during sleep. This category is divided into three subtypes: *non-REM movement sleep arousal disorders*, which involve incomplete awakening from sleep accompanied by either sleepwalking or sleep terror disorder; *nightmare disorder* in which nightmares induce awakening repeatedly and cause distress and impairment; and *REM sleep behavior disorder*, which is characterized by vocal or motor behavior during sleep.

Narcolepsy. Narcolepsy is marked by sleep attacks, usually with loss of muscle tone (cataplexy).

Breathing-Related Sleep Disorders. There are three subtypes of breathing-related sleep disorders. The most common of the three is *obstructive sleep apnea hypopnea* in which apneas (absence of airflow) and hypopneas (reduction in airflow) occur repeatedly during sleep, causing snoring and daytime sleepiness. *Central sleep apnea* is the presence of Cheyne-Stokes breathing in addition to apneas and hypopneas. Last, *sleep-related hypoventilation* causes elevated CO₂ levels from decreased respiration.

Restless Legs Syndrome. Restless legs syndrome is the compulsive movement of legs during sleep.

Substance/Medication-Induced Sleep Disorder. This category includes sleep disorders that are caused by a drug or medication (e.g., alcohol, caffeine).

Circadian Rhythm Sleep-Wake Disorders. Underlying these disorders is a pattern of sleep disruption that alters or misaligns a person's circadian system, resulting in insomnia or excessive sleepiness. There are six types: (1) *delayed sleep phase type* is characterized by sleep-wake times that are several hours later than desired or conventional times; (2) *advanced sleep phase type* is characterized by earlier than usual sleep-onset and wake-up times; (3) *irregular sleep-wake type* is characterized by fragmented sleep throughout the 24-hour day with no major sleep period and no discernible sleep-wake circadian rhythm; (4) *non-24-hour sleep-wake type* is a circadian period that is not aligned to the external 24-hour environment, most common among blind or visually impaired individuals; (5) *shift work type* is from working on a nightly schedule on a regular basis; and (6) *unspecified type* that does not meet any of the above criteria.

Sexual Dysfunctions

Sexual dysfunctions are divided into ten disorders that are related to change in sexual desire or performance.

Delayed Ejaculation. Delayed ejaculation is the inability or marked delay in the ability to ejaculate during coitus or masturbation.

Erectile Disorder. Erectile disorder is the inability to achieve or maintain an erection sufficient for coital penetration.

Female Orgasmic Disorder. Female orgasmic disorder is the absence of the ability to achieve orgasm or a significant reduction in the intensity of orgasmic sensations during masturbation or coitus.

Female Sexual Interest/Arousal Disorder. Female sexual interest/arousal disorder is absent or decreased interest in sexual fantasy or behavior that causes distress in the individual.

Genito-Pelvic Pain/Penetration Disorder. Genito-pelvic pain/penetration disorder replaces the terms *vaginismus* and *dyspareunia* (vaginal spasm and pain interfering with coitus). It is the anticipation of or actual pain during sex activities, particularly related to intromission.

Male Hypoactive Sexual Desire Disorder. Male hypoactive sexual desire disorder is absent or reduced sexual fantasy or desire in men.

Premature or Early Ejaculation. Premature ejaculation is manifested by ejaculation that occurs before or immediately after intromission during coitus.

Substance/Medication-Induced Sexual Dysfunction. Substance/medication-induced sexual dysfunction is impaired function due to substances (e.g., fluoxetine).

Other Unspecified Sexual Dysfunction. These include sexual disorder due to a medical condition (e.g., multiple sclerosis).

Gender Dysphoria

Gender dysphoria, previously called Gender Identity Disorder, is characterized by a persistent discomfort with one's biological sex and, in some cases, the desire to have sex organs of the opposite sex. It is subdivided into *gender dysphoria in children* and *gender dysphoria in adolescents and adults*.

Disruptive, Impulse-Control, and Conduct Disorders

Included in this category are conditions involving problems in the self-control of emotions and behaviors.

Oppositional Defiant Disorder. Oppositional defiant disorder is diagnosed in children and adolescents. Symptoms include anger, irritability, defiance, and refusal to comply with regulations.

Intermittent Explosive Disorder. Intermittent explosive disorder involves uncontrolled outbursts of aggression.

Conduct Disorder. Conduct disorder is diagnosed in children and adolescents and is characterized by fighting and bullying.

Pyromania. Repeated fire setting is the distinguishing feature of pyromania.

Kleptomania. Repeated stealing is the distinguishing feature of kleptomania.

SUBSTANCE-RELATED DISORDERS

Substance-Induced Disorders. Psychoactive and other substances may cause intoxication and withdrawal syndrome and induce psychiatric disorders, including bipolar and related disorders, obsessive-compulsive and related disorders, sleep disorders, sexual dysfunction, delirium, and neurocognitive disorders.

Substance Use Disorders. Sometimes referred to as addiction, this is a group of disorders diagnosed by the substance abused—alcohol, cocaine, cannabis, hallucinogens, inhalants, opioids, sedative, stimulant, or tobacco.

Alcohol-Related Disorders. Alcohol-related disorders result in impairment caused by excessive use of alcohol. They include alcohol use disorder, which is recurrent alcohol use with developing tolerance and withdrawal; alcohol intoxication, which is simple drunkenness; and alcohol withdrawal, which can involve delirium tremens.

Other Alcohol-Induced Disorders. This group of disorders includes psychotic, bipolar, depressive, anxiety, sleep, sexual, and neurocognitive disorders, including amnesic disorder (also known as Korsakoff's syndrome). Wernicke's encephalopathy, a neurologic condition of ataxia, ophthalmoplegia, and confusion, develops from chronic alcohol use. The two may coexist (Wernicke-Korsakoff syndrome). *Alcohol-induced persisting dementia* is differentiated from Korsakoff's syndrome by multiple cognitive deficits.

Similar categories (intoxication, withdrawal, and induced disorders) exist for caffeine, cannabis, phencyclidine, other hallucinogens, inhalants, opioids, sedative, hypnotic, or anxiolytics, stimulants, and tobacco.

Gambling Disorder. Gambling disorder is classified as a *non-substance-related disorder*. It involves compulsive gambling with an inability to stop or cut down, leading to social and financial difficulties. Some clinicians believe sexual addiction should be classified in the same way, but it is not a DSM-5 diagnosis.

NEUROCOGNITIVE DISORDERS

These are disorders characterized by changes in brain structure and function that result in impaired learning, orientation judgment, memory, and intellectual functions. (They were previously called dementia, delirium, amnesic, and other cognitive disorders in DSM-IV.) They are divided into three categories.

Delirium. Delirium is marked by short-term confusion and cognition caused by substance intoxication or withdrawal (cocaine, opioids, phencyclidine), medication (cortisol), general medical condition (infection), or other causes (sleep deprivation).

Mild Neurocognitive Disorder. Mild neurocognitive disorder is a mild or modest decline in cognitive function. It must be distinguished from normal age-related cognitive change (normal age-related senescence).

Major Neurocognitive Disorder. Major neurocognitive disorder (a term that may be used synonymously with *dementia*, which is still preferred by most psychiatrists) is marked by severe impairment in memory, judgment, orientation, and cognition. There are 13 subtypes (Table 6-2): *Alzheimer's disease*, which usually occurs in persons older than age 65 years and is manifested by progressive intellectual deterioration and dementia; *vascular dementia*, which is a stepwise progression in cognitive deterioration caused by vessel thrombosis or hemorrhage; *frontotemporal lobar degeneration*, which is marked by behavioral inhibition (also known as Pick's disease); *Lewy body disease*, which involves hallucinations with dementia; *traumatic brain injury* from physical trauma; *HIV disease*; *prion disease*, which is caused by slow-growing transmissible prion protein; *Parkinson's disease*; *Huntington's disease*; *caused by a medical condition*; *substance/medication-induced* (e.g., alcohol causing Korsakoff's syndrome); *multiple etiologies*; and *unspecified dementia*.

Table 6-2
Major Subtypes of Neurocognitive Disorder (Dementia)

Alzheimer's disease
Vascular dementia
Lewy body disease
Parkinson's disease
Frontotemporal dementia (Pick's disease)
Traumatic brain injury
HIV infection
Substance/medication-induced dementia
Huntington's disease
Prion disease
Other medical condition (known as amnesic syndrome in DSM-IV-TR)
Multiple etiologies
Unspecified dementia

Personality Disorders

Personality disorders are characterized by deeply engrained, generally lifelong maladaptive patterns of behavior that are usually recognizable at adolescence or earlier.

Paranoid Personality Disorder. Paranoid personality disorder is characterized by unwarranted suspicion, hypersensitivity, jealousy, envy, rigidity, excessive self-importance, and a tendency to blame and ascribe evil motives to others.

Schizoid Personality Disorder. Schizoid personality disorder is characterized by shyness, oversensitivity, seclusiveness, avoidance of close or competitive relationships, eccentricity, no loss of capacity to recognize reality, daydreaming, and an ability to express hostility and aggression.

Schizotypal Personality Disorder. Schizotypal personality disorder is similar to schizoid personality, but the person also exhibits slight losses of reality testing, has odd beliefs, and is aloof and withdrawn.

Obsessive-Compulsive Personality Disorder (OCPD). OCPD is characterized by excessive concern with conformity and standards of conscience; the individual may be rigid, overconscientious, overdutiful, overinhibited, and unable to relax (three *Ps*—punctual, parsimonious, and precise).

Histrionic Personality Disorder. Histrionic personality disorder is characterized by emotional instability, excitability, overreactivity, vanity, immaturity, dependency, and self-dramatization that is attention seeking and seductive.

Avoidant Personality Disorder. Avoidant personality disorder is characterized by low levels of energy, easy fatigability, lack of enthusiasm, inability to enjoy life, and oversensitivity to stress.

Antisocial Personality Disorder. Antisocial personality disorder covers persons in conflict with society. They are incapable of loyalty, selfish, callous, irresponsible, impulsive, and unable to feel guilt or learn from experience; they have low levels of frustration tolerance and a tendency to blame others.

Narcissistic Personality Disorder. Narcissistic personality disorder is characterized by grandiose feelings, a sense of entitlement, a lack of empathy, envy, manipulateness, and a need for attention and admiration.

Borderline Personality Disorder. Borderline personality disorder is characterized by instability, impulsiveness, chaotic sexuality, suicidal acts, self-mutilating behavior, identity problems, ambivalence, and feeling of emptiness and boredom.

Dependent Personality Disorder. This is characterized by passive and submissive behavior; the person is unsure of himself or herself and becomes entirely dependent on others.

Personality Changes Due to Another Medical Condition. This category includes alterations to a person's personality due to a medical condition (e.g., brain tumor).

Unspecified Personality Disorder. This category involves other personality traits that do not fit any of the patterns described above.

Paraphilic Disorders and Paraphilia

In *paraphilia*, a person's sexual interests are directed primarily toward objects rather than toward people, toward sexual acts not usually associated with coitus, or toward coitus performed under bizarre circumstances. A *paraphilic disorder* is acted out sexual behavior that can cause possible harm to another person. Included are *exhibitionism* (genital exposure), *voyeurism* (watching sexual acts), *frotteurism* (rubbing against another person), *pedophilia* (sexual attraction toward children), *sexual masochism* (receiving pain), *sexual sadism* (inflicting pain), *fetishism* (arousal from an inanimate object), and *transvestism* (cross-dressing).

Other Mental Disorders

This is a residual category that includes four disorders that do not meet the full criteria for any of the previously described mental disorders: (1) *other specified mental disorder due to another medical condition* (e.g., dissociative symptoms secondary to temporal lobe epilepsy), (2) *unspecified mental disorder due to another medical condition* (e.g., temporal lobe epilepsy producing unspecified symptoms), (3) *other specified mental disorder* in which symptoms are present but subthreshold for a specific mental illness, and (4) *unspecified mental disorder* in which symptoms are present but subthreshold for any mental disorder.

Some clinicians use the term *forme fruste* (French, "unfinished form") to describe atypical or attenuated manifestation of a disease or syndrome, with the implication of incompleteness or partial presence of the condition or disorder. This term might apply to 3 and 4 above.

Medication-Induced Movement Disorders and Other Adverse Effects of Medication

Ten disorders are included: (1) *neuroleptic or other medication-induced Parkinsonism* presents as rhythmic tremor, rigidity, akinesia, or bradykinesia that is reversible when the causative drug is withdrawn or its dosage reduced; (2) *neuroleptic malignant syndrome* presents as muscle rigidity, dystonia, or hyperthermia; (3) *medication-induced acute dystonia* consists of slow, sustained contracture of musculature, causing postural deviations; (4) *medication-induced acute akathisia* presents as motor restlessness with constant movement; (5) *tardive dyskinesia* is characterized by involuntary movement of the lips, jaw, and tongue and other involuntary dyskinesic movements; (6) *tardive dystonia or akathisia* is a variant of tardive dyskinesia that involves extrapyramidal syndrome; (7) *medication-induced postural tremor* is a fine tremor, usually at rest, that is caused by medication; (8) *other medication-induced movement disorder* describes atypical extrapyramidal syndrome from a medication; (9) *antidepressant discontinuation syndrome* is a withdrawal syndrome that arises after abrupt cessation of antidepressant drugs (e.g., fluoxetine); and (10) *other adverse effect of medication* includes changes in blood pressure, diarrhea, and so on due to medication.

Other Conditions That May Be a Focus of Clinical Attention

These are conditions that may interfere with overall functioning but are not severe enough to warrant a psychiatric diagnosis. These conditions are not mental disorders but may aggravate an existing mental disorder. A broad range of life problems and stressors are included in this section, among which are (1) *relational problems*, including *problems related to family upbringing*, such as problems with siblings or upbringing away from parents, and *problems related to primary support group*, such as problems with a spouse or intimate partner, separation or divorce, family-expressed emotion, or uncomplicated bereavement; and (2) *abuse and neglect*, which includes *child maltreatment and neglect problems*, such as physical abuse, sexual abuse, neglect, or psychological abuse, and *adult maltreatment and neglect problems*, which involves spouse or partner physical, sexual, and psychological violence and neglect or adult abuse by a nonspouse or nonpartner. Borderline intellectual functioning is included here in DSM-5.

Conditions for Further Study

In addition to the diagnostic categories listed above, other categories of illness are listed in DSM-5 that require further study before they become part of the official nomenclature. Some of these disorders are controversial. There are eight disorders in this group: (1) *attenuated psychosis syndrome* refers to subthreshold signs and symptoms of psychosis that develops in adolescence; (2) *depressive episodes with short-duration hypomania* are short episodes (2–3 days) of hypomania that occur with major depression; (3) *persistent complex bereavement disorder* is bereavement that persists over 1 year after loss; (4) *caffeine use disorder* is dependence on caffeine with withdrawal syndrome; (5) *Internet gaming disorder* is the excessive use of Internet that disrupts normal living; (6) *neurobehavioral disorder associated with prenatal alcohol exposure* covers all developmental disorders that occur in utero due to excessive alcohol use by mother (e.g., fetal alcohol syndrome); (7) *suicidal behavior disorder* is repeated suicide attempts that occur irrespective of diagnostic category of mental illness; and (8) *non-suicidal self-injury* is skin cutting and other self-harm without suicidal intent.

Research Domain Criteria (RDC)

In contrast to DSM-5, which describes mental disorders as clusters of signs and symptoms, there is another way of classifying mental disorders that is based on neurobiological measures. Developed by the National Institute of Mental Health, this system requires integrating findings from genetic, imaging, neurochemical, neurophysiological, and clinical studies so that there is a common thread in understanding mental illness. The system relies on examining research domains that tap into the structure and function of the brain, including the mapping of neural circuits that elicit normal and abnormal behavioral patterns.

Five domains have been identified for study: (1) *negative valence systems*, which encompass fear, anxiety, and loss; (2) *positive valence systems*, which cover reward, reward learning, and reward valuation; (3) *cognitive systems*, which cover attention, perception, working memory, and cognitive control; (4) *systems for social processes*, which cover attachment formation, social communication, and perception of self and others; and (5) *arousal/modulatory systems*, which cover arousal, circadian rhythm, sleep, and wakefulness. By studying domains, common antecedents to mental disorders may be found. For example, studying patients with DSM diagnoses of psychotic disorders might reveal genetic polymorphisms and specific changes in certain brain areas that relate to the cognitive system domain. Similarly, patients with a variety of anxiety disorders might share biological characteristics associated with the arousal/modulatory dimension that represent one disease process rather than many.

The RDC classification system is in its infancy and is most useful for researchers mapping brain–behavior relationships as well as genomic discoveries in human and nonhuman animal studies. The ultimate goal is to develop a new classification system based on scientific findings to replace the descriptive DSM classification currently in use, thus bringing psychiatric diagnoses more in line with other branches of medicine. Until such time, however, DSM remains the best tool to guide psychiatrists and other mental health professionals to diagnose and treat patients with mental disorders.

Schizophrenia Spectrum and Other Psychotic Disorders

7.1 Schizophrenia

Although schizophrenia is discussed as if it is a single disease, it probably comprises a group of disorders with heterogeneous etiologies, and it includes patients whose clinical presentations, treatment response, and courses of illness vary. Signs and symptoms are variable and include changes in perception, emotion, cognition, thinking, and behavior. The expression of these manifestations varies across patients and over time, but the effect of the illness is always severe and is usually long lasting. The disorder usually begins before age 25 years, persists throughout life, and affects persons of all social classes. Both patients and their families often suffer from poor care and social ostracism because of widespread ignorance about the disorder. Schizophrenia is one of the most common of the serious mental disorders, but its essential nature remains to be clarified; thus, it is sometimes referred to as a syndrome, as the group of schizophrenias, or as in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), the schizophrenia spectrum. Clinicians should appreciate that the diagnosis of schizophrenia is based entirely on the psychiatric history and mental status examination. There is no laboratory test for schizophrenia.

HISTORY

Written descriptions of symptoms commonly observed today in patients with schizophrenia are found throughout history. Early Greek physicians described delusions of grandeur, paranoia, and deterioration in cognitive functions and personality. It was not until the 19th century, however, that schizophrenia emerged as a medical condition worthy of study and treatment. Two major figures in psychiatry and neurology who studied the disorder were Emil Kraepelin (1856–1926) and Eugene Bleuler (1857–1939). Earlier, Benedict Morel (1809–1873), a French psychiatrist, had used the term *démence précoce* to describe deteriorated patients whose illnesses began in adolescence.

Emil Kraepelin

Kraepelin (Fig. 7.1-1) translated Morel's *démence précoce* into *dementia precox*, a term that emphasized the change in cognition (dementia) and early onset (precox) of the disorder. Patients with dementia precox were described as having a long-term deteriorating course and the clinical symptoms of hallucinations and delusions. Kraepelin distinguished these patients from those who underwent distinct episodes of illness alternating with periods of normal functioning, which he classified as having manic-depressive psychosis. Another separate condition called *paranoia* was characterized by persistent persecutory delusions. These patients lacked the deteriorating course of dementia precox and the intermittent symptoms of manic-depressive psychosis.

