An accurate assessment of the epidemiology of delusional disorder is hampered by the relative rareness of the disorder, as well as by its changing definitions in recent history. Moreover, delusional disorder may be underreported because delusional patients rarely seek psychiatric help unless forced to do so by their families or by the courts. Even with these limitations, however, the literature does support the contention that delusional disorder, although uncommon, has a relatively steady rate.

The prevalence of delusional disorder in the United States is currently estimated to be 0.2 to 0.3 percent. Thus, delusional disorder is much rarer than schizophrenia, which has a prevalence of about 1 percent, and the mood disorders, which have a prevalence of about 5 percent. The annual incidence of delusional disorder is one to three new cases per 100,000 persons. The mean age of onset is about 40 years, but the range for age of onset runs from 18 years of age to the 90s. A slight preponderance of female patients exists. Men are more likely to develop paranoid delusions than women, who are more likely to develop delusions of erotomania. Many patients are married and employed, but some association is seen with recent immigration and low socioeconomic status.

ETIOLOGY

As with all major psychiatric disorders, the cause of delusional disorder is unknown. Moreover, patients currently classified as having delusional disorder probably have a heterogeneous group of conditions with delusions as the predominant symptom. The central concept about the cause of delusional disorder is its distinctness from schizophrenia and the mood disorders. Delusional disorder is much rarer than either schizophrenia or mood disorders, with a later onset than schizophrenia and a much less pronounced female predominance than the mood disorders. The most convincing data come from family studies that report an increased prevalence of delusional disorder and related personality traits (e.g., suspiciousness, jealousy, and secretiveness) in the relatives of delusional disorder probands. Family studies have reported neither an increased incidence of schizophrenia and mood disorders in the families of delusional disorder probands nor an increased incidence of delusional disorder in the families of probands with schizophrenia. Long-term follow-up of patients with delusional disorder indicates that the diagnosis of delusional disorder is relatively stable, with fewer than one-fourth of the patients eventually being reclassified as having schizophrenia and fewer than 10 percent of patients eventually being reclassified as having a mood disorder. These data indicate that delusional disorder is not simply an early stage in the development of one or both of these two more common disorders.

Biological Factors

A wide range of nonpsychiatric medical conditions and substances, including clear-cut biological factors, can cause delusions, but not everyone with a brain tumor, for example, has delusions. Unique, and not yet understood, factors in a patient's brain and personality are likely to be relevant to the specific pathophysiology of delusional disorder.

The neurological conditions most commonly associated with delusions affect the limbic system and the basal ganglia. Patients whose delusions are caused by neurological diseases and who show no intellectual impairment tend to have complex delusions similar to those in patients with delusional disorder. Conversely, patients with neurological disorder with intellectual impairments often have simple delusions unlike those in patients with delusional disorder. Thus, delusional disorder may involve the limbic system or basal ganglia in patients who have intact cerebral cortical functioning.

Delusional disorder can arise as a normal response to abnormal experiences in the environment, the peripheral nervous system, or the central nervous system (CNS). Thus, if patients have erroneous sensory experiences of being followed (e.g., hearing footsteps), they may come to believe that they are actually being followed. This hypothesis hinges on the presence of hallucinatory-like experiences that need to be explained. The presence of such hallucinatory experiences in delusional disorder has not been proved.

Psychodynamic Factors

Practitioners have a strong clinical impression that many patients with delusional disorder are socially isolated and have attained less than expected levels of achievement. Specific psychodynamic theories about the cause and the evolution of delusional symptoms involve suppositions regarding hypersensitive persons and specific ego mechanisms, which are reaction formation, projection, and denial.

Freud's Contributions. Sigmund Freud believed that delusions, rather than being symptoms of the disorder, are part of a healing process. In 1896, he described projection as the main defense mechanism in paranoia. Later, Freud read *Memories of My Nervous Illness*, an autobiographical account by Daniel Paul Schreber. Although he never met Schreber, Freud theorized from his review of the autobiography that unconscious homosexual tendencies are defended against by denial and projection. According to classic psychodynamic theory, the dynamics underlying the formation of delusions for a female patient are the same as for a male patient. Careful studies of patients with delusions have been unable to corroborate Freud's theories, although they may be relevant in individual cases. Overall, no higher incidence of homosexual ideation or activity is found in patients with delusions than in other groups. Freud's major contribution, however, was to demonstrate the role of projection in the formation of delusional thought.

Paranoid Pseudocommunity. Norman Cameron described seven situations that favor the development of delusional disorders: an increased expectation of receiving sadistic treatment, situations that increase distrust and suspicion, social isolation, situations that increase envy and jealousy, situations that lower self-esteem, situations that cause persons to see their own defects in others, and situations that increase the potential for rumination over probable meanings and motivations. When frustration from any combination of these conditions exceeds the tolerable limit, persons become withdrawn and anxious; they realize that something is wrong, seek an explanation for the problem, and crystallize a delusional system as a solution. Elaboration of the delusion to include imagined persons and attribution of malevolent motivations to both real and imagined persons results in the organization of the *pseudocommunity*—a perceived community of plotters. This delusional entity hypothetically binds together projected fears and wishes to justify the patient's aggression and to provide a tangible target for the patient's hostilities.

Other Psychodynamic Factors. Clinical observations indicate that many, if not all, paranoid patients experience a lack of trust in relationships. A hypothesis relates this distrust to a consistently hostile family environment, often with an overcontrolling mother and a distant or sadistic father. Erik Erikson's concept of trust versus mistrust in early development is a useful model to explain the suspiciousness of a paranoid individual who never went through the healthy experience of having his or her needs satisfied by what Erikson termed the "outer-providers." Thus, they have a general distrust of their environment.

Defense Mechanisms. Patients with delusional disorder use primarily the defense mechanisms of reaction formation, denial, and projection. They use reaction formation as a defense against aggression, dependence needs, and feelings of affection and transform the need for dependence into staunch independence. Patients use denial to avoid awareness of painful reality. Consumed with anger and hostility and unable to face responsibility for the rage, they project their resentment and anger onto others and use projection to protect themselves from

recognizing unacceptable impulses in themselves.

Other Relevant Factors. Delusions have been linked to a variety of additional factors such as social and sensory isolation, socioeconomic deprivation, and personality disturbance. Deaf and visually impaired individuals and possibly immigrants with limited ability in a new language may be more vulnerable to delusion formation than the normal population. Vulnerability is heightened with advanced age. Delusional disturbance and other paranoid features are common in elderly adults. In short, multiple risk factors are associated with the formation of delusions, and the source and pathogenesis of delusional disorders per se have yet to be specified (Table 7.4-1).

 **Table 7.4-1**
Risk Factors Associated with Delusional Disorder

Advanced age
Sensory impairment or isolation
Family history
Social isolation
Personality features (e.g., unusual interpersonal sensitivity)
Recent immigration

DIAGNOSIS AND CLINICAL FEATURES

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) criteria for delusional disorder are listed in Table 7.4-2.

 **Table 7.4-2**
DSM-5 Diagnostic Criteria for Delusional Disorder

- A. The presence of one (or more) delusions with a duration of 1 month longer.
- B. Criterion A for schizophrenia has never been met.
Note: Hallucinations, if present, are not prominent and are related to the delusional theme (e.g., the sensation of being infested with insects associated with delusions of infestations).
- C. Apart from the impact of the delusion(s) or its ramifications, functioning is not markedly impaired, and behavior is not obviously bizarre or odd.
- D. If manic or major depressive episodes have occurred, these have been brief relative to the duration of the delusional periods.
- E. The disturbance is not attributable to the physiological effects of a substance or another medical condition and is not better explained by another mental disorder, such as body dysmorphic disorder or obsessive-compulsive disorder.

Specify whether:

Erotomanic type: This subtype applies when the central theme of the delusion is that another person is in love with the individual.

Grandiose type: This subtype applies when the central theme of the delusion is the conviction of having some great (but unrecognized) talent or insight or having some important discovery.

Jealous type: This subtype applies when the central theme of the individual's delusion is that his or her spouse or lover is unfaithful.

Persecutory type: This subtype applies when the central theme of delusion involves the individual's belief that he or she is being conspired against, cheated, spied on, followed, poisoned or drugged, maliciously maligned, harassed, or obstructed in the pursuit of long-term goals.

Somatic type: This subtype applies when the central theme of the delusion involved bodily functions or sensations.

Mixed type: This subtype applies when no one delusional theme predominates.

Unspecified type: This subtype applies when the dominant delusional belief cannot be clearly determined or is not described in the specific types (e.g., referential delusions without a prominent persecutory or grandiose component).

Specify if:

With bizarre content: Delusions are deemed bizarre if they are clearly implausible, not understandable, and not derived from ordinary life experiences (e.g., an individual's belief that a stranger has removed his or her internal organs and replaced them with someone else's organs without leaving any wounds or scars).

Specify if:

The following course specifiers are only to be used after a 1-year duration of the disorder:

First episode, currently in acute episode: First manifestation of the disorder meeting the defining diagnostic symptom and time criteria. An *acute episode* is a time period in which the symptom criteria are fulfilled.

First episode, currently in partial remission: *Partial remission* is a time period during which an improvement after a previous episode is maintained and in which the defining criteria of the disorder are only partially fulfilled.

First episode, currently in full remission: *Full remission* is a period of time after a previous episode during which no disorder-specific symptoms are present.

Multiple episodes, currently in acute episode

Multiple episodes, currently in partial remission

Multiple episodes, currently in full remission

Continuous: Symptoms fulfilling the diagnostic symptom criteria of the disorder are remaining for the majority of the illness course, with subthreshold symptoms periods being very brief relative to the overall course.

Unspecified

Specify current severity:

Severity is rated by a qualitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, disorganized speech, abnormal psychomotor behavior and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe). (See Clinician-Rated Dimensions of Psychosis Symptom Severity in the chapter "Assessment Measures.")

Note: Diagnosis of delusional disorder can be made without using this severity specifier.

Mental Status

General Description. Patients are usually well groomed and well dressed, without evidence of gross disintegration of personality or of daily activities, yet they may seem eccentric, odd, suspicious, or hostile. They are sometimes litigious and may make this inclination clear to the examiner. The most remarkable feature of patients with delusional disorder is that the mental status examination shows them to be quite normal except for a markedly abnormal delusional system. Patients may attempt to engage clinicians as allies in their delusions, but a clinician should not pretend to accept the delusion; this collusion further confounds reality and sets the stage for eventual distrust between the patient and the therapist.

Mood, Feelings, and Affect. Patients' moods are consistent with the content of their delusions. A patient with grandiose delusions is

euphoric; one with persecutory delusions is suspicious. Whatever the nature of the delusional system, the examiner may sense some mild depressive qualities.

Perceptual Disturbances. By definition, patients with delusional disorder do not have prominent or sustained hallucinations. A few delusional patients have other hallucinatory experiences—virtually always auditory rather than visual.

Thought. Disorder of thought content, in the form of delusions, is the key symptom of the disorder. The delusions are usually systematized and are characterized as being possible (e.g., delusions of being persecuted, having an unfaithful spouse, being infected with a virus, or being loved by a famous person). These examples of delusional content contrast with the bizarre and impossible delusional content in some patients with schizophrenia. The delusional system itself can be complex or simple. Patients lack other signs of thought disorder, although some may be verbose, circumstantial, or idiosyncratic in their speech when they talk about their delusions. Clinicians should not assume that all unlikely scenarios are delusional; the veracity of a patient's beliefs should be checked before deeming their content to be delusional.

Sensorium and Cognition.

ORIENTATION. Patients with delusional disorder usually have no abnormality in orientation unless they have a specific delusion about a person, place, or time.

MEMORY. Memory and other cognitive processes are intact in patients with delusional disorder.

Impulse Control. Clinicians must evaluate patients with delusional disorder for ideation or plans to act on their delusional material by suicide, homicide, or other violence. Although the incidence of these behaviors is not known, therapists should not hesitate to ask patients about their suicidal, homicidal, or other violent plans. Destructive aggression is most common in patients with a history of violence; if aggressive feelings existed in the past, therapists should ask patients how they managed those feelings. If patients cannot control their impulses, hospitalization is probably necessary. Therapists can sometimes help foster a therapeutic alliance by openly discussing how hospitalization can help patients gain additional control of their impulses.

Judgment and Insight. Patients with delusional disorder have virtually no insight into their condition and are almost always brought to the hospital by the police, family members, or employers. Judgment can best be assessed by evaluating the patient's past, present, and planned behavior.

Reliability. Patients with delusional disorder are usually reliable in their information, except when it impinges on their delusional system.

TYPES

Persecutory Type

The delusion of persecution is a classic symptom of delusional disorder; persecutory-type and jealousy-type delusions are probably the forms seen most frequently by psychiatrists. Patients with this subtype are convinced that they are being persecuted or harmed. The persecutory beliefs are often associated with querulousness, irritability, and anger, and the individual who acts out his or her anger may at times be assaultive or even homicidal. At other times, such individuals may become preoccupied with formal litigation against their perceived persecutors. In contrast to persecutory delusions in schizophrenia, the clarity, logic, and systematic elaboration of the persecutory theme in delusional disorder leave a remarkable stamp on this condition. The absence of other psychopathology, of deterioration in personality, or of deterioration in most areas of functioning also contrasts with the typical manifestations of schizophrenia.

Mrs. S, 62 years old, was referred to a psychiatrist because of reports of being unable to sleep. She had previously worked full time taking care of children, and she played tennis almost every day and managed her household chores. However, she had now become preoccupied with the idea that her downstairs neighbor was doing a variety of things to harass her and wanted to get her to move away. At first, Mrs. S based her belief on certain looks that he gave her and damage done to her mailbox, but later she felt he might be leaving empty bottles of cleaning solutions in the basement so she would be overcome by fumes. As a result, the patient was fearful of falling asleep, convinced that she might be asphyxiated and unable to awaken in time to get help. She felt somewhat depressed and thought her appetite might be decreased from the stress of being harassed. However, she had not lost weight and still enjoyed playing tennis and going out with friends. At one point she considered moving to another apartment but then decided to fight back. The episode had gone on for 8 months when her daughter persuaded her to have a psychiatric assessment. In the interview, Mrs. S was pleasant and cooperative. Except for mild depressive symptoms and the specific delusion about being harassed by her neighbor, her mental status was normal.

Mrs. S had a past history of depression 30 years before, which followed the death of a close friend. She saw a counselor for several months and found this helpful, but she was not treated with medication. For the current episode, she agreed to take medications, although she believed her neighbor was more in need of treatment than she was. Her symptoms improved somewhat with risperidone (Risperdal) 2 mg at bedtime and clonazepam (Klonopin) 0.5 mg every morning and at bedtime.

This patient presented with a single delusion regarding her neighbor that was within the realm of possibility (i.e., not bizarre). Other areas of her functioning were normal. Although mild depressive symptoms were present, she did not meet criteria for major depressive disorder. Her prior symptoms of depression appeared to be related to a normal bereavement reaction and had not required pharmacotherapy or hospitalization. Thus, her current presentation is one of delusional disorder, persecutory type and not major depressive disorder with psychotic features. In terms of treatment, the ability to create a working alliance with the patient; avoiding the discussion of the veracity of her delusion; and focusing on her anxiety, depression, and difficulty falling asleep enabled her psychiatrist to introduce the medications with beneficial results. Jealous Type

Delusional disorder with delusions of infidelity has been called *conjugal paranoia* when it is limited to the delusion that a spouse has been unfaithful. The eponym *Othello syndrome* has been used to describe morbid jealousy that can arise from multiple concerns. The delusion usually affects men, often those with no prior psychiatric illness. It may appear suddenly and serve to explain a host of present and past events involving the spouse's behavior. The condition is difficult to treat and may diminish only on separation, divorce, or death of the spouse.

Marked jealousy (usually termed *pathological* or *morbid jealousy*) is thus a symptom of many disorders—including schizophrenia (in which

female patients more commonly display this feature), epilepsy, mood disorders, drug abuse, and alcoholism—for which treatment is directed at the primary disorder. Jealousy is a powerful emotion; when it occurs in delusional disorder or as part of another condition, it can be potentially dangerous and has been associated with violence, notably both suicide and homicide (Fig. 7.4-1). The forensic aspects of the symptom have been noted repeatedly, especially its role as a motive for murder. Physical and verbal abuse occur more frequently, however, than do extreme actions among individuals with this symptom. Caution and care in deciding how to deal with such presentations are essential not only for diagnosis but also from the point of view of safety.

FIGURE 7.4-1

A detail from the painting *An Allegory with Venus and Cupid* by Bronzino depicting a jealous lover. There is a high risk of homicide when morbid jealousy becomes the dominant theme in a relationship in which one partner is jealous of the other. That rage is well-depicted in Bronzino's painting.

Mr. M was a 51-year-old married white man who lived with his wife in their own home and who worked full time driving a sanitation truck. Before his hospitalization, he became concerned that his wife was having an affair. He began to follow her, kept notes on his observations, and badgered her constantly about this, often waking her up in the middle of the night to make accusations. Shortly before admission, these arguments led to physical violence, and he was brought to the hospital by police. In addition to concerns about his wife's fidelity, Mr. M reported feelings of depression over his wife's "betrayal of [their] marriage vows," but he noted no changes in sleep, appetite, or work-related functioning. He was treated with a low dose of an antipsychotic medication and described being less concerned about his wife's behavior. After discharge, he remained on medications and was seen by a psychiatrist monthly, but 10 years later, he continued to believe that his wife was unfaithful. His wife noted that he sometimes became upset about the delusion but that he had not become aggressive or required readmission.

This patient experienced a fixed, encapsulated delusion of jealousy that did not interfere with his other activities and that showed a partial response to antipsychotic medications. Although he initially reported feeling somewhat depressed over his wife's perceived infidelity, he did not have other symptoms suggestive of a major depressive episode. (Courtesy of Laura J. Fochtmann, M.D., Ramin Mojtabai, M.D., Ph.D., M.P.H., and Evelyn J. Bromet, Ph.D.)

Erotomaniac Type

In erotomania, which has also been referred to as *de Clérambault syndrome* or *psychose passionnelle*, the patient has the delusional conviction that another person, usually of higher status, is in love with him or her. Such patients also tend to be solitary, withdrawn, dependent, and sexually inhibited as well as to have poor levels of social or occupational functioning. The following operational criteria for the diagnosis of erotomania have been suggested: (1) a delusional conviction of amorous communication, (2) object of much higher rank, (3) object being the first to fall in love, (4) object being the first to make advances, (5) sudden onset (within a 7-day period), (6) object remains unchanged, (7) patient rationalizes paradoxical behavior of the object, (8) chronic course, and (9) absence of hallucinations. Besides being the key symptom in some cases of delusional disorder, it is known to occur in schizophrenia, mood disorder, and other organic disorders.

Patients with erotomania frequently show certain characteristics: They are generally unattractive women in low-level jobs who lead withdrawn, lonely lives; they are single and have few sexual contacts. They select secret lovers who differ substantially from them. They exhibit what has been called *paradoxical conduct*, the delusional phenomenon of interpreting all denials of love, no matter how clear, as secret affirmations of love. The course may be chronic, recurrent, or brief. Separation from the love object may be the only satisfactory intervention. Although men are less commonly affected by this condition than women, they may be more aggressive and possibly violent in their pursuit of love. Hence, in forensic populations, men with this condition predominate. The object of aggression may not be the loved individual but companions or protectors of the love object who are viewed as trying to come between the lovers. The tendency toward violence among men with erotomania may lead initially to police, rather than psychiatric, contact. In certain cases, resentment and rage in response to an absence of reaction from all forms of love communication may sufficiently escalate to put the love object in danger. So-called stalkers, who continually follow their perceived lovers, frequently have delusions. Although most stalkers are men, women also stalk, and both groups have a high potential for violence.

Mrs. D was a 32-year-old nurse who was married and had two children. She had worked in the hospital for 12 years and functioned well in her job. She had previously believed that one of the hospital's attending physicians was in love with her. Now she was referred by her supervisor for a psychiatric evaluation after she had assaulted one of the residents, claiming he was in love with her. Her current delusion began when the young physician entered a room where she was lying in bed after cosmetic surgery and pointed at her. She had not known him before, but at that moment she became convinced that he was in love with her. She tried to approach him several times

by letter and phone, and although he did not respond, she was convinced that he was trying to transmit his love through looks he gave her and through the tone of his voice. She did not report any associated hallucinatory experiences. The resident met her and denied being in love with her, but she began stalking him, culminating in the assault and the request for consultation.

Mrs. D initially refused to take any medications. She was treated with psychotherapy for several months, during which she continued to work and was able to avoid contact with the resident. The therapist arranged a three-way meeting with himself, the patient, and the resident. After this meeting, there was a small reduction in the intensity of Mrs. D's belief, but she continued to maintain it nonetheless. She subsequently agreed to take antipsychotic medications and was given perphenazine 16 mg per day, but there was no improvement. The delusion subsided only after the resident moved to another hospital.

This patient's presentation demonstrates a number of the features of the erotomanic type of delusional disorder. In particular, her delusion began abruptly with what she perceived to be a specific response to her by the resident. Her delusional conviction that he was in love with her persisted even after being confronted, and she rationalized his lack of apparent interest in her. The presence of a previous episode and the poor response to antipsychotic medications are consistent with the often chronic nature of the disorder, albeit with a different person being the object of her delusions. The absence of hallucinations and the preservation of her ability to function suggest a diagnosis of delusional disorder rather than schizophrenia. (Example provided by S. Fennig and originally published in Fennig S, Fochtmann LJ, Bromet EJ. Delusional disorder and shared psychotic disorder. In: Sadock BJ, Sadock VA, eds. *Kaplan and Sadock's Comprehensive Textbook of Psychiatry*. 8th edition. Philadelphia: Lippincott Williams & Wilkins; 2005:1525.)

Somatic Type

Delusional disorder with somatic delusions has been called *monosymptomatic hypochondriacal psychosis*. The condition differs from other conditions with hypochondriacal symptoms in the degree of reality impairment. In delusional disorder, the delusion is fixed, unarguable, and presented intensely because the patient is totally convinced of the physical nature of the disorder. In contrast, persons with hypochondriasis often admit that their fear of illness is largely groundless. The content of the somatic delusion can vary widely from case to case. The three main types are (1) delusions of infestation (including parasitosis); (2) delusions of dysmorphophobia, such as of misshapeness, personal ugliness, or exaggerated size of body parts (this category seems closest to that of body dysmorphic disorder); and (3) delusions of foul body odors or halitosis. This third category, sometimes referred to as *olfactory reference syndrome*, appears somewhat different from the category of delusions of infestation in that patients with the former have an earlier age of onset (mean, 25 years), male predominance, single status, and absence of past psychiatric treatment. Otherwise, the three groups, although individually low in prevalence, appear to overlap.

The onset of symptoms with the somatic type of delusional disorder may be gradual or sudden. In most patients, the illness is unremitting, although the delusion severity may fluctuate. Hyperalertness and high anxiety also characterize patients with this subtype. Some themes recur, such as concerns about infestation in delusional parasitosis, preoccupation with body features with the dysmorphic delusions, and delusional concerns about body odor, which are sometimes referred to as *bromosis*. In delusional parasitosis, tactile sensory phenomena are often linked to the delusional beliefs.

Patients with the somatic type of delusional disorder rarely present for psychiatric evaluation, and when they do, it is usually in the context of a psychiatric consultation or liaison service. Instead, patients generally present to a specific medical specialist for evaluation. Thus, these individuals are more often encountered by dermatologists, plastic surgeons, urologists, acquired immune deficiency syndrome (AIDS) specialists, and sometimes dentists or gastroenterologists.

Ms G. was a 56-year-old homemaker and mother of two who was hospitalized in the burn unit for wound care and skin grafting after sustaining chemical burns to her trunk and extremities. Six months before admission, Ms. G had become increasingly convinced that tiny bugs had burrowed underneath her skin. She tried to rid herself of them by washing multiple times each day with medicated soap and lindane shampoo. She also visited several dermatologists and had provided samples of "dead bugs" for them to examine under the microscope. All told her there was nothing wrong with her and suggested that her problems were psychiatric in nature. She became increasingly distressed by the infestation and worried that the bugs might invade her other organs if not eradicated. Consequently, she decided to asphyxiate the bugs by covering her body with gasoline and holding it against her skin with plastic wrap. She noted that her skin became red and felt as though it were burning, but she viewed this as a positive sign that the bugs were being killed and writhing around as they died. Several hours after she had applied the gasoline, her daughter came to the house, saw Ms. G's condition, and took her to the hospital. When evaluated in the burn unit, Ms. G spoke openly of her concerns about the bugs and was still unsure whether they were present or not. At the same time, she recognized that it had been a mistake to try to kill them with gasoline. She was oriented to person, place, and time and had no other delusional beliefs or auditory or visual hallucinations. She said her mood was "okay," although she was realistically concerned about the extensive treatment that she would require and the difficult process of recovering from her injury. She reported no suicidal ideas or intent before admission and had no history of psychiatric treatment. She also did not report any use of substances except for drinking several beers socially about twice each month. During her stay in the hospital, she was treated with haloperidol in doses of up to 5 mg per day with improvement in her delusions.

This patient demonstrates a classic presentation of delusional parasitosis, including the repeated visits to other physicians, the absolute conviction that an infestation is present, and the collection of "evidence" to support this belief. The lack of a significant history of alcohol or substance use suggests that the sensation of bugs crawling on her skin was not associated with substance intoxication or withdrawal. She also did not have disorientation or fluctuations in her level of consciousness that would suggest delirium, other psychotic symptoms that would suggest schizophrenia, or depressive symptoms that would suggest major depressive disorder with psychotic features. (Courtesy of Laura J. Fochtmann, M.D., Ramin Mojtabai, M.D., Ph.D., M.P.H., and Evelyn J. Bromet, Ph.D.)

Grandiose Type

Delusions of grandeur (megalomania) have been noted for years. They were first described by Kraepelin.

A 51-year-old man was arrested for disturbing the peace. Police had been called to a local park to stop him from carving his initials and those of a recently formed religious cult into various trees surrounding a pond in the park. When confronted, he had scornfully argued that having been chosen to begin a new town-wide religious revival, it was necessary for him to publicize his intent in a permanent fashion. The police were unsuccessful in preventing the man from cutting another tree and arrested him. Psychiatric examination was ordered at the state hospital, and the patient was observed there for several weeks. He denied any emotional difficulty and had never received psychiatric treatment. He had no history of euphoria or mood swings. The patient was angry about being hospitalized and only gradually permitted the doctor to interview him. In a few days, however, he was busy preaching to his fellow patients and letting them know that he had been given a special mandate from God to bring in new converts through his ability to heal. Eventually, his preoccupation with special powers diminished, and no other evidence of psychopathology was observed. The patient was

discharged, having received no medication at all. Two months later he was arrested at a local theater, this time for disrupting the showing of a film that depicted subjects he believed to be satanic.

Mixed Type

The category mixed type applies to patients with two or more delusional themes. This diagnosis should be reserved for cases in which no single delusional type predominates.

Unspecified Type

The category unspecified type is reserved for cases in which the predominant delusion cannot be subtyped within the previous categories. A possible example is certain delusions of misidentification, for example, Capgras syndrome, named for the French psychiatrist who described the *illusion des sosies*, or the illusion of doubles. The delusion in Capgras syndrome is the belief that a familiar person has been replaced by an impostor. Others have described variants of the Capgras syndrome, namely, the delusion that persecutors or familiar persons can assume the guise of strangers (*Frégoli's phenomenon*) and the very rare delusion that familiar persons can change themselves into other persons at will (*intermetamorphosis*). Each disorder is not only rare but may also be associated with schizophrenia, dementia, epilepsy, and other organic disorders. Reported cases have been predominantly in women, have had associated paranoid features, and have included feelings of depersonalization or derealization. The delusion may be short lived, recurrent, or persistent. It is unclear whether delusional disorder can appear with such a delusion. Certainly, the Frégoli and intermetamorphosis delusions have bizarre content and are unlikely, but the delusion in Capgras syndrome is a possible candidate for delusional disorder. The role of hallucination or perceptual disturbance in this condition needs to be explicated. Cases have appeared after sudden brain damage.

In the 19th century, the French psychiatrist Jules Cotard described several patients with a syndrome called *délire de négation*, sometimes referred to as *nihilistic delusional disorder* or *Cotard syndrome*. Patients with the syndrome complain of having lost not only possessions, status, and strength but also their heart, blood, and intestines. The world beyond them is reduced to nothingness. This relatively rare syndrome is usually considered a precursor to a schizophrenic or depressive episode. With the common use today of antipsychotic drugs, the syndrome is seen even less frequently than in the past.

SHARED PSYCHOTIC DISORDER

Shared psychotic disorder (also referred to over the years as *shared paranoid disorder*, *induced psychotic disorder*, *folie impose*, and *double insanity*) was first described by two French psychiatrists, Lasegue and Falret, in 1877, who named it *folie á deux*. In DSM-5, this disorder is referred to as "Delusional Symptoms in Partner of Individual with Delusional Disorder," an unnecessary nomenclature change in the view of most psychiatrists. It is probably rare, but incidence and prevalence figures are lacking, and the literature consists almost entirely of case reports.

The disorder is characterized by the transfer of delusions from one person to another. Both persons are closely associated for a long time and typically live together in relative social isolation. In its most common form, the individual who first has the delusion (the primary case) is often chronically ill and typically is the influential member of a close relationship with a more suggestible person (the secondary case) who also develops the delusion. The person in the secondary case is frequently less intelligent, more gullible, more passive, or more lacking in self-esteem than the person in the primary case. If the pair separates, the secondary person may abandon the delusion, but this outcome is not seen uniformly. The occurrence of the delusion is attributed to the strong influence of the more dominant member. Old age, low intelligence, sensory impairment, cerebrovascular disease, and alcohol abuse are among the factors associated with this peculiar form of psychotic disorder. A genetic predisposition to idiopathic psychoses has also been suggested as a possible risk factor.

Other special forms have been reported, such as *folie simultanée*, in which two persons become psychotic simultaneously and share the same delusion. Occasionally, more than two individuals are involved (e.g., *folie á trois*, *quatre*, *cing*; also *folie á famille*), but such cases are especially rare. The most common relationships in shared psychotic disorder are sister–sister, husband–wife, and mother–child, but other combinations have also been described. Almost all cases involve members of a single family.

A 52-year-old man was referred by the court for inpatient psychiatric examination, charged with disturbing the peace. He had been arrested for disrupting a trial, complaining of harassment by various judges. He had walked into a courtroom, marched to the bench, and begun to berate the probate judge. While in the hospital, he related a detailed account of conspiratorial goings-on in the local judiciary. A target of certain judges, he claimed he had been singled out for a variety of reasons for many years: he knew what was going on; he had kept records of wrongdoings; and he understood the significance of the whole matter. He refused to elaborate on the specific nature of the conspiracy. He had responded to it with frequent letters to newspapers, the local bar association, and even to a Congressional subcommittee. His mental state, apart from his story and a mildly depressed mood, was entirely normal.

A family interview revealed that his wife and several grown children shared the belief in a judicial conspiracy directed against the patient. There was no change in delusional thinking in the patient or the family after ten days of observation. The patient refused follow-up.

In this case, protection is provided by others who share the delusion and believe in the reasonableness of the response; such cases are uncommon, if not rare. (Courtesy of TC Manschreck, M.D.)

DIFFERENTIAL DIAGNOSIS

Medical Conditions

In making a diagnosis of delusional disorder, the first step is to eliminate medical disorders as a potential cause of delusions. Many medical conditions can be associated with the development of delusions (Table 7.4-3), at times accompanying a delirious state.

 **Table 7.4-3**
Potential Medical Etiologies of Delusional Syndromes

Disease or Disorder Class	Examples
Neurodegenerative disorders	Alzheimer's disease, Pick's disease, Huntington's disease, basal ganglia calcification, multiple sclerosis, metachromatic leukodystrophy
Other central nervous system disorders	Brain tumors, especially temporal lobe and deep hemispheric tumors; epilepsy, especially complex partial seizure disorder; head trauma (subdural hematoma); anoxic brain injury; fat embolism
Vascular disease	Atherosclerotic vascular disease, especially when associated with diffuse, temporoparietal, or subcortical lesions; hypertensive encephalopathy; subarachnoid hemorrhage, temporal arteritis
Infectious disease	Human immunodeficiency virus or acquired immune deficiency syndrome, encephalitis lethargica, Creutzfeldt-Jakob disease, syphilis, malaria, acute viral encephalitis
Metabolic disorder	Hypercalcemia, hyponatremia, hypoglycemia, uremia, hepatic encephalopathy, porphyria
Endocrinopathies	Addison's disease, Cushing's syndrome, hyper- or hypothyroidism, panhypopituitarism
Vitamin deficiencies	Vitamin B ₁₂ deficiency, folate deficiency, thiamine deficiency, niacin deficiency
Medications	Adrenocorticotrophic hormones, anabolic steroids, corticosteroids, cimetidine, antibiotics (cephalosporins, penicillin), disulfiram, anticholinergic agents
Substances	Amphetamines, cocaine, alcohol, cannabis, hallucinogens
Toxins	Mercury, arsenic, manganese, thallium

Toxic-metabolic conditions and disorders affecting the limbic system and basal ganglia are most often associated with the emergence of delusional beliefs. Complex delusions occur more frequently in patients with subcortical pathology. In Huntington's disease and in individuals with idiopathic basal ganglia calcifications, for example, more than 50 percent of patients demonstrated delusions at some point in their illness. After right cerebral infarction, types of delusions that are more prevalent include anosognosia and reduplicative paramnesia (i.e., individuals believing they are in different places at the same time). Capgras syndrome has been observed in a number of medical disorders, including CNS lesions, vitamin B₁₂ deficiency, hepatic encephalopathy, diabetes, and hypothyroidism. Focal syndromes have more often involved the right rather than the left hemisphere. Delusions of infestation, lycanthropy (i.e., the false belief that the patient is an animal, often a wolf or "werewolf"), heutoscopy (i.e., the false belief that one has a double), and erotomania have been reported in small numbers of patients with epilepsy, CNS lesions, or toxic-metabolic disorders.

Delirium, Dementia, and Substance-Related Disorders

Delirium and dementia should be considered in the differential diagnosis of a patient with delusions. Delirium can be differentiated by the presence of a fluctuating level of consciousness or impaired cognitive abilities. Delusions early in the course of a dementing illness, as in dementia of the Alzheimer's type, can give the appearance of a delusional disorder; however, neuropsychological testing usually detects cognitive impairment. Although alcohol abuse is an associated feature for patients with delusional disorder, delusional disorder should be distinguished from alcohol-induced psychotic disorder with hallucinations. Intoxication with sympathomimetics (including amphetamine), marijuana, or L-dopa is likely to result in delusional symptoms.

Other Disorders

The psychiatric differential diagnosis for delusional disorder includes malingering and factitious disorder with predominantly psychological signs and symptoms. The nonfactitious disorders in the differential diagnosis are schizophrenia, mood disorders, obsessive-compulsive disorder, somatoform disorders, and paranoid personality disorder. Delusional disorder is distinguished from schizophrenia by the absence of other schizophrenic symptoms and by the nonbizarre quality of the delusions; patients with delusional disorder also lack the impaired functioning seen in schizophrenia. The somatic type of delusional disorder may resemble a depressive disorder or a somatoform disorder. The somatic type of delusional disorder is differentiated from depressive disorders by the absence of other signs of depression and the lack of a pervasive quality to the depression. Delusional disorder can be differentiated from somatoform disorders by the degree to which the somatic belief is held by the patient. Patients with somatoform disorders allow for the possibility that their disorder does not exist, but patients with delusional disorder do not doubt its reality. Separating paranoid personality disorder from delusional disorder requires the sometimes difficult clinical distinction between extreme suspiciousness and frank delusion. In general, if clinicians doubt that a symptom is a delusion, the diagnosis of delusional disorder should not be made.

COURSE AND PROGNOSIS

Some clinicians and some research data indicate that an identifiable psychosocial stressor often accompanies the onset of delusional disorder. The nature of the stressor, in fact, may warrant some suspicion or concern. Examples of such stressors are recent immigration, social conflict with family members or friends, and social isolation. A sudden onset is generally thought to be more common than an insidious onset. Some clinicians believe that a person with delusional disorder is likely to have below-average intelligence and that the premorbid personality of such a person is likely to be extroverted, dominant, and hypersensitive. The person's initial suspicions or concerns gradually become elaborate, consume much of the person's attention, and finally become delusional. Persons may begin quarreling with coworkers; may seek protection from the Federal Bureau of Investigation (FBI) or the police; or may begin visiting many medical or surgical physicians to seek consultations, lawyers about suits, or police about delusional suspicions.

As mentioned, delusional disorder is considered a fairly stable diagnosis. About 50 percent of patients have recovered at long-term follow-up, 20 percent show decreased symptoms, and 30 percent exhibit no change. The following factors correlate with a good prognosis: high levels of occupational, social, and functional adjustments; female sex; onset before age 30 years; sudden onset; short duration of illness; and the presence of precipitating factors. Although reliable data are limited, patients with persecutory, somatic, and erotic delusions are thought to have a better prognosis than patients with grandiose and jealous delusions.

TREATMENT

Delusional disorder was generally regarded as resistant to treatment, and interventions often focused on managing the morbidity of the disorder by reducing the impact of the delusion on the patient's (and family's) life. In recent years, however, the outlook has become less pessimistic or restricted in planning effective treatment. The goals of treatment are to establish the diagnosis, to decide on appropriate interventions, and to manage complications (Table 7.4-4). The success of these goals depends on an effective and therapeutic doctor-patient relationship, which is far from easy to establish. The patients do not complain about psychiatric symptoms and often enter treatment against their will; even psychiatrists may be drawn into their delusional nets.

 **Table 7.4-4**
Diagnosis and Management of Delusional Disorder

Rule out other causes of paranoid features
Confirm the absence of other psychopathology
Assess consequences of delusion-related behavior
Demoralization
Despondency
Anger, fear
Depression
Impact of search for "medical diagnosis," "legal solution," "proof of infidelity," and so on (e.g., financial, legal, personal, occupational)
Assess anxiety and agitation
Assess potential for violence, suicide
Assess need for hospitalization
Institute pharmacological and psychological therapies
Maintain connection through recovery

In shared psychiatric disorder, the patients must be separated. If hospitalization is indicated, they should be placed on different units and have no contact. In general, the healthier of the two will give up the delusional belief (sometimes without any other therapeutic intervention). The sicker of the two will maintain the false fixed belief.

Psychotherapy

The essential element in effective psychotherapy is to establish a relationship in which patients begin to trust a therapist. Individual therapy seems to be more effective than group therapy; insight-oriented, supportive, cognitive, and behavioral therapies are often effective. Initially, a therapist should neither agree with nor challenge a patient's delusions. Although therapists must ask about a delusion to establish its extent, persistent questioning about it should probably be avoided. Physicians may stimulate the motivation to receive help by emphasizing a willingness to help patients with their anxiety or irritability without suggesting that the delusions be treated, but therapists should not actively support the notion that the delusions are real.

The unwavering reliability of therapists is essential in psychotherapy. Therapists should be on time and make appointments as regularly as possible, with the goal of developing a solid and trusting relationship with a patient. Overgratification may actually increase patients' hostility and suspiciousness because ultimately they must realize that not all demands can be met. Therapists can avoid overgratification by not extending the designated appointment period, by not giving extra appointments unless absolutely necessary, and by not being lenient about the fee.

Therapists should avoid making disparaging remarks about a patient's delusions or ideas but can sympathetically indicate to patients that their preoccupation with their delusions is both distressing to themselves and interferes with a constructive life. When patients begin to waver in their delusional beliefs, therapists may increase reality testing by asking the patients to clarify their concerns.