FIGURE 7.1-1
Emil Kraepelin, 1856–1926. (Courtesy of National Library of Medicine, Bethesda, MD.)

Eugene Bleuler

Bleuler (Fig. 7.1-2) coined the term *schizophrenia*, which replaced *dementia precox* in the literature. He chose the term to express the presence of schisms among thought, emotion, and behavior in patients with the disorder. Bleuler stressed that, unlike Kraepelin's concept of dementia precox, schizophrenia need not have a deteriorating course. This term is often misconstrued, especially by lay people, to mean split personality. Split personality, called dissociative identity disorder, differs completely from schizophrenia (see Chapter 12).

FIGURE 7.1-2

Eugene Bleuler, 1857–1939. (Courtesy of National Library of Medicine, Bethesda, MD.)

The Four As. Bleuler identified specific fundamental (or primary) symptoms of schizophrenia to develop his theory about the internal mental schisms of patients. These symptoms included associational disturbances of thought, especially looseness, affective disturbances, autism, and ambivalence, summarized as the four As: associations, affect, autism, and ambivalence. Bleuler also identified accessory (secondary) symptoms, which included the symptoms that Kraepelin saw as major indicators of dementia praecox: hallucinations and delusions.

Other Theorists

Ernst Kretschmer (1888–1926). Kretschmer compiled data to support the idea that schizophrenia occurred more often among persons with asthenic (i.e., slender, lightly muscled physiques), athletic, or dysplastic body types rather than among persons with pyknic (i.e., short, stocky physiques) body types. He thought the latter were more likely to incur bipolar disorders. His observations may seem strange, but they are not inconsistent with a superficial impression of the body types in many persons with schizophrenia.

Kurt Schneider (1887–1967). Schneider contributed a description of first-rank symptoms, which, he stressed, were not specific for schizophrenia and were not to be rigidly applied but were useful for making diagnoses. He emphasized that in patients who showed no first-rank symptoms, the disorder could be diagnosed exclusively on the basis of second-rank symptoms and an otherwise typical clinical appearance. Clinicians frequently ignore his warnings and sometimes see the absence of first-rank symptoms during a single interview as evidence that a person does not have schizophrenia.

Karl Jaspers (1883–1969). Jaspers, a psychiatrist and philosopher, played a major role in developing existential psychoanalysis. He was interested in the phenomenology of mental illness and the subjective feelings of patients with mental illness. His work paved the way toward trying to understand the psychological meaning of schizophrenic signs and symptoms such as delusions and hallucinations.

Adolf Meyer (1866–1950). Meyer, the founder of psychobiology, saw schizophrenia as a reaction to life stresses. It was a maladaptation that was understandable in terms of the patient's life experiences. Meyer's view was represented in the nomenclature of the 1950s, which referred to the schizophrenic reaction. In later editions of DSM, the term reaction was dropped.

EPIDEMIOLOGY

In the United States, the lifetime prevalence of schizophrenia is about 1 percent, which means that about one person in 100 will develop schizophrenia during their lifetime. The Epidemiologic Catchment Area study sponsored by the National Institute of Mental Health reported a lifetime prevalence of 0.6 to 1.9 percent. In the United States, about 0.05 percent of the total population is treated for schizophrenia in any single year, and only about half of all patients with schizophrenia obtain treatment, despite the severity of the disorder.

Gender and Age

Schizophrenia is equally prevalent in men and women. The two genders differ, however, in the onset and course of illness. Onset is earlier in men than in women. More than half of all male schizophrenia patients, but only one-third of all female schizophrenia patients, are first admitted to a psychiatric hospital before age 25 years. The peak ages of onset are 10 to 25 years for men and 25 to 35 years for women. Unlike men, women display a bimodal age distribution, with a second peak occurring in middle age. Approximately 3 to 10 percent of women with schizophrenia present with disease onset after age 40 years. About 90 percent of patients in treatment for schizophrenia are between 15 and 55 years old. Onset of schizophrenia before age 10 years or after age 60 years is extremely rare. Some studies have indicated that men are more likely to be impaired by negative symptoms (described later) than are women and that women are more likely to have better social functioning than are men before disease onset. In general, the outcome for female schizophrenia patients is better than that for male schizophrenia patients. When onset occurs after age 45 years, the disorder is characterized as late-onset schizophrenia.

Reproductive Factors

The use of psychopharmacological drugs, the open-door policies in hospitals, the deinstitutionalization in state hospitals, and the emphasis on rehabilitation and community-based care for patients have all led to an increase in the marriage and fertility rates among persons with

schizophrenia. Because of these factors, the number of children born to parents with schizophrenia is continually increasing. The fertility rate for persons with schizophrenia is close to that for the general population. First-degree biological relatives of persons with schizophrenia have a ten times greater risk for developing the disease than the general population.

Medical Illness

Persons with schizophrenia have a higher mortality rate from accidents and natural causes than the general population. Institution- or treatment-related variables do not explain the increased mortality rate, but the higher rate may be related to the fact that the diagnosis and treatment of medical and surgical conditions in schizophrenia patients can be clinical challenges. Several studies have shown that up to 80 percent of all schizophrenia patients have significant concurrent medical illnesses and that up to 50 percent of these conditions may be undiagnosed.

Infection and Birth Season

Persons who develop schizophrenia are more likely to have been born in the winter and early spring and less likely to have been born in late spring and summer. In the Northern Hemisphere, including the United States, persons with schizophrenia are more often born in the months from January to April. In the Southern Hemisphere, persons with schizophrenia are more often born in the months from July to September. Season-specific risk factors, such as a virus or a seasonal change in diet, may be operative. Another hypothesis is that persons with a genetic predisposition for schizophrenia have a decreased biological advantage to survive season-specific insults.

Studies have pointed to gestational and birth complications, exposure to influenza epidemics, maternal starvation during pregnancy, Rhesus factor incompatibility, and an excess of winter births in the etiology of schizophrenia. The nature of these factors suggests a neurodevelopmental pathological process in schizophrenia, but the exact pathophysiological mechanism associated with these risk factors is not known.

Epidemiological data show a high incidence of schizophrenia after prenatal exposure to influenza during several epidemics of the disease. Some studies show that the frequency of schizophrenia is increased after exposure to influenza—which occurs in the winter—during the second trimester of pregnancy. Other data supporting a viral hypothesis are an increased number of physical anomalies at birth, an increased rate of pregnancy and birth complications, seasonality of birth consistent with viral infection, geographical clusters of adult cases, and seasonality of hospitalizations.

Viral theories stem from the fact that several specific viral theories have the power to explain the particular localization of pathology necessary to account for a range of manifestations in schizophrenia without overt febrile encephalitis.

Substance Abuse

Substance abuse is common in schizophrenia. The lifetime prevalence of any drug abuse (other than tobacco) is often greater than 50 percent. For all drugs of abuse (other than tobacco), abuse is associated with poorer function. In one population-based study, the lifetime prevalence of alcohol within schizophrenia was 40 percent. Alcohol abuse increases risk of hospitalization and, in some patients, may increase psychotic symptoms. People with schizophrenia have an increased prevalence of abuse of common street drugs. There has been particular interest in the association between cannabis and schizophrenia. Those reporting high levels of cannabis use (more than 50 occasions) were at sixfold increased risk of schizophrenia compared with nonusers. The use of amphetamines, cocaine, and similar drugs should raise particular concern because of their marked ability to increase psychotic symptoms.

Nicotine. Up to 90 percent of schizophrenia patients may be dependent on nicotine. Apart from smoking-associated mortality, nicotine decreases the blood concentrations of some antipsychotics. There are suggestions that the increased prevalence in smoking is due, at least in part, to brain abnormalities in nicotinic receptors. A specific polymorphism in a nicotinic receptor has been linked to a genetic risk for schizophrenia. Nicotine administration appears to improve some cognitive impairments and parkinsonism in schizophrenia, possibly because of nicotine-dependent activation of dopamine neurons. Recent studies have also demonstrated that nicotine may decrease positive symptoms such as hallucinations in schizophrenia patients by its effect on nicotinic receptors in the brain that reduce the perception of outside stimuli, especially noise. In that sense, smoking is a form of self-medication.

Population Density

The prevalence of schizophrenia has been correlated with local population density in cities with populations of more than 1 million people. The correlation is weaker in cities of 100,000 to 500,000 people and is absent in cities with fewer than 10,000 people. The effect of population density is consistent with the observation that the incidence of schizophrenia in children of either one or two parents with schizophrenia is twice as high in cities as in rural communities. These observations suggest that social stressors in urban settings may affect the development of schizophrenia in persons at risk.

Socioeconomic and Cultural Factors

Economics. Because schizophrenia begins early in life; causes significant and long-lasting impairments; makes heavy demands for hospital care; and requires ongoing clinical care, rehabilitation, and support services, the financial cost of the illness in the United States is estimated to exceed that of all cancers combined. Patients with a diagnosis of schizophrenia are reported to account for 15 to 45 percent of homeless Americans.

Hospitalization. The development of effective antipsychotic drugs and changes in political and popular attitudes toward the treatment and the rights of persons who are mentally ill have dramatically changed the patterns of hospitalization for schizophrenia patients since the mid-1950s. Even with antipsychotic medication, however, the probability of readmission within 2 years after discharge from the first hospitalization is about 40 to 60 percent. Patients with schizophrenia occupy about 50 percent of all mental hospital beds and account for about 16 percent of all psychiatric patients who receive any treatment.

ETIOLOGY

Genetic Factors

There is a genetic contribution to some, perhaps all, forms of schizophrenia, and a high proportion of the variance in liability to schizophrenia is due to additive genetic effects. For example, schizophrenia and schizophrenia-related disorders (e.g., schizotypal personality disorder) occur at an increased rate among the biological relatives of patients with schizophrenia. The likelihood of a person having schizophrenia is correlated with the closeness of the relationship to an affected relative (e.g., first- or second-degree relative). In the case of monozygotic twins who have identical genetic endowment, there is an approximately 50 percent concordance rate for schizophrenia. This rate is four to five times the concordance rate in dizygotic twins or the rate of occurrence found in other first-degree relatives (i.e., siblings, parents, or offspring). The role of genetic factors is further reflected in the drop-off in the occurrence of schizophrenia among second- and third-degree relatives, in whom one would hypothesize a decreased genetic loading. The finding of a higher rate of schizophrenia among the

biological relatives of an adopted-away person who develops schizophrenia, compared with the adoptive, nonbiological relatives who rear the patient, provides further support to the genetic contribution in the etiology of schizophrenia. Nevertheless, the monozygotic twin data clearly demonstrate the fact that individuals who are genetically vulnerable to schizophrenia do not inevitably develop schizophrenia; other factors (e.g., environment) must be involved in determining a schizophrenia outcome. If a vulnerability-liability model of schizophrenia is correct in its postulation of an environmental influence, then other biological or psychosocial environment factors may prevent or cause schizophrenia in the genetically vulnerable individual.

Some data indicate that the age of the father has a correlation with the development of schizophrenia. In studies of schizophrenia patients with no history of illness in either the maternal or paternal line, it was found that those born from fathers older than the age of 60 years were vulnerable to developing the disorder. Presumably, spermatogenesis in older men is subject to greater epigenetic damage than in younger men.

The modes of genetic transmission in schizophrenia are unknown, but several genes appear to make a contribution to schizophrenia vulnerability. Linkage and association genetic studies have provided strong evidence for nine linkage sites: 1q, 5q, 6p, 6q, 8p, 10p, 13q, 15q, and 22q. Further analyses of these chromosomal sites have led to the identification of specific candidate genes, and the best current candidates are α -7 nicotinic receptor, *DISC 1*, *GRM 3*, *COMT*, *NRG 1*, *RGS 4*, and *G 72*. Recently, mutations of the genes dystrobrevin (*DTNBP1*) and neureglin 1 have been found to be associated with negative features of schizophrenia.

Biochemical Factors

Dopamine Hypothesis. The simplest formulation of the dopamine hypothesis of schizophrenia posits that schizophrenia results from too much dopaminergic activity. The theory evolved from two observations. First, the efficacy and the potency of many antipsychotic drugs (i.e., the dopamine receptor antagonists [DRAs]) are correlated with their ability to act as antagonists of the dopamine type 2 (D_2) receptor.

Second, drugs that increase dopaminergic activity, notably cocaine and amphetamine, are psychotomimetic. The basic theory does not elaborate on whether the dopaminergic hyperactivity is due to too much release of dopamine, too many dopamine receptors, hypersensitivity of the dopamine receptors to dopamine, or a combination of these mechanisms. Which dopamine tracts in the brain are involved is also not specified in the theory, although the mesocortical and mesolimbic tracts are most often implicated. The dopaminergic neurons in these tracts project from their cell bodies in the midbrain to dopaminergic neurons in the limbic system and the cerebral cortex.

Excessive dopamine release in patients with schizophrenia has been linked to the severity of positive psychotic symptoms. Positron emission tomography studies of dopamine receptors document an increase in D_2 receptors in the caudate nucleus of drug-free patients with schizophrenia. There have also been reports of increased dopamine concentration in the amygdala, decreased density of the dopamine transporter, and increased numbers of dopamine type 4 receptors in the entorhinal cortex.

Serotonin. Current hypotheses posit serotonin excess as a cause of both positive and negative symptoms in schizophrenia. The robust serotonin antagonist activity of clozapine and other second-generation antipsychotics coupled with the effectiveness of clozapine to decrease positive symptoms in chronic patients has contributed to the validity of this proposition.

Norepinephrine. Anhedonia—the impaired capacity for emotional gratification and the decreased ability to experience pleasure—has long been noted to be a prominent feature of schizophrenia. A selective neuronal degeneration within the norepinephrine reward neural system could account for this aspect of schizophrenic symptomatology. However, biochemical and pharmacological data bearing on this proposal are inconclusive.

GABA. The inhibitory amino acid neurotransmitter γ -aminobutyric acid (GABA) has been implicated in the pathophysiology of schizophrenia based on the finding that some patients with schizophrenia have a loss of GABAergic neurons in the hippocampus. GABA has a regulatory effect on dopamine activity, and the loss of inhibitory GABAergic neurons could lead to the hyperactivity of dopaminergic neurons.

Neuropeptides. Neuropeptides, such as substance P and neurotensin, are localized with the catecholamine and indolamine neurotransmitters and influence the action of these neurotransmitters. Alteration in neuropeptide mechanisms could facilitate, inhibit, or otherwise alter the pattern of firing these neuronal systems.

Glutamate. Glutamate has been implicated because ingestion of phencyclidine, a glutamate antagonist, produces an acute syndrome similar to schizophrenia. The hypotheses proposed about glutamate include those of hyperactivity, hypoactivity, and glutamate-induced neurotoxicity.

Acetylcholine and Nicotine. Postmortem studies in schizophrenia have demonstrated decreased muscarinic and nicotinic receptors in the caudate-putamen, hippocampus, and selected regions of the prefrontal cortex. These receptors play a role in the regulation of neurotransmitter systems involved in cognition, which is impaired in schizophrenia.

Neuropathology

In the 19th century, neuropathologists failed to find a neuropathological basis for schizophrenia, and thus they classified schizophrenia as a functional disorder. By the end of the 20th century, however, researchers had made significant strides in revealing a potential neuropathological basis for schizophrenia, primarily in the limbic system and the basal ganglia, including neuropathological or neurochemical abnormalities in the cerebral cortex, the thalamus, and the brainstem. The loss of brain volume widely reported in schizophrenic brains appears to result from reduced density of the axons, dendrites, and synapses that mediate associative functions of the brain. Synaptic density is highest at age 1 year and then is pared down to adult values in early adolescence. One theory, based in part on the observation that patients often develop schizophrenic symptoms during adolescence, holds that schizophrenia results from excessive pruning of synapses during this phase of development.

Cerebral Ventricles. Computed tomography (CT) scans of patients with schizophrenia have consistently shown lateral and third ventricular enlargement and some reduction in cortical volume. Reduced volumes of cortical gray matter have been demonstrated during the earliest stages of the disease. Several investigators have attempted to determine whether the abnormalities detected by CT are progressive or static. Some studies have concluded that the lesions observed on CT scan are present at the onset of the illness and do not progress. Other studies, however, have concluded that the pathological process visualized on CT scan continues to progress during the illness. Thus, whether an active pathological process is continuing to evolve in schizophrenia patients is still uncertain.

Reduced Symmetry. There is a reduced symmetry in several brain areas in schizophrenia, including the temporal, frontal, and occipital lobes. This reduced symmetry is believed by some investigators to originate during fetal life and to be indicative of a disruption in brain lateralization during neurodevelopment.

Limbic System. Because of its role in controlling emotions, the limbic system has been hypothesized to be involved in the pathophysiology of schizophrenia. Studies of postmortem brain samples from schizophrenia patients have shown a decrease in the size of the region, including the amygdala, the hippocampus, and the parahippocampal gyrus. This neuropathological finding agrees with the observation made by magnetic resonance imaging studies of patients with schizophrenia. The hippocampus is not only smaller in size in schizophrenia but is also functionally abnormal as indicated by disturbances in glutamate transmission. Disorganization of the neurons within the hippocampus has also been seen in brain tissue sections of schizophrenia patients compared with healthy control participants without schizophrenia.

Prefrontal Cortex. There is considerable evidence from postmortem brain studies that supports anatomical abnormalities in the prefrontal cortex in schizophrenia. Functional deficits in the prefrontal brain imaging region have also been demonstrated. It has long been noted that several symptoms of schizophrenia mimic those found in persons with prefrontal lobotomies or *frontal lobe syndromes*.

Thalamus. Some studies of the thalamus show evidence of volume shrinkage or neuronal loss, in particular subnuclei. The medial dorsal nucleus of the thalamus, which has reciprocal connections with the prefrontal cortex, has been reported to contain a reduced number of neurons. The total number of neurons, oligodendrocytes, and astrocytes is reduced by 30 to 45 percent in schizophrenia patients. This putative finding does not appear to be due to the effects of antipsychotic drugs because the volume of the thalamus is similar in size between patients with schizophrenia treated chronically with medication and neuroleptic-naïve subjects.

Basal Ganglia and Cerebellum. The basal ganglia and cerebellum have been of theoretical interest in schizophrenia for at least two reasons. First, many patients with schizophrenia show odd movements, even in the absence of medication-induced movement disorders (e.g., tardive dyskinesia). The odd movements can include an awkward gait, facial grimacing, and stereotypies. Because the basal ganglia and cerebellum are involved in the control of movement, disease in these areas is implicated in the pathophysiology of schizophrenia. Second, the movement disorders involving the basal ganglia (e.g., Huntington's disease, Parkinson's disease) are the ones most commonly associated with psychosis. Neuropathological studies of the basal ganglia have produced variable and inconclusive reports about cell loss or the reduction of volume of the globus pallidus and the substantia nigra. Studies have also shown an increase in the number of D₂ receptors in the caudate, the putamen, and the nucleus accumbens. The question remains, however, whether the increase is secondary to the patient having received antipsychotic medications. Some investigators have begun to study the serotonergic system in the basal ganglia; a role for serotonin in psychotic disorder is suggested by the clinical usefulness of antipsychotic drugs that are serotonin antagonists (e.g., clozapine, risperidone).

Neural Circuits

There has been a gradual evolution from conceptualizing schizophrenia as a disorder that involves discrete areas of the brain to a perspective that views schizophrenia as a disorder of brain neural circuits. For example, as mentioned previously, the basal ganglia and cerebellum are reciprocally connected to the frontal lobes, and the abnormalities in frontal lobe function seen in some brain imaging studies may be due to disease in either area rather than in the frontal lobes themselves. It is also hypothesized that an early developmental lesion of the dopaminergic tracts to the prefrontal cortex results in the disturbance of prefrontal and limbic system function and leads to the positive and negative symptoms and cognitive impairments observed in patients with schizophrenia.

Of particular interest in the context of neural circuit hypotheses linking the prefrontal cortex and limbic system are studies demonstrating a relationship between hippocampal morphological abnormalities and disturbances in prefrontal cortex metabolism or function (or both). Data from functional and structural imaging studies in humans suggest that whereas dysfunction of the anterior cingulate basal ganglia thalamocortical circuit underlies the production of positive psychotic symptoms, dysfunction of the dorsolateral prefrontal circuit underlies the production of primary, enduring, negative or deficit symptoms. There is a neural basis for cognitive functions that is impaired in patients with schizophrenia. The observation of the relationship among impaired working memory performance, disrupted prefrontal neuronal integrity, altered prefrontal, cingulate, and inferior parietal cortex, and altered hippocampal blood flow provides strong support for disruption of the normal working memory neural circuit in patients with schizophrenia. The involvement of this circuit, at least for auditory hallucinations, has been documented in a number of functional imaging studies that contrast hallucinating and nonhallucinating patients.

Brain Metabolism

Studies using magnetic resonance spectroscopy, a technique that measures the concentration of specific molecules in the brain, found that patients with schizophrenia had lower levels of phosphomonoester and inorganic phosphate and higher levels of phosphodiester than a control group. Furthermore, concentrations of N-acetyl aspartate, a marker of neurons, were lower in the hippocampus and frontal lobes of patients with schizophrenia.

Applied Electrophysiology

Electroencephalographic studies indicate that many schizophrenia patients have abnormal records, increased sensitivity to activation procedures (e.g., frequent spike activity after sleep deprivation), decreased alpha activity, increased theta and delta activity, possibly more epileptiform activity than usual, and possibly more left-sided abnormalities than usual. Schizophrenia patients also exhibit an inability to filter out irrelevant sounds and are extremely sensitive to background noise. The flooding of sound that results makes concentration difficult and may be a factor in the production of auditory hallucinations. This sound sensitivity may be associated with a genetic defect.

Complex Partial Epilepsy. Schizophrenia-like psychoses have been reported to occur more frequently than expected in patients with complex partial seizures, especially seizures involving the temporal lobes. Factors associated with the development of psychosis in these patients include a left-sided seizure focus, medial temporal location of the lesion, and an early onset of seizures. The first-rank symptoms described by Schneider may be similar to symptoms of patients with complex partial epilepsy and may reflect the presence of a temporal lobe disorder when seen in patients with schizophrenia.

Evoked Potentials. A large number of abnormalities in evoked potential among patients with schizophrenia has been described. The P300 has been most studied and is defined as a large, positive evoked-potential wave that occurs about 300 milliseconds after a sensory stimulus is detected. The major source of the P300 wave may be located in the limbic system structures of the medial temporal lobes. In patients with schizophrenia, the P300 has been reported to be statistically smaller than in comparison groups. Abnormalities in the P300 wave have also been reported to be more common in children who, because they have affected parents, are at high risk for schizophrenia. Whether the characteristics of the P300 represent a state or a trait phenomenon remains controversial. Other evoked potentials reported to be abnormal in patients with schizophrenia are the N100 and the contingent negative variation. The N100 is a negative wave that occurs about 100 milliseconds after a stimulus, and the contingent negative variation is a slowly developing, negative-voltage shift following the presentation of a sensory stimulus that is a warning for an upcoming stimulus. The evoked-potential data have been interpreted as indicating that although patients with schizophrenia are unusually sensitive to a sensory stimulus (larger early evoked potentials), they

compensate for the increased sensitivity by blunting the processing of information at higher cortical levels (indicated by smaller late evoked potentials).

Eye Movement Dysfunction

The inability to follow a moving visual target accurately is the defining basis for the disorders of smooth visual pursuit and disinhibition of saccadic eye movements seen in patients with schizophrenia. Eye movement dysfunction may be a trait marker for schizophrenia; it is independent of drug treatment and clinical state and is also seen in first-degree relatives of probands with schizophrenia. Various studies have reported abnormal eye movements in 50 to 85 percent of patients with schizophrenia compared with about 25 percent in psychiatric patients without schizophrenia and fewer than 10 percent in nonpsychiatrically ill control participant.

Psychoneuroimmunology

Several immunological abnormalities have been associated with patients who have schizophrenia. The abnormalities include decreased T-cell interleukin-2 production, reduced number and responsiveness of peripheral lymphocytes, abnormal cellular and humoral reactivity to neurons, and the presence of brain-directed (antibrain) antibodies. The data can be interpreted variously as representing the effects of a neurotoxic virus or of an endogenous autoimmune disorder. Most carefully conducted investigations that have searched for evidence of neurotoxic viral infections in schizophrenia have had negative results, although epidemiological data show a high incidence of schizophrenia after prenatal exposure to influenza during several epidemics of the disease. Other data supporting a viral hypothesis are an increased number of physical anomalies at birth, an increased rate of pregnancy and birth complications, seasonality of birth consistent with viral infection, geographical clusters of adult cases, and seasonality of hospitalizations. Nonetheless, the inability to detect genetic evidence of viral infection reduces the significance of all circumstantial data. The possibility of autoimmune brain antibodies has some data to support it; the pathophysiological process, if it exists, however, probably explains only a subset of the population with schizophrenia.

Psychoneuroendocrinology

Many reports describe neuroendocrine differences between groups of patients with schizophrenia and groups of control subjects. For example, results of the dexamethasone-suppression test have been reported to be abnormal in various subgroups of patients with schizophrenia, although the practical or predictive value of the test in schizophrenia has been questioned. One carefully done report, however, has correlated persistent nonsuppression on the dexamethasone-suppression test in schizophrenia with a poor long-term outcome.

Some data suggest decreased concentrations of luteinizing hormone or follicle-stimulating hormone, perhaps correlated with age of onset and length of illness. Two additional reported abnormalities may be correlated with the presence of negative symptoms: a blunted release of prolactin and growth hormone on gonadotropin-releasing hormone or thyrotropin-releasing hormone stimulation and a blunted release of growth hormone on apomorphine stimulation.

PSYCHOSOCIAL AND PSYCHOANALYTIC THEORIES

If schizophrenia is a disease of the brain, it is likely to parallel diseases of other organs (e.g., myocardial infarctions, diabetes) whose courses are affected by psychosocial stress. Thus, clinicians should consider both psychosocial and biological factors affecting schizophrenia.

The disorder affects individual patients, each of whom has a unique psychological makeup. Although many psychodynamic theories about the pathogenesis of schizophrenia seem outdated, perceptive clinical observations can help contemporary clinicians understand how the disease may affect a patient's psyche.

Psychoanalytic Theories. Sigmund Freud postulated that schizophrenia resulted from developmental fixations early in life. These fixations produce defects in ego development, and he postulated that such defects contributed to the symptoms of schizophrenia. Ego disintegration in schizophrenia represents a return to the time when the ego was not yet developed or had just begun to be established. Because the ego affects the interpretation of reality and the control of inner drives, such as sex and aggression, these ego functions are impaired. Thus, intrapsychic conflict arising from the early fixations and the ego defect, which may have resulted from poor early object relations, fuel the psychotic symptoms.

As described by Margaret Mahler, there are distortions in the reciprocal relationship between the infant and the mother. The child is unable to separate from, and progress beyond, the closeness and complete dependence that characterize the mother-child relationship in the oral phase of development. As a result, the person's identity never becomes secure.

Paul Federn hypothesized that the defect in ego functions permits intense hostility and aggression to distort the mother-infant relationship, which leads to eventual personality disorganization and vulnerability to stress. The onset of symptoms during adolescence occurs when teenagers need a strong ego to function independently, to separate from the parents, to identify tasks, to control increased internal drives, and to cope with intense external stimulation.

Harry Stack Sullivan viewed schizophrenia as a disturbance in interpersonal relatedness. The patient's massive anxiety creates a sense of unrelatedness that is transformed into parataxic distortions, which are usually, but not always, persecutory. To Sullivan, schizophrenia is an adaptive method used to avoid panic, terror, and disintegration of the sense of self. The source of pathological anxiety results from cumulative experiential traumas during development.

Psychoanalytic theory also postulates that the various symptoms of schizophrenia have symbolic meaning for individual patients. For example, fantasies of the world coming to an end may indicate a perception that a person's internal world has broken down. Feelings of inferiority are replaced by delusions of grandeur and omnipotence. Hallucinations may be substitutes for a patient's inability to deal with objective reality and may represent inner wishes or fears. Delusions, similar to hallucinations, are regressive, restitutive attempts to create a new reality or to express hidden fears or impulses (Fig. 7.1-3).

Regardless of the theoretical model, all psychodynamic approaches are founded on the premise that psychotic symptoms have meaning in schizophrenia. Patients, for example, may become grandiose after an injury to their self-esteem. Similarly, all theories recognize that human relatedness may be terrifying for persons with schizophrenia. Although research on the efficacy of psychotherapy with schizophrenia shows mixed results, concerned persons who offer compassion and a sanctuary in the confusing world of schizophrenia must be a cornerstone of any overall treatment plan. Long-term follow-up studies show that some patients who bury psychotic episodes probably do not benefit from exploratory psychotherapy, but those who are able to integrate the psychotic experience into their lives may benefit from some insight-oriented approaches. There is renewed interest in the use of long-term individual psychotherapy in the treatment of schizophrenia, especially when combined with medication.

FIGURE 7.1-3

This patient wore suits too large for him in the delusional belief that he would appear taller to others. (Courtesy of Emil Kraepelin, M.D.)

Learning Theories. According to learning theorists, children who later have schizophrenia learn irrational reactions and ways of thinking by imitating parents who have their own significant emotional problems. In learning theory, the poor interpersonal relationships of persons with schizophrenia develop because of poor models for learning during childhood.

Family Dynamics

In a study of British 4-year-old children, those who had a poor mother–child relationship had a sixfold increase in the risk of developing schizophrenia, and offspring from schizophrenic mothers who were adopted away at birth were more likely to develop the illness if they were reared in adverse circumstances compared with those raised in loving homes by stable adoptive parents. Nevertheless, no well-controlled evidence indicates that a specific family pattern plays a causative role in the development of schizophrenia. Some patients with schizophrenia do come from dysfunctional families, just as do many nonpsychiatrically ill persons. It is important, however, not to overlook pathological family behavior that can significantly increase the emotional stress with which a vulnerable patient with schizophrenia must cope.

Double Bind. The double-bind concept was formulated by Gregory Bateson and Donald Jackson to describe a hypothetical family in which children receive conflicting parental messages about their behavior, attitudes, and feelings. In Bateson's hypothesis, children withdraw into a psychotic state to escape the unsolvable confusion of the double bind. Unfortunately, the family studies that were conducted to validate the theory were seriously flawed methodologically. The theory has value only as a descriptive pattern, not as a causal explanation of schizophrenia. An example of a double bind is a parent who tells a child to provide cookies for his or her friends and then chastises the child for giving away too many cookies to playmates.

Schisms and Skewed Families. Theodore Lidz described two abnormal patterns of family behavior. In one family type, with a prominent schism between the parents, one parent is overly close to a child of the opposite gender. In the other family type, a skewed relationship between a child and one parent involves a power struggle between the parents and the resulting dominance of one parent. These dynamics stress the tenuous adaptive capacity of the person with schizophrenia.

Pseudomutual and Pseudohostile Families. As described by Lyman Wynne, some families suppress emotional expression by consistently using pseudomutual or pseudohostile verbal communication. In such families, a unique verbal communication develops, and when a child leaves home and must relate to other persons, problems may arise. The child's verbal communication may be incomprehensible to outsiders.

Expressed Emotion. Parents or other caregivers may behave with overt criticism, hostility, and overinvolvement toward a person with schizophrenia. Many studies have indicated that in families with high levels of expressed emotion, the relapse rate for schizophrenia is high. The assessment of expressed emotion involves analyzing both what is said and the manner in which it is said.

DIAGNOSIS

The DSM-5 diagnostic criteria include course specifiers (i.e., prognosis) that offer clinicians several options and describe actual clinical situations (Table 7.1-1). The presence of hallucinations or delusions is not necessary for a diagnosis of schizophrenia; the patient's disorder is

diagnosed as schizophrenia when the patient exhibits two of the symptoms listed in symptoms 1 through 5 of Criterion A in Table 7.1-1 (e.g., disorganized speech). Criterion B requires that impaired functioning, although not deteriorations, be present during the active phase of the illness. Symptoms must persist for at least 6 months, and a diagnosis of schizoaffective disorder or mood disorder must be absent.

Table 7.1-1
DSM-5 Diagnostic Criteria for Schizophrenia

- A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
1. Delusions
 2. Hallucinations
 3. Disorganized speech (e.g., frequent derailment or incoherence)
 4. Grossly disorganized or catatonic behavior
 5. Negative symptoms (i.e., diminished emotional expression or avolition).
- B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas of functioning, such as work, interpersonal relations, or self-care, is markedly below the level achieved before the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).
- C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).
- D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
- E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- F. If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

Specify if:

The following course specifiers are only to be used after a 1-year duration of the disorder and if they are not in contradiction to the diagnostic course criteria.

First episode, currently in acute episode: First manifestation of the disorder meeting the defining diagnostic symptom and time criteria. An *acute episode* is a time period in which the symptom criteria are fulfilled.

First episode, currently in partial remission: *Partial remission* is a period of time during which an improvement after a previous episode is maintained and in which the defining criteria of the disorder are only partially fulfilled.

First episode, currently in full remission: *Full remission* is a period of time after a previous episode during which no disorder-specific symptoms are present.

Multiple episodes, currently in acute episode: Multiple episodes may be determined after a minimum of two episodes (i.e., after a first episode, a remission and a minimum of one relapse).

Multiple episodes, currently in partial remission

Multiple episodes, currently in full remission

Continuous: Symptoms fulfilling the diagnostic symptoms criteria of the disorder are remaining for the majority of the illness course, with subthreshold symptom periods being very brief relative to the overall course.

Unspecified

Specify if:

With catatonia (refer to the criteria for catatonia associated with another mental disorder, for definition).

Coding note: Use additional code 293.89 (F06.1) catatonia associated with schizophrenia to indicate the presence of the comorbid catatonia.

Specify current severity:

Severity is rated by the quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe).

Note: Diagnosis of schizophrenia can be made without using this severity specifier.

Subtypes

Five subtypes of schizophrenia have been described based predominantly on clinical presentation: paranoid, disorganized, catatonic, undifferentiated, and residual. DSM-5 no longer uses these subtypes but they are listed in the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). They are included in this text because the authors believe them to be of clinical significance and they are still used by most clinicians in the United States and around the world to describe the phenomenology of schizophrenia.

Paranoid Type. The paranoid type of schizophrenia is characterized by preoccupation with one or more delusions or frequent auditory hallucinations. Classically, the paranoid type of schizophrenia is characterized mainly by the presence of delusions of persecution or grandeur (Fig. 7.1-4). Patients with paranoid schizophrenia usually have their first episode of illness at an older age than do patients with catatonic or disorganized schizophrenia. Patients in whom schizophrenia occurs in the late 20s or 30s have usually established a social life that may help them through their illness, and the ego resources of paranoid patients tend to be greater than those of patients with catatonic and disorganized schizophrenia. Patients with the paranoid type of schizophrenia show less regression of their mental faculties, emotional responses, and behavior than do patients with other types of schizophrenia.

FIGURE 7.1-4

This patient had an artificial eye that he believed had special powers when removed from the socket. (Courtesy of Emil Kraepelin, M.D.)

Patients with paranoid schizophrenia are typically tense, suspicious, guarded, reserved, and sometimes hostile or aggressive, but they can occasionally conduct themselves adequately in social situations. Their intelligence in areas not invaded by their psychosis tends to remain intact.

Disorganized Type. The disorganized type of schizophrenia is characterized by a marked regression to primitive, disinhibited, and unorganized behavior and by the absence of symptoms that meet the criteria for the catatonic type. The onset of this subtype is generally early, occurring before age 25 years. Disorganized patients are usually active but in an aimless, nonconstructive manner. Their thought disorder is pronounced, and their contact with reality is poor. Their personal appearance is disheveled, and their social behavior and their emotional responses are inappropriate. They often burst into laughter without any apparent reason. Incongruous grinning and grimacing are common in these patients, whose behavior is best described as silly or fatuous.

Patient AB, a 32-year-old woman, began to lose weight and became careless about her work, which deteriorated in quality and quantity. She believed that other women at her place of employment were circulating slanderous stories concerning her and complained that a young man employed in the same plant had put his arm around her and insulted her. Her family demanded that the charge be investigated, which showed not only that the charge was without foundation but also that the man in question had not spoken to her for months. One day she returned home from work, and as she entered the house, she laughed loudly, watched her sister-in-law suspiciously, refused to answer questions, and at the sight of her brother began to cry. She refused to go to the bathroom, saying that a man was looking in the windows at her. She ate no food, and the next day she declared that her sisters were “bad women,” that everyone was talking about her, and that someone had been having sexual relations with her, and although she could not see him, he was “always around.”

The patient was admitted to a public psychiatric hospital. As she entered the admitting office, she laughed loudly and repeatedly screamed in a loud tone, “She cannot stay here; she’s got to go home!” She grimaced and performed various stereotyped movements of her hands. When seen on the ward an hour later, she paid no attention to questions, although she talked to herself in a childish tone. She moved about constantly, walked on her toes in a dancing manner, pointed aimlessly about, and put out her tongue and sucked her lips in the manner of an infant. At times she moaned and cried like a child but shed no tears. As the months passed, she remained silly, childish, preoccupied, and inaccessible, grimacing, gesturing, pointing at objects in a stereotyped way, and usually chattering to herself in a peculiar high-pitched voice, with little of what she said being understood. Her condition continued to deteriorate, she remained unkempt, and she presented a picture of extreme introversion and regression, with no interest either in the activities of the institution or in her relatives who visited her. (Adapted from case of Arthur P. Noyes, M.D., and Lawrence C. Kolb, M.D.)