A useful approach in building a therapeutic alliance is to empathize with the patient's internal experience of being overwhelmed by persecution. It may be helpful to make such comments as, "You must be exhausted, considering what you have been through." Without agreeing with every delusional misperception, a therapist can acknowledge that from the patient's perspective, such perceptions create much distress. The ultimate goal is to help patients entertain the possibility of doubt about their perceptions. As they become less rigid, feelings of weakness and inferiority, associated with some depression, may surface. When a patient allows feelings of vulnerability to enter into the therapy, a positive therapeutic alliance has been established, and constructive therapy becomes possible.

When family members are available, clinicians may decide to involve them in the treatment plan. Without being delusionally seen as siding with the enemy, a clinician should attempt to enlist the family as allies in the treatment process. Consequently, both the patient and the family need to understand that the therapist maintains physician-patient confidentiality and that communications from relatives are discussed with the patient. The family may benefit from the therapist's support and thus may support the patient.

A good therapeutic outcome depends on a psychiatrist's ability to respond to the patient's mistrust of others and the resulting interpersonal conflicts, frustrations, and failures. The mark of successful treatment may be a satisfactory social adjustment rather than abatement of the patient's delusions.

Hospitalization

Patients with delusional disorder can generally be treated as outpatients, but clinicians should consider hospitalization for several reasons. First, patients may need a complete medical and neurological evaluation to determine whether a nonpsychiatric medical condition is causing the delusional symptoms. Second, patients need an assessment of their ability to control violent impulses (e.g., to commit suicide or homicide) that may be related to the delusional material. Third, patients' behavior about the delusions may have significantly affected their ability to function within their family or occupational settings; they may require professional intervention to stabilize social or occupational relationships.

If a physician is convinced that a patient would receive the best treatment in a hospital, then the physician should attempt to persuade the patient to accept hospitalization; failing that, legal commitment may be indicated. If a physician convinces a patient that hospitalization is inevitable, the patient often voluntarily enters a hospital to avoid legal commitment.

Pharmacotherapy

In an emergency, severely agitated patients should be given an antipsychotic drug intramuscularly. Although no adequately conducted clinical trials with large numbers of patients have been conducted, most clinicians consider antipsychotic drugs the treatment of choice for delusional disorder. Patients are likely to refuse medication because they can easily incorporate the administration of drugs into their delusional systems; physicians should not insist on medication immediately after hospitalization but, rather, should spend a few days establishing rapport with the patient. Physicians should explain potential adverse effects to patients, so that they do not later suspect that the physician lied.

A patient's history of medication response is the best guide to choosing a drug. A physician should often start with low doses (e.g., 2 mg of haloperidol [Haldol] or 2 mg of risperidone [Risperdal]) and increase the dose slowly. If a patient fails to respond to the drug at a reasonable dosage in a 6-week trial, antipsychotic drugs from other classes should be tried. Some investigators have indicated that pimozide may be particularly effective in delusional disorder, especially in patients with somatic delusions. A common cause of drug failure is noncompliance, which should also be evaluated. Concurrent psychotherapy facilitates compliance with drug treatment.

If the patient receives no benefit from antipsychotic medication, discontinue use of the drug. In patients who do respond to antipsychotic drugs, some data indicate that maintenance doses can be low. Although essentially no studies evaluate the use of antidepressants, lithium (Eskalith), or anticonvulsants (e.g., carbamazepine [Tegretol] and valproate [Depakene]) in the treatment of delusional disorder, trials with these drugs may be warranted in patients who do not respond to antipsychotic drugs. Trials of these drugs should also be considered when a patient has either the features of a mood disorder or a family history of mood disorders.

7.5 Brief Psychotic Disorder, Other Psychotic Disorders, and Catatonia

BRIEF PSYCHOTIC DISORDER

Brief psychotic disorder is defined as a psychotic condition that involves the sudden onset of psychotic symptoms, which lasts 1 day or more but less than 1 month. Remission is full, and the individual returns to the premorbid level of functioning. Brief psychotic disorder is an acute and transient psychotic syndrome.

History

Brief psychotic disorder has been poorly studied in psychiatry in the United States, partly because of the frequent changes in diagnostic criteria during the past 15 years. The diagnosis has been better appreciated and more completely studied in Scandinavia and other Western European countries than in the United States. Patients with disorders similar to brief psychotic disorder were previously classified as having reactive, hysterical, stress, and psychogenic psychoses.

Reactive psychosis was often used as a synonym for good-prognosis schizophrenia, but a diagnosis of brief psychotic disorder is not meant to imply a relation with schizophrenia. In 1913, Karl Jaspers described several essential features for the diagnosis of reactive psychosis, including an identifiable and extremely traumatic stressor, a close temporal relation between the stressor and the development of the psychosis, and a generally benign course for the psychotic episode. Jaspers also stated that the content of the psychosis often reflected the nature of the traumatic experience and that the development of the psychosis seemed to serve a purpose for the patient, often as an escape from a traumatic condition.

Epidemiology

The exact incidence and prevalence of brief psychotic disorder is not known, but it is generally considered uncommon. The disorder occurs more often among younger patients (20s and 30s) than among older patients. Brief psychotic disorder is more common in women than in men. Such epidemiological patterns are sharply distinct from those of schizophrenia. Some clinicians indicate that the disorder may be seen most frequently in patients from low socioeconomic classes and in those who have experienced disasters or major cultural changes (e.g., immigrants). The age of onset in industrialized settings may be higher than in developing countries. Persons who have gone through major psychosocial stressors may be at greater risk for subsequent brief psychotic disorder.

Comorbidity

The disorder is often seen in patients with personality disorders (most commonly, histrionic, narcissistic, paranoid, schizotypal, and borderline personality disorders).

Etiology

The cause of brief psychotic disorder is unknown. Patients who have a personality disorder may have a biological or psychological vulnerability for the development of psychotic symptoms, particularly those with borderline, schizoid, schizotypal, or paranoid qualities. Some patients with brief psychotic disorder have a history of schizophrenia or mood disorders in their families, but this finding is nonconclusive. Psychodynamic formulations have emphasized the presence of inadequate coping mechanisms and the possibility of secondary gain for patients with psychotic symptoms. Additional psychodynamic theories suggest that the psychotic symptoms are a defense against a prohibited fantasy, the fulfillment of an unattained wish, or an escape from a stressful psychosocial situation.

Diagnosis

A diagnosis of brief psychotic disorder is appropriate when psychotic symptoms last at least 1 day but less than 1 month and are not associated with a mood disorder, a substance-related disorder, or a psychotic disorder caused by a general medical condition. There are three subtypes of brief psychotic disorder: (1) the presence of a stressor, (2) the absence of a stressor, and (3) a postpartum onset. As with other acutely ill psychiatric patients, the history necessary to make the diagnosis may not be obtainable solely from the patient. Although psychotic symptoms may be obvious, information about prodromal symptoms, previous episodes of a mood disorder, and a recent history of ingestion of a psychotomimetic substance may not be available from the clinical interview alone. In addition, clinicians may not be able to obtain accurate information about the presence or absence of precipitating stressors. Such information is usually best and most accurately obtained from a relative or a friend.

Clinical Features

The symptoms of brief psychotic disorder always include at least one major symptom of psychosis, such as hallucinations, delusions, and disorganized thoughts, usually with an abrupt onset, but do not always include the entire symptom pattern seen in schizophrenia. Some clinicians have observed that labile mood, confusion, and impaired attention may be more common at the onset of brief psychotic disorder than at the onset of eventually chronic psychotic disorders. Characteristic symptoms in brief psychotic disorder include emotional volatility, strange or bizarre behavior, screaming or muteness, and impaired memory of recent events. Some of the symptoms suggest a diagnosis of delirium and warrant a medical workup, especially to rule out adverse reactions to drugs.

Scandinavian and other European literature describes several characteristic symptom patterns in brief psychotic disorder, although these may differ somewhat in Europe and America. The symptom patterns include acute paranoid reactions and reactive confusion, excitation, and depression. Some data suggest that, in the United States, paranoia is often the predominant symptom in the disorder. In French psychiatry, *bouffée délirante* is similar to brief psychotic disorder.

Precipitating Stressors. The clearest examples of precipitating stressors are major life events that would cause any person significant emotional upset. Such events include the loss of a close family member or a severe automobile accident. Some clinicians argue that the severity of the event must be considered in relation to the patient's life. This view, although reasonable, may broaden the definition of precipitating stressor to include events unrelated to the psychotic episode. Others have argued that the stressor may be a series of modestly stressful events rather than a single markedly stressful event, but evaluating the amount of stress caused by a sequence of events calls for an almost impossibly high degree of clinical judgment.

A 20-year-old man was admitted to the psychiatric ward of a hospital shortly after starting military duty. During the first week after his arrival to the military base, he thought the other recruits looked at him in a strange way. He watched the people around him to see whether they were out "to get" him. He heard voices calling his name several times. He became increasingly suspicious and after another week had to be admitted for psychiatric evaluation. There he was guarded, scowling, skeptical, and depressed. He gave the impression of being very shy and inhibited. His psychotic symptoms disappeared rapidly when he was treated with an antipsychotic drug. However, he had difficulties in adjusting to hospital life. Transfer to a long-term medical hospital was considered, but after 3 months, a decision was made to discharge him to his home. He was subsequently judged unfit to return to military services.

The patient was the eldest of five siblings. His father was an intemperate drinker who became angry and brutal when drunk. The family was poor, and there were constant fights between the parents. As a child, the patient was inhibited and fearful and often ran into the woods when troubled. He had academic difficulties.

When the patient got older, he preferred to spend time alone and disliked being with people. He occasionally took part in local parties. Although he was never a heavy drinker, he often got into fights when he had a drink or two.

The patient was reinterviewed by hospital personnel at 4 years, 7 years, and 23 years after his admission. He has had no recurrences of any psychotic symptoms and has been fully employed since 6 months after he left the hospital. He married, and at the last follow-up, he had two grown children.

After leaving the hospital, the patient worked for 2 years in a factory. For the past 20 years, he has managed a small business, and it has run well. He has been very happy at work and in his family life. He has made an effort to overcome his tendency toward isolation and has several friends.

The patient believes that his natural tendency is to be socially isolated and that his disorder was connected with the fact that in the military, he was forced to deal with other people. (Adapted from Laura J. Fochtmann, M.D., Ramin Mojtabai, M.D., Ph.D., M.P.H., and Evelyn J. Bromet, Ph.D.)

Differential Diagnosis

Clinicians must not assume that the correct diagnosis for a patient who is briefly psychotic is brief psychotic disorder, even when a clear precipitating psychosocial factor is identified. Such a factor may be merely coincidental. If psychotic symptoms are present longer than 1 month, the diagnoses of schizophreniform disorder, schizoaffective disorder, schizophrenia, mood disorders with psychotic features, delusional disorder, and psychotic disorder not otherwise specified must be entertained. If psychotic symptoms of sudden onset are present for less than 1 month in response to an obvious stressor, however, the diagnosis of brief psychotic disorder is strongly suggested. Other diagnoses to consider in the differential diagnosis include factitious disorder with predominantly psychological signs and symptoms, malingering, psychotic disorder caused by a general medical condition, and substance-induced psychotic disorder. In factitious disorder, symptoms are intentionally produced; in malingering, a specific goal is involved in appearing psychotic (e.g., to gain admission to the hospital); and when associated with a medical condition or drugs, the cause becomes apparent with proper medical or drug workups. If the patient admits to using illicit substances, the clinician can make the assessment of substance intoxication or substance withdrawal without the use of laboratory testing. Patients with epilepsy or delirium can also show psychotic symptoms that resemble those seen in brief psychotic disorder. Additional psychiatric disorders to be considered in the differential diagnosis include dissociative identity disorder and psychotic episodes associated with borderline and schizotypal personality disorders.

Course and Prognosis

By definition, the course of brief psychotic disorder is less than 1 month. Nonetheless, the development of such a significant psychiatric disorder may signify a patient's mental vulnerability. Approximately half of patients who are first classified as having brief psychotic disorder later display chronic psychiatric syndromes such as schizophrenia and mood disorders. Patients with brief psychotic disorder, however, generally have good prognoses, and European studies have indicated that 50 to 80 percent of all patients have no further major psychiatric problems.

The length of the acute and residual symptoms is often just a few days. Occasionally, depressive symptoms follow the resolution of the psychotic symptoms. Suicide is a concern during both the psychotic phase and the postpsychotic depressive phase. Several indicators have been associated with a good prognosis. See [Table 7.5-1](#) for a summary of good prognostic signs in brief psychotic disorder.

 **Table 7.5-1**
Good Prognostic Features for Brief Psychotic Disorder

Good premorbid adjustment
Few premorbid schizoid traits
Severe precipitating stressor
Sudden onset of symptoms
Affective symptoms
Confusion and perplexity during psychosis
Little affective blunting
Short duration of symptoms
Absence of relatives with schizophrenia

Treatment

Hospitalization. A patient who is acutely psychotic may need brief hospitalization for both evaluation and protection. Evaluation requires close monitoring of symptoms and assessment of the patient's level of danger to self and others. In addition, the quiet, structured setting of a hospital may help patients regain their sense of reality. While clinicians wait for the setting or the drugs to have their effects, seclusion, physical restraints, or one-to-one monitoring of the patient may be necessary.

Pharmacotherapy. The two major classes of drugs to be considered in the treatment of brief psychotic disorder are the antipsychotic drugs and the benzodiazepines. When an antipsychotic drug is chosen, a high-potency antipsychotic drug, such as haloperidol, or a serotonin dopamine agonist such as ziprasidone may be used. In patients who are at high risk for the development of extrapyramidal adverse effects (e.g., young men), a serotonin dopamine antagonist drug should be administered as prophylaxis against medication-induced movement disorder symptoms. Alternatively, benzodiazepines can be used in the short-term treatment of psychosis. Although benzodiazepines have limited or no usefulness in the long-term treatment of psychotic disorders, they can be effective for a short time and are associated with fewer adverse effects than the antipsychotic drugs. In rare cases, the benzodiazepines are associated with increased agitation and, more rarely still, with withdrawal seizures, which usually occur only with the sustained use of high dosages. The use of other drugs in the treatment of brief psychotic disorder, although reported in case studies, has not been supported in any large-scale studies. Anxiolytic medications, however, are often useful during the first 2 to 3 weeks after the resolution of the psychotic episode. Clinicians should avoid long-term use of any medication in the treatment of the disorder. If maintenance medication is necessary, a clinician may have to reconsider the diagnosis.

Psychotherapy. Although hospitalization and pharmacotherapy are likely to control short-term situations, the difficult part of treatment is the psychological integration of the experience (and possibly the precipitating trauma, if one was present) into the lives of the patients and their families. Psychotherapy is of use in providing an opportunity to discuss the stressors and the psychotic episode. Exploration and development of coping strategies are the major topics in psychotherapy. Associated issues include helping patients deal with the loss of self-esteem and to regain self-confidence. An individualized treatment strategy based on increasing problem-solving skills while strengthening the ego structure through psychotherapy appears to be the most efficacious. Family involvement in the treatment process may be crucial to a successful outcome.

PSYCHOTIC DISORDER NOT OTHERWISE SPECIFIED

Under the umbrella of psychosis not otherwise specified is a variety of clinical presentations that do not fit within current diagnostic rubrics. It includes psychotic symptomatology (i.e., delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior) about which there is inadequate information to make a specific diagnosis or about which there is contradictory information. It also includes disorders with psychotic symptoms that do not meet the criteria for any specific psychotic disorder, such as patients who present to hospital with persistent auditory hallucinations that are not accompanied by mood disturbances and that are not pathognomonic for schizophrenia.

Autoscopic Psychosis

Although not included in DSM-5, autoscopic psychosis is of clinical interest. The characteristic symptom of autoscopic psychosis is a visual hallucination of all or part of the person's own body. The hallucinatory perception, which is called a *phantom*, is usually colorless and transparent, and because the phantom imitates the person's movements, it is perceived as though appearing in a mirror. The phantom tends to appear suddenly and without warning.

Epidemiology. Autoscopy is a rare phenomenon. Some persons have an autoscopic experience only once or a few times; others have the experience more often. Although the data are limited, sex, age, heredity, and intelligence do not seem to be related to the occurrence of the syndrome.

Etiology. The cause of the autoscopic phenomenon is unknown. A biological hypothesis is that abnormal, episodic activity in areas of the temporoparietal lobes is involved with the sense of self, perhaps combined with abnormal activity in parts of the visual cortex. Psychological theories have associated the syndrome with personalities characterized by imagination; visual sensitivity; and, possibly, narcissistic personality disorder traits. Such persons may likely experience autoscopic phenomena during periods of stress.

Course and Prognosis. The classic descriptions of the phenomenon indicate that, in most cases, the syndrome is neither progressive nor incapacitating. Affected persons usually maintain some emotional distance from the phenomenon, an observation that suggests a specific neuroanatomical lesion. Rarely do the symptoms reflect the onset of schizophrenia or other psychotic disorders.

Treatment. Patients usually respond to antianxiety medication. In severe cases, antipsychotic medications may be needed.

Motility Psychosis

Motility psychosis is not considered an “official” DSM-5 diagnosis but is of clinical significance. It is probably a variant of brief psychotic disorder. The two forms of motility psychosis are akinetic and hyperkinetic. The akinetic form of motility psychosis has a clinical presentation similar to that of catatonic stupor. In contrast to the catatonic type of schizophrenia, however, akinetic motility psychosis has a rapidly resolving and favorable course that does not lead to personality deterioration. In its hyperkinetic form, motility psychosis can resemble manic or catatonic excitement. As with the akinetic form, the hyperkinetic form usually has a rapidly resolving and favorable course. Patients may switch from the akinetic to hyperkinetic form rapidly and may represent a danger to others during the excited phase. Mood is extremely labile in these patients.

Postpartum Psychosis

Postpartum psychosis (sometimes called *puerperal psychosis*) is an example of psychotic disorder not otherwise specified that occurs in women who have recently delivered a baby; the syndrome is most often characterized by the mother’s depression, delusions, and thoughts of harming either her infant or herself. For a more detailed discussion see [Section 21.1](#).

PSYCHOTIC DISORDERS DUE TO A GENERAL MEDICAL CONDITION AND SUBSTANCE- OR MEDICATION-INDUCED PSYCHOTIC DISORDER

The evaluation of a patient with psychotic disorders requires consideration of the possibility that the psychotic symptoms result from a general medical condition such as a brain tumor or the ingestion of a substance such as phencyclidine (PCP) or medication such as cortisol.

Epidemiology

Relevant epidemiological data about psychotic disorder caused by a general medical condition and substance-induced psychotic disorder are lacking. The disorders are most often encountered in patients who abuse alcohol or other substances on a long-term basis. The delusional syndrome that may accompany complex partial seizures is more common in women than in men.

Etiology

Physical conditions such as cerebral neoplasms, particularly of the occipital or temporal areas ([Fig. 7.5-1](#)), can cause hallucinations. Sensory deprivation, as in people who are blind or deaf, can also result in hallucinatory or delusional experiences. Lesions involving the temporal lobe and other cerebral regions, especially the right hemisphere and the parietal lobe, are associated with delusions.

FIGURE 7.5-1

Temporal meningioma. (From Rowland LP, Pedley TA. *Merritt’s Neurology*. 12th edition. Philadelphia: Lippincott Williams & Wilkins; 2010.)

Psychoactive substances are common causes of psychotic syndromes. The most commonly involved substances are alcohol, indole hallucinogens, such as lysergic acid diethylamide (LSD), amphetamine, cocaine, mescaline, PCP, and ketamine. Many other substances, including steroids and thyroxine, can produce hallucinations.

Diagnosis

Psychotic Disorder Due to a General Medical Condition. The diagnosis of psychotic disorder due to a general medical condition is defined by specifying the predominant symptoms. When the diagnosis is used, the medical condition, along with the predominant symptoms pattern, should be included in the diagnosis (e.g., psychotic disorder due to a brain tumor, with delusions). The disorder does not occur exclusively while a patient is delirious or demented, and the symptoms are not better accounted for by another mental disorder.

Substance- or Medication-Induced Psychotic Disorder. The diagnostic category of substance-induced psychotic disorder is reserved for those with psychotic symptoms and impaired reality testing caused by substances or medications. People with substance-induced psychotic symptoms (e.g., hallucinations) but with intact reality testing should be classified as having a substance-related disorder

(e.g., PCP intoxication with perceptual disturbances). The full diagnosis of substance-induced psychotic disorder should include the type of substance or medication involved, the stage of substance use when the disorder began (e.g., during intoxication or withdrawal), and the clinical phenomena (e.g., hallucinations or delusions). See Table 7.5-2 for the DSM-5 diagnostic criteria.

Table 7.5-2
DSM-5 Diagnostic Criteria for Substance- or Medication-Induced Psychotic Disorder

- A. Presence of one or both of the following symptoms:
 1. Delusions
 2. Hallucinations
 B. There is evidence from the history, physical examination, or laboratory findings of both (1) and (2):
 1. The symptoms in Criterion A developed during or soon after substance intoxication or withdrawal or after exposure to a medication.
 2. The involved substance or medication is capable of producing the symptoms in Criterion A.
 C. The disturbance is not better explained by a psychotic disorder that is not substance- or medication-induced. Such evidence of an independent psychotic disorder could include the following:
 The symptoms preceded the onset of the substance or medication use; the symptoms persist for a substantial period of time (e.g., about 1 month) after the cessation of acute withdrawal or severe intoxication; or there is other evidence of an independent non-substance- or medication-induced psychotic disorder (e.g., a history of recurrent non-substance- or medication-related episodes).
 D. The disturbance does not occur exclusively during the course of a delirium.
 E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Note: The diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the symptoms in Criterion A predominate in the clinical picture and when they are sufficiently severe to warrant clinical attention.

Coding note: The ICD-9-CM and ICD-10-CM codes for the [specific substance or medication]-induced psychotic disorders are indicated in the table below. Note that the ICD-10-CM code depends on whether or not there is a comorbid substance use disorder present for the same class of substance. If a mild substance use disorder is comorbid with the substance-induced psychotic disorder, the fourth position character is "1," and the clinician should record "mild [substance] use disorder" before the substance-induced psychotic disorder (e.g., "mild cocaine use disorder with cocaine-induced psychotic disorder"). If a moderate or severe substance use disorder is comorbid with the substance-induced psychotic disorder, the fourth position character is "2," and the clinician should record "moderate [substance] use disorder" or "severe [substance] use disorder," depending on the severity of the comorbid substance use disorder. If there is no comorbid substance use disorder (e.g., after a one-time heavy use of the substance), then the fourth position character is "9," and the clinician should record only the substance-induced psychotic disorder.

	ICD-10-CM			
	ICD-9-CM	With Use Disorder, Mild	With Use Disorder, Moderate or Severe	Without Use Disorder
Alcohol	291.9	F10.159	F10.259	F10.959
Cannabis	292.9	F12.159	F12.259	F12.959
Phencyclidine	292.9	F16.159	F16.259	F16.959
Other hallucinogen	292.9	F16.159	F16.259	F16.959
Inhalant	292.9	F18.159	F18.259	F18.959
Sedative, hypnotic or anxiolytic	292.9	F13.159	F13.259	F13.959
Amphetamine (or other stimulant)	292.9	F15.159	F15.259	F15.959
Cocaine	292.9	F14.159	F14.259	F14.959
Other (or unknown) substance	292.9	F19.159	F19.259	F19.959

Specify if (see Table 1 [in DSM-5] in the chapter "Substance-Related and Addictive Disorders" for diagnoses associated with substance class):

With onset during intoxication: If the criteria are met for intoxication with the substance and the symptoms develop during intoxication.

With onset during withdrawal: If the criteria are met for withdrawal from the substance and the symptoms develop and during, or shortly after, withdrawal.

Specify current severity:

Severity is rated by a quantitative assessment of the primary symptoms of psychosis, including delusions, hallucinations, abnormal psychomotor behavior, and negative symptoms. Each of these symptoms may be rated for its current severity (most severe in the last 7 days) on a 5-point scale ranging from 0 (not present) to 4 (present and severe). (See Clinician-Rated Dimensions of Psychosis Symptom Severity in the chapter "Assessment Measures.")

Note: Diagnosis of substance- or medication-induced psychotic disorder can be made without using this severity specifier.

Clinical Features

Hallucinations. Hallucinations can occur in one or more sensory modalities. Tactile hallucinations (e.g., a sensation of bugs crawling on the skin) are characteristic of cocaine use. Auditory hallucinations are usually associated with psychoactive substance abuse; auditory hallucinations can also occur in persons who are deaf. Olfactory hallucinations can result from temporal lobe epilepsy; visual hallucinations can occur in persons who are blind because of cataracts. Hallucinations are either recurrent or persistent and are experienced in a state of full wakefulness and alertness; a hallucinating patient shows no significant changes in cognitive functions. Visual hallucinations often take the form of scenes involving diminutive (lilliputian) human figures or small animals. Rare musical hallucinations typically feature religious songs. Patients with psychotic disorder caused by a general medical condition and substance-induced psychotic disorder may act on their hallucinations. In alcohol-related hallucinations, threatening, critical, or insulting third-person voices speak about the patients and may tell them to harm either themselves or others. Such patients are dangerous and are at significant risk for suicide or homicide. Patients may or may not believe that the hallucinations are real.

Delusions. Secondary and substance-induced delusions are usually present in a state of full wakefulness. Patients experience no change in the level of consciousness, although mild cognitive impairment may be observed. Patients may appear confused, disheveled, or eccentric, with tangential or even incoherent speech. Hyperactivity and apathy may be present, and an associated dysphoric mood is thought to be common. The delusions can be systematized or fragmentary, with varying content, but persecutory delusions are the most common.

Differential Diagnosis. Psychotic disorder due to a general medical condition and substance- or medication-induced psychotic disorder must be distinguished from delirium (in which patients have a clouded sensorium), from dementia (in which patients have major intellectual deficits), and from schizophrenia (in which patients have other symptoms of thought disorder and impaired functioning). Psychotic disorder due to a general medical condition and substance-induced psychotic disorder must also be differentiated from psychotic

mood disorders (in which other affective symptoms are pronounced).

Treatment

Treatment involves identifying the general medical condition or the particular substance involved. At that point, treatment is directed toward the underlying condition and the patient's immediate behavioral control. Hospitalization may be necessary to evaluate patients completely and to ensure their safety. Antipsychotic agents (e.g., olanzapine [Zyprexa] or haloperidol) may be necessary for immediate and short-term control of psychotic or aggressive behavior, although benzodiazepines may also be useful for controlling agitation and anxiety.

CATATONIC DISORDER

Catatonia is a new diagnostic category in DSM-5 introduced because it can occur over a broad spectrum of mental disorders, most often in severe psychotic and mood disorders. It can also be caused by an underlying medical condition or induced by a substance.

Definition

Catatonia is a clinical syndrome characterized by striking behavioral abnormalities that may include motoric immobility or excitement, profound negativism, or echolalia (mimicry of speech) or echopraxia (mimicry of movement). A diagnosis of catatonic disorder due to a general medical condition can be made if there is evidence that the condition is due to the physiological effects of a general medical condition. The diagnosis is not made if the catatonia is better explained by a primary mental disorder, such as schizophrenia or psychotic depression, or if catatonic symptoms occur exclusively within the course of delirium.

Epidemiology

Catatonia is an uncommon condition mostly seen in advanced primary mood or psychotic illnesses. Among inpatients with catatonia, 25 to 50 percent are related to mood disorders (e.g., major depressive episode, recurrent, with catatonic features), and approximately 10 percent are associated with schizophrenia. The prevalence of catatonia due to medical conditions of substances is unknown.

Etiology

Medical conditions that can cause catatonia include neurological disorders (e.g., nonconvulsive status epilepticus, and head trauma), infections (e.g., encephalitis), and metabolic disturbances (e.g., hepatic encephalopathy, hyponatremia, and hypercalcemia).

Medications that can cause catatonia include corticosteroids, immunosuppressants, and antipsychotic (i.e., neuroleptic) agents. Catatonic symptoms may be seen in extreme forms of neuroleptic-induced parkinsonism or neuroleptic malignant syndrome, a rare, potentially life-threatening disorder associated with fever, autonomic instability, impaired consciousness, and rigidity.

Diagnosis and Clinical Features

DSM-5 criteria for the diagnosis of catatonic disorder due to a general medical condition (Table 7.5-3) include behavioral changes characteristic of catatonia, evidence of a physiological basis for the symptoms, and exclusion of primary mental disorders and delirium. The diagnosis of catatonia due to a mental disorder is used when the disorder occurs in a psychiatric rather than another medical condition (Table 7.5-4). In either case, the signs and symptoms of catatonia are similar; it is the etiology that differs. Behavioral changes may include motoric immobility or excessive activity, extreme negativism or mutism, peculiarities of voluntary movement, and echolalia or echopraxia. Waxy flexibility, a form of artificial posturing often evident on physical examination, may be present (Fig. 7.5-2). Lethal catatonia is a rare advanced stage of the disorder that features fever and autonomic instability and may be fatal.

Table 7.5-3
DSM-5 Diagnostic Criteria for Catatonic Disorder Due to Another Medical Condition

- A. The clinical picture is dominated by three (or more) of the following symptoms:
 1. Stupor (i.e., no psychomotor activity; not actively relating to environment)
 2. Catalepsy (i.e., passive induction of a posture held against gravity)
 3. Waxy flexibility (i.e., slight, even resistance to positioning by examiner)
 4. Mutism (i.e., no, or very little, verbal response to instructions or external stimuli)
 5. Negativism (i.e., opposition or no response to instructions or external stimuli)
 6. Posturing (i.e., spontaneous and active maintenance of a posture against gravity)
 7. Mannerism (i.e., odd, circumstantial caricature of normal actions)
 8. Stereotypy (i.e., repetitive, abnormally frequent, non-goal-directed movements)
 9. Agitation, not influenced by external stimuli
 10. Grimacing
 11. Echolalia (i.e., mimicking another's speech)
 12. Echopraxia (i.e., mimicking another's movement)
 - B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct pathophysiological consequence of another medical condition.
 - C. The disturbance is not better explained by another mental disorder (e.g., manic episode).
 - D. The disturbance does not occur exclusively during the course of a delirium.
 - E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- Coding note:** Include the name of the medical condition in the name of the mental disorder (e.g., 2983.89 [F06.1] catatonic disorder due to hepatic encephalopathy). The other medical condition should be coded and listed separately immediately before the catatonic disorder due to the medical condition (e.g., 572.2 [K71.90] hepatic encephalopathy; 293.89 [F06.1] catatonic disorder due to hepatic encephalopathy).

Table 7.5-4
DSM-5 Diagnostic Criteria for Catatonia Associated with Another Mental Disorder

- A. The clinical picture is dominated by three (or more) of the following symptoms:
1. Stupor (i.e., not psychomotor activity; not actively relating to the environment)
 2. Catalepsy (i.e., passive induction of a posture held against gravity)
 3. Waxy flexibility (i.e., slight, even resistance to positioning by examiner)
 4. Mutism (i.e., no, or very little, verbal response [exclude if known aphasia])
 5. Negativism (i.e., opposition or no response to instructions or external stimuli)
 6. Posturing (i.e., spontaneous and active maintenance of a posture against gravity)
 7. Mannerism (i.e., odd, circumstantial caricature of normal actions)
 8. Stereotypy (i.e., repetitive, abnormally frequent, non-goal-directed movements)
 9. Agitation, not influenced by external stimuli
 10. Grimacing
 11. Echolalia (i.e., mimicking another's speech)
 12. Echopraxia (i.e., mimicking another's movements)

Coding note: indicate the name of the associated mental disorder when recording the name of the condition (i.e., 293.89 [F06.1] catatonia associated with major depressive disorder). Code first the associated mental disorder (e.g., neurodevelopmental disorder, brief psychotic disorder, schizophreniform disorder, schizophrenia, schizoaffective disorder, bipolar disorder, major depressive disorder, or other mental disorder) (e.g., 295.70 [F25.1] schizoaffective disorder, depressive type; 293.89 [F06.1] catatonia associated with schizoaffective disorder).

For catatonia secondary to antipsychotic agents, the diagnoses of neuroleptic-induced parkinsonism and neuroleptic malignant syndrome may be appropriate. For catatonia due to non-neuroleptic substances, the diagnosis of medication-induced movement disorder not otherwise specified is available.

Laboratory Examination

There are no pathognomonic laboratory findings in catatonia. The laboratory evaluation should be used to rule out an underlying medical condition. Appropriate medical tests may include complete blood counts, electrolytes, brain imaging, and electroencephalography (if seizures are suspected). In addition, serum creatinine phosphokinase, white blood cell count, and serum transaminases should be checked because the results of laboratory tests are elevated in patients with neuroleptic malignant syndrome.

Differential Diagnosis

Differential diagnoses include hypoactive delirium, end-stage dementia, and akinetic mutism, as well as catatonia due to a primary psychiatric disorder. It is important to identify cases of catatonia occurring in the setting of neuroleptic malignant syndrome because the latter diagnosis can be fatal. Features suggesting neuroleptic malignant syndrome include autonomic instability and delirium in addition to elevated serum creatinine phosphokinase, white blood cell count, and serum transaminases.

Course and Treatment

Catatonia impairs a person's ability to care for himself or herself and therefore requires hospitalization. In an excited state, the catatonic patient may represent a danger to others; hence, close supervision is needed. Fluid and nutrient intake must be maintained, often with intravenous lines or feeding tubes. The catatonic individual must be assisted with hygiene.

The primary treatment modality is identifying and correcting the underlying medical or pharmacological cause. Offending substances must be removed or minimized.

Benzodiazepines can provide temporary improvement in symptoms, and their use may improve patients' ability to communicate and to care for themselves. ECT is appropriate for catatonia due to a general medical condition, especially if the catatonia is life threatening (e.g., inability to eat) or has developed into lethal (malignant) catatonia. The mechanism behind the efficacy of ECT is unknown.

8.1 Major Depression and Bipolar Disorder

Mood can be defined as a pervasive and sustained emotion or feeling tone that influences a person's behavior and colors his or her perception of being in the world. Disorders of mood—sometimes called affective disorders—make up an important category of psychiatric illness consisting of depressive disorder, bipolar disorder, and other disorders, which are discussed in this section and in the section that follows.

A variety of adjectives are used to describe mood: depressed, sad, empty, melancholic, distressed, irritable, disconsolate, elated, euphoric, manic, gleeful, and many others, all descriptive in nature. Some can be observed by the clinician (e.g., an unhappy visage), and others can be felt only by the patient (e.g., hopelessness). Mood can be labile, fluctuating or alternating rapidly between extremes (e.g., laughing loudly and expansively one moment, tearful and despairing the next). Other signs and symptoms of mood disorders include changes in activity level, cognitive abilities, speech, and vegetative functions (e.g., sleep, appetite, sexual activity, and other biological rhythms). These disorders virtually always result in impaired interpersonal, social, and occupational functioning.

It is tempting to consider disorders of mood on a continuum with normal variations in mood. Patients with mood disorders, however, often report an ineffable, but distinct, quality to their pathological state. The concept of a continuum, therefore, may represent the clinician's overidentification with the pathology, thus possibly distorting his or her approach to patients with mood disorder.

Patients with only major depressive episodes are said to have *major depressive disorder* or *unipolar depression*. Patients with both manic and depressive episodes or patients with manic episodes alone are said to have *bipolar disorder*. The terms “unipolar mania” and “pure mania” are sometimes used for patients who are bipolar but who do not have depressive episodes.

Three additional categories of mood disorders are hypomania, cyclothymia, and dysthymia. Hypomania is an episode of manic symptoms that does not meet the criteria for manic episode. Cyclothymia and dysthymia are disorders that represent less severe forms of bipolar disorder and major depression, respectively.

The field of psychiatry has considered major depression and bipolar disorder to be two separate disorders, particularly in the past 20 years. The possibility that bipolar disorder is actually a more severe expression of major depression has been reconsidered recently, however. Many patients given a diagnosis of a major depressive disorder reveal, on careful examination, past episodes of manic or hypomanic behavior that have gone undetected. Many authorities see considerable continuity between recurrent depressive and bipolar disorders. This has led to widespread discussion and debate about the bipolar spectrum, which incorporates classic bipolar disorder, bipolar II, and recurrent depressions.

HISTORY

The Old Testament story of King Saul describes a depressive syndrome, as does the story of Ajax's suicide in Homer's *Iliad*. About 400 BCE, Hippocrates used the terms *mania* and *melancholia* to describe mental disturbances. Around 30 AD, the Roman physician Celsus described melancholia (from Greek *melan* [“black”] and *chole* [“bile”]) in his work *De re medicina* as a depression caused by black bile. The first English text (Fig. 8.1-1) entirely related to depression was Robert Burton's *Anatomy of Melancholy*, published in 1621.

FIGURE 8.1-1

Frontispiece of Robert Burton's *Anatomy of Melancholy* (1621). (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins, 2009.)

In 1854, Jules Falret described a condition called *folie circulaire*, in which patients experience alternating moods of depression and mania. In 1882, the German psychiatrist Karl Kahlbaum, using the term *cyclothymia*, described mania and depression as stages of the same illness. In 1899, Emil Kraepelin, building on the knowledge of previous French and German psychiatrists, described manic-depressive psychosis using most of the criteria that psychiatrists now use to establish a diagnosis of bipolar I disorder. According to Kraepelin, the absence of a dementing and deteriorating course in manic-depressive psychosis differentiated it from dementia precox (as schizophrenia was then called). Kraepelin also described a depression that came to be known as involuntional melancholia, which has since come to be viewed as a severe form of mood disorder that begins in late adulthood.

Depression

A major depressive disorder occurs without a history of a manic, mixed, or hypomanic episode. A major depressive episode must last at least 2 weeks, and typically a person with a diagnosis of a major depressive episode also experiences at least four symptoms from a list that includes changes in appetite and weight, changes in sleep and activity, lack of energy, feelings of guilt, problems thinking and making decisions, and recurring thoughts of death or suicide.

Mania

A manic episode is a distinct period of an abnormally and persistently elevated, expansive, or irritable mood lasting for at least 1 week or less if a patient must be hospitalized. A hypomanic episode lasts at least 4 days and is similar to a manic episode except that it is not sufficiently severe to cause impairment in social or occupational functioning, and no psychotic features are present. Both mania and hypomania are associated with inflated self-esteem, a decreased need for sleep, distractibility, great physical and mental activity, and overinvolvement in pleasurable behavior. Bipolar I disorder is defined as having a clinical course of one or more manic episodes and, sometimes, major depressive episodes. A mixed episode is a period of at least 1 week in which both a manic episode and a major depressive episode occur almost daily. A variant of bipolar disorder characterized by episodes of major depression and hypomania rather than mania is known as *bipolar II disorder*.

Dysthymia and Cyclothymia

Two additional mood disorders, dysthymic disorder and cyclothymic disorder (discussed fully in Section 8.2) have also been appreciated clinically for some time. Dysthymic disorder and cyclothymic disorder are characterized by the presence of symptoms that are less severe than those of major depressive disorder and bipolar I disorder, respectively. Dysthymic disorder is characterized by at least 2 years of depressed mood that is not sufficiently severe to fit the diagnosis of major depressive episode. Cyclothymic disorder is characterized by at least 2 years of frequently occurring hypomanic symptoms that cannot fit the diagnosis of manic episode and of depressive symptoms that cannot fit the diagnosis of major depressive episode.

EPIDEMIOLOGY

Incidence and Prevalence

Mood disorders are common. In the most recent surveys, major depressive disorder has the highest lifetime prevalence (almost 17 percent) of any psychiatric disorder. The lifetime prevalence rate of different forms of depressive disorder, according to community surveys, are shown in Table 8.1-1. The lifetime prevalence rate for major depression is 5 to 17 percent. The lifetime prevalence rates of different clinical forms of bipolar disorder are shown in Table 8.1-2. The annual incidence of bipolar illness is considered generally to be less than 1 percent, but it is difficult to estimate because milder forms of bipolar disorder are often missed.

Table 8.1-2
Lifetime Prevalence Rates of Bipolar I Disorder, Bipolar II Disorder, Cyclothymic Disorder, and Hypomania

	Lifetime Prevalence (%)
Bipolar I disorder	0–2.4
Bipolar II disorder	0.3–4.8
Cyclothymia	0.5–6.3
Hypomania	2.6–7.8

(Adapted from Rihmer Z, Angst A. Mood Disorders: Epidemiology. In: Sadock BJ, Sadock VA, eds. *Comprehensive Textbook of Psychiatry*. 8th edition. Baltimore: Lippincott Williams & Wilkins; 2004, with permission.)

Table 8.1-1
Lifetime Prevalence Rates of Depressive Disorders

	Type	Lifetime
Major depressive episode	Range	5–17
	Average	12
Dysthymic disorder	Range	3–6
	Average	5
Minor depressive disorder	Range	10
	Average	—
Recurrent brief depressive disorder	Range	16

(Adapted from Rihmer Z, Angst A. Mood Disorders: Epidemiology. In: Sadock BJ, Sadock VA, eds. *Comprehensive Textbook of Psychiatry*. 8th edition. Baltimore: Lippincott Williams & Wilkins; 2004, with permission.)

Sex

An almost universal observation, independent of country or culture, is the twofold greater prevalence of major depressive disorder in women than in men. The reasons for the difference are hypothesized to involve hormonal differences, the effects of childbirth, differing psychosocial stressors for women and for men, and behavioral models of learned helplessness. In contrast to major depressive disorder, bipolar I disorder has an equal prevalence among men and women. Manic episodes are more common in men, and depressive episodes are more common in women. When manic episodes occur in women, they are more likely than men to present a mixed picture (e.g., mania and depression). Women also have a higher rate of being rapid cyclers, defined as having four or more manic episodes in a 1-year period.

Age

The onset of bipolar I disorder is earlier than that of major depressive disorder. The age of onset for bipolar I disorder ranges from childhood (as early as age 5 or 6 years) to 50 years or even older in rare cases, with a mean age of 30 years. The mean age of onset for major depressive disorder is about 40 years, with 50 percent of all patients having an onset between the ages of 20 and 50 years. Major depressive disorder can also begin in childhood or in old age. Recent epidemiological data suggest that the incidence of major depressive disorder may be increasing among people younger than 20 years of age. This may be related to the increased use of alcohol and drugs of abuse in this age group.

Marital Status

Major depressive disorder occurs most often in persons without close interpersonal relationships and in those who are divorced or separated. Bipolar I disorder is more common in divorced and single persons than among married persons, but this difference may reflect the early onset and the resulting marital discord characteristic of the disorder.

Socioeconomic and Cultural Factors

No correlation has been found between socioeconomic status and major depressive disorder. A higher than average incidence of bipolar I disorder is found among the upper socioeconomic groups. Bipolar I disorder is more common in persons who did not graduate from college than in college graduates, however, which may also reflect the relatively early age of onset for the disorder. Depression is more common in rural areas than in urban areas. The prevalence of mood disorder does not differ among races. A tendency exists, however, for examiners to underdiagnose mood disorder and overdiagnose schizophrenia in patients whose racial or cultural background differs from theirs.

COMORBIDITY

Individuals with major mood disorders are at an increased risk of having one or more additional comorbid disorders. The most frequent disorders are alcohol abuse or dependence, panic disorder, obsessive-compulsive disorder (OCD), and social anxiety disorder. Conversely, individuals with substance use disorders and anxiety disorders also have an elevated risk of lifetime or current comorbid mood disorder. In both unipolar and bipolar disorder, whereas men more frequently present with substance use disorders, women more frequently present with comorbid anxiety and eating disorders. In general, patients who are bipolar more frequently show comorbidity of substance use and anxiety disorders than do patients with unipolar major depression. In the Epidemiological Catchment Area (ECA) study, the lifetime history of substance use disorders, panic disorder, and OCD was approximately twice as high among patients with bipolar I disorder (61 percent, 21 percent, and 21 percent, respectively) than in patients with unipolar major depression (27 percent, 10 percent, and 12 percent, respectively). Comorbid substance use disorders and anxiety disorders worsen the prognosis of the illness and markedly increase the risk of suicide among patients who are unipolar major depressive and bipolar.

ETIOLOGY

Biological Factors

Many studies have reported biological abnormalities in patients with mood disorders. Until recently, the monoamine neurotransmitters—norepinephrine, dopamine, serotonin, and histamine—were the main focus of theories and research about the etiology of these disorders. A progressive shift has occurred from focusing on disturbances of single neurotransmitter systems in favor of studying neurobehavioral systems, neural circuits, and more intricate neuroregulatory mechanisms. The monoaminergic systems, thus, are now viewed as broader, neuromodulatory systems, and disturbances are as likely to be secondary or epiphenomenal effects as they are directly or causally related to etiology and pathogenesis.

Biogenic Amines. Of the biogenic amines, norepinephrine and serotonin are the two neurotransmitters most implicated in the pathophysiology of mood disorders.

NOREPINEPHRINE. The correlation suggested by basic science studies between the downregulation or decreased sensitivity of β -adrenergic receptors and clinical antidepressant responses is probably the single most compelling piece of data indicating a direct role for the noradrenergic system in depression. Other evidence has also implicated the presynaptic β_2 -receptors in depression because activation of these receptors results in a decrease of the amount of norepinephrine released. Presynaptic β_2 -receptors are also located on serotonergic neurons and regulate the amount of serotonin released. The clinical effectiveness of antidepressant drugs with noradrenergic effects—for example, venlafaxine (Effexor)—further supports a role for norepinephrine in the pathophysiology of at least some of the symptoms of depression.

SEROTONIN. With the huge effect that the selective serotonin reuptake inhibitors (SSRIs)—for example, fluoxetine (Prozac)—have made on the treatment of depression, serotonin has become the biogenic amine neurotransmitter most commonly associated with depression. The identification of multiple serotonin receptor subtypes has also increased the excitement within the research community about the development of even more specific treatments for depression. Besides that SSRIs and other serotonergic antidepressants are effective in the treatment of depression, other data indicate that serotonin is involved in the pathophysiology of depression. Depletion of serotonin may precipitate depression, and some patients with suicidal impulses have low cerebrospinal fluid (CSF) concentrations of serotonin metabolites and low concentrations of serotonin uptake sites on platelets.

DOPAMINE. Although norepinephrine and serotonin are the biogenic amines most often associated with the pathophysiology of depression, dopamine has also been theorized to play a role. The data suggest that dopamine activity may be reduced in depression and increased in mania. The discovery of new subtypes of the dopamine receptors and an increased understanding of the presynaptic and postsynaptic regulation of dopamine function have further enriched research into the relation between dopamine and mood disorders. Drugs that reduce dopamine concentrations—for example, reserpine (Serpasil)—and diseases that reduce dopamine concentrations (e.g., Parkinson's disease) are associated with depressive symptoms. In contrast, drugs that increase dopamine concentrations, such as tyrosine, amphetamine, and bupropion (Wellbutrin), reduce the symptoms of depression. Two recent theories about dopamine and depression are that the mesolimbic dopamine pathway may be dysfunctional in depression and that the dopamine D_1 receptor may be hypoactive in depression.

Other Neurotransmitter Disturbances. Acetylcholine (ACh) is found in neurons that are distributed diffusely throughout the cerebral cortex. Cholinergic neurons have reciprocal or interactive relationships with all three monoamine systems. Abnormal levels of choline, which is a precursor to ACh, have been found at autopsy in the brains of some depressed patients, perhaps reflecting abnormalities in cell phospholipid composition. Cholinergic agonist and antagonist drugs have differential clinical effects on depression and mania. Agonists can produce lethargy, anergia, and psychomotor retardation in healthy subjects, can exacerbate symptoms in depression, and can reduce symptoms in mania. These effects generally are not sufficiently robust to have clinical applications, and adverse effects are problematic. In an animal model of depression, strains of mice that are super- or subsensitive to cholinergic agonists have been found susceptible or more resistant to developing learned helplessness (discussed later). Cholinergic agonists can induce changes in hypothalamic-pituitary-adrenal (HPA) activity and sleep that mimic those associated with severe depression. Some patients with mood disorders in remission, as well as their never-ill first-degree relatives, have a trait-like increase in sensitivity to cholinergic agonists.

γ -Aminobutyric acid (GABA) has an inhibitory effect on ascending monoamine pathways, particularly the mesocortical and mesolimbic systems. Reductions of GABA have been observed in plasma, CSF, and brain GABA levels in depression. Animal studies have also found that chronic stress can reduce and eventually can deplete GABA levels. By contrast, GABA receptors are upregulated by antidepressants, and some GABAergic medications have weak antidepressant effects.

The amino acids glutamate and glycine are the major excitatory and inhibitory neurotransmitters in the CNS. Glutamate and glycine bind to sites associated with the *N*-methyl-D-aspartate (NMDA) receptor, and an excess of glutamatergic stimulation can cause neurotoxic effects. Importantly, a high concentration of NMDA receptors exists in the hippocampus. Glutamate, thus, may work in conjunction with hypercortisolemia to mediate the deleterious neurocognitive effects of severe recurrent depression. Emerging evidence suggests that drugs that antagonize NMDA receptors have antidepressant effects.

Second Messengers and Intracellular Cascades. The binding of a neurotransmitter and a postsynaptic receptor triggers a cascade of membrane-bound and intracellular processes mediated by second messenger systems. Receptors on cell membranes interact with the intracellular environment via guanine nucleotide-binding proteins (G proteins). The G proteins, in turn, connect to various intracellular enzymes (e.g., adenylate cyclase, phospholipase C, and phosphodiesterase) that regulate utilization of energy and formation of second messengers, such as cyclic nucleotide (e.g., cyclic adenosine monophosphate [cAMP] and cyclic guanosine monophosphate [cGMP]), as well as phosphatidylinositols (e.g., inositol triphosphate and diacylglycerol) and calcium-calmodulin. Second messengers regulate the function of neuronal membrane ion channels. Increasing evidence also indicates that mood-stabilizing drugs act on G proteins or other second messengers.

Alterations of Hormonal Regulation. Lasting alterations in neuroendocrine and behavioral responses can result from severe early stress. Animal studies indicate that even transient periods of maternal deprivation can alter subsequent responses to stress. Activity of the gene coding for the neurokinin brain-derived neurotrophic growth factor (BDNF) is decreased after chronic stress, as is the process of neurogenesis. Protracted stress thus can induce changes in the functional status of neurons and, eventually, cell death. Recent studies in depressed humans indicate that a history of early trauma is associated with increased HPA activity accompanied by structural changes (i.e., atrophy or decreased volume) in the cerebral cortex.

Elevated HPA activity is a hallmark of mammalian stress responses and one of the clearest links between depression and the biology of chronic stress. Hypercortisolemia in depression suggests one or more of the following central disturbances: decreased inhibitory serotonin tone; increased drive from norepinephrine, ACh, or corticotropin-releasing hormone (CRH); or decreased feedback inhibition from the hippocampus.

Evidence of increased HPA activity is apparent in 20 to 40 percent of depressed outpatients and 40 to 60 percent of depressed inpatients. Elevated HPA activity in depression has been documented via excretion of urinary-free cortisol (UFC), 24-hour (or shorter time segments)

intravenous (IV) collections of plasma cortisol levels, salivary cortisol levels, and tests of the integrity of feedback inhibition. A disturbance of feedback inhibition is tested by administration of dexamethasone (Decadron) (0.5 to 2.0 mg), a potent synthetic glucocorticoid, which normally suppresses HPA axis activity for 24 hours. Nonsuppression of cortisol secretion at 8:00 AM the following morning or subsequent escape from suppression at 4:00 PM or 11:00 PM is indicative of impaired feedback inhibition. Hypersecretion of cortisol and dexamethasone nonsuppression are imperfectly correlated (approximately 60 percent concordance). A more recent development to improve the sensitivity of the test involves infusion of a test dose of CRH after dexamethasone suppression.

These tests of feedback inhibition are not used as a diagnostic test because adrenocortical hyperactivity (albeit usually less prevalent) is observed in mania, schizophrenia, dementia, and other psychiatric disorders.

THYROID AXIS ACTIVITY. Approximately 5 to 10 percent of people evaluated for depression have previously undetected thyroid dysfunction, as reflected by an elevated basal thyroid-stimulating hormone (TSH) level or an increased TSH response to a 500-mg infusion of the hypothalamic neuropeptide thyroid-releasing hormone (TRH). Such abnormalities are often associated with elevated antithyroid antibody levels and, unless corrected with hormone replacement therapy, can compromise response to treatment. An even larger subgroup of depressed patients (e.g., 20 to 30 percent) shows a blunted TSH response to TRH challenge. To date, the major therapeutic implication of a blunted TSH response is evidence of an increased risk of relapse despite preventive antidepressant therapy. Of note, unlike the dexamethasone-suppression test (DST), blunted TSH response to TRH does not usually normalize with effective treatment.

GROWTH HORMONE. Growth hormone (GH) is secreted from the anterior pituitary after stimulation by NE and dopamine. Secretion is inhibited by somatostatin, a hypothalamic neuropeptide, and CRH. Decreased CSF somatostatin levels have been reported in depression, and increased levels have been observed in mania.

PROLACTIN. Prolactin is released from the pituitary by serotonin stimulation and inhibited by dopamine. Most studies have not found significant abnormalities of basal or circadian prolactin secretion in depression, although a blunted prolactin response to various serotonin agonists has been described. This response is uncommon among premenopausal women, suggesting that estrogen has a moderating effect.

Alterations of Sleep Neurophysiology. Depression is associated with a premature loss of deep (slow-wave) sleep and an increase in nocturnal arousal. The latter is reflected by four types of disturbance: (1) an increase in nocturnal awakenings, (2) a reduction in total sleep time, (3) increased phasic rapid eye movement (REM) sleep, and (4) increased core body temperature. The combination of increased REM drive and decreased slow-wave sleep results in a significant reduction in the first period of non-REM (NREM) sleep, a phenomenon referred to as *reduced REM latency*. Reduced REM latency and deficits of slow-wave sleep typically persist after recovery of a depressive episode. Blunted secretion of GH after sleep onset is associated with decreased slow-wave sleep and shows similar state-independent or trait-like behavior. The combination of reduced REM latency, increased REM density, and decreased sleep maintenance identifies approximately 40 percent of depressed outpatients and 80 percent of depressed inpatients. False-negative findings are commonly seen in younger, hypersomnolent patients, who may actually experience an increase in slow-wave sleep during episodes of depression. Approximately 10 percent of otherwise healthy individuals have abnormal sleep profiles, and, as with dexamethasone nonsuppression, false-positive cases are not uncommonly seen in other psychiatric disorders.

Patients manifesting a characteristically abnormal sleep profile have been found to be less responsive to psychotherapy and to have a greater risk of relapse or recurrence and may benefit preferentially from pharmacotherapy.

Immunological Disturbance. Depressive disorders are associated with several immunological abnormalities, including decreased lymphocyte proliferation in response to mitogens and other forms of impaired cellular immunity. These lymphocytes produce neuromodulators, such as corticotropin-releasing factor (CRF), and cytokines, peptides known as *interleukins*. There appears to be an association with clinical severity, hypercortisolism, and immune dysfunction, and the cytokine interleukin-1 may induce gene activity for glucocorticoid synthesis.

Structural and Functional Brain Imaging. Computed axial tomography (CAT) and magnetic resonance imaging (MRI) scans have permitted sensitive, noninvasive methods to assess the living brain, including cortical and subcortical tracts, as well as white matter lesions. The most consistent abnormality observed in the depressive disorders is increased frequency of abnormal hyperintensities in subcortical regions, such as periventricular regions, the basal ganglia, and the thalamus. More common in bipolar I disorder and among elderly adults, these hyperintensities appear to reflect the deleterious neurodegenerative effects of recurrent affective episodes. Ventricular enlargement, cortical atrophy, and sulcal widening also have been reported in some studies. Some depressed patients also may have reduced hippocampal or caudate nucleus volumes, or both, suggesting more focal defects in relevant neurobehavioral systems. Diffuse and focal areas of atrophy have been associated with increased illness severity, bipolarity, and increased cortisol levels.

The most widely replicated positron emission tomography (PET) finding in depression is decreased anterior brain metabolism, which is generally more pronounced on the left side. From a different vantage point, depression may be associated with a relative increase in nondominant hemispheric activity. Furthermore, a reversal of hypofrontality occurs after shifts from depression into hypomania, such that greater left hemisphere reductions are seen in depression compared with greater right hemisphere reductions in mania. Other studies have observed more specific reductions of reduced cerebral blood flow or metabolism, or both, in the dopaminergically innervated tracts of the mesocortical and mesolimbic systems in depression. Again, evidence suggests that antidepressants at least partially normalize these changes.

In addition to a global reduction of anterior cerebral metabolism, increased glucose metabolism has been observed in several limbic regions, particularly among patients with relatively severe recurrent depression and a family history of mood disorder. During episodes of depression, increased glucose metabolism is correlated with intrusive ruminations.

Neuroanatomical Considerations. Both the symptoms of mood disorders and biological research findings support the hypothesis that mood disorders involve pathology of the brain. Modern affective neuroscience focuses on the importance of four brain regions in the regulation of normal emotions: the prefrontal cortex (PFC), the anterior cingulate, the hippocampus, and the amygdala. The PFC is viewed as the structure that holds representations of goals and appropriate responses to obtain these goals. Such activities are particularly important when multiple, conflicting behavioral responses are possible or when it is necessary to override affective arousal. Evidence indicates some hemispherical specialization in PFC function. For example, whereas left-sided activation of regions of the PFC is more involved in goal-directed or appetitive behaviors, regions of the right PFC are implicated in avoidance behaviors and inhibition of appetitive pursuits. Subregions in the PFC appear to localize representations of behaviors related to reward and punishment.

The anterior cingulate cortex (ACC) is thought to serve as the point of integration of attentional and emotional inputs. Two subdivisions have been identified: an affective subdivision in the rostral and ventral regions of the ACC and a cognitive subdivision involving the dorsal ACC. The former subdivision shares extensive connections with other limbic regions, and the latter interacts more with the PFC and other cortical regions. It is proposed that activation of the ACC facilitates control of emotional arousal, particularly when goal attainment has been thwarted or when novel problems have been encountered.

The hippocampus is most clearly involved in various forms of learning and memory, including fear conditioning, as well as inhibitory regulation of the HPA axis activity. Emotional or contextual learning appears to involve a direct connection between the hippocampus and the amygdala.

The amygdala appears to be a crucial way station for processing novel stimuli of emotional significance and coordinating or organizing

cortical responses. Located just above the hippocampi bilaterally, the amygdala has long been viewed as the heart of the limbic system. Although most research has focused on the role of the amygdala in responding to fearful or painful stimuli, it may be ambiguity or novelty, rather than the aversive nature of the stimulus per se, that brings the amygdala on line (Fig. 8.1-2).

Representation and Regulation of Emotion in Depression

Genetic Factors

Numerous family, adoption, and twin studies have long documented the heritability of mood disorders. Recently, however, the primary focus of genetic studies has been to identify specific susceptibility genes using molecular genetic methods.

Family Studies. Family studies address the question of whether a disorder is familial. More specifically, is the rate of illness in the family members of someone with the disorder greater than that of the general population? Family data indicate that if one parent has a mood disorder, a child will have a risk of between 10 and 25 percent for mood disorder. If both parents are affected, this risk roughly doubles. The more members of the family who are affected, the greater the risk is to a child. The risk is greater if the affected family members are first-degree relatives rather than more distant relatives. A family history of bipolar disorder conveys a greater risk for mood disorders in general and, specifically, a much greater risk for bipolar disorder. Unipolar disorder is typically the most common form of mood disorder in families of bipolar probands. This familial overlap suggests some degree of common genetic underpinnings between these two forms of mood disorder. The presence of more severe illness in the family also conveys a greater risk (Fig. 8.1-3).

Mendelian – Single Major Locus

Polygenic/QTL Threshold

Genetic Heterogeneity

FIGURE 8.1-3

Many different models of genetic transmission have been considered and tested to see if they would explain the transmission of mood disorders. This is a selection of some of the more prominent models. In Mendelian or single major locus transmission, one gene transmits the illness. In polygenic quantitative trait (QTL) model, multiple genes add together to contribute to a quantitative trait. In this figure, the X axis represents the number of polygenes that a given individual is carrying, as well as the value of the resulting quantitative trait. The frequency of that trait value in the population is represented on the axis represents the number of polygenes that a given individual is carrying, as well as the value of the resulting quantitative trait. The frequency of that trait value in the population is represented on the Y axis. In the bottom panel, some possible models or genetic heterogeneity are illustrated. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins, 2009.)

Adoption Studies. Adoption studies provide an alternative approach to separating genetic and environmental factors in familial transmission. Only a limited number of such studies have been reported, and their results have been mixed. One large study found a threefold increase in the rate of bipolar disorder and a twofold increase in unipolar disorder in the biological relatives of bipolar probands. Similarly, in a Danish sample, a threefold increase in the rate of unipolar disorder and a sixfold increase in the rate of completed suicide in the biological relatives of affectively ill probands were reported. Other studies, however, have been less convincing and have found no difference in the rates of mood disorders.

Twin Studies. Twin studies provide the most powerful approach to separating genetic from environmental factors, or "nature" from "nurture." The twin data provide compelling evidence that genes explain only 50 to 70 percent of the etiology of mood disorders. Environment or other nonheritable factors must explain the remainder. Therefore, it is a predisposition or susceptibility to disease that is inherited. Considering unipolar and bipolar disorders together, these studies find a concordance rate for mood disorder in the monozygotic (MZ) twins of 70 to 90 percent compared with the same-sex dizygotic (DZ) twins of 16 to 35 percent. This is the most compelling data for the role of genetic factors in mood disorders.

Linkage Studies. DNA markers are segments of DNA of known chromosomal location, which are highly variable among individuals. They are used to track the segregation of specific chromosomal regions within families affected with a disorder. When a marker is identified with disease in families, the disease is said to be *genetically linked* (Table 8.1-3). Chromosomes 18q and 22q are the two regions with strongest evidence for linkage to bipolar disorder. Several linkage studies have found evidence for the involvement of specific genes in clinical subtypes. For example, the linkage evidence on 18q has been shown to be derived largely from bipolar II–bipolar II sibling pairs and from families in which the probands had panic symptoms.

Table 8.1-3
Selected Chromosomal Regions with Evidence of Linkage to Bipolar Disorder

Chromosome 18	Data suggest the presence of as many as four different loci on this one chromosome. Studies have found linkage to 18q to preferentially occur in families in which affective illness was transmitted through the mother, suggesting a possible parent-of-origin effect.
Chromosome 21q	Regions have shown linkage or association to both schizophrenia and bipolar disorder.
Chromosome 22q	The breakpoint cluster region (BCR) gene is located on chromosome 22q11. The BCR gene encodes an activating protein, which is known to play important roles in neuron growth and axonal guidance.

Gene-mapping studies of unipolar depression have found very strong evidence of linkage to the locus for cAMP response element-binding protein (CREB1) on chromosome 2. Eighteen other genomic regions were found to be linked; some of these displayed interactions with the CREB1 locus. Another study has reported evidence for a gene–environment interaction in the development of major depression. Subjects who underwent adverse life events were shown, in general, to be at an increased risk for depression. Of such subjects, however, those with a variant in the serotonin transporter gene showed the greatest increase in risk. This is one of the first reports of a specific gene–environment interaction in a psychiatric disorder.

Psychosocial Factors

Life Events and Environmental Stress. A long-standing clinical observation is that stressful life events more often precede first, rather than subsequent, episodes of mood disorders. This association has been reported for both patients with major depressive disorder and patients with bipolar I disorder. One theory proposed to explain this observation is that the stress accompanying the first episode results in long-lasting changes in the brain's biology. These long-lasting changes may alter the functional states of various neurotransmitter and intraneuronal signaling systems, changes that may even include the loss of neurons and an excessive reduction in synaptic contacts. As a result, a person has a high risk of undergoing subsequent episodes of a mood disorder, even without an external stressor.

Some clinicians believe that life events play the primary or principal role in depression; others suggest that life events have only a limited role in the onset and timing of depression. The most compelling data indicate that the life event most often associated with development of depression is losing a parent before age 11 years. The environmental stressor most often associated with the onset of an episode of depression is the loss of a spouse. Another risk factor is unemployment; persons out of work are three times more likely to report symptoms of an episode of major depression than those who are employed. Guilt may also play a role.

Ms. C, a 23-year-old woman, became acutely depressed when she was accepted to a prestigious graduate school. Ms. C had been working diligently toward this acceptance for the past 4 years. She reported being “briefly happy, for about 20 minutes” when she learned the good news but rapidly slipped into a hopeless state in which she recurrently pondered the pointlessness of her aspirations, cried constantly, and had to physically stop herself from taking a lethal overdose of her roommate’s insulin. In treatment, she focused on her older brother, who had regularly insulted her throughout the course of her life, and how “he’s not doing well.” She found herself very worried about him. She mentioned that she was not used to being the “successful” one of the two of them. In connection with her depression, it emerged that Ms. C’s brother had had a severe, life-threatening, and disfiguring pediatric illness that had required much family time and attention throughout their childhood. Ms. C had become “used to” his insulting manner toward her. In fact, it seemed that she required her brother’s abuse of her in order not to feel overwhelmed by survivor guilt about being the “healthy, normal” child. “He might insult me, but I look up to him. I adore him. Any attention he pays to me is like a drug,” she said. Ms. C’s acceptance to graduate school had challenged her defensive and essential compensatory image of herself as being less successful, or damaged, in comparison with her brother, thereby overwhelming her with guilt. Her depression remitted in psychodynamic psychotherapy as she better understood her identification with and fantasy submission to her brother. (Courtesy of JC Markowitz, M.D., and BL Milrod, M.D.)

Personality Factors. No single personality trait or type uniquely predisposes a person to depression; all humans, of whatever personality pattern, can and do become depressed under appropriate circumstances. Persons with certain personality disorders—OCD, histrionic, and borderline—may be at greater risk for depression than persons with antisocial or paranoid personality disorder. The latter can use projection and other externalizing defense mechanisms to protect themselves from their inner rage. No evidence indicates that any particular personality disorder is associated with later development of bipolar I disorder; however, patients with dysthymic disorder and cyclothymic disorder are at risk of later developing major depression or bipolar I disorder.

Recent stressful events are the most powerful predictors of the onset of a depressive episode. From a psychodynamic perspective, the clinician is always interested in the meaning of the stressor. Research has demonstrated that stressors that the patient experiences as reflecting negatively on his or her self-esteem are more likely to produce depression. Moreover, what may seem to be a relatively mild stressor to outsiders may be devastating to the patient because of particular idiosyncratic meanings attached to the event.

Psychodynamic Factors in Depression. The psychodynamic understanding of depression defined by Sigmund Freud and expanded by Karl Abraham is known as the classic view of depression. That theory involves four key points: (1) disturbances in the infant–mother relationship during the oral phase (the first 10 to 18 months of life) predispose to subsequent vulnerability to depression; (2) depression can be linked to real or imagined object loss; (3) introjection of the departed objects is a defense mechanism invoked to deal with the distress connected with the object’s loss; and (4) because the lost object is regarded with a mixture of love and hate, feelings of anger are directed inward at the self.

Ms. E, a 21-year-old college student, presented with major depression and panic disorder since early adolescence. She reported hating herself, crying constantly, and feeling profoundly hopeless in part because of the chronicity of her illness. Even at the time of presentation, she noted her sensitivity to her mother’s moods. “My mother’s just always depressed, and it makes me so miserable. I just don’t know what to do,” she said. “I always want something from her, I don’t even know what, but I never get it. She always says the wrong thing, talks about how disturbed I am, stuff like that, makes me feel bad about myself.” In one session, Ms. E poignantly described her childhood: “I spent a lot of time with my mother, but she was always too tired, she never wanted to do anything or play with me. I remember building a house with blankets over the coffee table and peeking out, spying on her. She was always depressed and negative, like a negative sink in the room, making it empty and sad. I could never get her to do anything.” This patient experienced extreme guilt in her psychotherapy when she began to talk about her mother’s depression. “I feel so bad,” she sobbed. “It’s like I’m saying bad things about her. And I love her so much, and I know she loves me. I feel it’s so disloyal of me.” Her depression remitted in psychodynamic psychotherapy as she became more aware of and better able to tolerate her feelings of rage and disappointment with her mother. (Courtesy of JC Markowitz, M.D., and BL Milrod, M.D.)

Melanie Klein understood depression as involving the expression of aggression toward loved ones, much as Freud did. Edward Bibring regarded depression as a phenomenon that sets in when a person becomes aware of the discrepancy between extraordinarily high ideals and the inability to meet those goals. Edith Jacobson saw the state of depression as similar to a powerless, helpless child victimized by a tormenting parent. Silvano Arieti observed that many depressed people have lived their lives for someone else rather than for themselves. He referred to the person for whom depressed patients live as the dominant other, which may be a principle, an ideal, or an institution, as well as an individual. Depression sets in when patients realize that the person or ideal for which they have been living is never going to respond in a manner that will meet their expectations. Heinz Kohut’s conceptualization of depression, derived from his self-psychological theory, rests on the assumption that the developing self has specific needs that must be met by parents to give the child a positive sense of self-esteem and self-cohesion. When others do not meet these needs, there is a massive loss of self-esteem that presents as depression. John

Bowlby believed that damaged early attachments and traumatic separation in childhood predispose to depression. Adult losses are said to revive the traumatic childhood loss and so precipitate adult depressive episodes.

Psychodynamic Factors in Mania. Most theories of mania view manic episodes as a defense against underlying depression. Abraham, for example, believed that the manic episodes may reflect an inability to tolerate a developmental tragedy, such as the loss of a parent. The manic state may also result from a tyrannical superego, which produces intolerable self-criticism that is then replaced by euphoric self-satisfaction. Bertram Lewin regarded the manic patient's ego as overwhelmed by pleasurable impulses, such as sex, or by feared impulses, such as aggression. Klein also viewed mania as a defensive reaction to depression, using manic defenses such as omnipotence, in which the person develops delusions of grandeur.

Ms. G, a 42-year-old housewife and mother of a 4-year-old boy, developed symptoms of hypomania and later of frank mania without psychosis, when her only son was diagnosed with acute lymphocytic leukemia. A profoundly religious woman who had experienced 10 years of difficulty with conception, Ms. G was a devoted mother. She reported that she was usually rather down. Before her son's illness, she used to joke that she had become pregnant with him by divine intervention. When her son was diagnosed and subsequently hospitalized, he required painful medical tests and emergency chemotherapy, which made him very ill. The doctors regularly barraged Ms. G with bad news about his prognosis during the first few weeks of his illness.

Ms. G was ever present with her son at the hospital, never sleeping, always caring for him, yet the pediatricians noted that as the child became more debilitated and the prognosis more grim, she seemed to bubble over with renewed cheerfulness, good humor, and high spirits. She could not seem to stop herself from cracking jokes to the hospital staff during her son's painful procedures, and as the jokes became louder and more inappropriate, the staff grew more concerned. During her subsequent psychiatric consultation (requested by the pediatric staff), Ms. G reported that her current "happiness and optimism" were justified by her sense of "oneness" with Mary, the mother of God. "We are together now, she and I, and she has become a part of me. We have a special relationship," she winked. Despite these statements, Ms. G was not psychotic and said that she was "speaking metaphorically, of course, only as a good Catholic would." Her mania resolved when her son achieved remission and was discharged from the hospital. (Courtesy of JC Markowitz, M.D., and BL Milrod, M.D.)

Other Formulations of Depression

Cognitive Theory. According to cognitive theory, depression results from specific cognitive distortions present in persons susceptible to depression. These distortions, referred to as *depressogenic schemata*, are cognitive templates that perceive both internal and external data in ways that are altered by early experiences. Aaron Beck postulated a cognitive triad of depression that consists of (1) views about the self—a negative self-precept, (2) about the environment—a tendency to experience the world as hostile and demanding, and (3) about the future—the expectation of suffering and failure. Therapy consists of modifying these distortions. The elements of cognitive theory are summarized in Table 8.1-4.

 **Table 8.1-4**
Elements of Cognitive Theory

Element	Definition
Cognitive triad	Beliefs about oneself, the world, and the future
Schemas	Ways of organizing and interpreting experiences
Cognitive distortions	
Arbitrary inference	Drawing a specific conclusion without sufficient evidence
Specific abstraction	Focus on a single detail while ignoring other, more important aspects of an experience
Overgeneralization	Forming conclusions based on too little and too narrow experience
Magnification and minimization	Over- or undervaluing the significance of a particular event
Personalization	Tendency to self-reference external events without basis
Absolutist, dichotomous thinking	Tendency to place experience into all-or-none categories

(Courtesy of Robert M.A. Hirschfeld, M.D., and M. Tracie Shea, Ph.D.)

Learned Helplessness. The learned helplessness theory of depression connects depressive phenomena to the experience of uncontrollable events. For example, when dogs in a laboratory were exposed to electrical shocks from which they could not escape, they showed behaviors that differentiated them from dogs that had not been exposed to such uncontrollable events. The dogs exposed to the shocks would not cross a barrier to stop the flow of electric shock when put in a new learning situation. They remained passive and did not move. According to the learned helplessness theory, the shocked dogs learned that outcomes were independent of responses, so they had both cognitive motivational deficit (i.e., they would not attempt to escape the shock) and emotional deficit (indicating decreased reactivity to the shock). In the reformulated view of learned helplessness as applied to human depression, internal causal explanations are thought to produce a loss of self-esteem after adverse external events. Behaviorists who subscribe to the theory stress that improvement of depression is contingent on the patient's learning a sense of control and mastery of the environment.

DIAGNOSIS

Major Depressive Disorder

The DSM-5 diagnostic criteria for major depression are listed in Table 8.1-5; severity descriptors and other specifiers for a major depressive

episode are also listed in that table.

Table 8.1-5
DSM-5 Criteria for Major Depressive Disorder

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
Note: Do not include symptoms that are clearly attributable to another medical condition.
1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (**Note:** In children, consider failure to make expected weight gain.)
 4. Insomnia or hypersomnia nearly every day.
 5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
 6. Fatigue or loss of energy nearly every day.
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
 8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The episode is not attributable to the physiological effects of a substance or to another medical condition.
Note: Criteria A to C represent a major depressive episode.
Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.¹
- D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.
- E. There has never been a manic episode or a hypomanic episode.
Note: This exclusion does not apply if all of the manic-like or hypomanic-like episodes are substance-induced or are attributable to the physiological effects of another medical condition.

¹In distinguishing grief from a major depressive episode (MDE), it is useful to consider that in grief the predominant affect is feelings of emptiness and loss, while in MDE it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in grief is likely to decrease in intensity over days to weeks and occurs in waves, the so-called pangs of grief. These waves tend to be associated with thoughts or reminders of the deceased. The depressed mood of MDE is more persistent and not tied to specific thoughts or preoccupations. The pain of grief may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of MDE. The thought content associated with grief generally features a preoccupation with thoughts and memories of the deceased rather than the self-critical or pessimistic ruminations seen in MDE. In grief, self-esteem is generally preserved, whereas in MDE feelings of worthlessness and self-loathing are common. If self-derogatory ideation is present in grief, it typically involves perceived failings vis-à-vis the deceased (e.g., not visiting frequently enough, not telling the deceased how much he or she was loved). If a bereaved individual thinks about death and dying, such thoughts are general focused on the deceased and possibly "joining" the deceased, whereas in MDE, such thoughts are focused on ending one's own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

Coding and Recording Procedures

The diagnostic code for major depressive disorder is based on whether this is a single or recurrent episode, current severity, presence of psychotic features, and remission status. Current severity and psychotic features are only indicated if full criteria are not currently met for a major depressive episode. Codes are as follows:

Severity/Course Specifier	Single Episode	Recurrent Episode*
Mild (p. 188)	292.21 (F32.0)	296.31 (F33.0)
Moderate (p. 188)	296.22 (F32.1)	296.32 (F33.1)
Severe (p. 188)	296.23 (F32.2)	296.33 (F33.2)
With psychotic features [†] (p. 186)	296.24 (F32.3)	296.34 (F33.3)
In partial remission (p. 188)	296.25 (F32.4)	296.35 (F33.4)
In full remission (p. 188)	296.26 (F32.5)	296.36 (F33.42)
Unspecified	296.20 (F32.9)	296.30 (F33.9)

*For an episode to be considered recurrent, there must be an interval of at least 2 consecutive months between separate episodes in which criteria are not met for a major depressive episode. The definitions of specifiers are found on the indicated pages.

[†]If psychotic features are present, code the "with psychotic features" specifier irrespective of episode severity.

In recording the name of a diagnosis, terms should be listed in the following order: major depressive disorder, single or recurrent episode, severity/psychotic/remission specifiers followed by as many of the following specifiers without codes that apply to the current episode.

Specify:

- With anxious distress (p. 184)
- With mixed features (pp. 184–185)
- With melancholic features (pp. 184–185)
- With atypical features (pp. 185–186)
- With mood-congruent psychotic features (p. 186)
- With mood-incongruent psychotic features (p. 186)
- With catatonia (p. 186). Coding note: use additional code 293.89 (F06.1).
- With peripartum onset (pp. 186–187)
- With seasonal pattern (recurrent episode only) (pp. 187–188)

Major Depressive Disorder, Single Episode

Depression may occur as a single episode or may be recurrent. Differentiation between these patients and those who have two or more episodes of major depressive disorder is justified because of the uncertain course of the former patients' disorder. Several studies have reported data consistent with the notion that major depression covers a heterogeneous population of disorders. One type of study assessed the stability of a diagnosis of major depression in a patient over time. The study found that 25 to 50 percent of the patients were later reclassified as having a different psychiatric condition or a nonpsychiatric medical condition with psychiatric symptoms. A second type of study evaluated first-degree relatives of affectively ill patients to determine the presence and types of psychiatric diagnoses for these relatives over time. Both types of studies found that depressed patients with more depressive symptoms are more likely to have stable diagnoses over time and are more likely to have affectively ill relatives than are depressed patients with fewer depressive symptoms. Also, patients with bipolar I disorder and those with bipolar II disorder (recurrent major depressive episodes with hypomania) are likely to have stable diagnoses over time.

Major Depressive Disorder, Recurrent

Patients who are experiencing at least a second episode of depression are classified as having major depressive disorder, recurrent. The essential problem with diagnosing recurrent episodes of major depressive disorder is choosing the criteria to designate the resolution of each period. Two variables are the degree of resolution of the symptoms and the length of the resolution. DSM-5 requires that distinct episodes of depression be separated by at least 2 months during which a patient has no significant symptoms of depression.

Bipolar I Disorder

The DSM-5 criteria for a bipolar I disorder (Table 8.1-6) requires the presence of a distinct period of abnormal mood lasting at least 1 week and includes separate bipolar I disorder diagnoses for a single manic episode and a recurrent episode based on the symptoms of the most recent episode as described below.