Catatonic Type. The catatonic type of schizophrenia, which was common several decades ago, has become rare in Europe and North America. The classic feature of the catatonic type is a marked disturbance in motor function; this disturbance may involve stupor, negativism, rigidity, excitement, or posturing. Sometimes the patient shows a rapid alteration between extremes of excitement and stupor. Associated features include stereotypies, mannerisms, and waxy flexibility. Mutism is particularly common. During catatonic excitement, patients need careful supervision to prevent them from hurting themselves or others. Medical care may be needed because of malnutrition, exhaustion, hyperpyrexia, or self-inflicted injury.

AC, age 32 years, was admitted to the hospital. On arrival, he was noted to be an asthenic, poorly nourished man with dilated pupils, hyperactive tendon reflexes, and a pulse rate of 120 beats/min. He showed many mannerisms, laid down on the floor, pulled at his foot, made undirected violent striking movements, struck attendants, grimaced, assumed rigid and strange postures, refused to speak, and appeared to be having auditory hallucinations. When seen later in the day, he was found to be in a stuporous state. His face was without expression, he was mute and rigid, and he paid no attention to those about him or to their questions. His eyes were closed, and his eyelids could be separated only with effort. There was no response to pinpricks or other painful stimuli.

He gradually became accessible, and when asked concerning himself, he referred to his stuporous period as sleep and maintained that he had no recollection of any events occurring during it. He said, “I didn’t know anything. Everything seemed to be dark as far as my mind is concerned. Then I began to see a little light, like the shape of a star. Then my head got through the star gradually. I saw more and more light until I saw everything in a perfect form a few days ago.” He explained his mutism by saying that he had been afraid he would “say the wrong thing” and that he “didn’t know exactly what to talk about.” From his obviously inadequate emotional response and his statement that he was “a scientist and an inventor of the most extraordinary genius of the 20th century,” it was plain that he was still far from well. (Adapted from case of Arthur P. Noyes, M.D., and Lawrence C. Kolb, M.D.)

Undifferentiated Type. Frequently, patients who clearly have schizophrenia cannot be easily fit into one type or another. These patients are classified as having schizophrenia of the undifferentiated type.

Residual Type. The residual type of schizophrenia is characterized by continuing evidence of the schizophrenic disturbance in the absence of a complete set of active symptoms or of sufficient symptoms to meet the diagnosis of another type of schizophrenia. Emotional blunting, social withdrawal, eccentric behavior, illogical thinking, and mild loosening of associations commonly appear in the residual type. When delusions or hallucinations occur, they are neither prominent nor accompanied by strong affect.

Other Subtypes

The subtyping of schizophrenia has had a long history; other subtyping schemes appear in the literature, especially literature from countries other than the United States.

Bouffée Délirante (Acute Delusional Psychosis). This French diagnostic concept differs from a diagnosis of schizophrenia primarily on the basis of a symptom duration of less than 3 months. The diagnosis is similar to the DSM-5 diagnosis of schizophreniform disorder. French clinicians report that about 40 percent of patients with a diagnosis of *bouffée délirante* progress in their illness and are eventually classified as having schizophrenia.

Latent. The concept of latent schizophrenia was developed during a time when theorists conceived of the disorder in broad diagnostic terms. Currently, patients must be very mentally ill to warrant a diagnosis of schizophrenia, but with a broad diagnostic concept of schizophrenia, the condition of patients who would not currently be thought of as severely ill could have received a diagnosis of schizophrenia. Latent schizophrenia, for example, was often the diagnosis used for what are now called borderline, schizoid, and schizotypal personality disorders. These patients may occasionally show peculiar behaviors or thought disorders but do not consistently manifest psychotic symptoms. In the past, the syndrome was also termed *borderline schizophrenia*.

Oneiroid. The oneiroid state refers to a dream-like state in which patients may be deeply perplexed and not fully oriented in time and place. The term *oneiroid schizophrenia* has been used for patients who are engaged in their hallucinatory experiences to the exclusion of involvement in the real world. When an oneiroid state is present, clinicians should be particularly careful to examine patients for medical or neurological causes of the symptoms.

After a 20-year-old female college student had recovered from her schizophrenic breakdown, she wrote the following description of her experiences during the oneiroid phase:

This is how I remember it. The road has changed. It is twisted and it used to be straight. Nothing is constant—all is in motion. The trees are moving. They do not remain at rest. How is it my mother does not bump into the trees that are moving? I follow my mother. I am afraid, but I follow. I have to share my strange thoughts with someone. We are sitting on a bench. The bench seems low. It, too, has moved. "The bench is low," I say. "Yes," says my mother. "This isn't how it used to be. How come there are no people around? There are usually lots of people and it is Sunday and there are no people. This is strange." All these strange questions irritate my mother who then says she must be going soon. While I continue thinking I'm in a kind of nowhere....

There are no days; no nights; sometimes it is darker than other times—that's all. It is never quite black, just dark gray. There is no such thing as time—there is only eternity. There is no such thing as death—nor heaven and hell—there is only a timeless—hateful—spaceless—worsening of things. You can never go forward; you must always regress into this horrific mess....

The outside was moving rather swiftly, everything seemed topsy-turvy—things were flying about. It was very strange. I wanted to get back to the quiet very badly but when I got back I couldn't remember where anything was (e.g., the bathroom)....(Courtesy of Heinz E. Lehmann, M.D.)

Paraphrenia. The term *paraphrenia* is sometimes used as a synonym for paranoid schizophrenia or for either a progressively deteriorating course of illness or the presence of a well-systemized delusional system. The multiple meanings of the term render it ineffectual in communicating information.

Pseudoneurotic Schizophrenia. Occasionally, patients who initially have such symptoms as anxiety, phobias, obsessions, and compulsions later reveal symptoms of thought disorder and psychosis. These patients are characterized by symptoms of pananxiety, panphobia, panambivalence, and sometimes chaotic sexuality. Unlike persons with anxiety disorders, pseudoneurotic patients have free-floating anxiety that rarely subsides. In clinical descriptions, the patients seldom become overtly and severely psychotic. This condition is currently diagnosed as borderline personality disorder.

Simple Deteriorative Disorder (Simple Schizophrenia). Simple deteriorative disorder is characterized by a gradual, insidious loss of drive and ambition. Patients with the disorder are usually not overtly psychotic and do not experience persistent hallucinations or delusions. Their primary symptom is withdrawal from social and work-related situations. The syndrome must be differentiated from depression, a phobia, a dementia, or an exacerbation of personality traits. Clinicians should be sure that patients truly meet the diagnostic criteria for schizophrenia before making the diagnosis.

An unmarried man, 27 years old, was brought to the mental hospital because he had on several occasions become violent toward his father. For a few weeks, he had hallucinations and heard voices. The voices eventually ceased, but he then adopted a strange way of life. He would sit up all night, sleep all day, and become very angry when his father tried to get him out of bed. He did not shave or wash for weeks, smoked continuously, ate very irregularly, and drank enormous quantities of tea.

In the hospital, he adjusted rapidly to the new environment and was found to be generally cooperative. He showed no marked abnormalities of mental state or behavior, except for his lack of concern for just about anything. He kept to himself as much as possible and conversed little with patients or staff. His personal hygiene had to be supervised by the nursing staff; otherwise, he would quickly become dirty and untidy.

Six years after his admission to the hospital, he is described as shiftless and careless, sullen and unreasonable. He lies on a couch all day long. Although many efforts have been made to get the patient to accept therapeutic work assignments, he refuses to consider any kind of regular occupation. In the summer, he wanders about the hospital grounds or lies under a tree. In the winter, he wanders through the tunnels connecting the various hospital buildings and is often seen stretched out for hours under the warm pipes that carry the steam through the tunnels. (Courtesy of Heinz E. Lehmann, M.D.)

Postpsychotic Depressive Disorder of Schizophrenia. After an acute schizophrenia episode, some patients become depressed. The symptoms of postpsychotic depressive disorder of schizophrenia can closely resemble the symptoms of the residual phase of schizophrenia and the adverse effects of commonly used antipsychotic medications. The diagnosis should not be made if they are substance induced or part of a mood disorder due to a general medical condition. These depressive states occur in up to 25 percent of patients with schizophrenia and are associated with an increased risk of suicide.

Early-Onset Schizophrenia. A small minority of patients manifest schizophrenia in childhood. Such children may at first present diagnostic problems, particularly with differentiation from mental retardation and autistic disorder. Recent studies have established that the diagnosis of childhood schizophrenia may be based on the same symptoms used for adult schizophrenia. Its onset is usually insidious, its course tends to be chronic, and the prognosis is mostly unfavorable.

Late-Onset Schizophrenia. Late-onset schizophrenia is clinically indistinguishable from schizophrenia but has an onset after age 45 years. This condition tends to appear more frequently in women and tends to be characterized by a predominance of paranoid symptoms. The prognosis is favorable, and these patients usually do well on antipsychotic medication.

Deficit Schizophrenia. In the 1980s, criteria were promulgated for a subtype of schizophrenia characterized by enduring, idiopathic negative symptoms. These patients were said to exhibit the deficit syndrome. This group of patients is now said to have deficit schizophrenia (see the criteria for that putative disease diagnosis in [Table 7.1-2](#)). Patients with schizophrenia with positive symptoms are said to have nondéficit schizophrenia. The symptoms used to define deficit schizophrenia are strongly interrelated, although various combinations of the six negative symptoms in the criteria can be found.

 **Table 7.1-2**
Diagnostic Criteria for Deficit Schizophrenia

At least two of the following six features must be present and of clinically significant severity:

- ▶ Restricted affect
- ▶ Diminished emotional range
- ▶ Poverty of speech
- ▶ Curbing of interests
- ▶ Diminished sense of purpose
- ▶ Diminished social drive

Two or more of these features have been present for the preceding 12 months and were always present during periods of clinical stability (including chronic psychotic states). These symptoms may or may not be detectable during transient episodes of acute psychotic disorganization or decompensation.

Two or more of these enduring features are also idiopathic, that is, not secondary to factors other than the disease process.

Such factors include

- ▶ Anxiety
- ▶ Drug effect
- ▶ Suspiciousness
- ▶ Formal thought disorder
- ▶ Hallucinations or delusions
- ▶ Mental retardation
- ▶ Depression

The patient meets DSM criteria for schizophrenia.

Deficit patients have a more severe course of illness than nondéficit patients, with a higher prevalence of abnormal involuntary movements before administration of antipsychotic drugs and poorer social function before the onset of psychotic symptoms. The onset of the first psychotic episode is more often insidious, and these patients show less long-term recovery of function than do nondéficit patients. Deficit patients are also less likely to marry than are other patients with schizophrenia. However, despite their poorer level of function and greater social isolation, both of which should increase a patient's stress and, therefore, the risk of serious depression, deficit patients appear to have a decreased risk of major depression and probably have a decreased risk of suicide as well.

The risk factors of deficit patients differ from those of nondéficit patients; whereas deficit schizophrenia is associated with an excess of summer births, nondéficit patients have an excess of winter births. Deficit schizophrenia may also be associated with a greater familial risk of schizophrenia and of mild, deficit-like features in the nonpsychotic relatives of deficit probands. Within a family with multiple affected siblings, the deficit-nondéficit categorization tends to be uniform. The deficit group also has a higher prevalence of men. The psychopathology of deficit patients impacts treatment; their lack of motivation, lack of distress, greater cognitive impairment, and asocial nature undermine the efficacy of psychosocial interventions, as well as their adherence to medication regimens. Their cognitive impairment, which is greater than that of nondéficit subjects, also contributes to this lack of efficacy.

PSYCHOLOGICAL TESTING. Patients with schizophrenia generally perform poorly on a wide range of neuropsychological tests. Vigilance, memory, and concept formation are most affected and consistent with pathological involvement in the frontotemporal cortex.

Objective measures of neuropsychological performance, such as the Halstead-Reitan battery and the Luria-Nebraska battery, often give abnormal findings, such as bilateral frontal and temporal lobe dysfunction, including impairments in attention, retention time, and problem-solving ability. Motor ability is also impaired, possibly related to brain asymmetry.

INTELLIGENCE TESTS. When groups of patients with schizophrenia are compared with groups of psychiatric patients without schizophrenia or with the general population, the schizophrenia patients tend to score lower on intelligence tests. Statistically, the evidence suggests that low intelligence is often present at the onset, and intelligence may continue to deteriorate with the progression of the disorder.

PROJECTIVE AND PERSONALITY TESTS. Projective tests, such as the Rorschach test and the Thematic Apperception Test, may indicate bizarre ideation. Personality inventories, such as the Minnesota Multiphasic Personality Inventory, often give abnormal results in schizophrenia, but the contribution to diagnosis and treatment planning is minimal.

CLINICAL FEATURES

A discussion of the clinical signs and symptoms of schizophrenia raises three key issues. First, no clinical sign or symptom is pathognomonic for schizophrenia; every sign or symptom seen in schizophrenia occurs in other psychiatric and neurological disorders. This observation is

contrary to the often-heard clinical opinion that certain signs and symptoms are diagnostic of schizophrenia. Therefore, a patient's history is essential for the diagnosis of schizophrenia; clinicians cannot diagnose schizophrenia simply by results of a mental status examination, which may vary. Second, a patient's symptoms change with time. For example, a patient may have intermittent hallucinations and a varying ability to perform adequately in social situations, or significant symptoms of a mood disorder may come and go during the course of schizophrenia. Third, clinicians must take into account the patient's educational level, intellectual ability, and cultural and subcultural membership. An impaired ability to understand abstract concepts, for example, may reflect either the patient's education or his or her intelligence. Religious organizations and cults may have customs that seem strange to outsiders but are normal to those within the cultural setting.

Premorbid Signs and Symptoms

In theoretical formulations of the course of schizophrenia, premorbid signs and symptoms appear before the prodromal phase of the illness. The differentiation implies that premorbid signs and symptoms exist before the disease process evidences itself and that the prodromal signs and symptoms are parts of the evolving disorder. In the typical, but not invariable, premorbid history of schizophrenia, patients had schizoid or schizotypal personalities characterized as quiet, passive, and introverted; as children, they had few friends. Preschizophrenic adolescents may have no close friends and no dates and may avoid team sports. They may enjoy watching movies and television, listening to music, or playing computer games to the exclusion of social activities. Some adolescent patients may show a sudden onset of obsessive-compulsive behavior as part of the prodromal picture.

The validity of the prodromal signs and symptoms, almost invariably recognized after the diagnosis of schizophrenia has been made, is uncertain; after schizophrenia is diagnosed, the retrospective remembrance of early signs and symptoms is affected. Nevertheless, although the first hospitalization is often believed to mark the beginning of the disorder, signs and symptoms have often been present for months or even years. The signs may have started with complaints about somatic symptoms, such as headache, back and muscle pain, weakness, and digestive problems. The initial diagnosis may be malingered, chronic fatigue syndrome, or somatization disorder. Family and friends may eventually notice that the person has changed and is no longer functioning well in occupational, social, and personal activities. During this stage, a patient may begin to develop an interest in abstract ideas, philosophy, and the occult or religious questions (Fig. 7.1-5). Additional prodromal signs and symptoms can include markedly peculiar behavior, abnormal affect, unusual speech, bizarre ideas, and strange perceptual experiences.

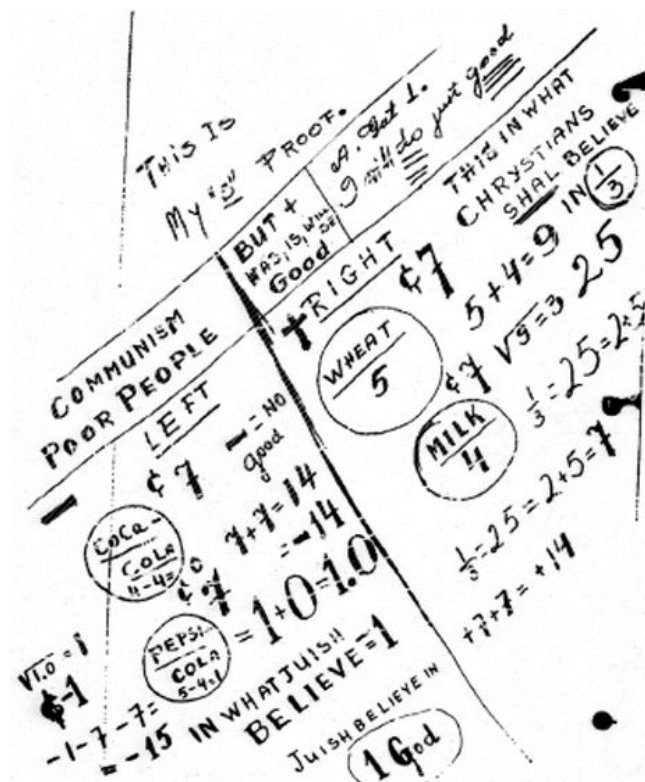

FIGURE 7.1-5 Schizophrenia patient schema. This illustrates his fragmented, abstract, and overly inclusive thinking and preoccupation with religious ideologies and mathematical proofs. (Courtesy of Heinz E. Lehmann.)

Mental Status Examination

General Description. The appearance of a patient with schizophrenia can range from that of a completely disheveled, screaming, agitated person to an obsessively groomed, completely silent, and immobile person. Between these two poles, patients may be talkative and may exhibit bizarre postures. Their behavior may become agitated or violent, apparently in an unprovoked manner, but usually in response to hallucinations. In contrast, in catatonic stupor, often referred to as catatonia, patients seem completely lifeless and may exhibit such signs as muteness, negativism, and automatic obedience. Waxy flexibility, once a common sign in catatonia, has become rare, as has manneristic behavior. A person with a less extreme subtype of catatonia may show marked social withdrawal and egocentricity, a lack of spontaneous speech or movement, and an absence of goal-directed behavior. Patients with catatonia may sit immobile and speechless in their chairs, respond to questions with only short answers, and move only when directed to move. Other obvious behavior may include odd clumsiness or stiffness in body movements, signs now seen as possibly indicating a disease process in the basal ganglia. Patients with schizophrenia are often poorly groomed, fail to bathe, and dress much too warmly for the prevailing temperatures. Other odd behaviors include tics; stereotypies; mannerisms; and, occasionally, echopraxia, in which patients imitate the posture or the behavior of the examiner.

PRECOX FEELING. Some experienced clinicians report a precox feeling, an intuitive experience of their inability to establish an emotional rapport with a patient. Although the experience is common, no data indicate that it is a valid or reliable criterion in the diagnosis of schizophrenia.