Table 8.1-6
DSM-5 Diagnostic Criteria for Bipolar I Disorder

For a diagnosis of bipolar I disorder, it is necessary to meet the following criteria for a manic episode. The manic episode may have been preceded by and may be followed by hypomanic or major depressive episodes.

Manic Episode

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).
- B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
 1. Inflated self-esteem or grandiosity.
 2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
 3. More talkative than usual or pressure to keep talking.
 4. Flight of ideas or subjective experience that thoughts are racing.
 5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
 6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal directed activity).
 7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
- C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
- D. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, or there are psychotic features).

Note: A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a manic episode and therefore a bipolar I disorder.

Note: Criteria A to D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

Hypomanic Episode

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.
- B. During the period of mood disturbance and increased energy and activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted, represent a noticeable change from usual behavior, and have been present to a significant degree:
 1. Inflated self-esteem or grandiosity.
 2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
 3. More talkative than usual or pressure to keep talking.
 4. Flight of ideas or subjective experience that thoughts are racing.
 5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
 6. Increase in goal-oriented activity (either socially, at work or school, or sexually) or psychomotor agitation.
 7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).
- C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.
- D. The disturbance in mood and the change in functioning are observable by others.
- E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.
- F. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment).

Note: A full hypomanic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a hypomanic episode diagnosis. However, caution is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for diagnosis of a hypomanic episode, nor necessarily indicative of a bipolar diathesis.

Note: Criteria A to F constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Major Depressive Episode

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.

 1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, or hopeless) or observation made by others (e.g., appears tearful). (Note: In children and adolescents, can be irritable mood.)
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation)
 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month) or decrease or increase in appetite nearly every day. (Note: In children, consider failure to make expected weight gain.)
 4. Insomnia or hypersomnia nearly every day.
 5. Psychomotor agitation or retardation nearly every day (observable by others; not merely subjective feelings of restlessness or being slowed down).
 6. Fatigue or loss of energy nearly every day.
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).

8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The episode is not attributable to the physiological effects of a substance or another medical condition.
- Note: Criteria A to C constitute a major depressive episode. Major depressive episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.
- Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.¹

¹In distinguishing grief from a major depressive episode (MDE), it is useful to consider that in grief the predominant affect is feelings of emptiness and loss, while in MDE it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in grief is likely to decrease in intensity over days to weeks and occurs in waves, the so-called pangs of grief. These waves tend to be associated with thoughts or reminders of the deceased. The depressed mood of MDE is more persistent and not tied to specific thoughts or preoccupations. The pain or grief may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of a major depressive episode. The thought content associated with grief generally features a preoccupation with thoughts and memories of the deceased, rather than a self-critical or pessimistic ruminations seen in a MDE. In grief, self-esteem is generally preserved, whereas in MDE, feelings of worthlessness and self-loathing are common. If self-derogatory ideation is present in grief, it typically involves perceived failings vis-à-vis the deceased (e.g., not visiting frequently enough, not telling the deceased how much he or she was loved). If a bereaved individual thinks about death and dying, such thoughts are generally focused on the deceased and possibly "joining" the deceased, whereas in a major depressive episode such thoughts are focused on ending one's own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

Bipolar I Disorder

- A. Criteria have been met for at least one manic episode (Criteria A to D under "Manic Episode" above).
- B. The occurrence of the manic and major depressive episode(s) is not better explained by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.

Coding and Recording Procedures

The diagnostic code for bipolar disorder is based on type of current or most recent episode and its status with respect to current severity, presence of psychotic features, and remission status. Current severity and psychotic features are only indicated if full criteria are currently met for a manic or major depressive episode. Remission specifiers are only indicated if the full criteria are not currently met for a manic, hypomanic, or major depressive episode. Codes are as follows:

Bipolar I Disorder	Current or Most Recent Episode Manic	Current or Most Recent Episode Hypomanic ^a	Current or Most Recent Episode Depressed	Current or Most Recent Episode Unspecified ^b
Mild (p. 154)	296.41 (F31.11)	NA	296.51 (F31.31)	NA
Moderate (p. 154)	296.43 (F31.12)	NA	296.52 (F31.32)	NA
Severe (p. 154)	296.43 (F31.13)	NA	296.53 (F31.4)	NA
With psychotic features ^c (p. 152)	296.44 (F31.2)	NA	296.54 (F31.5)	NA
In partial remission (p. 154)	296.45 (F31.73)	NA	296.55 (F31.75)	NA
In full remission (p. 154)	296.46 (F31.74)	NA	296.56 (F31.76)	NA
Unspecified	296.40 (F31.9)	NA	296.50 (F31.9)	NA

^aSeverity and psychotic specifiers do not apply; use code 296.40 (F31.0) for cases not in remission.

^bSeverity, psychotic, and remission specifiers do not apply. Code 296.7 (F31.9).

^cIf psychotic features are present, code the "with psychotic features" specifier irrespective of episode severity.

In recording the name of a diagnosis, terms should be listed in the following order: major depressive disorder; single or recurrent episode; and severity, psychotic, and remission specifiers followed by as many of the following specifiers without codes that apply to the current episode.

In recording the name of a diagnosis, terms should be listed in the following order: bipolar I disorder, type of current or most recent episode, severity/psychotic/remission specifiers, followed by as many specifiers without codes as apply to the current or most recent episode.

Specify:

- With anxious distress (p. 149)
- With mixed features (pp. 149–150)
- With rapid cycling (pp. 150–151)
- With melancholic features (p. 151)
- With atypical features (p. 151–152)
- With mood-congruent psychotic features (p. 152)
- With mood-incongruent psychotic features (p. 152)
- With catatonia (p. 152). Coding note: Use additional code 293.89 (F06.1).
- With peripartum onset (pp. 152–153)
- With seasonal pattern (pp. 153–154)

The designation bipolar I disorder is synonymous with what was formerly known as bipolar disorder—a syndrome in which a complete set of mania symptoms occurs during the course of the disorder. The diagnostic criteria for bipolar II disorder is characterized by depressive episodes and hypomanic episodes during the course of the disorder, but the episodes of manic-like symptoms do not quite meet the diagnostic criteria for a full manic syndrome.

Manic episodes clearly precipitated by antidepressant treatment (e.g., pharmacotherapy, electroconvulsive therapy [ECT]) do not indicate bipolar I disorder.

Bipolar I Disorder, Single Manic Episode. According to DSM-5, patients must be experiencing their first manic episode to meet the diagnostic criteria for bipolar I disorder, single manic episode. This requirement rests on the fact that patients who are having their first episode of bipolar I disorder depression cannot be distinguished from patients with major depressive disorder.

Bipolar I Disorder, Recurrent. The issues about defining the end of an episode of depression also apply to defining the end of an episode of mania. Manic episodes are considered distinct when they are separated by at least 2 months without significant symptoms of mania or hypomania.

Bipolar II Disorder

The diagnostic criteria for bipolar II disorder specify the particular severity, frequency, and duration of the hypomanic symptoms. The diagnostic criteria for a hypomanic episode are listed together with the criteria for bipolar II disorder (also in Table 8.1-6). The criteria have been established to decrease overdiagnosis of hypomanic episodes and the incorrect classification of patients with major depressive disorder as patients with bipolar II disorder. Clinically, psychiatrists may find it difficult to distinguish euthymia from hypomania in a patient who has been chronically depressed for many months or years. As with bipolar I disorder, antidepressant-induced hypomanic episodes are not diagnostic of bipolar II disorder.

Specifiers (Symptom Features)

In addition to the severity, psychotic, and remission descriptions, additional symptom features (specifiers) can be used to describe patients with various mood disorders.

With Psychotic Features. The presence of psychotic features in major depressive disorder reflects severe disease and is a poor prognostic indicator. A review of the literature comparing psychotic with nonpsychotic major depressive disorder indicates that the two conditions may be distinct in their pathogenesis. One difference is that bipolar I disorder is more common in the families of probands with psychotic depression than in the families of probands with nonpsychotic depression.

The psychotic symptoms themselves are often categorized as either mood congruent, that is, in harmony with the mood disorder (“I deserve to be punished because I am so bad”), or mood incongruent, not in harmony with the mood disorder. Patients with mood disorder with mood-congruent psychoses have a psychotic type of mood disorder; however, patients with mood disorder with mood-incongruent psychotic symptoms may have schizoaffective disorder or schizophrenia.

The following factors have been associated with a poor prognosis for patients with mood disorders: long duration of episodes, temporal dissociation between the mood disorder and the psychotic symptoms, and a poor premorbid history of social adjustment. The presence of psychotic features also has significant treatment implications. These patients typically require antipsychotic drugs in addition to antidepressants or mood stabilizers and may need ECT to obtain clinical improvement.

With Melancholic Features. *Melancholia* is one of the oldest terms used in psychiatry, dating back to Hippocrates in the 4th century to describe the dark mood of depression. It is still used to refer to a depression characterized by severe anhedonia, early morning awakening, weight loss, and profound feelings of guilt (often over trivial events). It is not uncommon for patients who are melancholic to have suicidal ideation. Melancholia is associated with changes in the autonomic nervous system and in endocrine functions. For that reason, melancholia is sometimes referred to as “endogenous depression” or depression that arises in the absence of external life stressors or precipitants. The DSM-5 melancholic features can be applied to major depressive episodes in major depressive disorder, bipolar I disorder, or bipolar II disorder.

With Atypical Features. The introduction of a formally defined depression with atypical features is a response to research and clinical data indicating that patients with atypical features have specific, predictable characteristics: overeating and oversleeping. These symptoms have sometimes been referred to as *reversed vegetative symptoms*, and the symptom pattern has sometimes been called *hysteroid dysphoria*. When patients with major depressive disorder with atypical features are compared with patients with typical depression features, the patients with atypical features are found to have a younger age of onset; more severe psychomotor slowing; and more frequent coexisting diagnoses of panic disorder, substance abuse or dependence, and somatization disorder. The high incidence and severity of anxiety symptoms in patients with atypical features have sometimes been correlated with the likelihood of their being misclassified as having an anxiety disorder rather than a mood disorder. Patients with atypical features may also have a long-term course, a diagnosis of bipolar I disorder, or a seasonal pattern to their disorder.

The DSM-5 atypical features can be applied to the most recent major depressive episode in major depressive disorder, bipolar I disorder, bipolar II disorder, or dysthymic disorder. Atypical depression may mask manic symptoms as in the following case.

Kevin, a 15-year-old adolescent, was referred to a sleep center to rule out narcolepsy. His main complaints were fatigue, boredom, and a need to sleep all the time. Although he had always started the day somewhat slowly, he now could not get out of bed to go to school. That alarmed his mother, prompting sleep consultation. Formerly a B student, he had been failing most of his courses in the 6 months before referral. Psychological counseling, predicated on the premise that his family's recent move from another city had led to Kevin's isolation, had not been beneficial. Extensive neurological and general medical workup findings had also proven negative. He slept 12 to 15 hours per day but denied cataplexy, sleep paralysis, and hypnagogic hallucinations. During psychiatric interview, he denied being depressed but admitted that he had lost interest in everything except his dog. He had no drive, participated in no activities, and had gained 30 pounds in 6 months. He believed that he was “brain damaged” and wondered whether it was worth living like that. The question of suicide disturbed him because it was contrary to his religious beliefs. These findings led to the prescription of desipramine (Norpramin) in a dosage that was gradually increased to 200 mg per day over 3 weeks. Not only did desipramine reverse the presenting complaints, but it also pushed him to the brink of a manic episode. (Courtesy of HS Akiskal, M.D.)

With Catatonic Features. As a symptom, catatonia can be present in several mental disorders, most commonly, schizophrenia and the mood disorders. The presence of catatonic features in patients with mood disorders may have prognostic and treatment significance.

The hallmark symptoms of catatonia—stuporousness, blunted affect, extreme withdrawal, negativism, and marked psychomotor retardation—can be seen in both catatonic and noncatatonic schizophrenia, major depressive disorder (often with psychotic features), and medical and neurological disorders. Clinicians often do not associate catatonic symptoms with bipolar I disorder because of the marked contrast between the symptoms of stuporous catatonia and the classic symptoms of mania. Because catatonic symptoms are a behavioral syndrome appearing in several medical and psychiatric conditions, catatonic symptoms do not imply a single diagnosis. Catatonia is discussed in detail in Section 7.5.

Postpartum Onset. DSM-5 allows the specification of a postpartum mood disturbance if the onset of symptoms is within 4 weeks postpartum. Postpartum mental disorders commonly include psychotic symptoms. Postpartum disorders are discussed in Section 26.1, Psychiatry and Reproductive Medicine.

Rapid Cycling. Patients with rapid cycling bipolar I disorder are likely to be female and to have had depressive and hypomanic episodes. No data indicate that rapid cycling has a familial pattern of inheritance; thus, an external factor such as stress or drug treatment may be involved in the pathogenesis of rapid cycling. The DSM-5 criteria specify that the patient must have at least four episodes within a 12-month period.

Seasonal Pattern. Patients with a seasonal pattern to their mood disorders tend to experience depressive episodes during a particular season, most commonly winter. The pattern has become known as seasonal affective disorder (SAD), although this term is not used in DSM-5. Two types of evidence indicate that the seasonal pattern may represent a separate diagnostic entity. First, the patients are likely to respond to treatment with light therapy, although no studies with controls to evaluate light therapy in nonseasonally depressed patients have been conducted. Second, research has shown that patients evince decreased metabolic activity in the orbital frontal cortex and in the left inferior parietal lobe. Further studies are necessary to differentiate depressed persons with seasonal pattern from other depressed persons. This disorder is discussed further in Section 16.2 on Sleep-Wake Disorders.

Non-DSM-5 Types. DSM-5 specifiers for depressive disorders are included in Table 8.1-7. Other systems that identify types of patients with mood disorders usually separate patients with good and poor prognoses or patients who may respond to one treatment or another. They also differentiate endogenous-reactive and primary-secondary schemes.

Table 8.1-7
DSM-5 Specifiers for Depressive Disorders

This category applies to the presentations in which symptoms characteristic of a depressive disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for any of the disorders in the depressive disorders diagnostic class. The unspecified depressive disorder category is used in situations in which the clinician chooses not to specify the reason that the criteria are not met for a specific depressive disorder, and includes presentations for which there is insufficient information to make a more specific diagnosis (e.g., in emergency room settings).

Specifiers for Depressive Disorders

Specify if:

With anxious distress: Anxious distress is defined as the presence of at least two of the following symptoms during the majority of days of a major depressive episode or persistent depressive disorder (dysthymia):

1. Feeling keyed up or tense.
2. Feeling unusually restless.
3. Difficulty concentrating because of worry.
4. Fear that something awful may happen.
5. Feeling that the individual might lose control of himself or herself.

Specify current severity:

Mild: Two symptoms.

Moderate: Three symptoms.

Moderate-severe: Four to five symptoms.

Severe: Four or five symptoms and with motor agitation.

Note: Anxious distress has been noted as a prominent feature of both bipolar and major depressive disorder in both primary care and specialty mental health settings. High levels of anxiety have been associated with higher suicide risk, longer duration of illness, and greater likelihood of treatment nonresponse. As a result, it is clinically useful to specify accurately the presence and severity levels of anxious distress for treatment planning and monitoring of response to treatment.

With mixed features:

A. At least three of the following manic/hypomanic symptoms are present nearly every day during the majority of days of a major depressive episode:

1. Elevated, expansive mood.
2. Inflated self-esteem or grandiosity.
3. More talkative than usual or pressure to keep talking.
4. Flight of ideas or subjective experience that thoughts are racing.
5. Increase in energy or goal-directed activity (either socially, at work or school, or sexually).
6. Increased or excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, foolish business investments).
7. Decreased need for sleep (feeling rested despite sleeping less than usual; to be contrasted with insomnia).

B. Mixed symptoms are observable by others and represent a change from the person's usual behavior.

C. For individuals whose symptoms meet full criteria for either mania or hypomania, the diagnosis should be bipolar I or bipolar II disorder.

D. The mixed symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication or other treatment).

Note: Mixed features associated with a major depressive episode have been found to be a significant risk factor for the development of bipolar I or bipolar II disorder. As a result, it is clinically useful to note the presence of this specifier for treatment planning and monitoring of response to treatment.

With melancholic features:

A. One of the following is present during the most severe period of the current episode:

1. Loss of pleasure in all, or almost all, activities.
2. Lack of reactivity to usually pleasurable stimuli (does not feel much better, even temporarily, when something good happens).

B. Three (or more) of the following:

1. A distinct quality of depressed mood characterized by profound despondency, despair, and/or moroseness or by so-called empty mood.
2. Depression that is regularly worse in the morning.
3. Early-morning awakening (i.e., at least 2 hours before usual awakening).
4. Marked psychomotor agitation or retardation.
5. Significant anorexia or weight loss.
6. Excessive or inappropriate guilt.

Note: The specifier "with melancholic features" is applied if these features are present at the most severe stage of the episode. There is a near-complete absence of the capacity for pleasure, not merely a diminution. A guideline for evaluating the lack of reactivity of mood is that even highly desired events are not associated with marked brightening of mood. Either mood does not brighten at all, or it brightens only partially (e.g., up to 20% to 40% of normal for only minutes at a time). The "distinct quality" of mood that is characteristic of the "with melancholic features" specifier is experienced as qualitatively different from that during a nonmelancholic depressive episode. A depressed mood that is described as merely more severe, longer lasting, or present without a reason is not considered distinct in quality. Psychomotor changes are nearly always present and are observable by others.

Melancholic features exhibit only a modest tendency to repeat across episodes in the same individual. They are more frequent in inpatients, as opposed to outpatients; are less likely to occur in milder than in more severe major depressive episodes; and are more likely to occur in those with psychotic features.

With atypical features: This specifier can be applied when these features predominate during the majority of days of the current or most recent major depressive episode or persistent depressive disorder.

A. Mood reactivity (i.e., mood brightens in response to actual or potential positive events).

B. Two (or more) of the following:

1. Significant weight gain or increase in appetite.
2. Hypersomnia.
3. Lead paralysis (i.e., heavy, laden feelings in arms or legs).
4. A long-standing pattern of interpersonal rejection sensitivity (not limited to episodes of mood disturbance) that results in significant social or occupational impairment.

C. Criteria are not met for "with melancholic features" or "with catatonia" during the same episode.

Note: "Atypical depression" has historical significance (i.e., atypical in contradistinction to the more classical agitated, "endogenous" presentations of depression that were the norm when depression was rarely diagnosed in outpatients and almost never in adolescents or older children) and today does not connote an uncommon or unusual clinical presentation as the term might imply.

Mood reactivity is the capacity to be cheered up when presented with positive events (e.g., a visit from children, compliments from others). Mood may become euthymic (not sad) even for extended periods of time if the external circumstances remain favorable. Increased appetite may be manifested by an obvious increase in food intake or by weight gain. Hypersomnia may include either an extended period of nighttime sleep or daytime napping that totals at least 10 hours of sleep per day (or at least 2 hours more than when not depressed). Lead paralysis is defined by feeling heavy, laden, or weighted down, usually in the arms or legs. This sensation is generally present for at least an hour a day but often lasts for many hours at a time. Unlike the other atypical features, pathological sensitivity to perceived interpersonal rejection is a trait that has an early onset and persists throughout most of adult life. Rejection sensitivity occurs both when the person is and is not depressed, though it may be exacerbated during depressive periods.

With psychotic features: Delusions and/or hallucinations are present.

With mood-congruent psychotic features: The content of all delusions and hallucinations is consistent with the typical depressive themes of personal inadequacy, guilt, disease, death, nihilism, or deserved punishment.

With mood-incongruent psychotic features: The content of the delusions or hallucinations does not involve typical depressive themes of personal inadequacy, guilt, disease, death, nihilism, or deserved punishment, or the content is a mixture of mood-incongruent and mood-congruent themes.

With catatonia: The catatonia specifier can apply to an episode of depression if catatonic features are present during most of the episode. See the criteria for catatonia associated with a mental disorder (for a description of catatonia, see the chapter "Schizophrenia Spectrum and Other Psychotic Disorders").

With peripartum onset: This specifier can be applied to the current of, if full criteria are not currently met for a major depressive episode, most recent episode of major depression if onset of mood symptoms occurs during pregnancy or in the 4 weeks following delivery.

Note: Mood episodes can have their onset during pregnancy or postpartum. Although the estimates differ according to the period of follow-up after delivery, between 3% and 6% of women will experience the onset of a major depressive episode during pregnancy or in the weeks following delivery. Fifty percent of "postpartum" major depressive episodes actually begin prior to delivery. Thus, these episodes are referred to collectively as *peripartum* episodes. Women with peripartum major depressive episodes often have severe anxiety and even panic attacks. Prospective studies have demonstrated that mood and anxiety symptoms during pregnancy, as well as the "baby blues," increase the risk for a postpartum major depressive episode.

Peripartum-onset mood episodes can present either with or without psychotic features. Infanticide is most often associated with postpartum psychotic episodes that are characterized by command hallucinations to kill the infant or delusions that the infant is possessed, but psychotic symptoms can also occur in severe postpartum mood episodes without such specific delusions of hallucinations.

Postpartum mood (major depressive or manic) episodes with psychotic features appear to occur in from 1 to 500 to 1 in 1,000 deliveries and may be more common in primiparous women. The risk of postpartum episodes with psychotic features is particularly increased for women with prior history of a depressive or bipolar disorder (especially bipolar I disorder) and those with a family history of bipolar disorders.

Once a woman has had a postpartum episode with psychotic features, the risk of recurrence with each subsequent delivery is between 30% and 50%. Postpartum episodes must be differentiated from delirium occurring in the postpartum period, which is distinguished by a fluctuating level of awareness or attention. The postpartum period is unique with respect to the degree of neuroendocrine alterations and psychosocial adjustments, the potential impact of breastfeeding on treatment planning, and the long-term implications of a history of postpartum mood disorder on subsequent family planning.

With seasonal pattern: This specifier applies to recurrent major depressive disorder.

A. There has been a regular temporal relationship between the onset of major depressive episodes in major depressive disorder and a particular time of the year (e.g., in the fall or winter).

Note: Do not include cases in which there is an obvious effect of seasonally related psychosocial stressors (e.g., regularly being unemployed every winter).

B. Full remissions (or a change from major depression to mania or hypomania) also occur at a characteristic time of the year (e.g., depression disappears in the spring).

C. In the past 2 years, two major depressive episodes have occurred that demonstrate the temporal seasonal relationships defined above, and no nonseasonal major depressive episodes have occurred during that same period.

D. Seasonal major depressive episodes (as described above) substantially outnumber the nonseasonal major depressive episodes that may have occurred over the individual's lifetime.

Note: The specifier "with seasonal pattern" can be applied to the pattern of major depressive episodes in major depressive disorder, recurrent. The essential feature is the onset and remission of major depressive episodes at characteristic times of the year. In most cases, the episodes begin in fall or winter and remit in spring. Less commonly, there may be recurrent summer depressive episodes. This pattern of onset and remission of episodes must have occurred during at least a 2-year period, without any nonseasonal episodes must have occurred during this period. In addition, the seasonal depressive episodes must substantially outnumber any nonseasonal depressive episodes over the individual's lifetime.

This specifier does not apply to those situations in which the pattern is better explained by seasonally linked psychosocial stressors (e.g., seasonal unemployment or school schedule). Major depressive episodes that occur in a seasonal pattern are often characterized by prominent energy, hypersomnia, overeating, weight gain, and a craving for carbohydrates. It is unclear whether a seasonal pattern is more likely in recurrent major depressive disorder or in bipolar disorders. However, within the bipolar disorders group, a seasonal pattern appears to be more likely in bipolar II disorder than in bipolar I disorder. In some individuals, the onset of manic or hypomanic episodes may also be linked to a particular season.

The prevalence of winter-type seasonal pattern appears to vary with latitude, age, and sex. Prevalence increases with higher latitudes. Age is also a strong predictor of seasonality, with younger persons at higher risk for winter depressive episodes.

Specify if:

In partial remission: Symptoms of the immediately previous major depressive episode are present, but full criteria are not met, or there is a period lasting less than 2 months without any significant symptoms of a major depressive episode following the end of such an episode.

In full remission: During the past 2 months, no significant signs or symptoms of the disturbance were present.

Specify current severity:

Severity is based on the number of criterion symptoms, the severity of those symptoms, and the degree of functional disability.

Mild: Few, if any, symptoms in excess of those required to make the diagnosis are present, the intensity of the symptoms is distressing but manageable, and the symptoms result in minor impairment in social or occupational functioning.

Moderate: The number of symptoms, intensity of symptoms, and/or functional impairment are between those specified for "mild" and "severe."

Severe: The number of symptoms is substantially in excess of that required to make the diagnosis, the intensity of the symptoms is seriously distressing and unmanageable, and the symptoms markedly interfere with social and occupational functioning.

The endogenous-reactive continuum is a controversial division. It implies that endogenous depressions are biological and that reactive depressions are psychological, primarily on the basis of the presence or absence of an identifiable precipitating stress. Other symptoms of endogenous depression have been described as diurnal variation, delusions, psychomotor retardation, early morning awakening, and feelings of guilt; thus, endogenous depression is similar to the DSM-5 diagnosis of major depressive disorder with psychotic features, melancholic features, or both. Symptoms of reactive depression have included initial insomnia, anxiety, emotional lability, and multiple somatic complaints.

Primary depressions are what DSM-5 refers to as mood disorders, except for the diagnoses of mood disorder caused by a general medical condition and substance-induced mood disorder, which are considered secondary depressions. Double depression is the condition in which major depressive disorder is superimposed on dysthymic disorder. A depressive equivalent is a symptom or syndrome that may be a *forme fruste* of a depressive episode. For example, a triad of truancy, alcohol abuse, and sexual promiscuity in a formerly well-behaved adolescent may constitute a depressive equivalent.

CLINICAL FEATURES

The two basic symptom patterns in mood disorders are depression and mania. Depressive episodes can occur in both major depressive disorder and bipolar I disorder. Researchers have attempted to find reliable differences between bipolar I disorder depressive episodes and episodes of major depressive disorder, but the differences are elusive. In a clinical situation, only the patient's history, family history, and future course can help differentiate the two conditions. Some patients with bipolar I disorder have mixed states with both manic and depressive features, and some seem to experience brief—minutes to a few hours—episodes of depression during manic episodes.

Depressive Episodes

A depressed mood and a loss of interest or pleasure are the key symptoms of depression. Patients may say that they feel blue, hopeless, in the dumps, or worthless. For a patient, the depressed mood often has a distinct quality that differentiates it from the normal emotion of sadness or grief. Patients often describe the symptom of depression as one of agonizing emotional pain and sometimes complain about being unable to cry, a symptom that resolves as they improve.

About two-thirds of all depressed patients contemplate suicide, and 10 to 15 percent commit suicide. Those recently hospitalized with a suicide attempt or suicidal ideation have a higher lifetime risk of successful suicide than those never hospitalized for suicidal ideation. Some depressed patients sometimes seem unaware of their depression and do not complain of a mood disturbance even though they exhibit withdrawal from family, friends, and activities that previously interested them. Almost all depressed patients (97 percent) complain about reduced energy; they have difficulty finishing tasks, are impaired at school and work, and have less motivation to undertake new projects. About 80 percent of patients complain of trouble sleeping, especially early morning awakening (i.e., terminal insomnia) and multiple awakenings at night, during which they ruminate about their problems. Many patients have decreased appetite and weight loss, but others experience increased appetite and weight gain and sleep longer than usual. These patients are classified as having atypical features.

Anxiety, a common symptom of depression, affects as many as 90 percent of all depressed patients. The various changes in food intake and rest can aggravate coexisting medical illnesses such as diabetes, hypertension, chronic obstructive lung disease, and heart disease. Other vegetative symptoms include abnormal menses and decreased interest and performance in sexual activities. Sexual problems can sometimes lead to inappropriate referrals, such as to marital counseling and sex therapy, when clinicians fail to recognize the underlying depressive disorder. Anxiety (including panic attacks), alcohol abuse, and somatic complaints (e.g., constipation and headaches) often complicate the treatment of depression. About 50 percent of all patients describe a diurnal variation in their symptoms, with increased severity in the morning and lessening of symptoms by evening. Cognitive symptoms include subjective reports of an inability to concentrate (84 percent of patients in one study) and impairments in thinking (67 percent of patients in another study).

Depression in Children and Adolescents. School phobia and excessive clinging to parents may be symptoms of depression in children. Poor academic performance, substance abuse, antisocial behavior, sexual promiscuity, truancy, and running away may be symptoms of depression in adolescents.

Depression in Older People. Depression is more common in older persons than it is in the general population. Various studies have reported prevalence rates ranging from 25 to almost 50 percent, although the percentage of these cases that are caused by major depressive disorder is uncertain. Several studies indicate that depression in older persons may be correlated with low socioeconomic status, the loss of a spouse, a concurrent physical illness, and social isolation. Other studies have indicated that depression in older persons is underdiagnosed and undertreated, perhaps particularly by general practitioners. The underrecognition of depression in older persons may occur because the disorder appears more often with somatic complaints in older, than in younger, age groups. Further, ageism may influence and cause clinicians to accept depressive symptoms as normal in older patients.

Manic Episodes

An elevated, expansive, or irritable mood is the hallmark of a manic episode. The elevated mood is euphoric and often infectious and can even cause a countertransference denial of illness by an inexperienced clinician. Although uninvolved persons may not recognize the unusual nature of a patient's mood, those who know the patient recognize it as abnormal. Alternatively, the mood may be irritable, especially when a patient's overtly ambitious plans are thwarted. Patients often exhibit a change of predominant mood from euphoria early in the course of the illness to later irritability.

The treatment of manic patients in an inpatient ward can be complicated by their testing of the limits of ward rules, tendency to shift responsibility for their acts onto others, exploitation of the weaknesses of others, and propensity to create conflicts among staff members. Outside the hospital, manic patients often drink alcohol excessively, perhaps in an attempt to self-medicate. Their disinhibited nature is reflected in excessive use of the telephone, especially in making long-distance calls during the early morning hours.

Pathological gambling, a tendency to disrobe in public places, wearing clothing and jewelry of bright colors in unusual or outlandish combinations, and inattention to small details (e.g., forgetting to hang up the telephone) are also symptomatic of the disorder. Patients act impulsively and at the same time with a sense of conviction and purpose. They are often preoccupied by religious, political, financial, sexual, or persecutory ideas that can evolve into complex delusional systems. Occasionally, manic patients become regressed and play with their urine and feces.

Mania in Adolescents. Mania in adolescents is often misdiagnosed as antisocial personality disorder or schizophrenia. Symptoms of mania in adolescents may include psychosis, alcohol or other substance abuse, suicide attempts, academic problems, philosophical brooding, OCD symptoms, multiple somatic complaints, marked irritability resulting in fights, and other antisocial behaviors. Although many of these symptoms are seen in normal adolescents, severe or persistent symptoms should cause clinicians to consider bipolar I disorder in the differential diagnosis.

Bipolar II Disorder

The clinical features of bipolar II disorder are those of major depressive disorder combined with those of a hypomanic episode. Although the data are limited, a few studies indicate that bipolar II disorder is associated with more marital disruption and with onset at an earlier age than bipolar I disorder. Evidence also indicates that patients with bipolar II disorder are at greater risk of both attempting and completing suicide than patients with bipolar I disorder and major depressive disorder.

Coexisting Disorders

Anxiety. In the anxiety disorders, DSM-5 notes the existence of mixed anxiety–depressive disorder. Significant symptoms of anxiety can and often do coexist with significant symptoms of depression. Whether patients who exhibit significant symptoms of both anxiety and depression are affected by two distinct disease processes or by a single disease process that produces both sets of symptoms is not yet resolved. Patients of both types may constitute the group of patients with mixed anxiety–depressive disorder.

Alcohol Dependence. Alcohol dependence frequently coexists with mood disorders. Both patients with major depressive disorder and those with bipolar I disorder are likely to meet the diagnostic criteria for an alcohol use disorder. The available data indicate that alcohol dependence is more strongly associated with a coexisting diagnosis of depression in women than in men. In contrast, the genetic and family data about men who have both a mood disorder and alcohol dependence indicate that they are likely to have two genetically distinct disease processes.

Other Substance-Related Disorders. Substance-related disorders other than alcohol dependence are also commonly associated with mood disorders. The abuse of substances may be involved in precipitating an episode of illness or, conversely, may represent patients' attempts to treat their own illnesses. Although manic patients seldom use sedatives to dampen their euphoria, depressed patients often use stimulants, such as cocaine and amphetamines, to relieve their depression.

Medical Conditions. Depression commonly coexists with medical conditions, especially in older persons. When depression and medical conditions coexist, clinicians must try to determine whether the underlying medical condition is pathophysiologically related to the depression or whether any drugs that the patient is taking for the medical condition are causing the depression. Many studies indicate that treatment of a coexisting major depressive disorder can improve the course of the underlying medical disorder, including cancer.

MENTAL STATUS EXAMINATION

General Description

Generalized psychomotor retardation is the most common symptom of depression, although psychomotor agitation is also seen, especially in older patients. Hand wringing and hair pulling are the most common symptoms of agitation. Classically, a depressed patient has a stooped posture; no spontaneous movements; and a downcast, averted gaze (Figs. 8.1-4 and 8.1-5). On clinical examination, depressed patients exhibiting gross symptoms of psychomotor retardation may appear identical to patients with catatonic schizophrenia.

FIGURE 8.1-4

A 38-year-old woman during a state of deep retarded depression (A) and 2 months later after recovery (B). The turned-down corners of her mouth, her stooped posture, her drab clothing, and her hairdo during the depressed episode are noteworthy. (Courtesy of Heinz E. Lehmann, M.D.)

FIGURE 8.1-5

The Swiss neuropsychiatrist Otto Veraguth described a peculiar triangle-shaped fold in the nasal corner of the upper eyelid. The fold is often associated with depression and referred to as Veraguth's fold. The photograph illustrates this physiognomic feature in a 50-year-old man during a major depressive episode. Veraguth's fold may also be seen in persons who are not clinically depressed, usually while they are harboring a mild depressive affect. Distinct changes in the tone of the corrugator and zygomatic facial muscles accompany depression, as shown on electromyograms. (Courtesy of Heinz E. Lehmann, M.D.)

Ms. A, a 34-year-old literature professor, presented to a mood clinic with the following complaint: "I am in a daze, confused, disoriented, staring. My thoughts do not flow, my mind is arrested....I seem to lack any sense of direction, purpose....I have such an inertia, I cannot assert myself. I cannot fight; I have no will."

Mood, Affect, and Feelings

Depression is the key symptom, although about 50 percent of patients deny depressive feelings and do not appear to be particularly depressed. Family members or employers often bring or send these patients for treatment because of social withdrawal and generally decreased activity.

Speech

Many depressed patients have decreased rate and volume of speech; they respond to questions with single words and exhibit delayed responses to questions. The examiner may literally have to wait 2 or 3 minutes for a response to a question.

Perceptual Disturbances

Depressed patients with delusions or hallucinations are said to have a major depressive episode with psychotic features. Even in the absence of delusions or hallucinations, some clinicians use the term *psychotic depression* for grossly regressed depressed patients—mute, not bathing, soiling. Such patients are probably better described as having catatonic features.

Delusions and hallucinations that are consistent with a depressed mood are said to be mood congruent. Mood-congruent delusions in a depressed person include those of guilt, sinfulness, worthlessness, poverty, failure, persecution, and terminal somatic illnesses (such as cancer and a "rotting" brain). The content of mood-incongruent delusions or hallucinations is not consistent with a depressed mood. For example, a mood-incongruent delusion in a depressed person might involve grandiose themes of exaggerated power, knowledge, and worth. When that occurs, a schizophrenic disorder should be considered.

A 42-year-old civil servant said that she was so paralyzed by depression that she felt that she had no personal initiative and volition left; she believed that some malignant force had taken over her actions and that it was commenting on every action that she was undertaking. The patient recovered fully with thymoleptic medication. There is no reason to believe that, in this patient, the feelings of somatic passability and running commentary indicated a schizophrenic process.

Thought

Depressed patients customarily have negative views of the world and of themselves. Their thought content often includes nondelusional ruminations about loss, guilt, suicide, and death. About 10 percent of all depressed patients have marked symptoms of a thought disorder, usually thought blocking and profound poverty of content.

Sensorium and Cognition

Orientation. Most depressed patients are oriented to person, place, and time, although some may not have sufficient energy or interest to answer questions about these subjects during an interview.

Memory. About 50 to 75 percent of all depressed patients have a cognitive impairment, sometimes referred to as *depressive pseudodementia*. Such patients commonly complain of impaired concentration and forgetfulness.

Impulse Control

About 10 to 15 percent of all depressed patients commit suicide, and about two-thirds have suicidal ideation. Depressed patients with psychotic features occasionally consider killing a person as a result of their delusional systems, but the most severely depressed patients often lack the motivation or the energy to act in an impulsive or violent way. Patients with depressive disorders are at increased risk of suicide as they begin to improve and regain the energy needed to plan and carry out a suicide (paradoxical suicide). It is usually clinically unwise to give a depressed patient a large prescription for a large number of antidepressants, especially tricyclic drugs, at the time of their discharge from the hospital. Similarly, drugs that may be activating, such as fluoxetine, may be prescribed in such a way that the energizing qualities are minimized (e.g., be given a benzodiazepine at the same time).

Judgment and Insight

Judgment is best assessed by reviewing patients' actions in the recent past and their behavior during the interview. Depressed patients' descriptions of their disorder are often hyperbolic; they overemphasize their symptoms, their disorder, and their life problems. It is difficult to convince such patients that improvement is possible.

Reliability

In interviews and conversations, depressed patients overemphasize the bad and minimize the good. A common clinical mistake is to unquestioningly believe a depressed patient who states that a previous trial of antidepressant medications did not work. Such statements may be false, and they require confirmation from another source. Psychiatrists should not view patients' misinformation as an intentional fabrication; the admission of any hopeful information may be impossible for a person in a depressed state of mind.

Objective Rating Scales for Depression

Objective rating scales for depression can be useful in clinical practice for documenting the depressed patient's clinical state.

Zung. The Zung Self-Rating Depression Scale is a 20-item report scale. A normal score is 34 or less; a depressed score is 50 or more. The scale provides a global index of the intensity of a patient's depressive symptoms, including the affective expression of depression.

Raskin. The Raskin Depression Scale is a clinician-rated scale that measures the severity of a patient's depression, as reported by the patient and as observed by the physician, on a 5-point scale of three dimensions: verbal report, displayed behavior, and secondary symptoms. The scale has a range of 3 to 13; a normal score is 3, and a depressed score is 7 or more.

Hamilton. The Hamilton Rating Scale for Depression (HAM-D) is a widely used depression scale with up to 24 items, each of which is rated 0 to 4 or 0 to 2, with a total score of 0 to 76. The clinician evaluates the patient's answers to questions about feelings of guilt, thoughts of suicide, sleep habits, and other symptoms of depression, and the ratings are derived from the clinical interview.

Manic Episodes

General Description. Manic patients are excited, talkative, sometimes amusing, and frequently hyperactive. At times, they are grossly psychotic and disorganized and require physical restraints and the intramuscular injection of sedating drugs.

Mood, Affect, and Feelings

Manic patients classically are euphoric, but they can also be irritable, especially when mania has been present for some time. They also have a low frustration tolerance, which can lead to feelings of anger and hostility. Manic patients may be emotionally labile, switching from laughter to irritability to depression in minutes or hours.

Speech

Manic patients cannot be interrupted while they are speaking, and they are often intrusive nuisances to those around them. Their speech is often disturbed. As the mania gets more intense, speech becomes louder, more rapid, and difficult to interpret. As the activated state increases, their speech is filled with puns, jokes, rhymes, plays on words, and irrelevancies. At a still greater activity level, associations become loosened, the ability to concentrate fades, and flight of ideas, clanging, and neologisms appear. In acute manic excitement, speech can be totally incoherent and indistinguishable from that of a person with schizophrenia.

Perceptual Disturbances. Delusions occur in 75 percent of all manic patients. Mood-congruent manic delusions are often concerned with great wealth, extraordinary abilities, or power. Bizarre and mood-incongruent delusions and hallucinations also appear in mania.

A 29-year-old female college graduate, mother of two children, and wife of a bank president, had experienced several manic and retarded depressive episodes that had responded to lithium carbonate. She was referred to the author because she had developed the delusion that she had been involved in an international plot. Careful probing revealed that the delusion represented further elaboration, in a rather fantastic fashion, of a grandiose delusion that she had experienced during her last postpartum manic episode. She believed that she had played an important role in uncovering the plot, thereby becoming a national hero. Nobody knew about it, she contended, because the circumstances of the plot were top secret. She further believed that she had saved her country from the international scheme and suspected that she was singled out for persecution by the perpetrators of the plot. At one point, she had even entertained the idea that the plotters sent special radio communications to intercept and to interrupt her thoughts. As is typical in such cases, she was on a heavy dosage of a lithium-antipsychotic combination. The consultation was requested because the primary mood symptoms were under control, yet, she had not given up her grandiose delusion. She flippantly remarked, "I must be crazy to believe in my involvement in an international plot," but she could not help but believe in it. Over several months, seen typically in 60-minute sessions weekly, the patient had developed sufficient trust that the author could gently challenge her beliefs.

She was, in effect, told that her self-professed role in the international scheme was highly implausible and that someone with her superior education and high social standing could not entertain a belief, to use her own words, "as crazy as that." She eventually broke into tears, saying that everyone in her family was so accomplished and famous that to keep up with them she had to be involved in something grand; in effect, the international scheme, she said, was her only claim to fame: "Nobody ever gives me credit for raising two kids, and throwing parties for my husband's business colleagues: My mother is a dean, my older brother holds high political office; my sister is a medical researcher with five discoveries to her credit [all true], and who am I? Nothing. Now, do you understand why I need to be a national hero?" As she alternated, over subsequent months, between such momentary flashes of insight and delusional denial, antipsychotic medication was gradually discontinued. Maintained on lithium, she now only makes passing reference to the grand scheme. She was encouraged to pursue her career goal toward a master's degree in library science. (Courtesy of HS Akiskal, M.D.)

Thought. The manic patient's thought content includes themes of self-confidence and self-aggrandizement. Manic patients are often easily distracted, and their cognitive functioning in the manic state is characterized by an unrestrained and accelerated flow of ideas.

Sensorium and Cognition. Although the cognitive deficits of patients with schizophrenia have been much discussed, less has been written about similar deficits in patients with bipolar I disorder. These deficits can be interpreted as reflecting diffuse cortical dysfunction; subsequent work may localize the abnormal areas. Grossly, orientation and memory are intact, although some manic patients may be so euphoric that they answer questions testing orientation incorrectly. Emil Kraepelin called the symptom "delirious mania."

Impulse Control. About 75 percent of all manic patients are assaultive or threatening. Manic patients do attempt suicide and homicide, but the incidence of these behaviors is unknown.

Judgment and Insight. Impaired judgment is a hallmark of manic patients. They may break laws about credit cards, sexual activities, and finances and sometimes involve their families in financial ruin. Manic patients also have little insight into their disorder.

Reliability. Manic patients are notoriously unreliable in their information. Because lying and deceit are common in mania, inexperienced clinicians may treat manic patients with inappropriate disdain.

DIFFERENTIAL DIAGNOSIS

Major Depressive Disorder

Medical Disorders. The diagnosis of mood disorder due to a general medical condition must be considered. Failure to obtain a good clinical history or to consider the context of a patient's current life situation can lead to diagnostic errors. Clinicians should have depressed adolescents tested for mononucleosis, and patients who are markedly overweight or underweight should be tested for adrenal and thyroid dysfunctions. Homosexuals, bisexual men, prostitutes, and persons who abuse a substance intravenously should be tested for acquired immune deficiency syndrome (AIDS). Older patients should be evaluated for viral pneumonia and other medical conditions.

Many neurological and medical disorders and pharmacological agents can produce symptoms of depression. Patients with depressive disorders often first visit their general practitioners with somatic complaints. Most medical causes of depressive disorders can be detected with a comprehensive medical history, a complete physical and neurological examination, and routine blood and urine tests. The workup should include tests for thyroid and adrenal functions because disorders of both of these endocrine systems can appear as depressive disorders. In substance-induced mood disorder, a reasonable rule of thumb is that any drug a depressed patient is taking should be considered a potential factor in the mood disorder. Cardiac drugs, antihypertensives, sedatives, hypnotics, antipsychotics, antiepileptics, antiparkinsonian drugs, analgesics, antibacterials, and antineoplastics are all commonly associated with depressive symptoms.

NEUROLOGICAL CONDITIONS. The most common neurological problems that manifest depressive symptoms are Parkinson's disease, dementing illnesses (including dementia of the Alzheimer's type), epilepsy, cerebrovascular diseases, and tumors. About 50 to 75 percent of all patients with Parkinson's disease have marked symptoms of depressive disorder that do not correlate with the patient's physical disability, age, or duration of illness but do correlate with the presence of abnormalities found on neuropsychological tests. The symptoms of depressive disorder can be masked by the almost identical motor symptoms of Parkinson's disease. Depressive symptoms often respond to antidepressant drugs or ECT. The interictal changes associated with temporal lobe epilepsy can mimic a depressive disorder, especially if the epileptic focus is on the right side. Depression is a common complicating feature of cerebrovascular diseases, particularly in the 2 years after the episode. Depression is more common in anterior brain lesions than in posterior brain lesions and, in both cases, often responds to antidepressant medications. Tumors of the diencephalic and temporal regions are particularly likely to be associated with depressive disorder symptoms.

PSEUDODEMENTIA. Clinicians can usually differentiate the pseudodementia of major depressive disorder from the dementia of a disease, such as dementia of the Alzheimer's type, on clinical grounds. The cognitive symptoms in major depressive disorder have a sudden onset, and other symptoms of the disorder, such as self-reproach, are also present. A diurnal variation in the cognitive problems, which is not seen in primary dementias, may occur. Whereas depressed patients with cognitive difficulties often do not try to answer questions ("I don't know"), patients with dementia may confabulate. During an interview, depressed patients can sometimes be coached and encouraged into remembering, an ability that demented patients lack.

Mental Disorders. Depression can be a feature of virtually any mental disorder, but the mental disorders listed in [Table 8.1-8](#) deserve particular consideration in the differential diagnosis.

Table 8.1-8
Mental Disorders That Commonly Have Depressive Features

- Adjustment disorder with depressed mood
- Alcohol use disorders
- Anxiety disorders
 - Generalized anxiety disorder
 - Mixed anxiety–depressive disorder
 - Panic disorder
 - Posttraumatic stress disorder
 - Obsessive-compulsive disorder
- Eating disorders
 - Anorexia nervosa
 - Bulimia nervosa
- Mood disorders
 - Bipolar I disorder
 - Bipolar II disorder
 - Cyclothymic disorder
 - Dysthymic disorder
 - Major depressive disorder
 - Minor depressive disorder
 - Mood disorder due to a general medical condition
 - Recurrent brief depressive disorder
 - Substance-induced mood disorder
- Schizophrenia
- Schizophreniform disorder
- Somatoform disorders (especially somatization disorder)

OTHER MOOD DISORDERS. Clinicians must consider a range of diagnostic categories before arriving at a final diagnosis. Mood disorder caused by a general medical condition and substance-induced mood disorder must be ruled out. Clinicians must also determine whether a patient has had episodes of mania-like symptoms, indicating bipolar I disorder (complete manic and depressive syndromes), bipolar II disorder (recurrent major depressive episodes with hypomania), or cyclothymic disorder (incomplete depressive and manic syndromes). If a patient's symptoms are limited to those of depression, clinicians must assess the severity and duration of the symptoms to differentiate among major depressive disorder (complete depressive syndrome for 2 weeks), minor depressive disorder (incomplete but episodic depressive syndrome), recurrent brief depressive disorder (complete depressive syndrome but for less than 2 weeks per episode), and dysthymic disorder (incomplete depressive syndrome without clear episodes).

OTHER MENTAL DISORDERS. Substance-related disorders, psychotic disorders, eating disorders, adjustment disorders, somatoform disorders, and anxiety disorders are all commonly associated with depressive symptoms and should be considered in the differential diagnosis of a patient with depressive symptoms. Perhaps the most difficult differential is that between anxiety disorders with depression and depressive disorders with marked anxiety. An abnormal result on the dexamethasone-suppression test, the presence of shortened REM latency on a sleep electroencephalogram (EEG), and a negative lactate infusion test result support a diagnosis of major depressive disorder in particularly ambiguous cases.

UNCOMPLICATED BEREAVEMENT. Uncomplicated bereavement is not considered a mental disorder even though about one-third of all bereaved spouses for a time meet the diagnostic criteria for major depressive disorder. Some patients with uncomplicated bereavement do develop major depressive disorder, but the diagnosis is not made unless no resolution of the grief occurs. The differentiation is based on the symptoms' severity and length. In major depressive disorder, common symptoms that evolve from unresolved bereavement are a morbid preoccupation with worthlessness; suicidal ideation; feelings that the person has committed an act (not just an omission) that caused the spouse's death; mummification (keeping the deceased's belongings exactly as they were); and a particularly severe anniversary reaction, which sometimes includes a suicide attempt.

In severe forms of bereavement depression, the patient simply pines away, unable to live without the departed person, usually a spouse. Such persons do have a serious medical condition. Their immune function is often depressed, and their cardiovascular status is precarious. Death can ensue within a few months of that of a spouse, especially among elderly men. Such considerations suggest that it would be clinically unwise to withhold antidepressants from many persons experiencing such an intense mourning.

A 75-year-old widow was brought to treatment by her daughter because of severe insomnia and total loss of interest in daily routines after her husband's death 1 year before. She had been agitated for the first 2 to 3 months and thereafter "sank into total inactivity—not wanting to get out of bed, not wanting to do anything, not wanting to go out." According to her daughter, she was married at 21 years of age, had four children, and had been a housewife until her husband's death from a heart attack. Her past psychiatric history was negative; premonitory adjustment had been characterized by compulsive traits. During the interview, she was dressed in black; appeared moderately slowed; and sobbed intermittently, saying "I search everywhere for him....I don't find him." When asked about life, she said, "Everything I see is black." Although she expressed no interest in food, she did not seem to have lost an appreciable amount of weight. Her DST [dexamethasone suppression test] result was 18 mg/dL. The patient declined psychiatric care, stating that she "preferred to join her husband rather than get well." She was too religious to commit suicide, but by refusing treatment, she felt that she would "pine away...find relief in death and reunion." (Courtesy of HS Akiskal, M.D.)

Schizophrenia. Much has been published about the clinical difficulty of distinguishing a manic episode from schizophrenia. Although difficult, a differential diagnosis is possible. Merriment, elation, and infectiousness of mood are much more common in manic episodes than in schizophrenia. The combination of a manic mood, rapid or pressured speech, and hyperactivity weighs heavily toward a diagnosis of a manic episode. The onset in a manic episode is often rapid and is perceived as a marked change from a patient's previous behavior. Half of all patients with bipolar I disorder have a family history of mood disorder. Catatonic features may be part of a depressive phase of bipolar I disorder. When evaluating patients with catatonia, clinicians should look carefully for a past history of manic or depressive episodes and for a family history of mood disorders. Manic symptoms in persons from minority groups (particularly blacks and Hispanics) are often misdiagnosed as schizophrenic symptoms.

Medical Conditions. In contrast to depressive symptoms, which are present in almost all psychiatric disorders, manic symptoms are more distinctive, although they can be caused by a wide range of medical and neurological conditions and substances. Antidepressant treatment can also be associated with the precipitation of mania in some patients.

Bipolar I Disorder

When a patient with bipolar I disorder has a depressive episode, the differential diagnosis is the same as that for a patient being considered for a diagnosis of major depressive disorder. When a patient is manic, however, the differential diagnosis includes bipolar I disorder, bipolar II disorder, cyclothymic disorder, mood disorder caused by a general medical condition, and substance-induced mood disorder. For manic symptoms, borderline, narcissistic, histrionic, and antisocial personality disorders need special consideration.

Bipolar II Disorder

The differential diagnosis of patients being evaluated for a mood disorder should include the other mood disorders, psychotic disorders, and borderline disorder. The differentiation between major depressive disorder and bipolar I disorder, on one hand, and bipolar II disorder, on the other hand, rests on the clinical evaluation of the mania-like episodes. Clinicians should not mistake euthymia in a chronically depressed patient for a hypomanic or manic episode. Patients with borderline personality disorder often have a severely disrupted life, similar to that of patients with bipolar II disorder, because of the multiple episodes of significant mood disorder symptoms.

Major Depressive Disorder versus Bipolar Disorder

The question of whether a patient has major depressive disorder or bipolar disorder has emerged as a major challenge in clinical practice. Numerous studies have shown that bipolar disorder is not only confused with personality, substance use, and schizophrenic disorders but also with depressive and anxiety disorders. Certain features—especially in combination—are predictive of bipolar disorder (Table 8.1-9).

 **Table 8.1-9**
Clinical Features Predictive of Bipolar Disorder

Early age at onset
Psychotic depression before 25 years of age
Postpartum depression, especially one with psychotic features
Rapid onset and offset of depressive episodes of short duration (<3 months)
Recurrent depression (more than five episodes)
Depression with marked psychomotor retardation
Atypical features (reverse vegetative signs)
Seasonality
Bipolar family history
High-density, three-generation pedigrees
Trait mood lability (cyclothymia)
Hyperthymic temperament
Hypomania associated with antidepressants
Repeated (at least three times) loss of efficacy of antidepressants after initial response
Depressive mixed state (with psychomotor excitement, irritable hostility, racing thoughts, and sexual arousal <i>during</i> major depression)

More broad indicators of bipolarity include the following conditions, none of which, by itself, confirms a bipolar diagnosis, but should raise clinical suspicion in that direction: agitated depression, cyclical depression, episodic sleep dysregulation, or a combination of these; refractory depression (failed antidepressants from three different classes); depression in someone with an extroverted profession, periodic impulsivity, such as gambling, sexual misconduct, and wanderlust, or periodic irritability, suicidal crises, or both; and depression with erratic personality disorders.

COURSE AND PROGNOSIS

Studies of the course and prognosis of mood disorders have generally concluded that mood disorders tend to have long courses and that patients tend to have relapses. Although mood disorders are often considered benign in contrast to schizophrenia, they exact a profound toll on affected patients.

Major Depressive Disorder

Course

ONSET. About 50 percent of patients having their first episode of major depressive disorder exhibited significant depressive symptoms before the first identified episode. Therefore, early identification and treatment of early symptoms may prevent the development of a full depressive episode. Although symptoms may have been present, patients with major depressive disorder usually have not had a premorbid personality disorder. The first depressive episode occurs before age 40 years in about 50 percent of patients. A later onset is associated with the absence of a family history of mood disorders, antisocial personality disorder, and alcohol abuse.

DURATION. An untreated depressive episode lasts 6 to 13 months; most treated episodes last about 3 months. The withdrawal of antidepressants before 3 months has elapsed almost always results in the return of the symptoms. As the course of the disorder progresses, patients tend to have more frequent episodes that last longer. Over a 20-year period, the mean number of episodes is five or six.

DEVELOPMENT OF MANIC EPISODES. About 5 to 10 percent of patients with an initial diagnosis of major depressive disorder have a manic episode 6 to 10 years after the first depressive episode. The mean age for this switch is 32 years, and it often occurs after two to four depressive episodes. Although the data are inconsistent and controversial, some clinicians report that the depression of patients who are later classified as having bipolar I disorder is often characterized by hypersomnia, psychomotor retardation, psychotic symptoms, a history of postpartum episodes, a family history of bipolar I disorder, and a history of antidepressant-induced hypomania.

Prognosis. Major depressive disorder is not a benign disorder. It tends to be chronic, and patients tend to relapse. Patients who have been hospitalized for a first episode of major depressive disorder have about a 50 percent chance of recovering in the first year. The percentage of patients recovering after repeated hospitalization decreases with passing time. Many unrecovered patients remain affected with dysthymic disorder. About 25 percent of patients experience a recurrence of major depressive disorder in the first 6 months after release from a hospital, about 30 to 50 percent in the following 2 years, and about 50 to 75 percent in 5 years. The incidence of relapse is lower than these figures in patients who continue prophylactic psychopharmacological treatment and in patients who have had only one or two depressive episodes. Generally, as a patient experiences more and more depressive episodes, the time between the episodes decreases, and the severity of each episode increases.

PROGNOSTIC INDICATORS. Many studies have focused on identifying both good and bad prognostic indicators in the course of major depressive disorder. Mild episodes, the absence of psychotic symptoms, and a short hospital stay are good prognostic indicators. Psychosocial indicators of a good course include a history of solid friendships during adolescence, stable family functioning, and generally sound social functioning for the 5 years preceding the illness. Additional good prognostic signs are the absence of a comorbid psychiatric disorder and of a personality disorder, no more than one previous hospitalization for major depressive disorder, and an advanced age of onset. The possibility of a poor prognosis is increased by coexisting dysthymic disorder, abuse of alcohol and other substances, anxiety disorder symptoms, and a history of more than one previous depressive episode. Men are more likely than women to experience a chronically impaired course.

Bipolar I Disorder

Course. The natural history of bipolar I disorder is such that it is often useful to make a graph of a patient's disorder and to keep it up to date as treatment progresses (Fig. 8.1-6). Although cyclothymic disorder is sometimes diagnosed retrospectively in patients with bipolar I disorder, no identified personality traits are specifically associated with bipolar I disorder.

FIGURE 8.1-6

Graphing the course of a mood disorder. Prototype of a life chart. (Courtesy of Robert M. Post, M.D.)

Bipolar I disorder most often starts with depression (75 percent of the time in women, 67 percent in men) and is a recurring disorder. Most patients experience both depressive and manic episodes, although 10 to 20 percent experience only manic episodes. The manic episodes typically have a rapid onset (hours or days) but may evolve over a few weeks. An untreated manic episode lasts about 3 months; therefore, clinicians should not discontinue giving drugs before that time. Of persons who have a single manic episode, 90 percent are likely to have another. As the disorder progresses, the time between episodes often decreases. After about five episodes, however, the interepisode interval often stabilizes at 6 to 9 months. Of persons with bipolar disorder, 5 to 15 percent have four or more episodes per year and can be classified as rapid cyclers.

BIPOLAR I DISORDER IN CHILDREN AND OLDER PERSONS. Bipolar I disorder can affect both the very young and older persons. The incidence of bipolar I disorder in children and adolescents is about 1 percent, and the onset can be as early as age 8 years. Common misdiagnoses are schizophrenia and oppositional defiant disorder.

Bipolar I disorder with such an early onset is associated with a poor prognosis. Manic symptoms are common in older persons, although the range of causes is broad and includes nonpsychiatric medical conditions, dementia, and delirium, as well as bipolar I disorder. The onset of true bipolar I disorder in older persons is relatively uncommon.

Prognosis. Patients with bipolar I disorder have a poorer prognosis than do patients with major depressive disorder. About 40 to 50 percent of patients with bipolar I disorder may have a second manic episode within 2 years of the first episode. Although lithium prophylaxis improves the course and prognosis of bipolar I disorder, probably only 50 to 60 percent of patients achieve significant control of their symptoms with lithium. One 4-year follow-up study of patients with bipolar I disorder found that a premorbid poor occupational status, alcohol dependence, psychotic features, depressive features, interepisode depressive features, and male gender were all factors that contributed a poor prognosis. Short duration of manic episodes, advanced age of onset, few suicidal thoughts, and few coexisting psychiatric

or medical problems predict a better outcome.

About 7 percent of patients with bipolar I disorder do not have a recurrence of symptoms; 45 percent have more than one episode, and 40 percent have a chronic disorder. Patients may have from two to 30 manic episodes, although the mean number is about nine. About 40 percent of all patients have more than ten episodes. On long-term follow-up, 15 percent of all patients with bipolar I disorder are well, 45 percent are well but have multiple relapses, 30 percent are in partial remission, and 10 percent are chronically ill. One third of all patients with bipolar I disorder have chronic symptoms and evidence of significant social decline.

Bipolar II Disorder

The course and prognosis of bipolar II disorder indicate that the diagnosis is stable because there is a high likelihood that patients with bipolar II disorder will have the same diagnosis up to 5 years later. Bipolar II disorder is a chronic disease that warrants long-term treatment strategies.

TREATMENT

Treatment of patients with mood disorders should be directed toward several goals. First, the patient's safety must be guaranteed. Second, a complete diagnostic evaluation of the patient is necessary. Third, a treatment plan that addresses not only the immediate symptoms but also the patient's prospective well-being should be initiated. Although current treatment emphasizes pharmacotherapy and psychotherapy addressed to the individual patient, stressful life events are also associated with increases in relapse rates. Thus, treatment should address the number and severity of stressors in patients' lives.

Overall, the treatment of mood disorders is rewarding for psychiatrists. Specific treatments are now available for both manic and depressive episodes, and data indicate that prophylactic treatment is also effective. Because the prognosis for each episode is good, optimism is always warranted and is welcomed by both the patient and the patient's family. Mood disorders are chronic, however, and the psychiatrist must educate the patient and the family about future treatment strategies.

Hospitalization

The first and most critical decision a physician must make is whether to hospitalize a patient or attempt outpatient treatment. Clear indications for hospitalization are the risk of suicide or homicide, a patient's grossly reduced ability to get food and shelter, and the need for diagnostic procedures. A history of rapidly progressing symptoms and the rupture of a patient's usual support systems are also indications for hospitalization.

A physician may safely treat mild depression or hypomania in the office if he or she evaluates the patient frequently. Clinical signs of impaired judgment, weight loss, or insomnia should be minimal. The patient's support system should be strong, neither overinvolved nor withdrawing from the patient. Any adverse changes in the patient's symptoms or behavior or the attitude of the patient's support system may suffice to warrant hospitalization.

Patients with mood disorders are often unwilling to enter a hospital voluntarily and may have to be involuntarily committed. These patients often cannot make decisions because of their slowed thinking, negative *Weltanschauung* (world view), and hopelessness. Patients who are manic often have such a complete lack of insight into their disorder that hospitalization seems absolutely absurd to them.

Psychosocial Therapy

Although most studies indicate—and most clinicians and researchers believe—that a combination of psychotherapy and pharmacotherapy is the most effective treatment for major depressive disorder, some data suggest another view: Either pharmacotherapy or psychotherapy alone is effective, at least in patients with mild major depressive episodes, and the regular use of combined therapy adds to the cost of treatment and exposes patients to unnecessary adverse effects.

Three types of short-term psychotherapies—cognitive therapy, interpersonal therapy, and behavior therapy—have been studied to determine their efficacy in the treatment of major depressive disorder. Although its efficacy in treating major depressive disorder is not as well researched as these three therapies, psychoanalytically oriented psychotherapy has long been used for depressive disorders, and many clinicians use the technique as their primary method. What differentiates the three short-term psychotherapy methods from the psychoanalytically oriented approach are the active and directive roles of the therapist, the directly recognizable goals, and the end points for short-term therapy.

Accumulating evidence is encouraging about the efficacy of dynamic therapy. In a randomized, controlled trial comparing psychodynamic therapy with cognitive behavior therapy, the outcome of the depressed patients was the same in the two treatments.

The National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program found the following predictors of response to various treatments: low social dysfunction suggested a good response to interpersonal therapy, low cognitive dysfunction suggested a good response to cognitive-behavioral therapy and pharmacotherapy, high work dysfunction suggested a good response to pharmacotherapy, and high depression severity suggested a good response to interpersonal therapy and pharmacotherapy.

Cognitive Therapy. Cognitive therapy, originally developed by Aaron Beck, focuses on the cognitive distortions postulated to be present in major depressive disorder. Such distortions include selective attention to the negative aspects of circumstances and unrealistically morbid inferences about consequences. For example, apathy and low energy result from a patient's expectation of failure in all areas. The goal of cognitive therapy is to alleviate depressive episodes and prevent their recurrence by helping patients identify and test negative cognitions; develop alternative, flexible, and positive ways of thinking; and rehearse new cognitive and behavioral responses.

Studies have shown that cognitive therapy is effective in the treatment of major depressive disorder. Most studies found that cognitive therapy is equal in efficacy to pharmacotherapy and is associated with fewer adverse effects and better follow-up than pharmacotherapy. Some of the best controlled studies have indicated that the combination of cognitive therapy and pharmacotherapy is more efficacious than either therapy alone, although other studies have not found that additive effect. At least one study, the NIMH Treatment of Depression Collaborative Research Program, found that pharmacotherapy, either alone or with psychotherapy, may be the treatment of choice for patients with severe major depressive episodes.

Interpersonal Therapy. Interpersonal therapy, developed by Gerald Klerman, focuses on one or two of a patient's current interpersonal problems. This therapy is based on two assumptions. First, current interpersonal problems are likely to have their roots in early dysfunctional relationships. Second, current interpersonal problems are likely to be involved in precipitating or perpetuating the current depressive symptoms. Controlled trials have indicated that interpersonal therapy is effective in the treatment of major depressive disorder and, not surprisingly, may be specifically helpful in addressing interpersonal problems. Some studies indicate that interpersonal therapy may be the most effective method for severe major depressive episodes when the treatment choice is psychotherapy alone.

The interpersonal therapy program usually consists of 12 to 16 weekly sessions and is characterized by an active therapeutic approach. Intrapsychic phenomena, such as defense mechanisms and internal conflicts, are not addressed. Discrete behaviors—such as lack of assertiveness, impaired social skills, and distorted thinking—may be addressed but only in the context of their meaning in, or their effect on, interpersonal relationships.

Behavior Therapy. Behavior therapy is based on the hypothesis that maladaptive behavioral patterns result in a person's receiving little positive feedback and perhaps outright rejection from society. By addressing maladaptive behaviors in therapy, patients learn to function in the world in such a way that they receive positive reinforcement. Behavior therapy for major depressive disorder has not yet been the subject of many controlled studies. The limited data indicate that it is an effective treatment for major depressive disorder.

Psychoanalytically Oriented Therapy. The psychoanalytic approach to mood disorders is based on psychoanalytic theories about depression and mania. The goal of psychoanalytic psychotherapy is to effect a change in a patient's personality structure or character, not simply to alleviate symptoms. Improvements in interpersonal trust, capacity for intimacy, coping mechanisms, the capacity to grieve, and the ability to experience a wide range of emotions are some of the aims of psychoanalytic therapy. Treatment often requires the patient to experience periods of heightened anxiety and distress during the course of therapy, which may continue for several years.

Family Therapy. Family therapy is not generally viewed as a primary therapy for the treatment of major depressive disorder, but increasing evidence indicates that helping a patient with a mood disorder to reduce and cope with stress can lessen the chance of a relapse. Family therapy is indicated if the disorder jeopardizes a patient's marriage or family functioning or if the mood disorder is promoted or maintained by the family situation. Family therapy examines the role of the mood-disordered member in the overall psychological well-being of the whole family; it also examines the role of the entire family in the maintenance of the patient's symptoms. Patients with mood disorders have a high rate of divorce, and about 50 percent of all spouses report that they would not have married or had children if they had known that the patient was going to develop a mood disorder.

Vagal Nerve Stimulation

Experimental stimulation of the vagus nerve in several studies designed for the treatment of epilepsy found that patients showed improved mood. This observation led to the use of left vagal nerve stimulation (VNS) using an electronic device implanted in the skin, similar to a cardiac pacemaker. Preliminary studies have shown that a number of patients with chronic, recurrent major depressive disorder went into remission when treated with VNS. The mechanism of action of VNS to account for improvement is unknown. The vagus nerve connects to the enteric nervous system and, when stimulated, may cause release of peptides that act as neurotransmitters. Extensive clinical trials are being conducted to determine the efficacy of VNS.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) shows promise as a treatment for depression. It involves the use of very short pulses of magnetic energy to stimulate nerve cells in the brain. It is specifically indicated for the treatment of depression in adult patients who have failed to achieve satisfactory improvement from one prior antidepressant medication at or above the minimal effective dose and duration in the current episode.

Repetitive transcranial magnetic stimulation (rTMS) produces focal secondary electrical stimulation of targeted cortical regions. It is nonconvulsive, requires no anesthesia, has a safe side effect profile, and is not associated with cognitive side effects.

The patients do not require anesthesia or sedation and remain awake and alert. It is a 40-minute outpatient procedure that is prescribed by a psychiatrist and performed in a psychiatrist's office. The treatment is typically administered daily for 4 to 6 weeks. The most common adverse event related to treatment was scalp pain or discomfort.

TMS therapy is contraindicated in patients with implanted metallic devices or nonremovable metallic objects in or around the head.

Sleep Deprivation

Mood disorders are characterized by sleep disturbance. Mania tends to be characterized by a decreased need for sleep, but depression can be associated with either hypersomnia or insomnia. Sleep deprivation may precipitate mania in patients with bipolar I disorder and temporarily relieve depression in those who have unipolar depression. Approximately 60 percent of patients with depressive disorders exhibit significant but transient benefits from total sleep deprivation. The positive results are typically reversed by the next night of sleep. Several strategies have been used in an attempt to achieve a more sustained response to sleep deprivation. One method used serial total sleep deprivation with a day or two of normal sleep in between. This method does not achieve a sustained antidepressant response because the depression tends to return with normal sleep cycles. Another approach used phase delay in the time patients go to sleep each night, or partial sleep deprivation. In this method, patients may stay awake from 2 AM to 10 PM daily. Up to 50 percent of patients get same-day antidepressant effects from partial sleep deprivation, but this benefit also tends to wear off in time. In some reports, however, serial partial sleep deprivation has been used successfully to treat insomnia associated with depression. The third, and probably most effective, strategy combines sleep deprivation with pharmacological treatment of depression. A number of studies have suggested that total and partial sleep deprivation followed by immediate treatment with an antidepressant or lithium (Eskalith) sustains the antidepressant effects of sleep deprivation. Likewise, several reports have suggested that sleep deprivation accelerates the response to antidepressants, including fluoxetine (Prozac) and nortriptyline (Aventyl, Pamelor). Sleep deprivation has also been noted to improve premenstrual dysphoria. (Premenstrual dysphoric disorder, which is classified as a depressive disorder in DSM-5, is discussed in detail in Section 26.1, Psychiatry and Reproductive Medicine.)

Phototherapy

Phototherapy (light therapy) was introduced in 1984 as a treatment for SAD (mood disorder with seasonal pattern). In this disorder, patients typically experience depression as the photoperiod of the day decreases with advancing winter. Women represent at least 75 percent of all patients with seasonal depression, and the mean age of presentation is 40 years. Patients rarely present older than the age of 55 years with seasonal affective disorder.

Phototherapy typically involves exposing the affected patient to bright light in the range of 1,500 to 10,000 lux or more, typically with a light box that sits on a table or desk. Patients sit in front of the box for approximately 1 to 2 hours before dawn each day, although some patients may also benefit from exposure after dusk. Alternatively, some manufacturers have developed light visors, with a light source built into the brim of the hat. These light visors allow mobility, but recent controlled studies have questioned the use of this type of light exposure. Trials have typically lasted 1 week, but longer treatment durations may be associated with greater response.

Phototherapy tends to be well tolerated. Newer light sources tend to use lower light intensities and come equipped with filters; patients are instructed not to look directly at the light source. As with any effective antidepressant, phototherapy, on rare occasions, has been implicated in switching some depressed patients into mania or hypomania.

In addition to seasonal depression, the other major indication for phototherapy may be in sleep disorders. Phototherapy has been used to decrease the irritability and diminished functioning associated with shift work. Sleep disorders in geriatric patients have reportedly improved with exposure to bright light during the day. Likewise, some evidence suggests that jet lag might respond to light therapy. Preliminary data indicate that phototherapy may benefit some patients with OCD that has a seasonal variation.

Pharmacotherapy

After a diagnosis has been established, a pharmacological treatment strategy can be formulated. Accurate diagnosis is crucial because unipolar and bipolar spectrum disorders require different treatment regimens.

The objective of pharmacologic treatment is symptom remission, not just symptom reduction. Patients with residual symptoms, as opposed to full remission, are more likely to experience a relapse or recurrence of mood episodes and to experience ongoing impairment of daily functioning.

Major Depressive Disorder. The use of specific pharmacotherapy approximately doubles the chances that a depressed patient will recover in 1 month. All currently available antidepressants may take up to 3 to 4 weeks to exert significant therapeutic effects, although they may begin to show their effects earlier. Choice of antidepressants is determined by the side effect profile least objectionable to a given patient's physical status, temperament, and lifestyle. That numerous classes of antidepressants (Table 8.1-10) are available, many with different mechanisms of action, represents indirect evidence for heterogeneity of putative biochemical lesions. Although the first antidepressant drugs, the monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs), are still in use, newer compounds have made the treatment of depression more "clinician and patient friendly."

Table 8.1-10
Antidepressant Medications

Generic (Brand) Name	Usual Daily Dose (mg)	Common Side Effects	Clinical Caveats
NE Reuptake Inhibitors			
Desipramine (Norpramin, Pertofrane)	75–300	Drowsiness, insomnia, OSH, agitation, CA, weight ↑, anticholinergic*	Overdose may be fatal. Dose titration is needed.
Protriptyline (Vivactil)	20–60	Drowsiness, insomnia, OSH, agitation, CA, anticholinergic*	Overdose may be fatal. Dose titration is needed.
Nortriptyline (Aventyl, Pamelor)	40–200	Drowsiness, OSH, CA, weight ↑, anticholinergic*	Overdose may be fatal. Dose titration is needed.
Maprotiline (Ludomil)	100–225	Drowsiness, CA, weight ↑, anticholinergic*	Overdose may be fatal. Dose titration is needed.
5-HT Reuptake Inhibitors			
Citalopram (Celexa)	20–60	All SSRIs may cause insomnia, agitation, sedation, GI distress, and sexual dysfunction	Many SSRIs inhibit various cytochrome P450 isoenzymes. They are better tolerated than tricyclics and have high safety in overdose. Shorter half-life SSRIs may be associated with discontinuation symptoms when abruptly stopped.
Escitalopram (Lexapro)	10–20		
Fluoxetine (Prozac)	10–40		
Fluvoxamine (Luvox) [†]	100–300		
Paroxetine (Paxil)	20–50		
Sertraline (Zoloft)	50–150		
NE and 5-HT Reuptake Inhibitors			
Amitriptyline (Elavil, Endep)	75–300	Drowsiness, OSH, CA, weight ↑, anticholinergic*	Overdose may be fatal. Dose titration is needed.
Doxepin (Triadapin, Sinequan)	75–300	Drowsiness, OSH, CA, weight ↑, anticholinergic*	Overdose may be fatal.
Imipramine (Tofranil)	75–300	Drowsiness, insomnia and agitation, OSH, CA, GI distress, weight ↑, anticholinergic*	Overdose may be fatal. Dose titration needed.
Trimipramine (Surmontil)	75–300	Drowsiness, OSH, CA, weight ↑, anticholinergic*	—
Venlafaxine (Effexor)	150–375	Sleep changes, GI distress, discontinuation syndrome	Higher doses may cause hypertension. Dose titration is needed. Abrupt discontinuation may result in discontinuation symptoms.
Duloxetine (Cymbalta)	30–60	GI distress, discontinuation syndrome	
Pre- and Postsynaptic Active Agents			
Nefazodone	300–600	Sedation	Dose titration is needed. No sexual dysfunction.
Mirtazapine (Remeron)	15–30	Sedation, weight ↑	No sexual dysfunction.
Dopamine Reuptake Inhibitor			
Bupropion (Wellbutrin)	200–400	Insomnia or agitation, GI distress	Twice-a-day dosing with sustained release. No sexual dysfunction or weight gain.
Mixed Action Agents			
Amoxapine (Asendin)	100–600	Drowsiness, insomnia or agitation, CA, weight ↑, OSH, anticholinergic*	Movement disorders may occur. Dose titration is needed.
Clomipramine (Anafranil)	75–300	Drowsiness, weight ↑	Dose titration is needed.
Trazodone (Desyrel)	150–600	Drowsiness, OSH, CA, GI distress, weight ↑	Priapism is possible.

Note: Dose ranges are for adults in good general medical health, taking no other medications, and age 18 to 60 years. Doses vary depending on the agent, concomitant medications, the presence of general medical or surgical conditions, age, genetic constitution, and other factors. Brand names are those used in the United States.

CA, cardiac arrhythmia; 5-HT, serotonin; GI, gastrointestinal; NE, norepinephrine; OSH, orthostatic hypotension; SSRI, selective serotonin reuptake inhibitor. *Dry mouth, blurred vision, urinary hesitancy, and constipation.

[†]Not approved as an antidepressant in the United States by the US Food and Drug Administration.

GENERAL CLINICAL GUIDELINES. The most common clinical mistake leading to an unsuccessful trial of an antidepressant drug is the use of too low a dosage for too short a time. Unless adverse events prevent it, the dosage of an antidepressant should be raised to the maximum recommended level and maintained at that level for at least 4 or 5 weeks before a drug trial is considered unsuccessful. Alternatively, if a patient is improving clinically on a low dosage of the drug, this dosage should not be raised unless clinical improvement stops before maximal benefit is obtained. When a patient does not begin to respond to appropriate dosages of a drug after 2 or 3 weeks, clinicians may decide to obtain a plasma concentration of the drug if the test is available for the particular drug being used. The test may indicate either noncompliance or particularly unusual pharmacokinetic disposition of the drug and may thereby suggest an alternative dosage.

DURATION AND PROPHYLAXIS. Antidepressant treatment should be maintained for at least 6 months or the length of a previous episode, whichever is greater. Prophylactic treatment with antidepressants is effective in reducing the number and severity of recurrences. One study concluded that when episodes are less than 2¹/₂ years apart, prophylactic treatment for 5 years is probably indicated. Another factor suggesting prophylactic treatment is the seriousness of previous depressive episodes. Episodes that have involved significant suicidal ideation or impairment of psychosocial functioning may indicate that clinicians should consider prophylactic treatment. When antidepressant treatment is stopped, the drug dose should be tapered gradually over 1 to 2 weeks, depending on the half-life of the particular compound. Several studies indicate that maintenance antidepressant medication appears to be safe and effective for the treatment of chronic depression.

Prevention of new mood episodes (i.e., recurrences) is the aim of the maintenance phase of treatment. Only patients with recurrent or chronic depressions are candidates for maintenance treatment.

INITIAL MEDICATION SELECTION. The available antidepressants do not differ in overall efficacy, speed of response, or long-term effectiveness. Antidepressants, however, do differ in their pharmacology, drug–drug interactions, short- and long-term side effects, likelihood of discontinuation symptoms, and ease of dose adjustment. Failure to tolerate or to respond to one medication does not imply that other medications will also fail. Selection of the initial treatment depends on the chronicity of the condition, course of illness (a recurrent or chronic course is associated with increased likelihood of subsequent depressive symptoms without treatment), family history of illness and treatment response, symptom severity, concurrent general medical or other psychiatric conditions, prior treatment responses to other acute phase treatments, potential drug–drug interactions, and patient preference. In general, approximately 45 to 60 percent of all outpatients with uncomplicated (i.e., minimal psychiatric and general medical comorbidity), nonchronic, nonpsychotic major depressive disorder who begin treatment with medication respond (i.e., achieve at least a 50 percent reduction in baseline symptoms); however, only 35 to 50 percent achieve remission (i.e., the virtual absence of depressive symptoms).