Mood, Feelings, and Affect

Two common affective symptoms in schizophrenia are reduced emotional responsiveness, sometimes severe enough to warrant the label of anhedonia, and overly active and inappropriate emotions such as extremes of rage, happiness, and anxiety. A flat or blunted affect can be a symptom of the illness itself, of the parkinsonian adverse effects of antipsychotic medications, or of depression, and differentiating these symptoms can be a clinical challenge. Overly emotional patients may describe exultant feelings of omnipotence, religious ecstasy, terror at the disintegration of their souls, or paralyzing anxiety about the destruction of the universe. Other feeling tones include perplexity, a sense of isolation, overwhelming ambivalence, and depression.

Perceptual Disturbances

HALLUCINATIONS. Any of the five senses may be affected by hallucinatory experiences in patients with schizophrenia. The most common hallucinations, however, are auditory, with voices that are often threatening, obscene, accusatory, or insulting. Two or more voices may converse among themselves, or a voice may comment on the patient's life or behavior. Visual hallucinations are common (Fig. 7.1-6), but tactile, olfactory, and gustatory hallucinations are unusual; their presence should prompt the clinician to consider the possibility of an underlying medical or neurological disorder that is causing the entire syndrome.

FIGURE 7.1-6

A symbolic representation of the strange perceptions of the schizophrenia patient. (Courtesy of Arthur Tress.)

A 48-year-old man, who had been diagnosed with schizophrenia while in the army at age 21 years, led an isolated and often frightened existence, living alone and supported by disability payments. Although he would confirm that he had chronic auditory hallucinations, he was never comfortable with discussing the content of these hallucinations, and a review of records showed this was a long-term pattern for the patient. Otherwise the patient had good rapport with his psychiatrist and was enthusiastic about the possibility of participating in a study of a novel antipsychotic agent. During the informed consent procedure, the patient asked about the possibility that the new medication might decrease his chronic auditory hallucinations. When it was acknowledged that any response was possible, including decreases in his hallucinations, the patient broke off the discussion abruptly and left the office. At a later visit, he reported that his most reliable pleasure in life was nightly discussions of gossip with hallucinations of voices he believed belonged to 17th- century French courtiers, and the chance that he might lose these conversations and the companionship they offered was too frightening for him to consider. (Adapted from Stephen Lewis, M.D., P. Rodrigo Escalona, M.D., and Samuel J. Keith, M.D.)

Cenesthetic Hallucinations. Cenesthetic hallucinations are unfounded sensations of altered states in bodily organs. Examples of cenesthetic hallucinations include a burning sensation in the brain, a pushing sensation in the blood vessels, and a cutting sensation in the bone marrow. Bodily distortions may also occur.

ILLUSIONS. As differentiated from hallucinations, whereas illusions are distortions of real images or sensations, hallucinations are not based on real images or sensations. Illusions can occur in schizophrenia patients during active phases, but they can also occur during the prodromal phases and during periods of remission. Whenever illusions or hallucinations occur, clinicians should consider the possibility of a substance-related cause for the symptoms, even when patients have already received a diagnosis of schizophrenia.

Thought. Disorders of thought are the most difficult symptoms for many clinicians and students to understand, but they may be the core symptoms of schizophrenia. Dividing the disorders of thought into disorders of thought content, form of thought, and thought process is one way to clarify them.

THOUGHT CONTENT. Disorders of thought content reflect the patient's ideas, beliefs, and interpretations of stimuli. Delusions, the most obvious example of a disorder of thought content, are varied in schizophrenia and may assume persecutory, grandiose, religious, or somatic forms.

Patients may believe that an outside entity controls their thoughts or behavior or, conversely, that they control outside events in an extraordinary fashion (such as causing the sun to rise and set or by preventing earthquakes). Patients may have an intense and consuming preoccupation with esoteric, abstract, symbolic, psychological, or philosophical ideas. Patients may also worry about allegedly life-threatening but bizarre and implausible somatic conditions, such as the presence of aliens inside the patient's testicles affecting his ability to father children.

The phrase *loss of ego boundaries* describes the lack of a clear sense of where the patient's own body, mind, and influence end and where those of other animate and inanimate objects begin. For example, patients may think that other persons, the television, or the newspapers are referring to them (*ideas of reference*). Other symptoms of the loss of ego boundaries include the sense that the patient has physically fused with an outside object (e.g., a tree or another person) or that the patient has disintegrated and fused with the entire universe (*cosmic identity*). With such a state of mind, some patients with schizophrenia doubt their gender or their sexual orientation. These symptoms should not be confused with transvestism, transsexuality, or other gender identity problems.

FORM OF THOUGHT. Disorders of the form of thought are objectively observable in patients' spoken and written language (Fig. 7.1-7). The disorders include looseness of associations, derailment, incoherence, tangentiality, circumstantiality, neologisms, echolalia, verbigeration, word salad, and mutism. Although looseness of associations was once described as pathognomonic for schizophrenia, the symptom is frequently seen in mania. Distinguishing between looseness of associations and tangentiality can be difficult for even the most experienced clinicians.

FIGURE 7.1-7 Sample of noncommunicative writing by a patient with chronic paranoid schizophrenia. This letter, written to the patient's psychiatrist, illustrates manneristic writing, verbigeration, and neologisms.

The following sample is taken from a memo typed by a secretary with schizophrenia who was still able to work part time in an office. Note her preoccupation with the mind, the Trinity, and other esoteric matters. Also note that peculiar restructuring of concepts by hyphenating the words germ-any (the patient had a distinct fear of germs) and infer-no (inferring that there will be no salvation). The "chain reaction" is a reference to atomic piles.

Mental health is the Blessed Trinity, and as man cannot be without God, it is futile to deny His Son. For the Creation understand germ-any in Voice New Order, not lie of chained reaction, spawning mark in temple Cain with Babel grave'n image to wanton V day "Israel."

Lucifer fell Jew prostitute and lambeth walks by roam to sex ritual, in Bible six million of the Babylon woman, infer-no Salvation.

The one common factor in the thought process above is a preoccupation with invisible forces, radiation, witchcraft, religion, philosophy, and psychology and a leaning toward the esoteric, the abstract, and the symbolic. Consequently, the thinking of a person with schizophrenia is characterized simultaneously by both an overly concrete and an overly symbolic nature.

THOUGHT PROCESS. Disorders in thought process concern the way ideas and languages are formulated. The examiner infers a disorder from what and how the patient speaks, writes, or draws. The examiner may also assess the patient's thought process by observing his or her behavior, especially in carrying out discrete tasks (e.g., in occupational therapy). Disorders of thought process include flight of ideas, thought blocking, impaired attention, poverty of thought content, poor abstraction abilities, perseveration, idiosyncratic associations (e.g., identical predicates, clang associations), overinclusion, and circumstantiality. *Thought control*, in which outside forces are controlling what the patient thinks or feels, is common, as is *thought broadcasting*, in which patients think others can read their minds or that their thoughts are broadcast through television sets or radios.

Impulsiveness, Violence, Suicide, and Homicide. Patients with schizophrenia may be agitated and have little impulse control when ill. They may also have decreased social sensitivity and appear to be impulsive when, for example, they grab another patient's cigarettes, change television channels abruptly, or throw food on the floor. Some apparently impulsive behavior, including suicide and homicide attempts, may be in response to hallucinations commanding the patient to act.

VIOLENCE. Violent behavior (excluding homicide) is common among untreated schizophrenia patients. Delusions of a persecutory nature, previous episodes of violence, and neurological deficits are risk factors for violent or impulsive behavior. Management includes appropriate antipsychotic medication. Emergency treatment consists of restraints and seclusion. Acute sedation with lorazepam (Ativan), 1 to 2 mg intramuscularly, repeated every hour as needed, may be necessary to prevent the patient from harming others. If a clinician feels fearful in the presence of a schizophrenia patient, it should be taken as an internal clue that the patient may be on the verge of acting out violently. In such cases, the interview should be terminated or be conducted with an attendant at the ready.

SUICIDE. Suicide is the single leading cause of premature death among people with schizophrenia. Suicide attempts are made by 20 to 50 percent of the patients, with long-term rates of suicide estimated to be 10 to 13 percent. According to DSM-5 approximately 5 to 6 percent of schizophrenic patients die by suicide, but this is probably an underestimation. Often, suicide in schizophrenia seems to occur "out of the blue," without prior warnings or expressions of verbal intent. The most important factor is the presence of a major depressive episode. Epidemiological studies indicate that up to 80 percent of schizophrenia patients may have a major depressive episode at some time in their lives. Some data suggest that those patients with the best prognosis (few negative symptoms, preservation of capacity to experience affects, better abstract thinking) can paradoxically also be at highest risk for suicide. The profile of the patient at greatest risk is a young man who

once had high expectations, declined from a higher level of functioning, realizes that his dreams are not likely to come true, and has lost faith in the effectiveness of treatment. Other possible contributors to the high rate of suicide include command hallucinations and drug abuse. Two-thirds or more of schizophrenic patients who commit suicide have seen an apparently unsuspecting clinician within 72 hours of death. A large pharmacological study suggests that clozapine (Clozaril) may have particular efficacy in reducing suicidal ideation in schizophrenia patients with prior hospitalizations for suicidality. Adjunctive antidepressant medications have been shown to be effective in alleviating co-occurring major depression in schizophrenia.

The following is an example of an unpredictable suicide in a patient with schizophrenia who had been responding to psychiatric treatment:

The patient had been an autistic child and did not speak until he was 7 years old. He had responded well to psychiatric treatment, and at age 13 his IQ was reported as 122. At age 17 he became violent toward his parents, shaved all his hair off, and made such statements as, "I like bank robbers knocking people unconscious" and "I think tough gangs are funny because they beat down people." While saying this, he laughed loudly. He was admitted to a mental hospital, where he responded with definite improvement to pharmacotherapy and psychotherapy, and he went home regularly for weekends.

He left various notes on his desk before committing suicide. Among these notes was an eight-page list giving 211 "inexcusable mistakes throughout my life." Each one was dated, for example, "1952, 2nd of November: throwing up in my friend's house on a shoe-box. 1953, 17th August: accidentally wearing a watch that wasn't water-proof in the bath-tub. 1956, 23rd of September: slamming back-door of Meteor after getting in."

He then proceeded in his notes to give "the causes of the mistakes:" "Montreal having a mountain; I have a receding hair-line; my height since I was nine years old; Canada having two languages...." He also wrote: "My feelings of tension since 1962 is getting worse most of the time. I planned the date of my death without the slightest trace of emotion...."

The boy hanged himself at age 18 in the family garage. An experienced psychiatrist who had repeatedly interviewed him noted no signs of depression only a week before. (Courtesy of Heinz E. Lehmann, M.D.)

HOMICIDE. Despite the sensational attention that the news media provides when a patient with schizophrenia murders someone, the available data indicate that these patients are no more likely to commit homicide than is a member of the general population. When a patient with schizophrenia does commit homicide, it may be for unpredictable or bizarre reasons based on hallucinations or delusions. Possible predictors of homicidal activity are a history of previous violence, dangerous behavior while hospitalized, and hallucinations or delusions involving such violence.

Sensorium and Cognition

Orientation. Patients with schizophrenia are usually oriented to person, time, and place. The lack of such orientation should prompt clinicians to investigate the possibility of a medical or neurological brain disorder. Some patients with schizophrenia may give incorrect or bizarre answers to questions about orientation, for example, "I am Christ; this is heaven; and it is AD 35."

Memory. Memory, as tested in the mental status examination, is usually intact, but there can be minor cognitive deficiencies. It may not be possible, however, to get the patient to attend closely enough to the memory tests for the ability to be assessed adequately.

Cognitive Impairment. An important development in the understanding of the psychopathology of schizophrenia is an appreciation of the importance of cognitive impairment in the disorder. In outpatients, cognitive impairment is a better predictor of level of function than is the severity of psychotic symptoms. Patients with schizophrenia typically exhibit subtle cognitive dysfunction in the domains of attention, executive function, working memory, and episodic memory. Although a substantial percentage of patients have normal intelligence quotients, it is possible that every person who has schizophrenia has cognitive dysfunction compared with what he or she would be able to do without the disorder. Although these impairments cannot function as diagnostic tools, they are strongly related to the functional outcome of the illness and, for that reason, have clinical value as prognostic variables, as well as for treatment planning.

The cognitive impairment seems already to be present when patients have their first episode and appears largely to remain stable over the course of early illness. (There may be a small subgroup of patients who have a true dementia in late life that is not due to other cognitive disorders, such as Alzheimer's disease.) Cognitive impairments are also present in attenuated forms in nonpsychotic relatives of schizophrenia patients.

The cognitive impairments of schizophrenia have become the target of pharmacological and psychosocial treatment trials. It is likely that effective treatments will become widely available within a few years, and these are likely to lead to an improvement in the quality of life and level of functioning of people with schizophrenia.

Judgment and Insight. Classically, patients with schizophrenia are described as having poor insight into the nature and the severity of their disorder. The so-called lack of insight is associated with poor compliance with treatment. When examining schizophrenia patients, clinicians should carefully define various aspects of insight, such as awareness of symptoms, trouble getting along with people, and the reasons for these problems. Such information can be clinically useful in tailoring a treatment strategy and theoretically useful in postulating what areas of the brain contribute to the observed lack of insight (e.g., the parietal lobes).

Reliability. A patient with schizophrenia is no less reliable than any other psychiatric patient. The nature of the disorder, however, requires the examiner to verify important information through additional sources.

Somatic Comorbidity

Neurological Findings. Localizing and nonlocalizing neurological signs (also known as hard and soft signs, respectively) have been reported to be more common in patients with schizophrenia than in other psychiatric patients. Nonlocalizing signs include dysdiadochokinesia, astereognosis, primitive reflexes, and diminished dexterity. The presence of neurological signs and symptoms correlates with increased severity of illness, affective blunting, and a poor prognosis. Other abnormal neurological signs include tics, stereotypies, grimacing, impaired fine motor skills, abnormal motor tone, and abnormal movements. One study has found that only about 25 percent of patients with schizophrenia are aware of their own abnormal involuntary movements and that the lack of awareness is correlated with a lack of insight about the primary psychiatric disorder and the duration of illness.

Eye Examination. In addition to the disorder of smooth ocular pursuit (saccadic movement), patients with schizophrenia have an elevated blink rate. The elevated blink rate is believed to reflect hyperdopaminergic activity. In primates, blinking can be increased by dopamine agonists and reduced by dopamine antagonists.

Speech. Although the disorders of speech in schizophrenia (e.g., looseness of associations) are classically considered to indicate a

thought disorder, they may also indicate a *forme fruste* of aphasia, perhaps implicating the dominant parietal lobe. The inability of schizophrenia patients to perceive the prosody of speech or to inflect their own speech can be seen as a neurological symptom of a disorder in the nondominant parietal lobe. Other parietal lobe–like symptoms in schizophrenia include the inability to carry out tasks (i.e., apraxia), right–left disorientation, and lack of concern about the disorder.

Other Comorbidity

Obesity. Patients with schizophrenia appear to be more obese, with higher body mass indexes (BMIs) than age- and gender-matched cohorts in the general population. This is due, at least in part, to the effect of many antipsychotic medications, as well as poor nutritional balance and decreased motor activity. This weight gain, in turn, contributes to an increased risk of cardiovascular morbidity and mortality, an increased risk of diabetes, and other obesity-related conditions such as hyperlipidemia and obstructive sleep apnea.

Diabetes Mellitus. Schizophrenia is associated with an increased risk of type II diabetes mellitus. This is probably due, in part, to the association with obesity noted previously, but there is also evidence that some antipsychotic medications cause diabetes through a direct mechanism.

Cardiovascular Disease. Many antipsychotic medications have direct effects on cardiac electrophysiology. In addition, obesity; increased rates of smoking, diabetes, hyperlipidemia; and a sedentary lifestyle all independently increase the risk of cardiovascular morbidity and mortality.

HIV. Patients with schizophrenia appear to have a risk of HIV infection that is 1.5 to 2 times that of the general population. This association is thought to be due to increased risk behaviors, such as unprotected sex, multiple partners, and increased drug use.

Chronic Obstructive Pulmonary Disease. Rates of chronic obstructive pulmonary disease are reportedly increased in schizophrenia compared with the general population. The increased prevalence of smoking is an obvious contributor to this problem and may be the only cause.

Rheumatoid Arthritis. Patients with schizophrenia have approximately one-third the risk of rheumatoid arthritis that is found in the general population. This inverse association has been replicated several times, the significance of which is unknown.

DIFFERENTIAL DIAGNOSIS

Secondary Psychotic Disorders

A wide range of nonpsychiatric medical conditions and a variety of substances can induce symptoms of psychosis and catatonia (Table 7.1-3). The most appropriate diagnosis for such psychosis or catatonia is psychotic disorder due to a general medical condition, catatonic disorder due to a general medical condition, or substance-induced psychotic disorder.

Table 7.1-3
Differential Diagnosis of Schizophrenia-Like Symptoms

Medical and Neurological

Substance induced—amphetamine, hallucinogens, belladonna alkaloids, alcohol hallucinosis, barbiturate withdrawal, cocaine, phencyclidine

Epilepsy—especially temporal lobe epilepsy

Neoplasm, cerebrovascular disease, or trauma—especially frontal or limbic

Other conditions

Acute intermittent porphyria

AIDS

Vitamin B₁₂ deficiency

Carbon monoxide poisoning

Cerebral lipoidosis

Creutzfeldt-Jakob disease

Fabry's disease

Fahr's disease

Hallervorden-Spatz disease

Heavy metal poisoning

Herpes encephalitis

Homocystinuria

Huntington's disease

Metachromatic leukodystrophy

Neurosyphilis

Normal pressure hydrocephalus

Pellagra

Systemic lupus erythematosus

Wernicke-Korsakoff syndrome

Wilson's disease

Psychiatric

Atypical psychosis

Autistic disorder

Brief psychotic disorder

Delusional disorder

Factitious disorder with predominantly psychological signs and symptoms

Malingering

Mood disorders

Normal adolescence

Obsessive-compulsive disorder

Personality disorders—schizotypal, schizoid, borderline, paranoid

Schizoaffective disorder

Schizophrenia

Schizophreniform disorder

When evaluating a patient with psychotic symptoms, clinicians should follow the general guidelines for assessing nonpsychiatric conditions. First, clinicians should aggressively pursue an undiagnosed nonpsychiatric medical condition when a patient exhibits any unusual or rare symptoms or any variation in the level of consciousness. Second, clinicians should attempt to obtain a complete family history, including a history of medical, neurological, and psychiatric disorders. Third, clinicians should consider the possibility of a nonpsychiatric medical condition, even in patients with previous diagnoses of schizophrenia. A patient with schizophrenia is just as likely to have a brain tumor that produces psychotic symptoms as is a patient without schizophrenia.