TREATMENT OF DEPRESSIVE SUBTYPES. Clinical types of major depressive episodes may have varying responses to particular antidepressants or to drugs other than antidepressants. Patients with major depressive disorder with atypical features may preferentially respond to treatment with MAOIs or SSRIs. Antidepressants with dual action on both serotonergic and noradrenergic receptors demonstrate greater efficacy in melancholic depressions. Patients with seasonal winter depression can be treated with light therapy. Treatment of major depressive episodes with psychotic features may require a combination of an antidepressant and an atypical antipsychotic. Several studies have also shown that ECT is effective for this indication—perhaps more effective than pharmacotherapy. For those with atypical symptom features, strong evidence exists for the effectiveness of MAOIs. SSRIs and bupropion (Wellbutrin) are also of use in atypical depression.

COMORBID DISORDERS. The concurrent presence of another disorder can affect initial treatment selection. For example, the successful treatment of OCD associated with depressive symptoms usually results in remission of the depression. Similarly, when panic disorder occurs with major depression, medications with demonstrated efficacy in both conditions are preferred (e.g., tricyclics and SSRIs). In general, the nonmood disorder dictates the choice of treatment in comorbid states.

Concurrent substance abuse raises the possibility of a substance-induced mood disorder, which must be evaluated by history or by requiring abstinence for several weeks. Abstinence often results in remission of depressive symptoms in substance-induced mood disorders. For those with continuing significant depressive symptoms, even with abstinence, an independent mood disorder is diagnosed and treated.

General medical conditions are established risk factors in the development of depression. The presence of a major depressive episode is associated with increased morbidity or mortality of many general medical conditions (e.g., cardiovascular disease, diabetes, cerebrovascular disease, and cancer).

THERAPEUTIC USE OF SIDE EFFECTS. Choosing more sedating antidepressants (e.g., amitriptyline [Elavil, Endep]) for more anxious, depressed patients or more activating agents (e.g., desipramine) for more psychomotor-retarded patients is not generally helpful. For example, any short-term benefits with paroxetine, mirtazapine, or amitriptyline (more sedating drugs) on symptoms of anxiety or insomnia may become liabilities over time. These drugs often continue to be sedating in the longer run, which can lead to patients prematurely discontinuing medication and increase the risk of relapse or recurrence. Some practitioners use adjunctive medications (e.g., sleeping pills or anxiolytics) combined with antidepressants to provide more immediate symptom relief or to cover those side effects to which most patients ultimately adapt.

A patient's prior treatment history is important because an earlier response typically predicts current response. A documented failure on a properly conducted trial of a particular antidepressant class (e.g., SSRIs, tricyclics, or MAOIs) suggests choosing an agent from an alternative class. The history of a first-degree relative responding to a particular drug is associated with a good response to the same class of agents in the patient.

ACUTE TREATMENT FAILURES. Patients may not respond to a medication, because (1) they cannot tolerate the side effects, even in the face of a good clinical response; (2) an idiosyncratic adverse event may occur; (3) the clinical response is not adequate; or (4) the wrong diagnosis has been made. Acute phase medication trials should last 4 to 6 weeks to determine if meaningful symptom reduction is attained. Most (but not all) patients who ultimately respond fully show at least a partial response (i.e., at least a 20 to 25 percent reduction in pretreatment depressive symptom severity) by week 4 if the dose is adequate during the initial weeks of treatment. Lack of a partial response by 4 to 6 weeks indicates that a treatment change is needed. Longer time periods—8 to 12 weeks or longer—are needed to define the ultimate degree of symptom reduction achievable with a medication. Approximately half of patients require a second medication treatment trial because the initial treatment is poorly tolerated or ineffective.

SELECTING SECOND TREATMENT OPTIONS. When the initial treatment is unsuccessful, switching to an alternative treatment or augmenting the current treatment is a common option. The choice between switching from the initial single treatment to a new single treatment (as opposed to adding a second treatment to the first one) rests on the patient's prior treatment history, the degree of benefit achieved with the initial treatment, and patient preference. As a rule, switching rather than augmenting is preferred after an initial medication failure. On the other hand, augmentation strategies are helpful with patients who have gained some benefit from the initial treatment but who have not achieved remission. The best-documented augmentation strategies involve lithium (Eskalith) or thyroid hormone. A combination of an SSRI and bupropion (Wellbutrin) is also widely used. In fact, no combination strategy has been conclusively shown to be more effective than another. ECT is effective in psychotic and nonpsychotic forms of depression but is recommended generally only for repeatedly nonresponsive cases or in patients with very severe disorders.

A new therapy involves the use of the anesthetic agent ketamine, which has been shown to be effective in treatment resistant depression. It has a mechanism of action that inhibits the postsynaptic glutamate binding protein *N*-methyl-D-aspartate (NDMA) receptor. Because abnormalities in glutamatergic signaling have been implicated in major depressive

disorder, this may account for its efficacy. Patients usually receive a single infusion of ketamine over a 30-minute period at a concentration of 0.5 mg/kg. A positive response is usually seen within 24 hours, and improved mood lasts for about 2 to 7 days. The most common side effects are dizziness, headache, and poor coordination, which are transitory. Dissociative symptoms, including hallucinations, may also occur.

COMBINED TREATMENT. Medication and formal psychotherapy are often combined in practice. If physicians view mood disorders as fundamentally evolving from psychodynamic issues, their ambivalence about the use of drugs may result in a poor response, noncompliance and probably inadequate dosages for too short a treatment period. Alternatively, if physicians ignore the psychosocial needs of a patient, the outcome of pharmacotherapy may be compromised. Several trials of a combination of pharmacotherapy and psychotherapy for chronically depressed outpatients have shown a higher response and higher remission rates for the combination than for either treatment used alone.

Bipolar Disorders. The pharmacological treatment of bipolar disorders is divided into both acute and maintenance phases. Bipolar treatment, however, also involves the formulation of different strategies for the patient who is experiencing mania or hypomania or depression. Lithium and its augmentation by antidepressants, antipsychotics, and benzodiazepines has been the major approach to the illness, but three anticonvulsant mood stabilizers—carbamazepine (Tegretol), valproate (Depakene), and lamotrigine (Lamictal)—have been added more recently, as well as a series of atypical antipsychotics, most of which are approved for the treatment of acute mania, one also for monotherapy of acute depression, and three for prophylactic treatment (Table 8.1-11). Each of these medications is associated with a unique side effect and safety profile, and no one drug is predictably effective for all patients. Often, it is necessary to try different medications before an optimal treatment is found.

Table 8.1-11
Mechanistic Classes of Medications Used in Bipolar Illness: Preliminary Evidence of Spectrum of Efficacy in Mania or Depression

Class of Medication	Mania	Depression	Anxiety
Antimanics			
Typical antipsychotics block D ₂ receptors			
Trifluoperazine (Stelazine)	+++	--	±
Haloperidol (Haldol)	+++	--	±
Molindone (Moban)	++	--	±
High-potency benzodiazepines ↑ Cl ⁻ influx, potentiate GABA			
Clonazepam (Klonopin)	++	±	++
Lorazepam (Ativan)	++	±	++
Atypical antipsychotics block mesolimbic D ₁ , D ₂ , and D ₄ receptors and 5-HT type 2 receptors			
Clozapine (Clozaril)	+++	+	±
Risperidone (Risperdal)	+++	+	+
Olanzapine (Zyprexa)	+++	++	+
Quetiapine (Seroquel)	+++	+++	+++
Ziprasidone (Geodon)	+++	+	+
Atypical antipsychotic partial agonist at D ₁ , D ₂ , D ₃ , 5-HT type 1A receptors			
Aripiprazole (Abilify)	+++	++	++
Possible Mood Stabilizers			
↓ Second messengers, G proteins, and inositol transport			
Lithium (Eskalith)	+++	++	0
Carbamazepine (Tegretol)	+++	++	+
Oxcarbazepine (Trileptal)	++	+	+
Valproate	+++	+	+++
↑ Brain GABA			
Valproate	+++	+	+++
Gabapentin (Neurontin)	0	±	++
Pregabalin (Lyrica)	(0)	±	++
Tiagabine (Gabitril)	0	±	+
Topiramate (Topamax)	0	+	+

↓ Glutamate release via (↓ Na ⁺)			
Carbamazepine	+++	++	+
Lamotrigine (Lamictal)	+	+++	++
Topiramate	0	+	+
Zonisamide (Zonegran)	++	+	(±)
Dihydropyridine ↓ L-type Ca ²⁺ _v			
Nimodipine (Nimotop)	++	++	+
Isradipine (DynaCirc)	+	+	+
Amlodipine (Norvasc)	±	±	±
Phenylalkylamine ↓ L-type Ca ²⁺ _v			
Verapamil (Calan)	++	0	0
Thyroid augmentation			
Triiodothyronine	±	++	0
High-dose thyroxine	+	+	0
Atypical antipsychotics (see above)			
Antidepressants			
Dopamine			
Bupropion (Wellbutrin)	0, -	++	+
Pramipexole (Mirapex)	0, -	++	+
5-HT SSRIs as a class	0, -	++	++
Fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), Citalopram (Celexa)			
5-HT plus			
Nefazodone (Serzone)	0, -	++	++
Mirtazapine (Remeron)	0, -	++	++
NE			
Desipramine (Norpramin)	-	++	++
Nortriptyline (Aventyl)	-	++	++
Maprotiline (Ludiomil)	-	++	++
Reboxetine (Edronax)	-	(++)	(++)
Atomoxetine (Strattera)	-	++	++
5-HT and NE			
Clomipramine (Anafranil)	-	++	++
Venlafaxine (Effexor)	--	++	++
Duloxetine (Cymbalta)	(--)	++	++

–, worsen; 0, –, ineffective, may worsen; 0, ineffective; ±, possibly effective; +, substantial open data; ++, much open or some controlled data; +++, (good controlled data or wide use); ambiguous data; D₁, dopamine type 1; D₂, dopamine type 2; D₃, dopamine type 3; GABA, γ-aminobutyric acid; 5-HT, serotonin; NE, norepinephrine; SSRI, selective serotonin reuptake inhibitor.

TREATMENT OF ACUTE MANIA. The treatment of acute mania, or hypomania, usually is the easiest phases of bipolar disorders to treat. Agents can be used alone or in combination to bring the patient down from a high. Patients with severe mania are best treated in the hospital where aggressive dosing is possible and an adequate response can be achieved within days or weeks. Adherence to treatment, however, is often a problem because patients with mania frequently lack insight into their illness and refuse to take medication. Because impaired judgment, impulsivity, and aggressiveness combine to put the patient or others at risk, many patients in the manic phase are medicated to protect themselves and others from harm.

Lithium Carbonate. Lithium carbonate is considered the prototypical “mood stabilizer.” Yet because the onset of antimanic action with lithium can be slow, it usually is supplemented in the early phases of treatment by atypical antipsychotics, mood-stabilizing anticonvulsants, or high-potency benzodiazepines. Therapeutic lithium levels are between 0.6 and 1.2 mEq/L. The acute use of lithium has been limited in recent years by its unpredictable efficacy, problematic side effects, and the need for frequent laboratory tests. The introduction of newer drugs with more favorable side effects, lower toxicity, and less need for frequent laboratory testing has resulted in a decline in lithium use. For many patients, however, its clinical benefits can be remarkable.

Valproate. Valproate (valproic acid [Depakene] or divalproex sodium [Depakote]) has surpassed lithium in use for acute mania. Unlike lithium, valproate is only indicated for acute mania, although most experts agree it also has prophylactic effects. Typical dose levels of valproic acid are 750 to 2,500 mg per day, achieving blood levels between 50 and 120 µg/mL. Rapid oral loading with 15 to 20 mg/kg of divalproex sodium from day 1 of treatment has been well tolerated and associated with a rapid onset of response. A number of laboratory tests are required during valproate treatment.

Carbamazepine and Oxcarbazepine. Carbamazepine has been used worldwide for decades as a first-line treatment for acute mania but has only gained approval in the United States in 2004. Typical doses of carbamazepine to treat acute mania range between 600 and 1,800 mg per day associated with blood levels of between 4 and 12 µg/mL. The keto congener of carbamazepine, oxcarbazepine, may possess similar antimanic properties. Higher doses than those of carbamazepine are required because 1,500 mg of oxcarbazepine approximates 1,000 mg of carbamazepine.

Clonazepam and Lorazepam. The high-potency benzodiazepine anticonvulsants used in acute mania include clonazepam (Klonopin) and lorazepam (Ativan). Both may be effective and are widely used for adjunctive treatment of acute manic agitation, insomnia, aggression, and dysphoria, as well as panic. The safety and the benign side effect profile of these agents render them ideal adjuncts to lithium, carbamazepine, or valproate.

Atypical and Typical Antipsychotics. All of the atypical antipsychotics—olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole—have demonstrated antimanic efficacy and are approved by the Food and Drug Administration for this indication. Compared with older agents, such as haloperidol (Haldol) and chlorpromazine (Thorazine), atypical antipsychotics have a lesser liability for excitatory postsynaptic potential and tardive dyskinesia; many do not increase prolactin. However, they have a wide range of substantial to no risk for

weight gain with its associated problems of insulin resistance, diabetes, hyperlipidemia, hypercholesteremia, and cardiovascular impairment. Some patients, however, require maintenance treatment with an antipsychotic medication.

TREATMENT OF ACUTE BIPOLAR DEPRESSION. The relative usefulness of standard antidepressants in bipolar illness, in general, and in rapid cycling and mixed states, in particular, remains controversial because of their propensity to induce cycling, mania, or hypomania. Accordingly, antidepressant drugs are often enhanced by a mood stabilizer in the first-line treatment for a first or isolated episode of bipolar depression. A fixed combination of olanzapine and fluoxetine (Symbyax) has been shown to be effective in treating acute bipolar depression for an 8-week period without inducing a switch to mania or hypomania.

Paradoxically, many patients who are bipolar in the depressed phase do not respond to treatment with standard antidepressants. In these instances, lamotrigine or low-dose ziprasidone (20 to 80 mg per day) may prove effective.

Electroconvulsive therapy may also be useful for patients with bipolar depression who do not respond to lithium or other mood stabilizers and their adjuncts, particularly in cases in which intense suicidal tendency presents as a medical emergency.

Other Agents. When standard treatments fail, other types of compounds may prove effective. The calcium channel antagonist verapamil (Calan, Isoptin) has acute antimanic efficacy. Gabapentin, topiramate, zonisamide, levetiracetam, and tiagabine have not been shown to have acute antimania effects, although some patients may benefit from a trial of these agents when standard therapies have failed. Lamotrigine does not possess acute antimanic properties but does help prevent recurrence of manic episodes. Small studies suggest the potential acute antimanic and prophylactic efficacy of phenytoin. ECT is effective in acute mania. Bilateral treatments are required because unilateral, nondominant treatments have been reported to be ineffective or even to exacerbate manic symptoms. ECT is reserved for patients with rare refractory mania and for patients with medical complications, as well as extreme exhaustion (malignant hyperthermia or lethal catatonia).

MAINTENANCE TREATMENT OF BIPOLAR DISORDER. Preventing recurrences of mood episodes is the greatest challenge facing clinicians. Not only must the chosen regimen achieve its primary goal—sustained euthymia—but the medications should not produce unwanted side effects that affect functioning. Sedation, cognitive impairment, tremor, weight gain, and rash are some side effects that lead to treatment discontinuation.

Lithium, carbamazepine, and valproic acid, alone or in combination, are the most widely used agents in the long-term treatment of patients with bipolar disorder. Lamotrigine has prophylactic antidepressant and, potentially, mood-stabilizing properties. Patients with bipolar I disorder depression taking lamotrigine exhibit a rate of switch into mania that is the same as the rate with placebo. Lamotrigine appears to have superior acute and prophylactic antidepressant properties compared with antimanic properties. Given that breakthrough depressions are a difficult problem during prophylaxis, lamotrigine has a unique therapeutic role. Very slow increases of lamotrigine help avoid the rare side effect of lethal rash. A dose of 200 mg per day appears to be the average in many studies. The incidence of severe rash (i.e., Stevens-Johnson syndrome, a toxic epidermal necrolysis) is now thought to be approximately two in 10,000 adults and four in 10,000 children.

Thyroid supplementation is frequently necessary during long-term treatment. Many patients treated with lithium develop hypothyroidism, and many patients with bipolar disorder have idiopathic thyroid dysfunction. T₃ (25 to 50 µg per day), because of its short half-life, is often recommended for acute augmentation strategies, but T₄ is frequently used for long-term maintenance. In some centers, hypermetabolic doses of thyroid hormone are used. Data indicate improvement in both manic and depressive phases with hypermetabolic T₄-augmenting strategies. Table 8.1-12 summarizes the principles of treatment of bipolar disorders.

 **Table 8.1-12**
Principles in the Treatment of Bipolar Disorders

-
- Maintain dual treatment focus: (1) acute short term and (2) prophylaxis.
 - Chart illness retrospectively and prospectively.
 - Mania as medical emergency: Treat first; chemistries later.
 - Load valproate and lithium (Eskalith); titrate lamotrigine (Lamic-tal) slowly.
 - Careful combination treatment can decrease adverse effects.
 - Augment rather than substitute in treatment-resistant patient.
 - Retain lithium in regimen for its antisuicide and neuroprotective effects.
 - Taper lithium slowly, if at all.
 - Educate patient and family about illness and risk-to-benefit ratios of acute and prophylactic treatments.
 - Give statistics (i.e., 50 percent relapse in first 5 months off lithium).
 - Assess compliance and suicidality regularly.
 - Develop an early warning system for identification and treatment of emergent symptoms.
 - Contract with patient as needed for suicide and substance use avoidance.
 - Use regular visits; monitor course and adverse effects.
 - Arrange for interval phone contact when needed.
 - Develop fire drill for mania reemergence.
 - Inquire about and address comorbid alcohol and substance abuse.
 - Targeted psychotherapy; use medicalization of illness.
 - Treat patient as a coinvestigator in the development of effective clinical approaches to the illness.
 - If treatment is successful, be conservative in making changes, maintain the course, and continue full-dose pharmacoprophylaxis in absence of side effects.
 - If treatment response is inadequate, be aggressive in searching for more effective alternatives.

8.2 Dysthymia and Cyclothymia

DYSTHYMIA

The most typical features of dysthymia, also known as persistent depressive disorder, is the presence of a depressed mood that lasts most of the day and is present almost continuously. There are associated feelings of inadequacy, guilt, irritability, and anger; withdrawal from society; loss of interest; and inactivity and lack of productivity. The term *dysthymia*, which means “ill humored,” was introduced in 1980. Before that time, most patients now classified as having dysthymia were classified as having depressive neurosis (also called neurotic depression).

Dysthymia is distinguished from major depressive disorder by the fact that patients complain that they have always been depressed. Thus, most cases are of early onset, beginning in childhood or adolescence and certainly occurring by the time patients reach their 20s. A late-onset subtype, much less prevalent and not well characterized clinically, has been identified among middle-aged and geriatric populations, largely through epidemiological studies in the community.

Although dysthymia can occur as a secondary complication of other psychiatric disorders, the core concept of dysthymia refers to a subaffective or subclinical depressive disorder with (1) low-grade chronicity for at least 2 years; (2) insidious onset, with origin often in childhood or adolescence; and (3) a persistent or intermittent course. The family history of patients with dysthymia is typically replete with both depressive and bipolar disorders, which is one of the more robust findings supporting its link to primary mood disorder.

Epidemiology

Dysthymia is common among the general population and affects 5 to 6 percent of all persons. It is seen among patients in general psychiatric clinics, where it affects between half and one-third of all patients. No gender differences are seen for incidence rates. The disorder is more common in women younger than 64 years of age than in men of any age and is more common among unmarried and young persons and in those with low incomes. Dysthymia frequently coexists with other mental disorders, particularly major depressive disorder, and in persons with major depressive disorder, there is less likelihood of full remission between episodes. The patients may also have coexisting anxiety disorders (especially panic disorder), substance abuse, and borderline personality disorder. The disorder is more common among those with first-degree relatives with major depressive disorder. Patients with dysthymia are likely to be taking a wide range of psychiatric medications, including antidepressants, antimanic agents such as lithium (Eskalith) and carbamazepine (Tegretol), and sedative-hypnotics.

Etiology

Biological Factors. The biological basis for the symptoms of dysthymia and major depressive disorder are similar, but the biological bases for the underlying pathophysiology in the two disorders differ.

SLEEP STUDIES. Decreased rapid eye movement (REM) latency and increased REM density are two state markers of depression in major depressive disorder that also occur in a significant proportion of patients with dysthymia.

NEUROENDOCRINE STUDIES. The two most studied neuroendocrine axes in major depressive disorder and dysthymia are the adrenal axis and the thyroid axis, which have been tested by using the dexamethasone-suppression test (DST) and the thyrotropin-releasing hormone (TRH)-stimulation test, respectively. Although the results of studies are not absolutely consistent, most indicate that patients with dysthymia are less likely to have abnormal results on a DST than are patients with major depressive disorder.

Psychosocial Factors. Psychodynamic theories about the development of dysthymia posit that the disorder results from personality and ego development and culminates in difficulty adapting to adolescence and young adulthood. Karl Abraham, for example, thought that the conflicts of depression center on oral- and anal-sadistic traits. Anal traits include excessive orderliness, guilt, and concern for others; they are postulated to be a defense against preoccupation with anal matter and with disorganization, hostility, and self-preoccupation. A major defense mechanism used is reaction formation. Low self-esteem, anhedonia, and introversion are often associated with the depressive character.

FREUD. In *Mourning and Melancholia*, Sigmund Freud asserted that an interpersonal disappointment early in life can cause a vulnerability to depression that leads to ambivalent love relationships as an adult; real or threatened losses in adult life then trigger depression. Persons susceptible to depression are orally dependent and require constant narcissistic gratification. When deprived of love, affection, and care, they

become clinically depressed; when they experience a real loss, they internalize or introject the lost object and turn their anger on it and thus on themselves.

COGNITIVE THEORY. The cognitive theory of depression also applies to dysthymia. It holds that a disparity between actual and fantasized situations leads to diminished self-esteem and a sense of helplessness. The success of cognitive therapy in the treatment of some patients with dysthymia may provide some support for the theoretical model.

Diagnosis and Clinical Features

The DSM-5 diagnosis criteria for dysthymia (Table 8.2-1) stipulate the presence of a depressed mood most of the time for at least 2 years (or 1 year for children and adolescents). To meet the diagnostic criteria, a patient should not have symptoms that are better accounted for as major depressive disorder and should never have had a manic or hypomanic episode. DSM-5 allows clinicians to specify whether the onset was early (before age 21 years) or late (age 21 years or older). DSM-5 also allows specification of atypical features in dysthymia.

 **Table 8.2-1**
DSM-5 Diagnostic Criteria for Dysthymia

This disorder represents a consolidation of DSM-IV-defined chronic major depressive disorder and dysthymic disorder.

A. Depressed mood for most of the day, for more days than not, as indicated by either subjective account or observation by others, for at least 2 years.

Note: In children and adolescents, mood can be irritable, and duration must be at least 1 year.

B. Presence, while depressed, of two (or more) of the following:

1. Poor appetite or overeating.
2. Insomnia or hypersomnia.
3. Low energy or fatigue.
4. Low self-esteem.
5. Poor concentration or difficulty making decisions.
6. Feelings of hopelessness.

C. During the 2-year period (1 year for children or adolescents) of the disturbance, the individual has never been without the symptoms in Criteria A and B for more than 2 months at a time.

D. Criteria for a major depressive disorder may be continuously present for 2 years.

E. There has never been a manic episode or hypomanic episode, and criteria have never been met for cyclothymic disorder.

F. The disturbance is not better explained by a persistent schizoaffective disorder, schizophrenia, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.

G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hypothyroidism).

H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Note: Because the criteria for a major depressive episode include four symptoms that are absent from the symptom list for persistent depressive disorder (dysthymia), a very limited number of individuals will have depressive symptoms that have persisted longer than 2 years but will not meet criteria for persistent depressive disorder. If full criteria for a major depressive episode have been met at some point during the current episode of illness, they should be given a diagnosis of major depressive disorder. Otherwise, a diagnosis of other specified depressive disorder or unspecified depressive disorder is warranted.

Specify if:

- With anxious distress (p. 184)
- With mixed features (pp. 184–185)
- With melancholic features (p. 185)
- With atypical features (pp. 185–186)
- With mood-congruent psychotic features (p. 186)
- With mood-incongruent psychotic features (p. 186)
- With peripartum onset (pp. 186–187)

Specify if:

- In partial remission (p. 188)
- In full remission (p. 188)

Specify if:

- Early onset: If onset is before 21 years of age.
- Late onset: If onset is at age 21 years or older.

Specify if (for most recent 2 years of persistent depressive disorder):

- With pure dysthymic syndrome: Full criteria for a major depressive episode have not been met in at least the preceding 2 years.
- With persistent major depressive episode: Full criteria for a major depressive episode have been met throughout the preceding 2-year period.
- With intermittent major depressive episodes, with current episode: Full criteria for a major depressive episode are currently met, but there have been periods of at least 8 weeks in at least the preceding 2 years with symptoms below the threshold for a full major depressive episode.
- With intermittent major depressive episodes, without current episode: Full criteria for a major depressive episode are not currently met, but there has been one or more major depressive episodes in at least the preceding 2 years.

Specify current severity:

- Mild (p. 188)
- Moderate (p. 188)
- Severe (p. 188)

The profile of dysthymia overlaps with that of major depressive disorder but differs from it in that symptoms tend to outnumber signs (more subjective than objective depression). This means that disturbances in appetite and libido are uncharacteristic, and psychomotor agitation or retardation is not observed. This all translates into a depression with attenuated symptomatology. Subtle endogenous features are observed, however, including inertia, lethargy, and anhedonia that are characteristically worse in the morning. Because patients presenting clinically often fluctuate in and out of a major depression, the core DSM-5 criteria for dysthymia tend to emphasize vegetative dysfunction; however, cognitive symptoms are often present.

Dysthymia is quite heterogeneous. Anxiety is not a necessary part of its clinical picture, yet dysthymia is often diagnosed in patients with anxiety and phobic disorders. That clinical situation is sometimes diagnosed as mixed anxiety depressive disorder. For greater operational

clarity, it is best to restrict dysthymia to a primary disorder, one that cannot be explained by another psychiatric disorder. The essential features of such primary dysthymia include habitual gloom, brooding, lack of joy in life, and preoccupation with inadequacy. Dysthymia then is best characterized as long-standing, fluctuating, low-grade depression, experienced as part of the habitual self and representing an accentuation of traits observed in the depressive temperament (Table 8.2-2). The clinical picture of dysthymia is varied, with some patients proceeding to major depression and others manifesting the pathology largely at the personality level.

Table 8.2-2
Attributes, Assets, and Liabilities of Depressive and Hyperthymic Temperaments

Depressive	Hyperthymic
Gloomy, incapable of fun, complaining	Cheerful and exuberant
Humorless	Articulate and jocular
Pessimistic and given to brooding	Overoptimistic and carefree
Guilt-prone, low self-esteem, and preoccupied with inadequacy or failure	Overconfident, self-assured, boastful, and grandiose
Introverted with restricted social life	Extroverted and people seeking
Sluggish, living a life out of action	High energy level, full of plans
Few but constant interests	Versatile with broad interests
Passive	Overinvolved and meddling
Reliable, dependable, and devoted	Uninhibited and stimulus seeking

(Courtesy of Hagop S. Akiskal, M.D.)

A 27-year-old male grade-school teacher presented with the chief complaint that life was a painful duty that had always lacked luster for him. He said that he felt “enveloped by a sense of gloom” that was nearly always with him. Although he was respected by his peers, he felt “like a grotesque failure, a self-concept I have had since childhood.” He stated that he merely performed his responsibilities as a teacher and that he had never derived any pleasure from anything he had done in life. He said that he had never had any romantic feelings; sexual activity, in which he had engaged with two different women, had involved pleasureless orgasm. He said that he felt empty, going through life without any sense of direction, ambition, or passion, a realization that itself was tormenting. He had bought a pistol to put an end to what he called his “useless existence” but did not carry out suicide, believing that it would hurt his students and the small community in which he lived. (Courtesy of HS Akiskal, M.D.)

Dysthymic Variants. Dysthymia is common in patients with chronically disabling physical disorders, particularly among elderly adults. Dysthymia-like, clinically significant, subthreshold depression lasting 6 or more months has also been described in neurological conditions, including stroke. According to a recent World Health Organization (WHO) conference, this condition aggravates the prognosis of the underlying neurological disease and therefore deserves pharmacotherapy.

Prospective studies on children have revealed an episodic course of dysthymia with remissions, exacerbations, and eventual complications by major depressive episodes, 15 to 20 percent of which might even progress to hypomanic, manic, or mixed episodes postpuberty. Persons with dysthymia presenting clinically as adults tend to pursue a chronic unipolar course that may or may not be complicated by major depression. They rarely develop spontaneous hypomania or mania. When treated with antidepressants, however, some of them may develop brief hypomanic switches that typically disappear when the antidepressant dose is decreased.

Differential Diagnosis

The differential diagnosis for dysthymia is essentially identical to that for major depressive disorder. Many substances and medical illnesses can cause chronic depressive symptoms. Two disorders are particularly important to consider in the differential diagnosis of dysthymia—minor depressive disorder and recurrent brief depressive disorder.

Minor Depressive Disorder. Minor depressive disorder (discussed in Section 8.1) is characterized by episodes of depressive symptoms that are less severe than those seen in major depressive disorder. The difference between dysthymia and minor depressive disorder is primarily the episodic nature of the symptoms in the latter. Between episodes, patients with minor depressive disorder have a euthymic mood, but patients with dysthymia have virtually no euthymic periods.

Recurrent Brief Depressive Disorder. Recurrent brief depressive disorder (discussed in Section 8.1) is characterized by brief periods (less than 2 weeks) during which depressive episodes are present. Patients with the disorder would meet the diagnostic criteria for major depressive disorder if their episodes lasted longer. Patients with recurrent brief depressive disorder differ from patients with dysthymia on two counts: They have an episodic disorder, and their symptoms are more severe.

Double Depression. An estimated 40 percent of patients with major depressive disorder also meet the criteria for dysthymia, a combination often referred to as *double depression*. Available data support the conclusion that patients with double depression have a poorer prognosis than patients with only major depressive disorder. The treatment of patients with double depression should be directed toward both disorders because the resolution of the symptoms of major depressive episode still leaves these patients with significant psychiatric impairment.

Alcohol and Substance Abuse. Patients with dysthymia commonly meet the diagnostic criteria for a substance-related disorder. This comorbidity can be logical; patients with dysthymia tend to develop coping methods for their chronically depressed state that involve substance abuse. Therefore, they are likely to use alcohol, stimulants such as cocaine, or marijuana, the choice perhaps depending primarily on a patient’s social context. The presence of a comorbid diagnosis of substance abuse presents a diagnostic dilemma for clinicians; the long-term use of many substances can result in a symptom picture indistinguishable from that of dysthymia.

Course and Prognosis

About 50 percent of patients with dysthymia experience an insidious onset of symptoms before age 25 years. Despite the early onset, patients often suffer with the symptoms for a decade before seeking psychiatric help and may consider early-onset dysthymia simply part of life. Patients with an early onset of symptoms are at risk for either major depressive disorder or bipolar I disorder in the course of their disorder. Studies of patients with the diagnosis of dysthymia indicate that about 20 percent progressed to major depressive disorder, 15 percent to bipolar II disorder, and fewer than 5 percent to bipolar I disorder.

The prognosis for patients with dysthymia varies. Antidepressive agents and specific types of psychotherapies (e.g., cognitive and behavior therapies) have positive effects on the course and prognosis of dysthymia. The available data about previously available treatments indicate that only 10 to 15 percent of patients are in remission 1 year after the initial diagnosis. About 25 percent of all patients with dysthymia never attain a complete recovery. Overall, however, the prognosis is good with treatment.

Treatment

Historically, patients with dysthymia either received no treatment or were seen as candidates for long-term, insight-oriented psychotherapy. Contemporary data offer the most objective support for cognitive therapy, behavior therapy, and pharmacotherapy. The combination of pharmacotherapy and some form of psychotherapy may be the most effective treatment for the disorder.

Cognitive Therapy. Cognitive therapy is a technique in which patients are taught new ways of thinking and behaving to replace faulty negative attitudes about themselves, the world, and the future. It is a short-term therapy program oriented toward current problems and their resolution.

Behavior Therapy. Behavior therapy for depressive disorders is based on the theory that depression is caused by a loss of positive reinforcement as a result of separation, death, or sudden environmental change. The various treatment methods focus on specific goals to increase activity, to provide pleasant experiences, and to teach patients how to relax. Altering personal behavior in depressed patients is believed to be the most effective way to change the associated depressed thoughts and feelings. Behavior therapy is often used to treat the learned helplessness of some patients who seem to meet every life challenge with a sense of impotence.

Insight-Oriented (Psychoanalytic) Psychotherapy. Individual insight-oriented psychotherapy is the most common treatment method for dysthymia, and many clinicians consider it the treatment of choice. The psychotherapeutic approach attempts to relate the development and maintenance of depressive symptoms and maladaptive personality features to unresolved conflicts from early childhood. Insight into depressive equivalents (e.g., substance abuse) or into childhood disappointments as antecedents to adult depression can be gained through treatment. Ambivalent current relationships with parents, friends, and others in the patient's current life are examined. Patients' understanding of how they try to gratify an excessive need for outside approval to counter low self-esteem and a harsh superego is an important goal of this therapy.

Interpersonal Therapy. In interpersonal therapy for depressive disorders, a patient's current interpersonal experiences and ways of coping with stress are examined to reduce depressive symptoms and to improve self-esteem. Interpersonal therapy lasts for about 12 to 16 weekly sessions and can be combined with antidepressant medication.

Family and Group Therapies. Family therapy may help both the patient and the patient's family deal with the symptoms of the disorder, especially when a biologically based subaffective syndrome seems to be present. Group therapy may help withdrawn patients learn new ways to overcome their interpersonal problems in social situations.

Pharmacotherapy. Because of long-standing and commonly held theoretical beliefs that dysthymia is primarily a psychologically determined disorder, many clinicians avoid prescribing antidepressants for patients; however, many studies have shown therapeutic success with antidepressants. The data generally indicate that selective serotonin reuptake inhibitors (SSRIs) venlafaxine and bupropion are an effective treatment for patients with dysthymia. Monoamine oxidase inhibitors (MAOIs) are effective in a subgroup of patients with the disorder, a group who may also respond to the judicious use of amphetamines.

Hospitalization. Hospitalization is usually not indicated for patients with dysthymia, but particularly severe symptoms, marked social or professional incapacitation, the need for extensive diagnostic procedures, and suicidal ideation are all indications for hospitalization.

CYCLOTHYMIC DISORDER

Cyclothymic disorder is symptomatically a mild form of bipolar II disorder, characterized by episodes of hypomania and mild depression. In DSM-5, cyclothymic disorder is defined as a "chronic, fluctuating mood disturbance" with many periods of hypomania and of depression. The disorder is differentiated from bipolar II disorder, which is characterized by the presence of major (not minor) depressive and hypomanic episodes. As with dysthymia, the inclusion of cyclothymic disorder with the mood disorders implies a relation, probably biological, to bipolar I disorder. Some psychiatrists, however, consider cyclothymic disorder to have no biological component and to result from chaotic object relations early in life.

Contemporary conceptualization of cyclothymic disorder is based to some extent on the observations of Emil Kraepelin and Kurt Schneider that one-third to two-thirds of patients with mood disorders exhibit personality disorders. Kraepelin described four types of personality disorders: depressive (gloomy), manic (cheerful and uninhibited), irritable (labile and explosive), and cyclothymic. He described the irritable personality as simultaneously depressive and manic and the cyclothymic personality as the alternation of the depressive and manic personalities.

Epidemiology

Patients with cyclothymic disorder may constitute from 3 to 5 percent of all psychiatric outpatients, perhaps particularly those with significant complaints about marital and interpersonal difficulties. In the general population, the lifetime prevalence of cyclothymic disorder is estimated to be about 1 percent. This figure is probably lower than the actual prevalence because, as with patients with bipolar I disorder, the patients may not be aware that they have a psychiatric problem. Cyclothymic disorder, as with dysthymia, frequently coexists with borderline personality disorder. An estimated 10 percent of outpatients and 20 percent of inpatients with borderline personality disorder have a coexisting diagnosis of cyclothymic disorder. The female-to-male ratio in cyclothymic disorder is about 3 to 2, and 50 to 75 percent of all patients have an onset between ages 15 and 25 years. Families of persons with cyclothymic disorder often contain members with substance-related disorder.

Etiology

As with dysthymia, controversy exists about whether cyclothymic disorder is related to the mood disorders, either biologically or

psychologically. Some researchers have postulated that cyclothymic disorder has a closer relation to borderline personality disorder than to the mood disorders. Despite these controversies, the preponderance of biological and genetic data favors the idea of cyclothymic disorder as a bona fide mood disorder.

Biological Factors. About 30 percent of all patients with cyclothymic disorder have positive family histories for bipolar I disorder; this rate is similar to the rate for patients with bipolar I disorder. Moreover, the pedigrees of families with bipolar I disorder often contain generations of patients with bipolar I disorder linked by a generation with cyclothymic disorder. Conversely, the prevalence of cyclothymic disorder in the relatives of patients with bipolar I disorder is much higher than the prevalence of cyclothymic disorder either in the relatives of patients with other mental disorders or in persons who are mentally healthy. The observations that about one-third of patients with cyclothymic disorder subsequently have major mood disorders, that they are particularly sensitive to antidepressant-induced hypomania, and that about 60 percent respond to lithium add further support to the idea of cyclothymic disorder as a mild or attenuated form of bipolar II disorder.

Psychosocial Factors. Most psychodynamic theories postulate that the development of cyclothymic disorder lies in traumas and fixations during the oral stage of infant development. Freud hypothesized that the cyclothymic state is the ego's attempt to overcome a harsh and punitive superego. Hypomania is explained psychodynamically as the lack of self-criticism and an absence of inhibitions occurring when a depressed person throws off the burden of an overly harsh superego. The major defense mechanism in hypomania is denial, by which the patient avoids external problems and internal feelings of depression.

Patients with cyclothymic disorder are characterized by periods of depression alternating with periods of hypomania. Psychoanalytic exploration reveals that such patients defend themselves against underlying depressive themes with their euphoric or hypomanic periods. Hypomania is frequently triggered by a profound interpersonal loss. The false euphoria generated in such instances is a patient's way to deny dependence on love objects and simultaneously disavowing any aggression or destructiveness that may have contributed to the loss of the loved person.

Diagnosis and Clinical Features

Although many patients seek psychiatric help for depression, their problems are often related to the chaos that their manic episodes have caused. Clinicians must consider a diagnosis of cyclothymic disorder when a patient appears with what may seem to be sociopathic behavioral problems. Marital difficulties and instability in relationships are common complaints because patients with cyclothymic disorder are often promiscuous and irritable while in manic and mixed states. Although there are anecdotal reports of increased productivity and creativity when patients are hypomanic, most clinicians report that their patients become disorganized and ineffective in work and school during these periods.

The DSM-5 diagnostic criteria for cyclothymic disorder stipulate that a patient has never met the criteria for a major depressive episode and did not meet the criteria for a manic episode during the first 2 years of the disturbance. The criteria also require the more or less constant presence of symptoms for 2 years (or 1 year for children and adolescents).

Signs and Symptoms. The symptoms of cyclothymic disorder are identical to the symptoms of bipolar II disorder except that they are generally less severe. On occasion, however, the symptoms may be equally severe but of shorter duration than those seen in bipolar II disorder. About half of all patients with cyclothymic disorder have depression as their major symptom, and these patients are most likely to seek psychiatric help while depressed. Some patients with cyclothymic disorder have primarily hypomanic symptoms and are less likely to consult a psychiatrist than are primarily depressed patients. Almost all patients with cyclothymic disorder have periods of mixed symptoms with marked irritability.

Most patients with cyclothymic disorder seen by psychiatrists have not succeeded in their professional and social lives as a result of their disorder, but a few have become high achievers who have worked especially long hours and have required little sleep. Some persons' ability to control the symptoms of the disorder successfully depends on multiple individual, social, and cultural attributes.

The lives of most patients with cyclothymic disorder are difficult. The cycles of the disorder tend to be much shorter than those in bipolar I disorder. In cyclothymic disorder, the changes in mood are irregular and abrupt and sometimes occur within hours. The unpredictable nature of the mood changes produces great stress. Patients often feel that their moods are out of control. In irritable, mixed periods, they may become involved in unprovoked disagreements with friends, family, and coworkers.

Mr. B, a 25-year-old single man, came for evaluation due to irritability, insomnia, jumpiness, and excessive energy. He reported that such episodes lasted from a few days to a few weeks and alternated with longer periods of feeling hopeless, dejected, and worn out with thoughts of suicide. Mr. B reported having been this way for as long as he could remember. He had never been treated for his symptoms. He denied using drugs and said he had "only the occasional drink to relax."

As a child, Mr. B went from one foster family to another and was an irresponsible and trouble-making child. He frequently ran away from home, was absent from school, and committed minor crimes. He ran away from his last foster family at the age of 16 years and drifted ever since, taking occasional odd jobs. When he became restless at one location or job, he quickly moved on to the next. He did not have close friends because he would form and end friendships quickly.

Substance Abuse. Alcohol abuse and other substance abuse are common in patients with cyclothymic disorder, who use substances either to self-medicate (with alcohol, benzodiazepines, and marijuana) or to achieve even further stimulation (with cocaine, amphetamines, and hallucinogens) when they are manic. About 5 to 10 percent of all patients with cyclothymic disorder have substance dependence. Persons with this disorder often have a history of multiple geographical moves, involvements in religious cults, and dilettantism.

Differential Diagnosis

When a diagnosis of cyclothymic disorder is under consideration, all the possible medical and substance-related causes of depression and mania, such as seizures and particular substances (cocaine, amphetamine, and steroids), must be considered. Borderline, antisocial, histrionic, and narcissistic personality disorders should also be considered in the differential diagnosis. Attention-deficit/hyperactivity disorder (ADHD) can be difficult to differentiate from cyclothymic disorder in children and adolescents. A trial of stimulants helps most patients with ADHD and exacerbates the symptoms of most patients with cyclothymic disorder. The diagnostic category of bipolar II disorder (discussed in Section 8.1) is characterized by the combination of major depressive and hypomanic episodes.

Course and Prognosis

Some patients with cyclothymic disorder are characterized as having been sensitive, hyperactive, or moody as young children. The onset of frank symptoms of cyclothymic disorder often occurs insidiously in the teens or early 20s. The emergence of symptoms at that time hinders a person's performance in school and the ability to establish friendships with peers. The reactions of patients to such a disorder vary; patients

with adaptive coping strategies or ego defenses have better outcomes than patients with poor coping strategies. About one-third of all patients with cyclothymic disorder develop a major mood disorder, most often bipolar II disorder.

Treatment

Biological Therapy. The mood stabilizers and antimanic drugs are the first line of treatment for patients with cyclothymic disorder. Although the experimental data are limited to studies with lithium, other antimanic agents—for example, carbamazepine and valproate (Depakene)—are reported to be effective. Dosages and plasma concentrations of these agents should be the same as those in bipolar I disorder. Antidepressant treatment of depressed patients with cyclothymic disorder should be done with caution because these patients have increased susceptibility to antidepressant-induced hypomanic or manic episodes. About 40 to 50 percent of all patients with cyclothymic disorder who are treated with antidepressants experience such episodes.

Psychosocial Therapy. Psychotherapy for patients with cyclothymic disorder is best directed toward increasing patients' awareness of their condition and helping them develop coping mechanisms for their mood swings. Therapists usually need to help patients repair any damage, both work and family related, done during episodes of hypomania. Because of the long-term nature of cyclothymic disorder, patients often require lifelong treatment. Family and group therapies may be supportive, educational, and therapeutic for patients and for those involved in their lives. The psychiatrist conducting psychotherapy is able to evaluate the degree of cyclothymia and so provide an early-warning system to prevent full-blown manic attacks before they occur.

9.1 Overview

Anxiety represents a core phenomenon around which considerable psychiatric theory has been organized. Thus, the term “anxiety” has played a central role in psychodynamic theory, as well as in neuroscience-focused research and various schools of thought heavily influenced by cognitive-behavioral principles. Anxiety disorders are associated with significant morbidity and often are chronic and resistant to treatment. Anxiety disorders can be viewed as a family of related but distinct mental disorders, which include (1) panic disorder, (2) agoraphobia, (3) specific phobia, (4) social anxiety disorder or phobia, and (5) generalized anxiety disorder. Each of these disorders is discussed in detail in the sections that follow.

A fascinating aspect of anxiety disorders is the exquisite interplay of genetic and experiential factors. Little doubt exists that abnormal genes predispose to pathological anxiety states; however, evidence clearly indicates that traumatic life events and stress are also etiologically important. Thus, the study of anxiety disorders presents a unique opportunity to understand the relation between nature and nurture in the etiology of mental disorders.

NORMAL ANXIETY

Everyone experiences anxiety. It is characterized most commonly as a diffuse, unpleasant, vague sense of apprehension, often accompanied by autonomic symptoms such as headache, perspiration, palpitations, tightness in the chest, mild stomach discomfort, and restlessness, indicated by an inability to sit or stand still for long. The particular constellation of symptoms present during anxiety tends to vary among persons (Table 9.1-1).

Table 9.1-1
Peripheral Manifestations of Anxiety

Diarrhea
Dizziness, lightheadedness
Hyperhidrosis
Hyperreflexia
Palpitations
Pupillary mydriasis
Restlessness (e.g., pacing)
Syncope
Tachycardia
Tingling in the extremities
Tremors
Upset stomach (“butterflies”)
Urinary frequency, hesitancy, urgency

Fear versus Anxiety

Anxiety is an alerting signal; it warns of impending danger and enables a person to take measures to deal with a threat. Fear is a similar alerting signal, but it should be differentiated from anxiety. Fear is a response to a known, external, definite, or nonconflictual threat; anxiety is a response to a threat that is unknown, internal, vague, or conflictual.

This distinction between fear and anxiety arose accidentally. When Freud’s early translator mistranslated *angst*, the German word for “fear,” as anxiety, Freud himself generally ignored the distinction that associates anxiety with a repressed, unconscious object and fear with a known, external object. The distinction may be difficult to make because fear can also be caused by an unconscious, repressed, internal object displaced to another object in the external world. For example, a boy may fear barking dogs because he actually fears his father and unconsciously associates his father with barking dogs.

Nevertheless, according to postfreudian psychoanalytic formulations, the separation of fear and anxiety is psychologically justifiable. The emotion caused by a rapidly approaching car as a person crosses the street differs from the vague discomfort a person may experience when meeting new persons in a strange setting. The main psychological difference between the two emotional responses is the suddenness of fear and the insidiousness of anxiety.

In 1896, Charles Darwin gave the following psychophysiological description of acute fear merging into terror:

Fear is often preceded by astonishment, and is so far akin to it, that both lead to the senses of sight and learning being instantly aroused. In both cases the eyes and mouth are widely opened, and the eyebrows raised. The frightened man at first stands like a statue motionless and breathless, or crouches down as if instinctively to escape observation. The heart beats quickly and violently, so that it palpitates or knocks against the ribs; but it is very doubtful whether it then works more efficiently than usual, so as to send a greater supply of blood to all parts of the body; for the skin instantly becomes pale, as during incipient faintness. This paleness of the surface, however, is probably in large part, or exclusively, due to the vasomotor center being affected in such a manner as to cause the contraction of the small arteries of the skin. That the skin is much affected under the sense of great fear, we see in the marvelous and inexplicable manner in which perspiration immediately exudes from it. This exudation is all the more remarkable, as the surface is then cold, and hence the term a cold sweat; whereas, the sudorific glands are properly excited into action when the surface is heated. The hairs also on the skin stand erect; and the superficial muscles shiver. In connection with the disturbed action of the heart, the breathing is hurried. The salivary glands act imperfectly; the mouth becomes dry, and is often opened and shut. I have also noticed that under slight fear there is a strong tendency to yawn. One of the best-marked symptoms is the trembling of all the muscles of the body; and this is often first seen in the lips. From this cause, and from the dryness of the mouth, the voice becomes husky or indistinct, or may altogether fail....

As fear increases into an agony of terror, we behold, as under all violent emotions, diversified results. The heart beats wildly or may fail to act and faintness ensues; there is a deathlike pallor; the breathing is labored; the wings of the nostrils are widely dilated; there is a gasping and convulsive motion on the lips, a tremor on the hollow cheek, a gulping and catching of the throat; the uncovered and protruding eyeballs are fixed on the object of terror; or they may roll restlessly from side to side. The pupils are said to be enormously

dilated. All the muscles of the body may become rigid, or may be thrown into convulsive movements. The hands are alternately clenched and opened, often with a twitching movement. The arms may be protruded, as if to avert some dreadful danger, or may be thrown wildly over the head....In other cases there is a sudden and uncontrollable tendency to headlong flight; and so strong is this, that the boldest soldiers may be seized with a sudden panic.

Is Anxiety Adaptive?

Anxiety and fear both are alerting signals and act as a warning of an internal and external threat. Anxiety can be conceptualized as a normal and adaptive response that has lifesaving qualities and warns of threats of bodily damage, pain, helplessness, possible punishment, or the frustration of social or bodily needs; of separation from loved ones; of a menace to one's success or status; and ultimately of threats to unity or wholeness. It prompts a person to take the necessary steps to prevent the threat or to lessen its consequences. This preparation is accompanied by increased somatic and autonomic activity controlled by the interaction of the sympathetic and parasympathetic nervous systems. Examples of a person warding off threats in daily life include getting down to the hard work of preparing for an examination, dodging a ball thrown at the head, sneaking into the dormitory after curfew to prevent punishment, and running to catch the last commuter train. Thus, anxiety prevents damage by alerting the person to carry out certain acts that forestall the danger.

Stress and Anxiety

Whether an event is perceived as stressful depends on the nature of the event and on the person's resources, psychological defenses, and coping mechanisms. All involve the ego, a collective abstraction for the process by which a person perceives, thinks, and acts on external events or internal drives. A person whose ego is functioning properly is in adaptive balance with both external and internal worlds; if the ego is not functioning properly and the resulting imbalance continues sufficiently long, the person experiences chronic anxiety.

Whether the imbalance is external, between the pressures of the outside world and the person's ego, or internal, between the person's impulses (e.g., aggressive, sexual, and dependent impulses) and conscience, the imbalance produces a conflict. Whereas externally caused conflicts are usually interpersonal, those that are internally caused are intrapsychic or intrapersonal. A combination of the two is possible, as in the case of employees whose excessively demanding and critical boss provokes impulses that they must control for fear of losing their jobs. Interpersonal and intrapsychic conflicts, in fact, are usually intertwined. Because human beings are social, their main conflicts are usually with other persons.

Symptoms of Anxiety

The experience of anxiety has two components: the awareness of the physiological sensations (e.g., palpitations and sweating) and the awareness of being nervous or frightened. A feeling of shame may increase anxiety—"Others will recognize that I am frightened." Many persons are astonished to find out that others are not aware of their anxiety or, if they are, do not appreciate its intensity.

In addition to motor and visceral effects, anxiety affects thinking, perception, and learning. It tends to produce confusion and distortions of perception, not only of time and space but also of persons and the meanings of events. These distortions can interfere with learning by lowering concentration, reducing recall, and impairing the ability to relate one item to another—that is, to make associations.

An important aspect of emotions is their effect on the selectivity of attention. Anxious persons likely select certain things in their environment and overlook others in their effort to prove that they are justified in considering the situation frightening. If they falsely justify their fear, they augment their anxieties by the selective response and set up a vicious circle of anxiety, distorted perception, and increased anxiety. If, alternatively, they falsely reassure themselves by selective thinking, appropriate anxiety may be reduced, and they may fail to take necessary precautions.

PATHOLOGICAL ANXIETY

Epidemiology

The anxiety disorders make up one of the most common groups of psychiatric disorders. The National Comorbidity Study reported that one of four persons met the diagnostic criteria for at least one anxiety disorder and that there is a 12-month prevalence rate of 17.7 percent. Women (30.5 percent lifetime prevalence) are more likely to have an anxiety disorder than are men (19.2 percent lifetime prevalence). The prevalence of anxiety disorders decreases with higher socioeconomic status.

Contributions of Psychological Sciences

Three major schools of psychological theory—psychoanalytic, behavioral, and existential—have contributed theories about the causes of anxiety. Each theory has both conceptual and practical usefulness in treating anxiety disorders.

Psychoanalytic Theories. Although Freud originally believed that anxiety stemmed from a physiological buildup of libido, he ultimately redefined anxiety as a signal of the presence of danger in the unconscious. Anxiety was viewed as the result of psychic conflict between unconscious sexual or aggressive wishes and corresponding threats from the superego or external reality. In response to this signal, the ego mobilized defense mechanisms to prevent unacceptable thoughts and feelings from emerging into conscious awareness. In his classic paper "Inhibitions, Symptoms, and Anxiety," Freud states that "it was anxiety which produced repression and not, as I formerly believed, repression which produced anxiety." Today, many neurobiologists continue to substantiate many of Freud's original ideas and theories. One example is the role of the amygdala, which subserves the fear response without any reference to conscious memory and substantiates Freud's concept of an unconscious memory system for anxiety responses. One of the unfortunate consequences of regarding the symptom of anxiety as a disorder rather than a signal is that the underlying sources of the anxiety may be ignored. From a psychodynamic perspective, the goal of therapy is not necessary to eliminate all anxiety but to increase anxiety tolerance—that is, the capacity to experience anxiety—and use it as a signal to investigate the underlying conflict that has created it. Anxiety appears in response to various situations during the life cycle, and although psychopharmacological agents may ameliorate symptoms, they may do nothing to address the life situation or its internal correlates that have induced the state of anxiety. In the following case, a disturbing fantasy precipitated an anxiety attack.

A married man 32 years of age was referred for therapy for severe and incapacitating anxiety, which was clinically manifested as repeated outbreaks of acute attacks of panic. Initially, he had absolutely no idea what had precipitated his attacks, nor were they associated with any conscious mental content. In the early weeks of treatment, he spent most of his time trying to impress the doctor with how hard he had worked and how effectively he had functioned before he was taken ill. At the same time, he described how fearful he was that he would fail at a new business venture he had embarked on. One day, with obvious acute anxiety that practically prevented him from talking, he revealed a fantasy that had suddenly popped into his mind a day or two before and had led to the outbreak of a severe anxiety attack. He had had the image of a large spike being driven through his penis. He also recalled that, as a child of 7, he was fascinated by his mother's clothing and that, on occasion, when she was out of the house, he dressed himself up in them. As an adult, he

was fascinated by female lingerie and would sometimes find himself impelled by a desire to wear women's clothing. He had never yielded to the impulse, but on those occasions when the idea entered his consciousness, he became overwhelmed by acute anxiety and panic.

To understand fully a particular patient's anxiety from a psychodynamic view, it is often useful to relate the anxiety to developmental issues. At the earliest level, disintegration anxiety may be present. This anxiety derives from the fear that the self will fragment because others are not responding with needed affirmation and validation. Persecutory anxiety can be connected with the perception that the self is being invaded and annihilated by an outside malevolent force. Another source of anxiety involves a child who fears losing the love or approval of a parent or loved object. Freud's theory of castration anxiety is linked to the oedipal phase of development in boys, in which a powerful parental figure, usually the father, may damage the little boy's genitals or otherwise cause bodily harm. At the most mature level, superego anxiety is related to guilt feelings about not living up to internalized standards of moral behavior derived from the parents. Often, a psychodynamic interview can elucidate the principal level of anxiety with which a patient is dealing. Some anxiety is obviously related to multiple conflicts at various developmental levels.

Behavioral Theories. The behavioral or learning theories of anxiety postulate that anxiety is a conditioned response to a specific environmental stimulus. In a model of classic conditioning, a girl raised by an abusive father, for example, may become anxious as soon as she sees the abusive father. Through generalization, she may come to distrust all men. In the social learning model, a child may develop an anxiety response by imitating the anxiety in the environment, such as in anxious parents.

Existential Theories. Existential theories of anxiety provide models for generalized anxiety, in which no specifically identifiable stimulus exists for a chronically anxious feeling. The central concept of existential theory is that persons experience feelings of living in a purposeless universe. Anxiety is their response to the perceived void in existence and meaning. Such existential concerns may have increased since the development of nuclear weapons and bioterrorism.

Contributions of Biological Sciences

Autonomic Nervous System. Stimulation of the autonomic nervous system causes certain symptoms—cardiovascular (e.g., tachycardia), muscular (e.g., headache), gastrointestinal (e.g., diarrhea), and respiratory (e.g., tachypnea). The autonomic nervous systems of some patients with anxiety disorder, especially those with panic disorder, exhibit increased sympathetic tone, adapt slowly to repeated stimuli, and respond excessively to moderate stimuli.

Neurotransmitters. The three major neurotransmitters associated with anxiety on the bases of animal studies and responses to drug treatment are norepinephrine (NE), serotonin, and γ -aminobutyric acid (GABA). Much of the basic neuroscience information about anxiety comes from animal experiments involving behavioral paradigms and psychoactive agents. One such experiment to study anxiety was the conflict test, in which the animal is simultaneously presented with stimuli that are positive (e.g., food) and negative (e.g., electric shock). Anxiolytic drugs (e.g., benzodiazepines) tend to facilitate the adaptation of the animal to this situation, but other drugs (e.g., amphetamines) further disrupt the animal's behavioral responses.

NOREPINEPHRINE. Chronic symptoms experienced by patients with anxiety disorder, such as panic attacks, insomnia, startle, and autonomic hyperarousal, are characteristic of increased noradrenergic function. The general theory about the role of norepinephrine in anxiety disorders is that affected patients may have a poorly regulated noradrenergic system with occasional bursts of activity. The cell bodies of the noradrenergic system are primarily localized to the locus ceruleus in the rostral pons, and they project their axons to the cerebral cortex, the limbic system, the brainstem, and the spinal cord. Experiments in primates have demonstrated that stimulation of the locus ceruleus produces a fear response in the animals and that ablation of the same area inhibits or completely blocks the ability of the animals to form a fear response.

Human studies have found that in patients with panic disorder, β -adrenergic receptor agonists (e.g., isoproterenol [Isuprel]) and α_2 -adrenergic receptor antagonists (e.g., yohimbine [Yocon]) can provoke frequent and severe panic attacks. Conversely, clonidine (Catapres), an α_2 -receptor agonist, reduces anxiety symptoms in some experimental and therapeutic situations. A less consistent finding is that patients with anxiety disorders, particularly panic disorder, have elevated cerebrospinal fluid (CSF) or urinary levels of the noradrenergic metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG).

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS. Consistent evidence indicates that many forms of psychological stress increase the synthesis and release of cortisol. Cortisol serves to mobilize and to replenish energy stores and contributes to increased arousal, vigilance, focused attention, and memory formation; inhibition of the growth and reproductive system; and containment of the immune response. Excessive and sustained cortisol secretion can have serious adverse effects, including hypertension, osteoporosis, immunosuppression, insulin resistance, dyslipidemia, dyscoagulation, and, ultimately, atherosclerosis and cardiovascular disease. Alterations in hypothalamic-pituitary-adrenal (HPA) axis function have been demonstrated in PTSD. In patients with panic disorder, blunted adrenocorticoid hormone (ACTH) responses to corticotropin-releasing factor (CRF) have been reported in some studies and not in others.

CORTICOTROPIN-RELEASING HORMONE (CRH). One of the most important mediators of the stress response, CRH coordinates the adaptive behavioral and physiological changes that occur during stress. Hypothalamic levels of CRH are increased by stress, resulting in activation of the HPA axis and increased release of cortisol and dehydroepiandrosterone (DHEA). CRH also inhibits a variety of neurovegetative functions, such as food intake, sexual activity, and endocrine programs for growth and reproduction.

SEROTONIN. The identification of many serotonin receptor types has stimulated the search for the role of serotonin in the pathogenesis of anxiety disorders. Different types of acute stress result in increased 5-hydroxytryptamine (5-HT) turnover in the prefrontal cortex, nucleus accumbens, amygdala, and lateral hypothalamus. The interest in this relation was initially motivated by the observation that serotonergic antidepressants have therapeutic effects in some anxiety disorders—for example, clomipramine (Anafranil) in obsessive-compulsive disorder (OCD). The effectiveness of buspirone (BuSpar), a serotonin 5-HT_{1A} receptor agonist, in the treatment of anxiety disorders also suggests the possibility of an association between serotonin and anxiety. The cell bodies of most serotonergic neurons are located in the raphe nuclei in the rostral brainstem and project to the cerebral cortex, the limbic system (especially, the amygdala and the hippocampus), and the hypothalamus. Several reports indicate that meta-chlorophenylpiperazine (mCPP), a drug with multiple serotonergic and nonserotonergic effects, and fenfluramine (Pondimin), which causes the release of serotonin, do cause increased anxiety in patients with anxiety disorders; and many anecdotal reports indicate that serotonergic hallucinogens and stimulants—for example, lysergic acid diethylamide (LSD) and 3,4-methylenedioxyamphetamine (MDMA)—are associated with the development of both acute and chronic anxiety disorders in persons who use these drugs. Clinical studies of 5-HT function in anxiety disorders have had mixed results. One study found that patients with panic disorder had lower levels of circulating 5-HT compared with control participants. Thus, no clear pattern of abnormality in 5-HT function in panic disorder has emerged from analysis of peripheral blood elements.

GABA. A role of GABA in anxiety disorders is most strongly supported by the undisputed efficacy of benzodiazepines, which enhance the activity of GABA at the GABA type A (GABA_A) receptor, in the treatment of some types of anxiety disorders. Although low-potency benzodiazepines are most effective for the symptoms of generalized anxiety disorder, high-potency benzodiazepines, such as alprazolam (Xanax), and clonazepam are effective in the treatment of panic disorder. Studies in primates have found that autonomic nervous system symptoms of anxiety disorders are induced when a benzodiazepine inverse agonist, β -carboline-3-carboxylic acid (BCCE), is administered. BCCE also causes anxiety in normal control volunteers. A benzodiazepine antagonist, flumazenil (Romazicon), causes frequent severe panic attacks in patients with panic disorder. These data have led researchers to hypothesize that some patients with anxiety disorders have abnormal functioning of their GABA_A receptors, although this connection has not been shown directly.

APLYSIA. A neurotransmitter model for anxiety disorders is based on the study of *Aplysia californica* by Nobel Prize winner Eric Kandel, M.D. *Aplysia* is a sea snail that reacts to danger by moving away, withdrawing into its shell, and decreasing its feeding behavior. These behaviors can be classically conditioned, so that the snail responds to a neutral stimulus as if it were a dangerous stimulus. The snail can also be sensitized by random shocks, so that it exhibits a flight response in the absence of real danger. Parallels have previously been drawn between classic conditioning and human phobic anxiety. The classically conditioned *Aplysia* shows measurable changes in presynaptic facilitation, resulting in the release of increased amounts of neurotransmitter. Although the sea snail is a simple animal, this work shows an experimental approach to complex neurochemical processes potentially involved in anxiety disorders in humans.

NEUROPEPTIDE Y. Neuropeptide Y (NPY) is a highly conserved 36–amino acid peptide, which is among the most abundant peptides found in mammalian brain. Evidence suggesting the involvement of the amygdala in the anxiolytic effects of NPY is robust, and it probably occurs via the NPY-Y1 receptor. NPY has counterregulatory effects on corticotropin-releasing hormone (CRH) and LC-NE systems at brain sites that are important in the expression of anxiety, fear, and depression. Preliminary studies in special operations soldiers under extreme training stress indicate that high NPY levels are associated with better performance.

GALANIN. Galanin is a peptide that, in humans, contains 30 amino acids. It has been demonstrated to be involved in a number of physiological and behavioral functions, including learning and memory, pain control, food intake, neuroendocrine control, cardiovascular regulation, and, most recently, anxiety. A dense galanin immunoreactive fiber system originating in the LC innervates forebrain and midbrain structures, including the hippocampus, hypothalamus, amygdala, and prefrontal cortex. Studies in rats have shown that galanin administered centrally modulates anxiety-related behaviors. Galanin and NPY receptor agonists may be novel targets for antianxiety drug development.

Brain Imaging Studies. A range of brain imaging studies, almost always conducted with a specific anxiety disorder, has produced several possible leads in the understanding of anxiety disorders. Structural studies—for example, computed tomography (CT) and magnetic resonance imaging (MRI)—occasionally show some increase in the size of cerebral ventricles. In one study, the increase was correlated with the length of time patients had been taking benzodiazepines. In one MRI study, a specific defect in the right temporal lobe was noted in patients with panic disorder. Several other brain imaging studies have reported abnormal findings in the right hemisphere but not the left hemisphere; this finding suggests that some types of cerebral asymmetries may be important in the development of anxiety disorder symptoms in specific patients. Functional brain imaging (fMRI) studies—for example, positron emission tomography (PET), single-photon emission computed tomography (SPECT), and electroencephalography (EEG)—of patients with anxiety disorder have variously reported abnormalities in the frontal cortex; the occipital and temporal areas; and, in a study of panic disorder, the parahippocampal gyrus. Several functional neuroimaging studies have implicated the caudate nucleus in the pathophysiology of OCD. In posttraumatic stress disorder, fMRI studies have found increased activity in the amygdala, a brain region associated with fear (see [Color Plate 9.1-1](#)). A conservative interpretation of these data is that some patients with anxiety disorders have a demonstrable functional cerebral pathological condition and that the condition may be causally relevant to their anxiety disorder symptoms.

Genetic Studies. Genetic studies have produced solid evidence that at least some genetic component contributes to the development of anxiety disorders. Heredity has been recognized as a predisposing factor in the development of anxiety disorders. Almost half of all patients with panic disorder have at least one affected relative. The figures for other anxiety disorders, although not as high, also indicate a higher frequency of the illness in first-degree relatives of affected patients than in the relatives of nonaffected persons. Although adoption studies with anxiety disorders have not been reported, data from twin registries also support the hypothesis that anxiety disorders are at least partially genetically determined. Clearly, a linkage exists between genetics and anxiety disorders, but no anxiety disorder is likely to result from a simple mendelian abnormality. One report has attributed about 4 percent of the intrinsic variability of anxiety within the general population to a polymorphic variant of the gene for the serotonin transporter, which is the site of action of many serotonergic drugs. Persons with the variant produce less transporter and have higher levels of anxiety.

In 2005, a scientific team, led by National Institute of Mental Health grantee and Noble Laureate Dr. Eric Kandel demonstrated that knocking out a gene in the brain's fear hub creates mice unperturbed by situations that would normally trigger instinctive or learned fear responses. The gene codes for *stathmin*, a protein that is critical for the amygdala to form fear memories. Stathmin knockout mice showed less anxiety when they heard a tone that had previously been associated with a shock, indicating less learned fear. The knockout mice also were more susceptible to explore novel open space and maze environments, a reflection of less innate fear. Kandel suggests that stathmin knockout mice can be used as a model of anxiety states of mental disorders with innate and learned fear components: these animals could be used to develop new antianxiety agents. Whether stathmin is similarly expressed and pivotal for anxiety in the human amygdala remains to be confirmed.

Neuroanatomical Considerations. The locus ceruleus and the raphe nuclei project primarily to the limbic system and the cerebral cortex. In combination with the data from brain imaging studies, these areas have become the focus of much hypothesis-forming about the neuroanatomical substrates of anxiety disorders.

LIMBIC SYSTEM. In addition to receiving noradrenergic and serotonergic innervation, the limbic system also contains a high concentration of GABA_A receptors. Ablation and stimulation studies in nonhuman primates have also implicated the limbic system in the generation of anxiety and fear responses. Two areas of the limbic system have received special attention in the literature: increased activity in the septohippocampal pathway, which may lead to anxiety; and the cingulate gyrus, which has been implicated particularly in the pathophysiology of OCD.

CEREBRAL CORTEX. The frontal cerebral cortex is connected with the parahippocampal region, the cingulate gyrus, and the hypothalamus and thus may be involved in the production of anxiety disorders. The temporal cortex has also been implicated as a pathophysiological site in anxiety disorders. This association is based in part on the similarity in clinical presentation and electrophysiology between some patients with temporal lobe epilepsy and patients with OCD.

▲ 9.2 Panic Disorder

An acute intense attack of anxiety accompanied by feelings of impending doom is known as *panic disorder*. The anxiety is characterized by discrete periods of intense fear that can vary from several attacks during one day to only a few attacks during a year. Patients with panic disorder present with a number of comorbid conditions, most commonly agoraphobia, which refers to a fear of or anxiety regarding places from which escape might be difficult.

HISTORY

The idea of panic disorder may have its roots in the concept of irritable heart syndrome, which the physician Jacob Mendes DaCosta (1833–1900) noted in soldiers in the American Civil War. DaCosta's syndrome included many psychological and somatic symptoms that have since been included among the diagnostic criteria for panic disorder. In 1895, Sigmund Freud introduced the concept of anxiety neurosis, consisting of acute and chronic psychological and somatic symptoms.

EPIDEMIOLOGY

The lifetime prevalence of panic disorder is in the 1 to 4 percent range, with 6-month prevalence approximately 0.5 to 1.0 percent and 3 to 5.6 percent for panic attacks. Women are two to three times more likely to be affected than men, although underdiagnosis of panic disorder in men may contribute to the skewed distribution. The differences among Hispanics, whites, and blacks are few. The only social factor identified as contributing to the development of panic disorder is a recent history of divorce or separation. Panic disorder most commonly develops in young adulthood—the mean age of presentation is about 25 years—but both panic disorder and agoraphobia can develop at any age. Panic disorder has been reported in children and adolescents, and it is probably underdiagnosed in these age groups.

COMORBIDITY

Of patients with panic disorder, 91 percent have at least one other psychiatric disorder. About one-third of persons with panic disorders have major depressive disorder before onset; about two-thirds first experience panic disorder during or after the onset of major depression.

Other disorders also commonly occur in persons with panic disorder. Of persons with panic disorder, 15 to 30 percent also have social anxiety disorder or social phobia, 2 to 20 percent have specific phobia, 15 to 30 percent have generalized anxiety disorder, 2 to 10 percent have PTSD, and up to 30 percent have OCD. Other common comorbid conditions are hypochondriasis or illness anxiety disorder, personality disorders, and substance-related disorders.

ETIOLOGY

Biological Factors

Research on the biological basis of panic disorder has produced a range of findings; one interpretation is that the symptoms of panic disorder are related to a range of biological abnormalities in brain structure and function. Most work has used biological stimulants to induce panic attacks in patients with panic disorder. Considerable evidence indicates that abnormal regulation of brain noradrenergic systems is also involved in the pathophysiology of panic disorder. These and other studies have produced hypotheses implicating both peripheral and central nervous system (CNS) dysregulation in the pathophysiology of panic disorder. The autonomic nervous systems of some patients with panic disorder have been reported to exhibit increased sympathetic tone, to adapt slowly to repeated stimuli, and to respond excessively to moderate stimuli. Studies of the neuroendocrine status of these patients have shown several abnormalities, although the studies have been inconsistent in their findings.

The major neurotransmitter systems that have been implicated are those for norepinephrine, serotonin, and GABA. Serotonergic dysfunction is quite evident in panic disorder, and various studies with mixed serotonin agonist–antagonist drugs have demonstrated increased rates of anxiety. Such responses may be caused by postsynaptic serotonin hypersensitivity in panic disorder. Preclinical evidence suggests that attenuation of local inhibitory GABAergic transmission in the basolateral amygdala, midbrain, and hypothalamus can elicit anxiety-like physiological responses. The biological data have led to a focus on the brainstem (particularly the noradrenergic neurons of the locus ceruleus and the serotonergic neurons of the median raphe nucleus), the limbic system (possibly responsible for the generation of anticipatory anxiety), and the prefrontal cortex (possibly responsible for the generation of phobic avoidance). Among the various neurotransmitters involved, the noradrenergic system has also attracted much attention, with the presynaptic α_2 -adrenergic receptors, particularly, playing a significant role. Patients with panic disorder are sensitive to the anxiogenic effects of yohimbine in addition to having exaggerated MHPG, cortisol, and cardiovascular responses. They have been identified by pharmacological challenges with the α_2 -receptor agonist clonidine (Catapres) and the α_2 -receptor antagonist yohimbine (Yocon), which stimulates firing of the locus ceruleus and elicits high rates of panic-like activity in those with panic disorder.

Panic-Inducing Substances. Panic-inducing substances (sometimes called *panicogens*) induce panic attacks in most patients with panic disorder and in a much smaller proportion of persons without panic disorder or a history of panic attacks. So-called respiratory panic-inducing substances cause respiratory stimulation and a shift in the acid–base balance. These substances include carbon dioxide (5 to 35

percent mixtures), sodium lactate, and bicarbonate. Neurochemical panic-inducing substances that act through specific neurotransmitter systems include yohimbine, an α_2 -adrenergic receptor antagonist; mCPP, an agent with multiple serotonergic effects; m-Caroline drugs; GABA_B receptor inverse agonists; flumazenil (Romazicon), a GABA_B receptor antagonist; cholecystokinin; and caffeine. Isoproterenol (Isuprel) is also a panic-inducing substance, although its mechanism of action in inducing panic attacks is poorly understood. The respiratory panic-inducing substances may act initially at the peripheral cardiovascular baroreceptors and relay their signal by vagal afferents to the nucleus tractus solitarius and then on to the nucleus paragigantocellularis of the medulla. The hyperventilation in patients with panic disorder may be caused by a hypersensitive suffocation alarm system whereby increasing PCO₂ and brain lactate concentrations prematurely activate a physiological asphyxia monitor. The neurochemical panic-inducing substances are presumed to primarily affect the noradrenergic, serotonergic, and GABA receptors of the CNS directly.

Brain Imaging. Structural brain imaging studies, for example, MRI, in patients with panic disorder have implicated pathological involvement in the temporal lobes, particularly the hippocampus and the amygdala. One MRI study reported abnormalities, especially cortical atrophy, in the right temporal lobe of these patients. Functional brain imaging studies, for example, positron emission tomography (PET), have implicated dysregulation of cerebral blood flow (smaller increase or an actual decrease in cerebral blood flow). Specifically, anxiety disorders and panic attacks are associated with cerebral vasoconstriction, which may result in CNS symptoms, such as dizziness, and in peripheral nervous system symptoms that may be induced by hyperventilation and hypocapnia. Most functional brain imaging studies have used a specific panic-inducing substance (e.g., lactate, caffeine, or yohimbine) in combination with PET or SPECT to assess the effects of the panic-inducing substance and the induced panic attack on cerebral blood flow.

Mitral Valve Prolapse. Although great interest was formerly expressed in an association between mitral valve prolapse and panic disorder, research has almost completely erased any clinical significance or relevance to the association. Mitral valve prolapse is a heterogeneous syndrome consisting of the prolapse of one of the mitral valve leaflets, resulting in a midsystolic click on cardiac auscultation. Studies have found that the prevalence of panic disorder in patients with mitral valve prolapse is the same as the prevalence of panic disorder in patients without mitral valve prolapse.

Genetic Factors

Various studies have found that the first-degree relatives of patients with panic disorder have a four- to eightfold higher risk for panic disorder than first-degree relatives of other psychiatric patients. The twin studies conducted to date have generally reported that monozygotic twins are more likely to be concordant for panic disorder than are dizygotic twins. At this point, no data exist indicating an association between a specific chromosomal location or mode of transmission and this disorder.

Psychosocial Factors

Psychoanalytic theories have been developed to explain the pathogenesis of panic disorder. Psychoanalytic theories conceptualize panic attacks as arising from an unsuccessful defense against anxiety-provoking impulses. What was previously a mild signal anxiety becomes an overwhelming feeling of apprehension, complete with somatic symptoms.

Many patients describe panic attacks as coming out of the blue, as though no psychological factors were involved, but psychodynamic exploration frequently reveals a clear psychological trigger for the panic attack. Although panic attacks are correlated neurophysiologically with the locus ceruleus, the onset of panic is generally related to environmental or psychological factors. Patients with panic disorder have a higher incidence of stressful life events (particularly loss) than control subjects in the months before the onset of panic disorder. Moreover, the patients typically experience greater distress about life events than control subjects do.

The hypothesis that stressful psychological events produce neurophysiological changes in panic disorder is supported by a study of female twins. Separation from the mother early in life was clearly more likely to result in panic disorder than was paternal separation in the cohort of 1,018 pairs of female twins. Another etiological factor in adult female patients appears to be childhood physical and sexual abuse. Approximately 60 percent of women with panic disorder have a history of childhood sexual abuse compared with 31 percent of women with other anxiety disorders. Further support for psychological mechanisms in panic disorder can be inferred from a study of panic disorder in which patients received successful treatment with cognitive therapy. Before the therapy, the patients responded to panic attack induction with lactate. After successful cognitive therapy, lactate infusion no longer produced a panic attack.

The research indicates that the cause of panic attacks is likely to involve the unconscious meaning of stressful events and that the pathogenesis of the panic attacks may be related to neurophysiological factors triggered by the psychological reactions. Psychodynamic clinicians should always thoroughly investigate possible triggers whenever assessing a patient with panic disorder. The psychodynamics of panic disorder are summarized in [Table 9.2-1](#).

 **Table 9.2-1**
Psychodynamic Themes in Panic Disorder

1. Difficulty tolerating anger
2. Physical or emotional separation from significant person both in childhood and in adult life
3. May be triggered by situations of increased work responsibilities
4. Perception of parents as controlling, frightening, critical, and demanding
5. Internal representations of relationships involving sexual or physical abuse
6. A chronic sense of feeling trapped
7. Vicious cycle of anger at parental rejecting behavior followed by anxiety that the fantasy will destroy the tie to parents
8. Failure of signal anxiety function in ego related to self-fragmentation and self-other boundary confusion
9. Typical defense mechanisms: reaction formation, undoing, somatization, and externalization

DIAGNOSIS

Panic Attacks

A panic attack is a sudden period of intense fear or apprehension that may last from minutes to hours. Panic attacks can occur in mental disorders other than panic disorder, particularly in specific phobia, social phobia, and PTSD. Unexpected panic attacks occur at any time and are not associated with any identifiable situational stimulus, but panic attacks need not be unexpected. Attacks in patients with social and specific phobias are usually expected or cued to a recognized or specific stimulus. Some panic attacks do not fit easily into the distinction between unexpected and expected, and these attacks are referred to as *situationally predisposed panic attacks*. They may or may not occur when a patient is exposed to a specific trigger, or they may occur either immediately after exposure or after a considerable delay.