Other Psychotic Disorders

The psychotic symptoms of schizophrenia can be identical with those of schizophreniform disorder, brief psychotic disorder, schizoaffective disorder, and delusional disorders. *Schizophreniform disorder* differs from schizophrenia in that the symptoms have a duration of at least 1 month but less than 6 months. *Brief psychotic disorder* is the appropriate diagnosis when the symptoms have lasted at least 1 day but less than 1 month and when the patient has not returned to the premorbid state of functioning within that time. There may also be a precipitating traumatic event. When a manic or depressive syndrome develops concurrently with the major symptoms of schizophrenia, *schizoaffective disorder* is the appropriate diagnosis. Nonbizarre delusions present for at least 1 month without other symptoms of schizophrenia or a mood disorder warrant the diagnosis of *delusional disorder*.

Mood Disorders

A patient with a major depressive episode may present with delusions and hallucinations, whether the patient has unipolar or bipolar mood disorder. Delusions seen with psychotic depression are typically mood congruent and involve themes such as guilt, self-depreciation, deserved punishment, and incurable illnesses. In mood disorders, psychotic symptoms resolve completely with the resolution of depression. A depressive episode that is this severe may also result in loss of functioning, decline in self-care, and social isolation, but these are secondary to the depressive symptoms and should not be confused with the negative symptoms of schizophrenia.

A full-blown manic episode often presents with delusions and sometimes hallucinations. Delusions in mania are most often mood congruent and typically involve grandiose themes. The flight of ideas seen in mania may, at times, be confused with the thought disorder of schizophrenia. Special attention during mental status examination of a patient with a flight of ideas is required to note whether the

associative links between topics are conserved, although the conversation is difficult for the observer to follow because of the patient's accelerated rate of thinking.

Personality Disorders

Various personality disorders may have some features of schizophrenia. Schizotypal, schizoid, and borderline personality disorders are the personality disorders with the most similar symptoms. Severe obsessive-compulsive personality disorder may mask an underlying schizophrenic process. Personality disorders, unlike schizophrenia, have mild symptoms and a history of occurring throughout a patient's life; they also lack an identifiable date of onset.

Malingering and Factitious Disorders

For a patient who imitates the symptoms of schizophrenia but does not actually have the disorder, either malingering or factitious disorder may be an appropriate diagnosis. Persons have faked schizophrenic symptoms and have been admitted into and treated at psychiatric hospitals. The condition of patients who are completely in control of their symptom production may qualify for a diagnosis of malingering; such patients usually have some obvious financial or legal reason to want to be considered mentally ill. The condition of patients who are less in control of their falsification of psychotic symptoms may qualify for a diagnosis of factitious disorder. Some patients with schizophrenia, however, may falsely complain of an exacerbation of psychotic symptoms to obtain increased assistance benefits or to gain admission to a hospital.

COURSE AND PROGNOSIS

Course

A premorbid pattern of symptoms may be the first evidence of illness, although the importance of the symptoms is usually recognized only retrospectively. Characteristically, the symptoms begin in adolescence and are followed by the development of prodromal symptoms in days to a few months. Social or environmental changes, such as going away to college, using a substance, or a relative's death, may precipitate the disturbing symptoms, and the prodromal syndrome may last a year or more before the onset of overt psychotic symptoms.

The classic course of schizophrenia is one of exacerbations and remissions. After the first psychotic episode, a patient gradually recovers and may then function relatively normally for a long time. Patients usually relapse, however, and the pattern of illness during the first 5 years after the diagnosis generally indicates the patient's course. Further deterioration in the patient's baseline functioning follows each relapse of the psychosis. This failure to return to baseline functioning after each relapse is the major distinction between schizophrenia and the mood disorders. Sometimes a clinically observable postpsychotic depression follows a psychotic episode, and the schizophrenia patient's vulnerability to stress is usually lifelong. Positive symptoms tend to become less severe with time, but the socially debilitating negative or deficit symptoms may increase in severity. Although about one-third of all schizophrenia patients have some marginal or integrated social existence, most have lives characterized by aimlessness; inactivity; frequent hospitalizations; and, in urban settings, homelessness and poverty.

Prognosis

Several studies have shown that over the 5- to 10-year period after the first psychiatric hospitalization for schizophrenia, only about 10 to 20 percent of patients can be described as having a good outcome. More than 50 percent of patients can be described as having a poor outcome, with repeated hospitalizations, exacerbations of symptoms, episodes of major mood disorders, and suicide attempts. Despite these glum figures, schizophrenia does not always run a deteriorating course, and several factors have been associated with a good prognosis (Table 7.1-4).

 **Table 7.1-4**
Features Weighting Toward Good to Poor Prognosis in Schizophrenia

Good Prognosis	Poor Prognosis
Late onset	Young onset
Obvious precipitating factors	No precipitating factors
Acute onset	Insidious onset
Good premorbid social, sexual, and work histories	Poor premorbid social, sexual, and work histories
Mood disorder symptoms (especially depressive disorders)	Withdrawn, autistic behavior
Married	Single, divorced, or widowed
Family history of mood disorders	Family history of schizophrenia
Good support systems	Poor support systems
Positive symptoms	Negative symptoms
	Neurological signs and symptoms
	History of perinatal trauma
	No remissions in 3 years
	Many relapses
	History of assaultiveness

Reported remission rates range from 10 to 60 percent, and a reasonable estimate is that 20 to 30 percent of all schizophrenia patients are able to lead somewhat normal lives. About 20 to 30 percent of patients continue to experience moderate symptoms, and 40 to 60 percent of patients remain significantly impaired by their disorder for their entire lives. Patients with schizophrenia do much poorer than patients with mood disorders, although 20 to 25 percent of mood disorder patients are also severely disturbed at long-term follow-up.

TREATMENT

Although antipsychotic medications are the mainstay of the treatment for schizophrenia, research has found that psychosocial interventions, including psychotherapy, can augment the clinical improvement. Just as pharmacological agents are used to treat presumed chemical imbalances, nonpharmacological strategies must treat nonbiological issues. The complexity of schizophrenia usually renders any single therapeutic approach inadequate to deal with the multifaceted disorder. Psychosocial modalities should be integrated into the drug

treatment regimen and should support it. Patients with schizophrenia benefit more from the combined use of antipsychotic drugs and psychosocial treatment than from either treatment used alone.

Hospitalization

Hospitalization is indicated for diagnostic purposes; for stabilization of medications; for patients' safety because of suicidal or homicidal ideation; and for grossly disorganized or inappropriate behavior, including the inability to take care of basic needs such as food, clothing, and shelter. Establishing an effective association between patients and community support systems is also a primary goal of hospitalization.

Short stays of 4 to 6 weeks are just as effective as long-term hospitalizations, and hospital settings with active behavioral approaches produce better results than do custodial institutions. Hospital treatment plans should be oriented toward practical issues of self-care, quality of life, employment, and social relationships. During hospitalization, patients should be coordinated with aftercare facilities, including their family homes, foster families, board-and-care homes, and halfway houses. Day care centers and home visits by therapists or nurses can help patients remain out of the hospital for long periods and can improve the quality of their daily lives.

Pharmacotherapy

The introduction of chlorpromazine (Thorazine) in 1952 may be the most important single contribution to the treatment of a psychiatric illness. Henri Laborit, a surgeon in Paris, noticed that administering chlorpromazine to patients before surgery resulted in an unusual state in which they seemed less anxious regarding the procedure. Chlorpromazine was subsequently shown to be effective at reducing hallucinations and delusions, as well as excitement. It was also noted that it caused side effects that appeared similar to parkinsonism.

Antipsychotics diminish psychotic symptom expression and reduce relapse rates. Approximately 70 percent of patients treated with any antipsychotic achieve remission.

The drugs used to treat schizophrenia have a wide variety of pharmacological properties, but all share the capacity to antagonize postsynaptic dopamine receptors in the brain. Antipsychotics can be categorized into two main groups: the older conventional antipsychotics, which have also been called *first-generation antipsychotics* or dopamine receptor antagonists, and the newer drugs, which have been called *second-generation antipsychotics* or *serotonin dopamine antagonists (SDAs)*.

Clozapine (Clozaril), the first effective antipsychotic with negligible extrapyramidal side effects, was discovered in 1958 and first studied during the 1960s. However, in 1976, it was noted that clozapine was associated with a substantial risk of agranulocytosis. This property resulted in delays in the introduction of clozapine. In 1990, clozapine finally became available in the United States, but its use was restricted to patients who responded poorly to other agents.

PHASES OF TREATMENT IN SCHIZOPHRENIA

Treatment of Acute Psychosis

Acute psychotic symptoms require immediate attention. Treatment during the acute phase focuses on alleviating the most severe psychotic symptoms. This phase usually lasts from 4 to 8 weeks. Acute schizophrenia is typically associated with severe agitation, which can result from such symptoms as frightening delusions, hallucinations, or suspiciousness, or from other causes (including stimulant abuse). Patients with akathisia can appear agitated when they experience a subjective feeling of motor restlessness. Differentiating akathisia from psychotic agitation can be difficult, particularly when patients are incapable of describing their internal experience. If patients are receiving an agent associated with extrapyramidal side effects, usually a first-generation antipsychotic, a trial with an anticholinergic anti-Parkinson medication, benzodiazepine, or propranolol (Inderal) may be helpful in making the discrimination.

Clinicians have a number of options for managing agitation that results from psychosis. Antipsychotics and benzodiazepines can result in relatively rapid calming of patients. With highly agitated patients, intramuscular administration of antipsychotics produces a more rapid effect. An advantage of an antipsychotic is that a single intramuscular injection of haloperidol (Haldol), fluphenazine (Prolixin, Permitil), olanzapine (Zyprexa), or ziprasidone (Geodon) will often result in calming effect without excessive sedation. Low-potency antipsychotics are often associated with sedation and postural hypotension, particularly when they are administered intramuscularly. Intramuscular ziprasidone and olanzapine are similar to their oral counterparts in not causing substantial extrapyramidal side effects during acute treatment. This can be an important advantage over haloperidol or fluphenazine, which can cause frightening dystonias or akathisia in some patients. A rapidly dissolving oral formulation of olanzapine (Zydis) may also be helpful as an alternative to an intramuscular injection.

Benzodiazepines are also effective for agitation during acute psychosis. Lorazepam (Ativan) has the advantage of reliable absorption when it is administered either orally or intramuscularly. The use of benzodiazepines may also reduce the amount of antipsychotic that is needed to control psychotic patients.

Treatment During Stabilization and Maintenance Phase

In the stable or maintenance phase, the illness is in a relative stage of remission. The goals during this phase are to prevent psychotic relapse and to assist patients in improving their level of functioning. As newer medications have been introduced with a substantively reduced risk of tardive dyskinesia, one of the major concerns about long-term treatment has been diminished. During this phase, patients are usually in a relative state of remission with only minimal psychotic symptoms. Stable patients who are maintained on an antipsychotic have a much lower relapse rate than patients who have their medications discontinued. Data suggest that 16 to 23 percent of patients receiving treatment will experience a relapse within 1 year, and 53 to 72 percent will relapse without medications. Even patients who have had only one episode have a four in five chance of relapsing at least once over the following 5 years. Stopping medication increases this risk fivefold. Although published guidelines do not make definitive recommendations about the duration of maintenance treatment after the first episode, recent data suggest that 1 or 2 years might not be adequate. This is a particular concern when patients have achieved good employment status or are involved in educational programs because they have a lot to lose if they experience another psychotic decompensation.

It is generally recommended that multipisode patients receive maintenance treatment for at least 5 years, and many experts recommend pharmacotherapy on an indefinite basis.

Noncompliance. Noncompliance with long-term antipsychotic treatment is very high. An estimated 40 to 50 percent of patients become noncompliant within 1 or 2 years. Compliance increases when long-acting medication is used instead of oral medication.

When beginning long-acting drugs, some oral supplementation is necessary while peak plasma levels are being achieved. Fluphenazine and haloperidol have been formulated as long-acting injectables. Long-acting forms of risperidone, paliperidone, aripiprazole, and olanzapine are also available.

There are a number of advantages to using long-acting injectable medication. Clinicians know immediately when noncompliance occurs and have some time to initiate appropriate interventions before the medication effect dissipates; there is less day-to-day variability in blood levels, making it easier to establish a minimum effective dose; and finally, many patients prefer it to having to remember dosage schedules of daily oral preparations.

STRATEGIES FOR POOR RESPONDERS

When patients with acute schizophrenia are administered an antipsychotic medication, approximately 60 percent will improve to the extent that they will achieve a complete remission or experience only mild symptoms; the remaining 40 percent of patients will improve but still demonstrate variable levels of positive symptoms that are resistant to the medications. Rather than categorizing patients into responders and nonresponders, it is more accurate to consider the degree to which the illness is improved by medication. Some resistant patients are so severely ill that they require chronic institutionalization. Others respond to an antipsychotic with substantial suppression of their psychotic symptoms but demonstrate persistent symptoms, such as hallucinations or delusions.

Before considering a patient a poor responder to a particular drug, it is important to assure that they received an adequate trial of the medication. A 4- to 6-week trial on an adequate dose of an antipsychotic represents a reasonable trial for most patients. Patients who demonstrate even a mild amount of improvement during this period may continue to improve at a steady rate for 3 to 6 months. It may be helpful to confirm that the patient is receiving an adequate amount of the drug by monitoring the plasma concentration. This information is available for a number of antipsychotics, including haloperidol, clozapine, fluphenazine, trifluoperazine (Stelazine), and perphenazine (Trilafon). A very low plasma concentration may indicate that the patient has been noncompliant or, more commonly, only partially compliant. It may also suggest that the patient is a rapid metabolizer of the antipsychotic or that the drug is not being adequately absorbed. Under these conditions, raising the dose may be helpful. If the level is relatively high, clinicians should consider whether side effects may be interfering with therapeutic response.

If the patient is responding poorly, one may increase the dose above the usual therapeutic level; however, higher doses are not usually associated with greater improvement than conventional doses. Changing to another drug is preferable to titrating to a high dose.

If a patient has responded poorly to a conventional DRA, it is unlikely that this individual will do well on another DRA. Changing to an SDA is more likely to be helpful.

Clozapine is effective for patients who respond poorly to DRAs. Double-blind studies comparing clozapine with other antipsychotics indicated that clozapine had the clearest advantage over conventional drugs in patients with the most severe psychotic symptoms, as well as in those who had previously responded poorly to other antipsychotics. When clozapine was compared with chlorpromazine in a severely psychotic group of individuals who had failed in trials with at least three antipsychotics, clozapine was significantly more effective in nearly every dimension of psychopathology, including both positive symptoms and negative symptoms.

MANAGING SIDE EFFECTS

Patients frequently experience side effects of an antipsychotic before they experience clinical improvement. Whereas a clinical response may be delayed for days or weeks after drugs are started, side effects may begin almost immediately. For low-potency drugs, these side effects are likely to include sedation, postural hypotension, and anticholinergic effects, whereas high-potency drugs are likely to cause extrapyramidal side effects.

Extrapyramidal Side Effects

Clinicians have a number of alternatives for treating extrapyramidal side effects. These include reducing the dose of the antipsychotic (which is most commonly a DRA), adding an anti-Parkinson medication, and changing the patient to an SDA that is less likely to cause extrapyramidal side effects. The most effective anti-Parkinson medications are the anticholinergic anti-Parkinson drugs. However, these medications have their own side effects, including dry mouth; constipation; blurred vision; and, often, memory loss. Also, these medications are often only partially effective, leaving patients with substantial amounts of lingering extrapyramidal side effects. Centrally acting β -blockers, such as propranolol, are also often effective for treating akathisia. Most patients respond to dosages between 30 and 90 mg per day.

If conventional antipsychotics are being prescribed, clinicians may consider prescribing prophylactic anti-Parkinson medications for patients who are likely to experience disturbing extrapyramidal side effects. These include patients who have a history of extrapyramidal side effect sensitivity and those who are being treated with relatively high doses of high-potency drugs. Prophylactic anti-Parkinson medications may also be indicated when high-potency drugs are prescribed for young men who tend to have an increased vulnerability for developing dystonias. Again, these patients should be candidates for newer drugs.

Some individuals are highly sensitive to extrapyramidal side effects at the dose that is necessary to control their psychosis. For many of these patients, medication side effects may seem worse than the illness itself. These patients should be treated routinely with an SDA because these agents result in substantially fewer extrapyramidal side effects than the DRAs. However, these highly sensitive individuals may even experience extrapyramidal side effects on an SDA. Risperidone may cause extrapyramidal side effects even at low doses—for example, 0.5 mg—but the severity and risk are increased at higher doses—for example, more than 6 mg. Olanzapine and ziprasidone are also associated with dose-related parkinsonism and akathisia.

Tardive Dyskinesia

About 20 to 30 percent of patients on long-term treatment with a conventional DRA will exhibit symptoms of tardive dyskinesia. About 3 to 5 percent of young patients receiving a DRA develop tardive dyskinesia each year. The risk in elderly patients is much higher. Although seriously disabling dyskinesia is uncommon, it can affect walking, breathing, eating, and talking when it occurs. Individuals who are more sensitive to acute extrapyramidal side effects appear to be more vulnerable to developing tardive dyskinesia. Patients with comorbid cognitive or mood disorders may also be more vulnerable to tardive dyskinesia than those with only schizophrenia.

The onset of the abnormal movements usually occurs either while the patient is receiving an antipsychotic or within 4 weeks of discontinuing an oral antipsychotic or 8 weeks after the withdrawal of a depot antipsychotic. There is a slightly lower risk of tardive dyskinesia with new-generation drugs. However, the risk of tardive dyskinesia is not absent with the SDAs.

Recommendations for preventing and managing tardive dyskinesia include (1) using the lowest effective dose of antipsychotic; (2) prescribing cautiously with children, elderly patients, and patients with mood disorders; (3) examining patients on a regular basis for evidence of tardive dyskinesia; (4) considering alternatives to the antipsychotic being used and considering dosage reduction when tardive dyskinesia is diagnosed; and (5) considering a number of options if the tardive dyskinesia worsens, including discontinuing the antipsychotic or switching to a different drug. Clozapine has been shown to be effective in reducing severe tardive dyskinesia or tardive dystonia.

Other Side Effects

Sedation and postural hypotension can be important side effects for patients who are being treated with low-potency DRAs, such as perphenazine. These effects are often most severe during the initial dosing with these medications. As a result, patients treated with these medications—particularly clozapine—may require weeks to reach a therapeutic dose. Although most patients develop tolerance to sedation and postural hypotension, sedation may continue to be a problem. In these patients, daytime drowsiness may interfere with a patient's attempts to return to community life.

All DRAs, as well as SDAs, elevate prolactin levels, which can result in galactorrhea and irregular menses. Long-term elevations in prolactin and the resultant suppression in gonadotropin-releasing hormone can cause suppression in gonadal hormones. These, in turn, may have effects on libido and sexual functioning. There is also concern that elevated prolactin may cause decreases in bone density and lead to osteoporosis. The concerns about hyperprolactinemia, sexual functioning, and bone density are based on experiences with prolactin

elevations related to tumors and other causes. It is unclear if these risks are also associated with the lower elevations that occur with prolactin-elevating drugs.

Health Monitoring in Patients Receiving Antipsychotics

Because of the effects of the SDAs on insulin metabolism, psychiatrists should monitor a number of health indicators, including BMI, fasting blood glucose, and lipid profiles. Patients should be weighed and their BMIs calculated for every visit for 6 months after a medication change.

Side Effects of Clozapine

Clozapine has a number of side effects that make it a difficult drug to administer. The most serious is a risk of agranulocytosis. This potentially fatal condition occurs in approximately 0.3 percent of patients treated with clozapine during the first year of exposure. Subsequently, the risk is substantially lower. As a result, patients who receive clozapine in the United States are required to be in a program of weekly blood monitoring for the first 6 months and biweekly monitoring for the next 6 months. After 1 year of treatment without hematological problems, monitoring can be performed monthly.

Clozapine is also associated with a higher risk of seizures than other antipsychotics. The risk reaches nearly 5 percent at doses of more than 600 mg. Patients who develop seizures with clozapine can usually be managed by reducing the dose and adding an anticonvulsant, usually valproate (Depakene). Myocarditis has been reported to occur in approximately five patients per 100,000 patient-years. Other side effects with clozapine include hypersalivation, sedation, tachycardia, weight gain, diabetes, fever, and postural hypotension.

OTHER BIOLOGICAL THERAPIES

Electroconvulsive therapy (ECT) has been studied in both acute and chronic schizophrenia. Studies in recent-onset patients indicate that ECT is about as effective as antipsychotic medications and more effective than psychotherapy. Other studies suggest that supplementing antipsychotic medications with ECT is more effective than antipsychotic medications alone. Antipsychotic medications should be administered during and after ECT treatment. Although psychosurgery is no longer considered an appropriate treatment, it is practiced on a limited experimental basis for severe, intractable cases.

PSYCHOSOCIAL THERAPIES

Psychosocial therapies include a variety of methods to increase social abilities, self-sufficiency, practical skills, and interpersonal communication in schizophrenia patients. The goal is to enable persons who are severely ill to develop social and vocational skills for independent living. Such treatment is carried out at many sites, including hospitals, outpatient clinics, mental health centers, day hospitals, and home or social clubs.

Social Skills Training

Social skills training is sometimes referred to as behavioral skills therapy. Along with pharmacological therapy, this therapy can be directly supportive and useful to the patient. In addition to the psychotic symptoms seen in patients with schizophrenia, other noticeable symptoms involve the way the person relates to others, including poor eye contact, unusual delays in response, odd facial expressions, lack of spontaneity in social situations, and inaccurate perception or lack of perception of emotions in other people. Behavioral skills training addresses these behaviors through the use of videotapes of others and of the patient, role playing in therapy, and homework assignments for the specific skills being practiced. Social skills training has been shown to reduce relapse rates as measured by the need for hospitalization.

Family-Oriented Therapies

Because patients with schizophrenia are often discharged in an only partially remitted state, a family to which a patient returns can often benefit from a brief but intensive (as often as daily) course of family therapy. The therapy should focus on the immediate situation and should include identifying and avoiding potentially troublesome situations. When problems do emerge with the patient in the family, the aim of the therapy should be to resolve the problem quickly.

In wanting to help, family members often encourage a relative with schizophrenia to resume regular activities too quickly, both from ignorance about the disorder and from denial of its severity. Without being overly discouraging, therapists must help both the family and the patient understand and learn about schizophrenia and must encourage discussion of the psychotic episode and the events leading up to it. Ignoring the psychotic episode, a common occurrence, often increases the shame associated with the event and does not exploit the freshness of the episode to understand it better. Psychotic symptoms often frighten family members, and talking openly with the psychiatrist and with the relative with schizophrenia often eases all parties. Therapists can direct later family therapy toward long-range application of stress-reducing and coping strategies and toward the patient's gradual reintegration into everyday life.

Therapists must control the emotional intensity of family sessions with patients with schizophrenia. The excessive expression of emotion during a session can damage a patient's recovery process and undermine potentially successful future family therapy. Several studies have shown that family therapy is especially effective in reducing relapses.

National Alliance on Mental Illness (NAMI). The NAMI and similar organizations offer support groups for family members and friends of patients who are mentally ill and for patients themselves. These organizations offer emotional and practical advice about obtaining care in the sometimes complex health care delivery system and are useful sources to which to refer family members. NAMI has also waged a campaign to destigmatize mental illness and to increase government awareness of the needs and rights of persons who are mentally ill and their families.

Case Management

Because a variety of professionals with specialized skills, such as psychiatrists, social workers, and occupational therapists, among others, are involved in a treatment program, it is helpful to have one person aware of all the forces acting on the patient. The case manager ensures that their efforts are coordinated and that the patient keeps appointments and complies with treatment plans; the case manager may make home visits and even accompany the patient to work. The success of the program depends on the educational background, training, and competence of the individual case manager, which vary. Case managers often have too many cases to manage effectively. The ultimate benefits of the program have yet to be demonstrated.

Assertive Community Treatment

The Assertive Community Treatment (ACT) program was originally developed by researchers in Madison, Wisconsin, in the 1970s, for the delivery of services for persons with chronic mental illness. Patients are assigned to one multidisciplinary team (e.g., case manager, psychiatrist, nurse, general physicians). The team has a fixed caseload of patients and delivers all services when and where needed by the

patient, 24 hours a day, 7 days a week. This is mobile and intensive intervention that provides treatment, rehabilitation, and support activities. These include home delivery of medications, monitoring of mental and physical health, in vivo social skills, and frequent contact with family members. There is a high staff-to-patient ratio (1:12). ACT programs can effectively decrease the risk of rehospitalization for persons with schizophrenia, but they are labor-intensive and expensive programs to administer.

Group Therapy

Group therapy for persons with schizophrenia generally focuses on real-life plans, problems, and relationships. Groups may be behaviorally oriented, psychodynamically or insight oriented, or supportive. Some investigators doubt that dynamic interpretation and insight therapy are valuable for typical patients with schizophrenia. But group therapy is effective in reducing social isolation, increasing the sense of cohesiveness, and improving reality testing for patients with schizophrenia. Groups led in a supportive manner appear to be most helpful for schizophrenia patients.

Cognitive Behavioral Therapy

Cognitive behavioral therapy has been used in schizophrenia patients to improve cognitive distortions, reduce distractibility, and correct errors in judgment. There are reports of ameliorating delusions and hallucinations in some patients using this method. Patients who might benefit generally have some insight into their illness.

Individual Psychotherapy

Studies of the effects of individual psychotherapy in the treatment of schizophrenia have provided data that the therapy is helpful and that the effects are additive to those of pharmacological treatment. In psychotherapy with a schizophrenia patient, developing a therapeutic relationship that the patient experiences as safe is critical. The therapist's reliability, the emotional distance between the therapist and the patient, and the genuineness of the therapist as interpreted by the patient all affect the therapeutic experience. Psychotherapy for a schizophrenia patient should be thought of in terms of decades, rather than sessions, months, or even years.

Some clinicians and researchers have emphasized that the ability of a patient with schizophrenia to form a therapeutic alliance with a therapist is predictive of the outcome. Schizophrenia patients who are able to form a good therapeutic alliance are likely to remain in psychotherapy, to remain compliant with their medications, and to have good outcomes at 2-year follow-up evaluations.

The relationship between clinicians and patients differs from that encountered in the treatment of nonpsychotic patients. Establishing a relationship is often difficult. Persons with schizophrenia are desperately lonely, yet defend against closeness and trust; they are likely to become suspicious, anxious, or hostile or to regress when someone attempts to draw close (Fig. 7.1-8). Therapists should scrupulously respect a patient's distance and privacy and should demonstrate simple directness, patience, sincerity, and sensitivity to social conventions in preference to premature informality and the condescending use of first names. The patient is likely to perceive exaggerated warmth or professions of friendship as attempts at bribery, manipulation, or exploitation.

FIGURE 7.1-8

Patients with schizophrenia live in a state of chronic anxiety and fear. The environment is seen as hostile and threatening as symbolized in this illustration. (Courtesy of Arthur Tress.)

In the context of a professional relationship, however, flexibility is essential in establishing a working alliance with the patient. A therapist may have meals with the patient, sit on the floor, go for a walk, eat at a restaurant, accept and give gifts, play table tennis, remember the patient's birthday, or just sit silently with the patient. The major aim is to convey the idea that the therapist is trustworthy, wants to understand the patient and tries to do so, and has faith in the patient's potential as a human, no matter how disturbed, hostile, or bizarre the patient may be at the moment.

Personal Therapy

A flexible type of psychotherapy called personal therapy is a recently developed form of individual treatment for schizophrenia patients. Its objective is to enhance personal and social adjustment and to forestall relapse. It is a select method using social skills and relaxation exercises, psychoeducation, self-reflection, self-awareness, and exploration of individual vulnerability to stress. The therapist provides a setting that stresses acceptance and empathy. Patients receiving personal therapy show improvement in social adjustment (a composite measure that includes work performance, leisure, and interpersonal relationships) and have a lower relapse rate after 3 years than patients not receiving personal therapy.

Dialectical Behavior Therapy

This form of therapy, which combines cognitive and behavioral theories in both individual and group settings, has proved useful in borderline states and may have benefit in schizophrenia. Emphasis is placed on improving interpersonal skills in the presence of an active and empathic therapist.

Vocational Therapy

A variety of methods and settings are used to help patients regain old skills or develop new ones. These include sheltered workshops, job clubs, and part-time or transitional employment programs. Enabling patients to become gainfully employed is both a means toward, and a sign of, recovery. Many schizophrenia patients are capable of performing high-quality work despite their illness. Others may exhibit exceptional skill or even brilliance in a limited field as a result of some idiosyncratic aspect of their disorder.

Art Therapy

Many schizophrenia patients benefit from art therapy, which provides them with an outlet for their constant bombardment of imagery. It helps them communicate with others and share their inner, often frightening world with others.

Cognitive Training

Cognitive training or cognitive remediation is a technique introduced recently for the treatment of schizophrenia. Utilizing computer generated exercises, neural networks are influenced in such a way that cognition, including working memory, is improved which translates into more effective social functioning. The field is in its infancy and further work and replication of studies is needed; however, it is a technique that is easily learned and administered and holds great promise.

7.2 Schizoaffective Disorder

Schizoaffective disorder has features of both schizophrenia and mood disorders. In current diagnostic systems, patients can receive the diagnosis of schizoaffective disorder if they fit into one of the following six categories: (1) patients with schizophrenia who have mood symptoms, (2) patients with mood disorder who have symptoms of schizophrenia, (3) patients with both mood disorder and schizophrenia, (4) patients with a third psychosis unrelated to schizophrenia and mood disorder, (5) patients whose disorder is on a continuum between schizophrenia and mood disorder, and (6) patients with some combination of the above.

George H. Kirby, in 1913, and August Hoch, in 1921, both described patients with mixed features of schizophrenia and affective (mood) disorders. Because their patients did not have the deteriorating course of dementia praecox, Kirby and Hoch classified them in Emil Kraepelin's manic-depressive psychosis group.

In 1933, Jacob Kasanin introduced the term *schizoaffective disorder* to refer to a disorder with symptoms of both schizophrenia and mood disorders. In patients with the disorder, the onset of symptoms was sudden and often occurred in adolescence. Patients tended to have a good premorbid level of functioning, and often a specific stressor preceded the onset of symptoms. The family histories of the patients often included a mood disorder. Because Eugen Bleuler's broad concept of schizophrenia had eclipsed Kraepelin's narrow concept, Kasanin believed that the patients had a type of schizophrenia. From 1933 to about 1970, patients whose symptoms were similar to those of Kasanin's patients were variously classified as having schizoaffective disorder, atypical schizophrenia, good-prognosis schizophrenia, remitting schizophrenia, and cycloid psychosis—terms that emphasized a relation to schizophrenia.

Around 1970, two sets of data shifted the view of schizoaffective disorder from a schizophrenic illness to a mood disorder. First, lithium carbonate (Eskalith) was shown to be an effective and specific treatment for both bipolar disorders and some cases of schizoaffective disorder. Second, the United States–United Kingdom study published in 1968 by John Cooper and his colleagues showed that the variation in the number of patients classified as schizophrenic in the United States and in the United Kingdom resulted from an overemphasis in the United States on the presence of psychotic symptoms as a diagnostic criterion for schizophrenia.

EPIDEMIOLOGY

The lifetime prevalence of schizoaffective disorder is less than 1 percent, possibly in the range of 0.5 to 0.8 percent. These figures, however, are estimates; various studies of schizoaffective disorder have used varying diagnostic criteria. In clinical practice, a preliminary diagnosis of schizoaffective disorder is frequently used when a clinician is uncertain of the diagnosis.

Gender and Age Differences

Sex differences in the rates of schizoaffective disorder in clinical samples generally parallel sex differences seen in mood disorders, with approximately equal numbers of men and women who have the bipolar subtype and are more than twofold female to male predominance

among individuals with the depressed subtype of schizoaffective disorder. The depressive type of schizoaffective disorder may be more common in older persons than in younger persons, and the bipolar type may be more common in young adults than in older adults. The age of onset for women is later than that for men, as in schizophrenia. Men with schizoaffective disorder are likely to exhibit antisocial behavior and to have a markedly flat or inappropriate affect.

ETIOLOGY

The cause of schizoaffective disorder is unknown. The disorder may be a type of schizophrenia, a type of mood disorder, or the simultaneous expression of each. Schizoaffective disorder may also be a distinct third type of psychosis, one that is unrelated to either schizophrenia or a mood disorder. The most likely possibility is that schizoaffective disorder is a heterogeneous group of disorders encompassing all of these possibilities.

Studies designed to explore the etiology have examined family histories, biological markers, short-term treatment responses, and long-term outcomes. Most studies have considered patients with schizoaffective disorder to be a homogeneous group, but recent studies have examined the bipolar and depressive types of schizoaffective disorder separately.

Although much of the family and genetic research in schizoaffective disorder is based on the premise that schizophrenia and the mood disorders are completely separate entities, some data indicate that they may be genetically related. Studies of the disrupted in schizophrenia 1 (*DISC1*) gene, located on chromosome 1q42, suggest its possible involvement in schizoaffective disorder as well as schizophrenia and bipolar disorder.

As a group, patients with schizoaffective disorder have a better prognosis than patients with schizophrenia and a worse prognosis than patients with mood disorders. Also, as a group, patients with schizoaffective disorder tend to have a nondeteriorating course and respond better to lithium than do patients with schizophrenia.

Consolidation of Data

A reasonable conclusion from the available data is that patients with schizoaffective disorder are a heterogeneous group: some have schizophrenia with prominent affective symptoms, others have a mood disorder with prominent schizophrenic symptoms, and still others have a distinct clinical syndrome. The hypothesis that patients with schizoaffective disorder have both schizophrenia and a mood disorder is untenable because the calculated co-occurrence of the two disorders is much lower than the incidence of schizoaffective disorder.

DIAGNOSIS AND CLINICAL FEATURES

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) criteria for schizoaffective disorder are provided in [Table 7.2-1](#). The clinician must accurately diagnose the affective illness, making sure it meets the criteria of either a manic or a depressive episode but also determining the exact length of each episode (not always easy or even possible).

Table 7.2-1
DSM-5 Diagnostic Criteria for Schizoaffective Disorder

- A. An uninterrupted period of illness during which there is a major mood episode (major depressive or manic) concurrent with Criterion A of schizophrenia.
Note: The major depressive episode must include Criterion A1: Depressed mood.
- B. Delusions or hallucinations for 2 or more weeks in the absence of a major mood episode (depressive or manic) during the lifetime duration of the illness.
- C. Symptoms that meet criteria for a major mood episode are present for the majority of the total duration of the active and residual portions of the illness.
- D. The disturbance is not attributable to the effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- Specify whether:**
295.70 (F25.0) **Bipolar type:** This subtype applies if a manic episode is part of the presentation. Major depressive episodes may also occur.
295.70 (F25.1) **Depressive type:** This subtype applies if only major depressive episodes are part of the presentation.
- Specify if:**
With catatonia (refer to the criteria for catatonia associated with another mental disorder, pp. 119–120, for definition).
Coding note: Use additional code 293.89 (F06.1) catatonia associated with schizoaffective disorder to indicate the presence of the comorbid catatonia.
- Specify if:**
The following course specifiers are only to be used after a 1-year duration of the disorder and if they are not in contradiction to the diagnostic course criteria.
First episode, currently in acute episode: First manifestation of the disorder meeting the defining diagnostic symptom and time criteria. An *acute episode* is a time period in which the symptom criteria are fulfilled.
First episode, currently in partial remission: *Partial remission* is a time period during which an improvement after a previous episode is maintained and in which the defining criteria of the disorder are only partially fulfilled.
First episode, currently in full remission: *Full remission* is a period of time after a previous episode during which no disorder are only partially fulfilled.
Multiple episodes, currently in acute episode: Multiple episodes may be determined after a minimum of two episodes (i.e., after a first episode, a remission and a minimum of one relapse).
Multiple episodes, currently in partial remission
Multiple episodes, currently in full remission
Continuous: Symptoms fulfilling the diagnostic symptom criteria of the disorder are remaining for the majority of the illness course, with subthreshold symptom periods being very brief relative to the overall course.
Unspecified
- Specify current severity:**
Severity is rated by a quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe). (See Clinician-Rated Dimensions of Psychosis Symptom Severity in the chapter “Assessment Measures.”)
Note: Diagnosis of schizoaffective disorder can be made without using this severity specifier.

The length of each episode is critical for two reasons. First, to meet the Criterion B (psychotic symptoms in the absence of a major mood

episode [depressive or manic]), it is important to know when the affective episode ends and the psychosis continues. Second, to meet Criterion C, the length of all mood episodes must be combined and compared with the total length of the illness. If the mood component is present for the majority (>50 percent) of the total illness, then that criterion is met. As with most psychiatric diagnoses, schizoaffective disorder should not be used if the symptoms are caused by substance abuse or a secondary medical condition.

Mr. C was 24 years old with no previous psychiatric history. Pregnancy, birth, early development, and adjustment through army service as a paramedic were normal. After discharge from the army, he began to study law but then quit school and traveled in Asia, where he used cannabis. Family members who saw him during this time noticed several changes: He insisted on changing his name, he began to isolate himself, and he believed that he was the heir of the Dali Lama. When he became aggressive and argumentative, he was brought home and hospitalized. On admission, he was dressed like a Tibetan monk, with his head shaved. Although oriented to time and place, he had delusions of grandeur, stating that he was the most clever man on the planet and was the ancestor of the Messiah. He was also suspicious, arrogant, and argumentative. On laboratory assessment, he was also found to have hepatitis A. He was treated with perphenazine 28 mg per day and ultimately discharged to outpatient treatment. He tried again to attend law school but could not persist for more than a year before quitting. When his psychiatrist agreed to stop his antipsychotic medications, he relapsed a month later. His second admission occurred following a manic episode during which he spent money lavishly, had angry outbursts, was excessively talkative, was hyperactive, and believed he was the Messiah. He was treated with haloperidol 5 mg per day and lithium (Eskalith) 1,200 mg. After discharge and another attempt at law school, he traveled to India. He was brought home, rehospitalized with another manic episode, and discharged on depot antipsychotic medications. After being rehospitalized because of extrapyramidal side effects, he was prescribed olanzapine 20 mg per day and valproic acid (Depakene) 1,000 mg per day. During that hospitalization, his mood seemed more depressed, but he did not meet the criteria for an episode of major depressive disorder. During the subsequent 5 years, he remained out of the hospital and had no episodes of mood disorder. He was careful to avoid using cannabis or other substances. He does not work but functions well as a husband and father. From time to time he has thoughts that he might be hurt by other people inflicting injury on his liver, but these thoughts never last more than a few days.

The first aspect of establishing a differential diagnosis was determining whether the psychosis was due to a general medical condition or a substance-use disorder. These possibilities seemed unlikely because hepatitis would rarely be associated with the development of an acute manic syndrome. Although cannabis use can precipitate psychosis, the patient's psychotic symptoms and mood disturbance also occurred in the absence of substance use. In addition, the patient's longitudinal course was not consistent with either a substance-induced disorder or a psychosis due to a general medical condition. Mr. C's mood episodes were distinct, but he also had clear psychotic symptoms in the absence of a mood episode, making schizoaffective disorder a more appropriate diagnosis than bipolar disorder with psychotic features. His course also showed a lack of return to his premorbid level of function despite reasonable control of his symptoms with an antipsychotic and a mood stabilizing anticonvulsant. The duration of his mood symptoms relative to the total illness duration was significant and consistent with a diagnosis of schizoaffective disorder.

Mrs. P is a 47-year-old, divorced, unemployed woman who lived alone and who experienced chronic psychotic symptoms despite treatment with olanzapine 20 mg per day and citalopram (Celexa) 20 mg per day. She believed that she was getting messages from God and the police department to go on a mission to fight against drugs. She also believed that an organized crime group was trying to stop her in this pursuit. The onset of her illness began at age 20 years when she experienced the first of several depressive episodes. She also described periods when she felt more energetic and talkative; had a decreased need for sleep; and was more active, sometimes cleaning her house throughout the night. About 4 years after the onset of her symptoms, she began to hear "voices" that became stronger when she was depressed but were still present and disturbed her even when her mood was euthymic. About 10 years after her illness began, she developed the belief that policemen were everywhere and that the neighbors were spying on her. She was hospitalized voluntarily. Two years later, she had another depressive episode, and the auditory hallucinations told her she could not live in her apartment. She was tried on lithium, antidepressants, and antipsychotic medications but continued to be chronically symptomatic with mood symptoms as well as psychosis.

Mrs. P demonstrates a "classic" presentation of schizoaffective disorder in which clear depressive and hypomanic episodes are present in combination with continuous psychotic illness and first-rank symptoms. Her course is typical of many individuals with schizoaffective disorder.

DIFFERENTIAL DIAGNOSIS

The psychiatric differential diagnosis includes all the possibilities usually considered for mood disorders and for schizophrenia. In any differential diagnosis of psychotic disorders, a complete medical workup should be performed to rule out organic causes for the symptoms. A history of substance use (with or without positive results on a toxicology screening test) may indicate a substance-induced disorder. Preexisting medical conditions, their treatment, or both can cause psychotic and mood disorders. Any suspicion of a neurological abnormality warrants consideration of a brain scan to rule out anatomical pathology and an electroencephalogram to determine any possible seizure disorders (e.g., temporal lobe epilepsy). Psychotic disorder caused by seizure disorder is more common than that seen in the general population. It tends to be characterized by paranoia, hallucinations, and ideas of reference. Patients with epilepsy with psychosis are believed to have a better level of function than patients with schizophrenic spectrum disorders. Better control of the seizures can reduce the psychosis.

COURSE AND PROGNOSIS

Considering the uncertainty and evolving diagnosis of schizoaffective disorder, it is difficult to determine the long-term course and prognosis. Given the definition of the diagnosis, patients with schizoaffective disorder might be expected to have a course similar to an episodic mood disorder, a chronic schizophrenic course, or some intermediate outcome. It has been presumed that an increasing presence of schizophrenic symptoms predicted a worse prognosis. After 1 year, patients with schizoaffective disorder had different outcomes, depending on whether their predominant symptoms were affective (better prognosis) or schizophrenic (worse prognosis). One study that followed patients diagnosed with schizoaffective disorder for 8 years found that the outcomes of these patients more closely resembled schizophrenia than a mood disorder with psychotic features.

TREATMENT

Mood stabilizers are a mainstay of treatment for bipolar disorders and would be expected to be important in the treatment of patients with schizoaffective disorder. One study that compared lithium with carbamazepine (Tegretol) found that carbamazepine was superior for schizoaffective disorder, depressive type, but found no difference in the two agents for the bipolar type. In practice, however, these medications are used extensively alone, in combination with each other, or with an antipsychotic agent. In manic episodes, patients who are schizoaffective should be treated aggressively with dosages of a mood stabilizer in the middle to high therapeutic blood concentration range. As the patient enters maintenance phase, the dosage can be reduced to a low to middle range to avoid adverse effects and potential effects on organ systems (e.g., thyroid and kidney) and to improve ease of use and compliance. Laboratory monitoring of plasma drug

concentrations and periodic screening of thyroid, kidney, and hematological functioning should be performed.

By definition, many patients who are schizoaffective have major depressive episodes. Treatment with antidepressants mirrors treatment of bipolar depression. Care should be taken not to precipitate a cycle of rapid switches from depression to mania with the antidepressant. The choice of antidepressant should take into account previous antidepressant successes or failures. Selective serotonin reuptake inhibitors (e.g., fluoxetine [Prozac] and sertraline [Zoloft]) are often used as first-line agents because they have less effect on cardiac status and have a favorable overdose profile. Agitated or insomniac patients, however, may benefit from a tricyclic drug. As in all cases of intractable mania, the use of ECT should be considered. As mentioned, antipsychotic agents are important in the treatment of the psychotic symptoms of schizoaffective disorder.

Psychosocial Treatment

Patients benefit from a combination of family therapy, social skills training, and cognitive rehabilitation. Because the psychiatric field has had difficulty deciding on the exact diagnosis and prognosis of schizoaffective disorder, this uncertainty must be explained to the patient. The range of symptoms can be vast because patients contend with both ongoing psychosis and varying mood states. It can be very difficult for family members to keep up with the changing nature and needs of these patients. Medication regimens can be complicated, with multiple medications from all classes of drugs.

7.3 Schizophreniform Disorder

The concept of schizophreniform disorder was introduced in 1939 by Gabriel Langfeldt (1895–1983) to describe a condition with a sudden onset and benign course associated with mood symptoms and clouding of consciousness. The symptoms of schizophreniform are similar to those of schizophrenia; however, with schizophreniform disorder, the symptoms last for at least 1 month but less than 6 months. In contrast, for a patient to meet the diagnostic criteria for schizophrenia, the symptoms must have been present for at least 6 months. Patients with schizophreniform disorder return to their baseline level of functioning after the disorder has resolved.

EPIDEMIOLOGY

Little is known about the incidence, prevalence, and sex ratio of schizophreniform disorder. The disorder is most common in adolescents and young adults and is less than half as common as schizophrenia. A fivefold greater rate of schizophreniform disorder has been found in men than in women. A 1-year prevalence rate of 0.09 percent and a lifetime prevalence rate of 0.11 percent have been reported.

Several studies have shown that the relatives of patients with schizophreniform disorder are at high risk of having other psychiatric disorders, but the distribution of the disorders differs from the distribution seen in the relatives of patients with schizophrenia and bipolar disorders. Specifically, the relatives of patients with schizophreniform disorders are more likely to have mood disorders than are the relatives of patients with schizophrenia. In addition, the relatives of patients with schizophreniform disorder are more likely to have a diagnosis of a psychotic mood disorder than are the relatives of patients with bipolar disorders.

ETIOLOGY

The cause of schizophreniform disorder is not known. As Langfeldt noted in 1939, patients with this diagnostic label are likely to be heterogeneous. In general, whereas some patients have a disorder similar to schizophrenia, others have a disorder similar to a mood disorder. Because of the generally good outcome, the disorder probably has similarities to the episodic nature of mood disorders. Some data, however, indicate a close relation to schizophrenia.

In support of the relation to mood disorders, several studies have shown that patients with schizophreniform disorder, as a group, have more affective symptoms (especially mania) and a better outcome than patients with schizophrenia. Also, the increased occurrence of mood disorders in the relatives of patients with schizophreniform disorder indicates a relation to mood disorders. Thus, the biological and epidemiological data are most consistent with the hypothesis that the current diagnostic category defines a group of patients, some of whom have a disorder similar to schizophrenia; others have a disorder resembling a mood disorder.

Brain Imaging

A relative activation deficit in the inferior prefrontal region of the brain while the patient is performing a region-specific psychological task (the Wisconsin Card Sorting Test), as reported for patients with schizophrenia, has been reported in patients with schizophreniform disorder. One study showed the deficit to be limited to the left hemisphere and found impaired striatal activity suppression limited to the left hemisphere during the activation procedure. The data can be interpreted to indicate a physiological similarity between the psychosis of schizophrenia and the psychosis of schizophreniform disorder. Additional central nervous system factors, as yet unidentified, may lead to either the long-term course of schizophrenia or the foreshortened course of schizophreniform disorder.

Although some data indicate that patients with schizophreniform disorder may have enlarged cerebral ventricles, as determined by

computed tomography and magnetic resonance imaging, other data indicate that, unlike the enlargement seen in schizophrenia, the ventricular enlargement in schizophreniform disorder is not correlated with either outcome or other biological measures.

Other Biological Measures

Although brain imaging studies point to a similarity between schizophreniform disorder and schizophrenia, at least one study of electrodermal activity indicated a difference. Patients with schizophrenia who were born during the winter and spring months (a period of high risk for the birth of these patients) had hyporesponsive skin conductances, but this association was absent in patients with schizophreniform disorder. The significance and the meaning of this single study are difficult to interpret, but the results do suggest caution in assuming similarity between patients with schizophrenia and those with schizophreniform disorder. Data from at least one study of eye tracking in the two groups also indicate that they may differ in some biological measures.

DIAGNOSTIC AND CLINICAL FEATURES

The DSM-5 criteria for schizophreniform disorder are listed in [Table 7.3-1](#). Schizophreniform disorder is an acute psychotic disorder that has a rapid onset and lacks a long prodromal phase. Although many patients with schizophreniform disorder may experience functional impairment at the time of an episode, they are unlikely to report a progressive decline in social and occupational functioning. The initial symptom profile is the same as that of schizophrenia in that two or more psychotic symptoms (hallucinations, delusions, disorganized speech and behavior, or negative symptoms) must be present. Schneiderian first-rank symptoms are frequently observed. Also an increased likelihood is found of emotional turmoil and confusion, the presence of which may indicate a good prognosis. Although negative symptoms may be present, they are relatively uncommon in schizophreniform disorder and are considered poor prognostic features. In a small series of first-admission patients with schizophreniform, one-fourth had moderate to severe negative symptoms. Almost all were initially categorized as having “schizophreniform disorder without good prognostic features,” and 2 years later, 73 percent were re-diagnosed with schizophrenia compared with 38 percent of those with “good prognostic features.”

Table 7.3-1
DSM-5 Diagnostic Criteria for Schizophreniform Disorder

- A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
1. Delusions
 2. Hallucinations.
 3. Disorganized speech (e.g., frequent derailment or incoherence).
 4. Grossly disorganized or catatonic behavior.
 5. Negative symptoms (i.e., diminished emotional expression or avolition).
- B. An episode of the disorder lasts at least 1 month but less than 6 months. When the diagnosis must be made without waiting for recovery, it should be qualified as “provisional.”
- C. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
- D. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify if:

With good prognostic features: This specifier requires the presence of at least two of the following features: onset of prominent psychotic symptoms within 4 weeks of the first noticeable change in usual behavior or functioning; confusion or perplexity; good premorbid social and occupational functioning; and absence of blunted or flat affect.

Without good prognostic features: This specifier is applied if two or more of the above features have not been present.

Specify if:

With catatonia (refer to the criteria for catatonia associated with another mental disorder for definition).

Coding note: Use additional code 293.89 (F06.1) catatonia associated with schizophreniform disorder to indicate the presence of the comorbid catatonia.

Specify current severity:

Severity is rated by a quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe).

Note: Diagnosis of schizophreniform disorder can be made without using this severity specifier.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (Copyright ©2013). American Psychiatric Association. All Rights Reserved.

By definition, patients with schizophreniform disorder return to their baseline state within 6 months. In some instances, the illness is episodic, with more than one episode occurring after long periods of full remission. If the combined duration of symptomatology exceeds 6 months, however, then schizophrenia should be considered.

Mr. C, a 28-year-old accountant, was brought to the emergency department by the police in handcuffs. He was disheveled, and shouted and struggled with the police officers. It was apparent that he was hearing voices because he would respond to them with shouts such as, “Shut up! I told you I won’t do it!” However, when confronted about the voices, he denied hearing anything. Mr. C had a hypervigilant stare and jumped at the slightest noise. He stated that he must run away quickly because he knew he would be killed shortly otherwise.

Mr. C was functioning well until 2 months before hospitalization. He was an accountant at a prestigious company and had close friends and a live-in girlfriend. Most people who knew him would describe him as friendly, but he was occasionally quarrelsome.

When his girlfriend suddenly broke off the relationship and moved out of their apartment, Mr. C was distressed. However, he was convinced that he could win her back, so he began to “accidentally” run into her at her job or her new apartment with flowers and various gifts. When she strongly told him that she wanted nothing more to do with him and requested that he leave her alone, Mr. C was convinced that she wanted him dead. He became so preoccupied with this notion that his work began to suffer. Out of fear for his life, Mr. C took off from work frequently, and when he did report to work, he was often tardy and did subpar work, making many errors. His supervisor confronted Mr. C about his behavior, threatening termination if it continued. Mr. C was embarrassed and resented his supervisor for the confrontation. He believed that his ex-girlfriend had hired the supervisor to kill him.

His beliefs were confirmed by a voice that would mock him. The voice told him time and again that he should quit his job, relocate to another city, and forget about his ex-girlfriend, but Mr. C refused, believing it would give them “more satisfaction than they deserved.” He

continued working, albeit cautiously, all the while fearing for his life.

Through it all, Mr. C believed himself to be the lone victim. He would awake abruptly at night from nightmares but would be able to fall right back to sleep. He had not lost any weight and had no other vegetative symptoms. His affect alternated between rage and terror. His mind was unusually alert and active, but he was not otherwise hyperactive, excessively energetic, or expansive. He did not display any formal thought disorder.

Mr. C was hospitalized and treated with antipsychotic medication. His symptoms remitted after several weeks of treatment, and he was well and able to return to work shortly after discharge.

DIFFERENTIAL DIAGNOSIS

It is important to first differentiate schizophreniform disorder from psychoses that can arise from medical conditions. This is accomplished by taking a detailed history and physical examination and, when indicated, performing laboratory tests or imaging studies. A detailed history of medication use, including over-the-counter medications and herbal products, is essential because many therapeutic agents can also produce an acute psychosis. Although it is not always possible to distinguish substance-induced psychosis from other psychotic disorders cross-sectionally, a rapid onset of psychotic symptoms in a patient with a significant substance history should raise the suspicion of a substance-induced psychosis. A detailed substance use history and toxicological screen are also important for treatment planning in an individual with a new onset of psychosis.

The duration of psychotic symptoms is one factor that distinguishes schizophreniform disorder from other syndromes. Schizophrenia is diagnosed if the duration of the prodromal, active, and residual phases lasts for more than 6 months; symptoms that occur for less than 1 month indicate a brief psychotic disorder. In general, a diagnosis of brief psychotic disorder does not require that a major stressor be present.

Distinguishing mood disorders with psychotic features from schizophreniform disorder is sometimes difficult. Furthermore, schizophreniform disorder and schizophrenia can be highly comorbid with mood and anxiety disorders. Additional confounds are that mood symptoms, such as loss of interest and pleasure, may be difficult to distinguish from negative symptoms, avolition, and anhedonia. Some mood symptoms may also be present during the early course of schizophrenia. A thorough longitudinal history is important in elucidating the diagnosis because the presence of psychotic symptoms exclusively during periods of mood disturbance is an indication of a primary mood disorder.

COURSE AND PROGNOSIS

The course of schizophreniform disorder, for the most part, is defined in the criteria. It is a psychotic illness lasting more than 1 month and less than 6 months. The real issue is what happens to persons with this illness over time. Most estimates of progression to schizophrenia range between 60 and 80 percent. What happens to the other 20 to 40 percent is currently not known. Some will have a second or third episode during which they will deteriorate into a more chronic condition of schizophrenia. A few, however, may have only this single episode and then continue on with their lives, which is clearly the outcome desired by all clinicians and family members, although it is probably a rare occurrence and should not be held out as likely.

TREATMENT

Hospitalization, which is often necessary in treating patients with schizophreniform disorder, allows effective assessment, treatment, and supervision of a patient's behavior. The psychotic symptoms can usually be treated by a 3- to 6-month course of antipsychotic drugs (e.g., risperidone). Several studies have shown that patients with schizophreniform disorder respond to antipsychotic treatment much more rapidly than patients with schizophrenia. In one study, about 75 percent of patients with schizophreniform disorder and only 20 percent of the patients with schizophrenia responded to antipsychotic medications within 8 days. A trial of lithium (Eskalith), carbamazepine (Tegretol), or valproate (Depakene) may be warranted for treatment and prophylaxis if a patient has a recurrent episode. Psychotherapy is usually necessary to help patients integrate the psychotic experience into their understanding of their own minds and lives. ECT may be indicated for some patients, especially those with marked catatonic or depressed features.

Finally, most patients with schizophreniform disorder progress to full-blown schizophrenia despite treatment. In those cases, a course of management consistent with a chronic illness must be formulated.

7.4 Delusional Disorder and Shared Psychotic Disorder

Delusions are false fixed beliefs not in keeping with the culture. They are among the most interesting of psychiatric symptoms because of the great variety of false beliefs that can be held by so many people and because they are so difficult to treat. The diagnosis of delusional disorder is made when a person exhibits nonbizarre delusions of at least 1 month's duration that cannot be attributed to other psychiatric disorders. *Nonbizarre* means that the delusions must be about situations that can occur in real life, such as being followed, infected, loved at

a distance, and so on; that is, they usually have to do with phenomena that, although not real, are nonetheless possible. Several types of delusions may be present and the predominant type is specified when the diagnosis is made.

EPIDEMIOLOGY