Panic Disorder

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) diagnostic criteria for panic disorder are listed in [Table 9.2-2](#). Some community surveys have indicated that panic attacks are common, and a major issue in developing diagnostic criteria for panic disorder was determining a threshold number or frequency of panic attacks required to meet the diagnosis. Setting the threshold too low results in the diagnosis of panic disorder in patients who do not have an impairment from an occasional panic attack; setting the threshold too high results in a situation in which patients who are impaired by their panic attacks do not meet the diagnostic criteria.

Table 9.2-2
DSM-5 Diagnostic Criteria for Panic Disorder

- A. Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes and during which time four (or more) of the following symptoms occur:
Note: The abrupt surge can occur from a calm state or an anxious state.
1. Palpitations, pounding heart, or accelerated heart rate.
 2. Sweating.
 3. Trembling or shaking.
 4. Sensations of shortness of breath or smothering.
 5. Feelings of choking.
 6. Chest pain or discomfort.
 7. Nausea or abdominal distress.
 8. Feeling dizzy, unsteady, light-headed, or faint.
 9. Chills or heat sensations.
 10. Paresthesias (numbness or tingling sensations).
 11. Derealization (feelings of unreality) or depersonalization (being detached from one-self).
 12. Fear of losing control or “going crazy.”
 13. Fear of dying.
- Note:** Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.
- B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”).
 2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations).
- C. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).
- D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to separation from attachment figures, as in separation anxiety disorder).

CLINICAL FEATURES

The first panic attack is often completely spontaneous, although panic attacks occasionally follow excitement, physical exertion, sexual activity, or moderate emotional trauma. Clinicians should attempt to ascertain any habit or situation that commonly precedes a patient's panic attacks. Such activities may include the use of caffeine, alcohol, nicotine, or other substances; unusual patterns of sleeping or eating; and specific environmental settings, such as harsh lighting at work.

The attack often begins with a 10-minute period of rapidly increasing symptoms. The major mental symptoms are extreme fear and a sense of impending death and doom. Patients usually cannot name the source of their fear; they may feel confused and have trouble concentrating. The physical signs often include tachycardia, palpitations, dyspnea, and sweating. Patients often try to leave whatever situation they are in to seek help. The attack generally lasts 20 to 30 minutes and rarely more than an hour. A formal mental status examination during a panic attack may reveal rumination, difficulty speaking (e.g., stammering), and impaired memory. Patients may experience depression or depersonalization during an attack. The symptoms can disappear quickly or gradually. Between attacks, patients

may have anticipatory anxiety about having another attack. The differentiation between anticipatory anxiety and generalized anxiety disorder can be difficult, although patients with pain disorder with anticipatory anxiety can name the focus of their anxiety.

Somatic concerns of death from a cardiac or respiratory problem may be the major focus of patients' attention during panic attacks. Patients may believe that the palpitations and chest pain indicate that they are about to die. As many as 20 percent of such patients actually have syncopal episodes during a panic attack. The patients may be seen in emergency departments as young (20s), physically healthy persons who nevertheless insist that they are about to die from a heart attack. Rather than immediately diagnosing hypochondriasis, the emergency department physician should consider a diagnosis of panic disorder. Hyperventilation can produce respiratory alkalosis and other symptoms. The age-old treatment of breathing into a paper bag sometimes helps because it decreases alkalosis.

Mrs. K was a 35-year-old woman who initially presented for treatment at the medical emergency department at a large university-based medical center. She reported that while sitting at her desk at her job, she had suddenly experienced difficulty breathing, dizziness, tachycardia, shakiness, and a feeling of terror that she was going to die of a heart attack. A colleague drove her to the emergency department, where she received a full medical evaluation, including electrocardiography and routine blood work, which revealed no sign of cardiovascular, pulmonary, or other illness. She was subsequently referred for psychiatric evaluation, where she revealed that she had experienced two additional episodes over the past month, once when driving home from work and once when eating breakfast. However, she had not presented for medical treatment because the symptoms had resolved relatively quickly each time, and she worried that if she went to the hospital without ongoing symptoms, "people would think I'm crazy." Mrs. K reluctantly took the phone number of a local psychiatrist but did not call until she experienced a fourth episode of a similar nature. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

Associated Symptoms

Depressive symptoms are often present in panic disorder, and in some patients, a depressive disorder coexists with the panic disorder. Some studies have found that the lifetime risk of suicide in persons with panic disorder is higher than it is in persons with no mental disorder. Clinicians should be alert to the risk of suicide. In addition to agoraphobia, other phobias and OCD can coexist with panic disorder. The psychosocial consequences of panic disorder, in addition to marital discord, can include time lost from work, financial difficulties related to the loss of work, and alcohol and other substance abuse.

DIFFERENTIAL DIAGNOSIS

Panic Disorder

The differential diagnosis for a patient with panic disorder includes many medical disorders (Table 9.2-3), as well as many mental disorders.

 **Table 9.2-3**
Organic Differential Diagnosis for Panic Disorder

Cardiovascular Diseases	
Anemia	Hypertension
Angina	Mitral valve prolapse
Congestive heart failure	Myocardial infarction
Hyperactive β -adrenergic state	Paradoxical atrial tachycardia
Pulmonary Diseases	
Asthma	Pulmonary embolus
Hyperventilation	
Neurological Diseases	
Cerebrovascular disease	Migraine
Epilepsy	Multiple sclerosis
Huntington's disease	Transient ischemic attack
Infection	Tumor
Ménière's disease	Wilson's disease
Endocrine Diseases	
Addison's disease	Hypoglycemia
Carcinoid syndrome	Hypoparathyroidism
Cushing's syndrome	Menopausal disorders
Diabetes	Pheochromocytoma
Hyperthyroidism	Premenstrual syndrome
Drug Intoxications	
Amphetamine	Hallucinogens
Amyl nitrite	Marijuana
Anticholinergics	Nicotine
Cocaine	Theophylline
Drug Withdrawal	
Alcohol	Opiates and opioids
Antihypertensives	Sedative-hypnotics
Other Conditions	
Anaphylaxis	Systemic infections
B ₁₂ deficiency	Systemic lupus erythematosus
Electrolyte disturbances	Temporal arteritis
Heavy metal poisoning	Uremia

Medical Disorders

Panic disorder must be differentiated from a number of medical conditions that produce similar symptomatology. Panic attacks are associated with a variety of endocrinological disorders, including both hypo- and hyperthyroid states, hyperparathyroidism, and pheochromocytomas. Episodic hypoglycemia associated with insulinomas can also produce panic-like states, as can primary neuropathological processes. These include seizure disorders, vestibular dysfunction, neoplasms, or the effects of both prescribed and illicit substances on the CNS. Finally, disorders of the cardiac and pulmonary systems, including arrhythmias, chronic obstructive pulmonary disease, and asthma, can produce autonomic symptoms and accompanying crescendo anxiety that can be difficult to distinguish from panic disorder. Clues of an underlying medical etiology to panic-like symptoms include the presence of atypical features during panic attacks, such as ataxia, alterations in consciousness, or bladder dyscontrol; onset of panic disorder relatively late in life; and physical signs or symptoms indicative of a medical disorder.

Mental Disorders

Panic disorder also must be differentiated from a number of psychiatric disorders, particularly other anxiety disorders. Panic attacks occur in many anxiety disorders, including social and specific phobia, Panic may also occur in PTSD and OCD. The key to correctly diagnosing panic disorder and differentiating the condition from other anxiety disorders involves the documentation of recurrent spontaneous panic attacks at some point in the illness. Differentiation from generalized anxiety disorder can also be difficult. Classically, panic attacks are characterized by their rapid onset (within minutes) and short duration (usually less than 10 to 15 minutes), in contrast to the anxiety associated with generalized anxiety disorder, which emerges and dissipates more slowly. Making this distinction can be difficult, however, because the anxiety surrounding panic attacks can be more diffuse and slower to dissipate than is typical. Because anxiety is a frequent concomitant of many other psychiatric disorders, including the psychoses and affective disorders, discrimination between panic disorder and a multitude of disorders can also be difficult.

Specific and Social Phobias

Sometimes it is difficult to distinguish between panic disorder, on the one hand, and specific and social phobias, on the other hand. Some patients who experience a single panic attack in a specific setting (e.g., an elevator) may go on to have long-lasting avoidance of the specific setting, regardless of whether they ever have another panic attack. These patients meet the diagnostic criteria for a specific phobia, and clinicians must use their judgment about what is the most appropriate diagnosis. In another example, a person who experiences one or more panic attacks may then fear speaking in public. Although the clinical picture is almost identical to the clinical picture in social phobia, a diagnosis of social phobia is excluded because the avoidance of the public situation is based on fear of having a panic attack rather than on fear of the public speaking itself.

COURSE AND PROGNOSIS

Panic disorder usually has its onset in late adolescence or early adulthood, although onset during childhood, early adolescence, and midlife does occur. Some data implicate increased psychosocial stressors with the onset of panic disorder, although no psychosocial stressor can be definitely identified in most cases.

Panic disorder, in general, is a chronic disorder, although its course is variable, both among patients and within a single patient. The available long-term follow-up studies of panic disorder are difficult to interpret because they have not controlled for the effects of treatment. Nevertheless, about 30 to 40 percent of patients seem to be symptom free at long-term follow-up, about 50 percent have symptoms that are sufficiently mild not to affect their lives significantly, and about 10 to 20 percent continue to have significant symptoms.

After the first one or two panic attacks, patients may be relatively unconcerned about their condition; with repeated attacks, however, the symptoms may become a major concern. Patients may attempt to keep the panic attacks secret and thereby cause their families and friends concern about unexplained changes in behavior. The frequency and severity of the attacks can fluctuate. Panic attacks can occur several times in a day or less than once a month. Excessive intake of caffeine or nicotine can exacerbate the symptoms.

Depression can complicate the symptom picture in anywhere from 40 to 80 percent of all patients, as estimated by various studies. Although the patients do not tend to talk about suicidal ideation, they are at increased risk for committing suicide. Alcohol and other substance dependence occurs in about 20 to 40 percent of all patients, and OCD may also develop. Family interactions and performance in school and at work commonly suffer. Patients with good premorbid functioning and symptoms of brief duration tend to have good prognoses.

TREATMENT

With treatment, most patients exhibit dramatic improvement in the symptoms of panic disorder and agoraphobia. The two most effective treatments are pharmacotherapy and cognitive-behavioral therapy. Family and group therapy may help affected patients and their families adjust to the patient's disorder and to the psychosocial difficulties that the disorder may have precipitated.

Pharmacotherapy

Overview. Alprazolam (Xanax) and paroxetine (Paxil) are the two drugs approved by the US Food and Drug Administration (FDA) for the treatment of panic disorder. In general, experience is showing superiority of the selective serotonin reuptake inhibitors (SSRIs) and clomipramine (Anafranil) over the benzodiazepines, monoamine oxidase inhibitors (MAOIs), and tricyclic and tetracyclic drugs in terms of effectiveness and tolerance of adverse effects. Some reports have suggested a role for venlafaxine (Effexor), and buspirone (BuSpar) has been suggested as an additive medication in some cases. Venlafaxine is approved by the FDA for treatment of generalized anxiety disorder and may be useful in panic disorder combined with depression. β -adrenergic receptor antagonists have not been found to be particularly useful for panic disorder. A conservative approach is to begin treatment with paroxetine, sertraline (Zoloft), citalopram (Celexa), or fluvoxamine (Luvox) in isolated panic disorder. If rapid control of severe symptoms is desired, a brief course of alprazolam should be initiated concurrently with the SSRI followed by slowly tapering use of the benzodiazepine. In long-term use, fluoxetine (Prozac) is an effective drug for panic with comorbid depression, although its initial activating properties may mimic panic symptoms for the first several weeks, and it may be poorly tolerated on this basis. Clonazepam (Klonopin) can be prescribed for patients who anticipate a situation in which panic may occur (0.5 to 1 mg as required). Common dosages for antipanic drugs are listed in [Table 9.2-4](#).

Table 9.2-4
Recommended Dosages for Antipanic Drugs (Daily Unless Indicated Otherwise)

Drug	Starting (mg)	Maintenance (mg)
SSRIs		
Paroxetine	5–10	20–60
Paroxetine CR	12.5–25	62.5
Fluoxetine	2–5	20–60
Sertraline	12.5–25	50–200
Fluvoxamine	12.5	100–150
Citalopram	10	20–40
Escitalopram	10	20
Tricyclic Antidepressants		
Clomipramine	5–12.5	50–125
Imipramine	10–25	150–500
Desipramine	10–25	150–200
Benzodiazepines		
Alprazolam	0.25–0.5 tid	0.5–2 tid
Clonazepam	0.25–0.5 bid	0.5–2 bid
Diazepam	2–5 bid	5–30 bid
Lorazepam	0.25–0.5 bid	0.5–2 bid
MAOIs		
Phenelzine	15 bid	15–45 bid
Tranylcypromine	10 bid	10–30 bid
RIMAs		
Moclobemide	50	300–600
Brofaromine	50	150–200
Atypical Antidepressants		
Venlafaxine	6.25–25	50–150
Venlafaxine XR	37.5	150–225
Other Agents		
Valproic acid	125 bid	500–750 bid
Inositol	6,000 bid	6,000 bid

bid, twice a day; MAOI, monoamine oxidase inhibitors; RIMA, reversible inhibitor of monoamine oxidase type A; SSRIs, selective serotonin reuptake inhibitor; tid, three times a day.

Selective Serotonin Reuptake Inhibitors. All SSRIs are effective for panic disorder. Paroxetine and paroxetine CR have sedative effects and tend to calm patients immediately, which leads to greater compliance and less discontinuation, but this must be weighed against its weight gain potential. Citalopram, escitalopram (Lexapro), fluvoxamine, and sertraline are the next best tolerated. Anecdotal reports suggest that patients with panic disorder are particularly sensitive to the activating effects of SSRIs, particularly fluoxetine, so they should be given initially at small dosages and titrated up slowly. At therapeutic dosages—for example, 20 mg a day of paroxetine—some patients may experience increased sedation. One approach for patients with panic disorder is to give 5 or 10 mg a day of paroxetine or 12.5 to 25 mg of paroxetine CR for 1 to 2 weeks and then increase the dosage by 10 mg of paroxetine or 12.5 mg of paroxetine CR a day every 1 to 2 weeks to a maximum of 60 mg of paroxetine or 62.5 mg of paroxetine CR. If sedation becomes intolerable, then taper the paroxetine dosage down to 10 mg a day of paroxetine or 12.5 mg of paroxetine CR and switch to fluoxetine at 10 mg a day and titrate upward slowly. Other strategies can be used based on the experience of the clinician.

Benzodiazepines. Benzodiazepines have the most rapid onset of action against panic, often within the first week, and they can be used for long periods without the development of tolerance to the antipanic effects. Alprazolam has been the most widely used benzodiazepine for panic disorder, but controlled studies have demonstrated equal efficacy for lorazepam (Ativan), and case reports have also indicated that clonazepam may be effective. Some patients use benzodiazepines as needed when faced with a phobic stimulus. Benzodiazepines can reasonably be used as the first agent for treatment of panic disorder while a serotonergic drug is being slowly titrated to a therapeutic dose. After 4 to 12 weeks, benzodiazepine use can be slowly tapered (over 4 to 10 weeks) while the serotonergic drug is continued. The major reservation among clinicians regarding the use of benzodiazepines for panic disorder is the potential for dependence, cognitive impairment, and abuse, especially after long-term use. Patients should be instructed not to drive, abstain from alcohol or other CNS depressant medications, and avoid operating dangerous equipment while taking benzodiazepines. Whereas benzodiazepines elicit a sense of well-being, discontinuation of benzodiazepines produces a well-documented and unpleasant withdrawal syndrome. Anecdotal reports and small case series have indicated that addiction to alprazolam is one of the most difficult to overcome, and it may require a comprehensive program of detoxification. Benzodiazepine dosage should be tapered slowly, and all anticipated withdrawal effects should be thoroughly explained to the patient.

Tricyclic and Tetracyclic Drugs. At the present time, SSRIs are considered the first-line agents for the treatment of panic disorder. Data, however, show that among tricyclic drugs, clomipramine and imipramine (Tofranil) are the most effective in the treatment of panic disorder. Clinical experience indicates that the dosages must be titrated slowly upward to avoid overstimulation and that the full clinical benefit requires full dosages and may not be achieved for 8 to 12 weeks. Some data support the efficacy of desipramine (Norpramin), and less evidence suggests a role for maprotiline (Ludiomil), trazodone (Desyrel), nortriptyline (Pamelor), amitriptyline (Elavil), and doxepin (Adapin). Tricyclic drugs are less widely used than SSRIs because the tricyclic drugs generally have more severe adverse effects at the higher dosages required for effective treatment of panic disorder.

Monoamine Oxidase Inhibitors. The most robust data support the effectiveness of phenelzine (Nardil), and some data also support the use of tranylcypromine (Parnate). MAOIs appear less likely to cause overstimulation than either SSRIs or tricyclic drugs, but they may require full dosages for at least 8 to 12 weeks to be effective. The need for dietary restrictions has limited the use of MAOIs, particularly since the appearance of the SSRIs.

Treatment Nonresponse. If patients fail to respond to one class of drugs, another should be tried. Recent data support the effectiveness of venlafaxine. The combination of an SSRI or a tricyclic drug and a benzodiazepine or of an SSRI and lithium or a tricyclic drug can be tried. Case reports have suggested the effectiveness of carbamazepine (Tegretol), valproate (Depakene), and calcium channel inhibitors. Buspirone may have a role in the augmentation of other medications but has little effectiveness by itself. Clinicians should reassess the patient, particularly to establish the presence of comorbid conditions such as depression, alcohol use, or other substance use.

Duration of Pharmacotherapy. When it becomes effective, pharmacological treatment should generally continue for 8 to 12 months. Data indicate that panic disorder is a chronic, perhaps lifelong, condition that recurs when treatment is discontinued. Studies have reported that 30 to 90 percent of patients with panic disorder who have had successful treatment have a relapse when their medication is discontinued. Patients may be likely to relapse if they have been given benzodiazepines and the benzodiazepine therapy is terminated in a way that causes withdrawal symptoms.

Cognitive and Behavior Therapies

Cognitive and behavior therapies are effective treatments for panic disorder. Various reports have concluded that cognitive and behavior therapies are superior to pharmacotherapy alone; other reports have concluded the opposite. Several studies and reports have found that the combination of cognitive or behavior therapy with pharmacotherapy is more effective than either approach alone. Several studies that included long-term follow-up of patients who received cognitive or behavior therapy indicate that the therapies are effective in producing long-lasting remission of symptoms.

Cognitive Therapy. The two major foci of cognitive therapy for panic disorder are instruction about a patient's false beliefs and information about panic attacks. The instruction about false beliefs centers on the patient's tendency to misinterpret mild bodily sensations as indicating impending panic attacks, doom, or death. The information about panic attacks includes explanations that when panic attacks occur, they are time limited and not life threatening.

9.3 Agoraphobia

Agoraphobia refers to a fear of or anxiety regarding places from which escape might be difficult. It can be the most disabling of the phobias because it can significantly interfere with a person's ability to function in work and social situations outside the home. In the United States, most researchers of panic disorder believe that agoraphobia almost always develops as a complication in patients with panic disorder. That is, the fear of having a panic attack in a public place from which escape would be formidable is thought to cause the agoraphobia. Although agoraphobia often coexists with panic disorder, DSM-5 classifies agoraphobia as a separate condition that may or may not be comorbid with panic disorder.

HISTORY

The term *agoraphobia* was coined in 1871 to describe the condition of patients who were afraid to venture alone into public places. The term is derived from the Greek words *agora* and *phobos*, meaning “fear of the marketplace.”

EPIDEMIOLOGY

The lifetime prevalence of agoraphobia is somewhat controversial, varying between 2 to 6 percent across studies. According to the DSM-5, persons older than age 65 years have a 0.4 percent prevalence rate of agoraphobia, but this may be a low estimate. The major factor leading to this wide range of estimates relates to disagreement about the conceptualization of agoraphobia's relationship to panic disorder. Although studies of agoraphobia in psychiatric settings have reported that at least three fourths of the affected patients have panic disorder as well, studies of agoraphobia in community samples have found that as many as half the patients have agoraphobia without panic disorder. The reasons for these divergent findings are unknown but probably involve differences in ascertainment techniques. In many cases, the onset of agoraphobia follows a traumatic event.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-5 diagnostic criteria for agoraphobia stipulates marked fear or anxiety about at least one situation from two or more of five situation groups: (1) using public transportation (e.g., bus, train, cars, planes), (2) in an open space (e.g., park, shopping center, parking lot), (3) in an enclosed space (e.g., stores, elevators, theaters), (4) in a crowd or standing in line, or (5) alone outside of the home. The fear or anxiety must be persistent and last at least 6 months (Table 9.3-1).

 **Table 9.3-1**
DSM-5 Diagnostic Criteria for Agoraphobia

- A. Marked fear or anxiety about two (or more) of the following five situations:
1. Using public transportation (e.g., automobiles, buses, trains, ships, planes)
 2. Being in open spaces (e.g., parking lots, marketplaces, bridges)
 3. Being in enclosed places (e.g., shops, theaters, cinemas)
 4. Standing in line or being in a crowd
 5. Being outside of the home alone
- B. The individual fears or avoids these situations because of thoughts that escape might be difficult or help might not be available in the event of developing panic-like symptoms or other incapacitating or embarrassing symptoms (e.g., fear of falling in elderly adults; fear of incontinence).
- C. The agoraphobic situations almost always provoke fear or anxiety.
- D. The agoraphobic situations are actively avoided, require the presence of a companion, or are endured with intense fear or anxiety.
- E. The fear or anxiety is out of proportion to the actual danger posed by the agoraphobic situations and to the sociocultural context.
- F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
- G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. If another medical condition (e.g., inflammatory bowel disease, Parkinson's disease) is present, the fear, anxiety, or avoidance is clearly excessive.
- I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder—for example, the symptoms are not confined to specific phobia, situational type; do not involve only social situations (as in social anxiety disorder); and are not related exclusively to obsessions (as in obsessive-compulsive disorder), perceived defects or flaws in physical appearance (as in body dysmorphic disorder), reminders of traumatic events (as in posttraumatic stress disorder), or fear of separation (as in separation anxiety disorder).
- Note:** Agoraphobia is diagnosed irrespective of the presence of panic disorder. If an individual's presentation meets the criteria for panic disorder and agoraphobia, both diagnoses should be assigned.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Patients with agoraphobia rigidly avoid situations in which it would be difficult to obtain help. They prefer to be accompanied by a friend or a family member in busy streets, crowded stores, closed-in spaces (e.g., tunnels, bridges, and elevators), and closed-in vehicles (e.g., subways, buses, and airplanes). Patients may insist that they be accompanied every time they leave the house. The behavior can result in marital discord, which may be misdiagnosed as the primary problem. Severely affected patients may simply refuse to leave the house. Particularly before a correct diagnosis is made, patients may be terrified that they are going crazy.

Mrs. W was a 33-year-old married woman. She visited an anxiety clinic reporting that she felt like she was having a heart attack whenever she left her home. Her disorder began 8 years earlier while attending a yoga class when she suddenly noticed a dramatic increase in her heartbeat, felt stabbing pains in her chest, and had difficulty breathing. She began sweating and trembling and felt dizzy. She immediately went to the emergency department, where an electrocardiogram was performed. No abnormalities were detected. Over the next few months, Mrs. W experienced similar attacks of 15 to 30 minutes' duration about four times per month. She often sought medical advice after each episode, and each time no physical abnormalities were detected. After experiencing a few of these attacks, Mrs. W became afraid of having an attack away from home and would not leave her home unless absolutely necessary, in which case she needed to have her cell phone or be accompanied by someone. Even so, she avoided crowded places such as malls, movie theaters, and banks, where rapid escape is sometimes blocked. Her symptoms and avoidance dominated her life, although she was aware that they were irrational and excessive. She experienced mild depression and restlessness and had difficulty sleeping.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for agoraphobia includes all the medical disorders that can cause anxiety or depression. The psychiatric differential diagnosis includes major depressive disorder, schizophrenia, paranoid personality disorder, avoidance personality disorder, and

dependent personality disorder.

COURSE AND PROGNOSIS

Most cases of agoraphobia are thought to be caused by panic disorder. When the panic disorder is treated, the agoraphobia often improves with time. For rapid and complete reduction of agoraphobia, behavior therapy is sometimes indicated. Agoraphobia without a history of panic disorder is often incapacitating and chronic, and depressive disorders and alcohol dependence often complicate its course.

TREATMENT

Pharmacotherapy

Benzodiazepines. Benzodiazepines have the most rapid onset of action against panic. Some patients use them as needed when faced with a phobic stimulus. Alprazolam (Xanax) and lorazepam (Ativan) are the most commonly prescribed benzodiazepines. Clonazepam (Klonopin) has also been shown to be effective. The major reservations among clinicians regarding the use of benzodiazepines are the potential for dependence, cognitive impairment, and abuse, particularly with long-term use. However, when used appropriately under medical supervision, benzodiazepines are efficacious and generally well tolerated. The most common side effects are mild dizziness and sedation, both of which are generally attenuated by time or change of dose. Caution must be exercised when using heavy or dangerous machinery or when driving, especially when first starting the medication or when the dose is changed. Benzodiazepines should not be used in combination with alcohol because they can intensify its effects. Benzodiazepines are also best avoided in individuals with histories of alcohol or substance abuse unless there are compelling reasons, such as failure to respond to other classes of medications.

Selective Serotonin Reuptake Inhibitors. SSRIs have been shown to help reduce or prevent relapse from various forms of anxiety, including agoraphobia. Effective doses are essentially the same as for the treatment of depression, although it is customary to start with lower initial doses than in depression to minimize an initial anxiolytic effect, which is almost always short lived, and to titrate upward somewhat slower toward a therapeutic dose. The main advantages of SSRIs antidepressants include their improved safety profile in overdose and more tolerable side-effect burden. Common side effects of most SSRIs are sleep disturbance, drowsiness, lightheadedness, nausea, and diarrhea; many of these adverse effects improve with continued use. Another commonly reported side effect of SSRIs is sexual dysfunction (i.e., decreased libido, delayed ejaculation in men, delayed orgasm in women), which rarely improves with time or switching among SSRIs (or from an SSRI to a serotonin-norepinephrine reuptake inhibitor [SNRI]). Proposed strategies to combat sexual dysfunction in patients taking SSRIs include adjunctive use of yohimbine (Yocon), bupropion (Wellbutrin), or mirtazapine (Remeron); dose reduction; or adjunctive use of sildenafil (Viagra). Another issue to be considered when prescribing an SSRI is the possibility of a discontinuation syndrome if these medications are stopped abruptly. Commonly reported symptoms of this condition, which tend to occur 2 to 4 days after medication cessation, include increased anxiety, irritability, tearfulness, dizziness or lightheadedness, malaise, sleep disturbance, and concentration difficulties. This discontinuation syndrome is most common among SSRIs with shorter half-lives (e.g., paroxetine [Paxil]).

Tricyclic and Tetracyclic Drugs. Although SSRIs are considered the first-line agents for treatment of panic disorders with or without agoraphobia, the tricyclic drugs clomipramine (Anafranil) and imipramine (Tofranil) are the most effective in the treatment of these disorders. Dosages must be titrated slowly upward to avoid overstimulation (e.g., “jitteriness” syndrome), and the full clinical benefit requires full dosages and may not be achieved for 8 to 12 weeks. Therapeutic drug monitoring (TDM) may be useful to ensure that the patient is on an adequate dose of medication while avoiding issues of toxicity. The other adverse effects to these antidepressants are related to their effects on seizure threshold, as well as anticholinergic and potentially harmful cardiac effects, particularly in overdose.

Psychotherapy

Supportive Psychotherapy. Supportive psychotherapy involves the use of psychodynamic concepts and a therapeutic alliance to promote adaptive coping. Adaptive defenses are encouraged and strengthened, and maladaptive ones are discouraged. The therapist assists in reality testing and may offer advice regarding behavior.

Insight-Oriented Psychotherapy. In insight-oriented psychotherapy, the goal is to increase the patient’s development of insight into psychological conflicts that, if unresolved, can manifest as symptomatic behavior.

Behavior Therapy. In behavior therapy, the basic assumption is that change can occur without the development of psychological insight into underlying causes. Techniques include positive and negative reinforcement, systematic desensitization, flooding, implosion, graded exposure, response prevention, stop thought, relaxation techniques, panic control therapy, self-monitoring, and hypnosis.

Cognitive Therapy. This is based on the premise that maladaptive behavior is secondary to distortions in how people perceive themselves and in how other perceive them. Treatment is short term and interactive, with assigned homework and tasks to be performed between sessions that focus on correcting distorted assumptions and cognitions. The emphasis is on confronting and examining situations that elicit interpersonal anxiety and associated mild depression.

Virtual Therapy. Computer programs have been developed that allow patients to see themselves as avatars who are then placed in open or crowded spaces (e.g., a supermarket). As they identify with the avatars in repeated computer sessions, they are able to master their anxiety through deconditioning.

9.4 Specific Phobia

The term *phobia* refers to an excessive fear of a specific object, circumstance, or situation. A specific phobia is a strong, persisting fear of an object or situation. The diagnosis of specific phobia requires the development of intense anxiety, even to the point of panic, when exposed to the feared object. Persons with specific phobias may anticipate harm, such as being bitten by a dog, or may panic at the thought of losing control; for instance, if they fear being in an elevator, they may also worry about fainting after the door closes.

EPIDEMIOLOGY

Phobias are one of the most common mental disorders in the United States, where approximately 5 to 10 percent of the population is estimated to have these troubling and sometimes disabling disorders. The lifetime prevalence of specific phobia is about 10 percent. Specific phobia is the most common mental disorder among women and the second most common among men, second only to substance-related disorders. The 6-month prevalence of specific phobia is about 5 to 10 per 100 persons (Table 9.4-1). The rates of specific phobias in women (14 to 16 percent) were double those of men (5 to 7 percent), although the ratio is closer to 1 to 1 for the fear of blood, injection, or injury type. (Types of phobias are discussed below in this section.) The peak age of onset for the natural environment type and the blood-injection-injury type is in the range of 5 to 9 years, although onset also occurs at older ages. In contrast, the peak age of onset for the situational type (except fear of heights) is higher, in the mid-20s, which is closer to the age of onset for agoraphobia. The feared objects and situations in specific phobias (listed in descending frequency of appearance) are animals, storms, heights, illness, injury, and death.

Table 9.4-1
Lifetime Prevalence Rates of Specific Phobia

COMORBIDITY

Reports of comorbidity in specific phobia range from 50 to 80 percent. Common comorbid disorders with specific phobia include anxiety, mood, and substance-related disorders.

ETIOLOGY

General Principles of Phobias

Behavioral Factors. In 1920, John B. Watson wrote an article called “Conditioned Emotional Reactions,” in which he recounted his experiences with Little Albert, an infant with a fear of rats and rabbits. Unlike Sigmund Freud’s case of Little Hans, who had phobic symptoms (of horses) in the natural course of his maturation, Little Albert’s difficulties were the direct result of the scientific experiments of two psychologists who used techniques that had successfully induced conditioned responses in laboratory animals.

Watson’s hypothesis invoked the traditional pavlovian stimulus–response model of the conditioned reflex to account for the creation of the phobia: Anxiety is aroused by a naturally frightening stimulus that occurs in contiguity with a second inherently neutral stimulus. As a result of the contiguity, especially when the two stimuli are paired on several successive occasions, the originally neutral stimulus becomes capable of arousing anxiety by itself. The neutral stimulus, therefore, becomes a conditioned stimulus for anxiety production.

In the classic stimulus–response theory, the conditioned stimulus gradually loses its potency to arouse a response if it is not reinforced by periodic repetition of the unconditioned stimulus. In phobias, attenuation of the response to the stimulus does not occur; the symptom may last for years without any apparent external reinforcement. Operant conditioning theory provides a model to explain this phenomenon: Anxiety is a drive that motivates the organism to do whatever it can to obviate a painful affect. In the course of its random behavior, the organism learns that certain actions enable it to avoid the anxiety-provoking stimulus. These avoidance patterns remain stable for long periods as a result of the reinforcement they receive from their capacity to diminish anxiety. This model is readily applicable to phobias in that avoidance of the anxiety-provoking object or situation plays a central part. Such avoidance behavior becomes fixed as a stable symptom because of its effectiveness in protecting the person from the phobic anxiety.

Learning theory, which is particularly relevant to phobias, provides simple and intelligible explanations for many aspects of phobic symptoms. Critics contend, however, that learning theory deals mostly with surface mechanisms of symptom formation and is less useful than psychoanalytic theories in clarifying some of the complex underlying psychic processes involved.

Psychoanalytic Factors. Sigmund Freud’s formulation of phobic neurosis is still the analytic explanation of specific phobia and social phobia. Freud hypothesized that the major function of anxiety is to signal the ego that a forbidden unconscious drive is pushing for conscious expression and to alert the ego to strengthen and marshal its defenses against the threatening instinctual force. Freud viewed the phobia—*anxiety hysteria*, as he continued to call it—as a result of conflicts centered on an unresolved childhood oedipal situation. Because

sex drives continue to have a strong incestuous coloring in adults, sexual arousal can kindle an anxiety that is characteristically a fear of castration. When repression fails to be entirely successful, the ego must call on auxiliary defenses. In patients with phobias, the primary defense involved is displacement; that is, the sexual conflict is displaced from the person who evokes the conflict to a seemingly unimportant, irrelevant object or situation, which then has the power to arouse a constellation of affects, one of which is called *signal anxiety*. The phobic object or situation may have a direct associative connection with the primary source of the conflict and thus symbolizes it (the defense mechanism of symbolization).

Furthermore, the situation or the object is usually one that the person can avoid; with the additional defense mechanism of avoidance, the person can escape suffering serious anxiety. The end result is that the three combined defenses (repression, displacement, and symbolization) may eliminate the anxiety. The anxiety is controlled at the cost of creating a phobic neurosis, however. Freud first discussed the theoretical formulation of phobia formation in his famous case history of Little Hans, a 5-year-old boy who feared horses.

Although psychiatrists followed Freud's thought that phobias resulted from castration anxiety, recent psychoanalytic theorists have suggested that other types of anxiety may be involved. In agoraphobia, for example, separation anxiety clearly plays a leading role, and in erythrophobia (a fear of red that can be manifested as a fear of blushing), the element of shame implies the involvement of superego anxiety. Clinical observations have led to the view that anxiety associated with phobias has a variety of sources and colorings.

Phobias illustrate the interaction between a genetic constitutional diathesis and environmental stressors. Longitudinal studies suggest that certain children are constitutionally predisposed to phobias because they are born with a specific temperament known as behavioral inhibition to the unfamiliar, but a chronic environmental stress must act on a child's temperamental disposition to create a full-blown phobia. Stressors, such as the death of a parent, separation from a parent, criticism or humiliation by an older sibling, and violence in the household, may activate the latent diathesis within the child, who then becomes symptomatic. An overview of psychodynamic aspects of phobias is summarized in [Table 9.4-2](#).

 **Table 9.4-2**
Psychodynamic Themes in Phobias

- ▶ Principal defense mechanisms include displacement, projection, and avoidance.
- ▶ Environmental stressors, including humiliation and criticism from an older sibling, parental fights, or loss and separation from parents, interact with a genetic-constitutional diathesis.
- ▶ A characteristic pattern of internal object relations is externalized in social situations in the case of social phobia.
- ▶ Anticipation of humiliation, criticism, and ridicule is projected onto individuals in the environment.
- ▶ Shame and embarrassment are the principal affect states.
- ▶ Family members may encourage phobic behavior and serve as obstacles to any treatment plan.
- ▶ Self-exposure to the feared situation is a basic principle of all treatment.

COUNTERPHOBIC ATTITUDE. Otto Fenichel called attention to the fact that phobic anxiety can be hidden behind attitudes and behavior patterns that represent a denial, either that the dreaded object or situation is dangerous or that the person is afraid of it. Instead of being a passive victim of external circumstances, a person reverses the situation and actively attempts to confront and master whatever is feared. Persons with counterphobic attitudes seek out situations of danger and rush enthusiastically toward them. Devotees of potentially dangerous sports, such as parachute jumping and rock climbing, may be exhibiting counterphobic behavior. Such patterns may be secondary to phobic anxiety or may be normal means of dealing with a realistically dangerous situation. Children's play may exhibit counterphobic elements, as when children play doctor and give a doll the shot they received earlier that day in the pediatrician's office. This pattern of behavior may involve the related defense mechanism of identifying with the aggressor.

Specific Phobia

The development of specific phobia may result from the pairing of a specific object or situation with the emotions of fear and panic. Various mechanisms for the pairing have been postulated. In general, a nonspecific tendency to experience fear or anxiety forms the backdrop; when a specific event (e.g., driving) is paired with an emotional experience (e.g., an accident), the person is susceptible to a permanent emotional association between driving or cars and fear or anxiety. The emotional experience itself can be in response to an external incident, as a traffic accident, or to an internal incident, most commonly a panic attack. Although a person may never again experience a panic attack and may not meet the diagnostic criteria for panic disorder, he or she may have a generalized fear of driving, not an expressed fear of having a panic attack while driving. Other mechanisms of association between the phobic object and the phobic emotions include modeling, in which a person observes the reaction in another (e.g., a parent), and information transfer, in which a person is taught or warned about the dangers of specific objects (e.g., venomous snakes).

Genetic Factors. Specific phobia tends to run in families. The blood-injection-injury type has a particularly high familial tendency. Studies have reported that two-thirds to three-fourths of affected probands have at least one first-degree relative with specific phobia of the same type, but the necessary twin and adoption studies have not been conducted to rule out a significant contribution by nongenetic transmission of specific phobia.

DIAGNOSIS

The DSM-5 includes distinctive types of specific phobia: animal type, natural environment type (e.g., storms), blood-injection-injury type (e.g., needles), situational type (e.g., cars, elevators, planes), and other type (for specific phobias that do not fit into the previous four types). The key feature of each type of phobia is that fear symptoms occur only in the presence of a specific object ([Table 9.4-3](#)). The blood-injection-injury type is differentiated from the others in that bradycardia and hypotension often follow the initial tachycardia that is common to all phobias. The blood-injection-injury type of specific phobia is particularly likely to affect many members and generations of a family. One type of phobia of recently reported phobia is space phobia, in which persons fear falling when there is no nearby support, such as a wall or a chair. Some data indicate that affected persons may have abnormal right hemisphere function, possibly resulting in visual-spatial impairment. Balance disorders should be ruled out in such patients.

 **Table 9.4-3**
DSM-5 Diagnostic Criteria for Specific Phobia

- A. Marked fear or anxiety about a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).
Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging.
- B. The phobic object or situation almost always provokes immediate fear or anxiety.
- C. The phobic object or situation is actively avoided or endured with intense fear or anxiety.
- D. The fear or anxiety is out of proportion to the actual danger posed by the specific object or situation and to the socio-cultural context.
- E. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
- F. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- G. The disturbance is not better explained by the symptoms of another mental disorder, including fear, anxiety, and avoidance of situations associated with panic-like symptoms or other incapacitating symptoms (as in agoraphobia); objects or situations related to obsessions (as in obsessive-compulsive disorder); reminders of traumatic events (as in posttraumatic stress disorder); separation from home or attachment figures (as in separation anxiety disorder); or social situations (as in social anxiety disorder).

Specify if:

Code based on the phobic stimulus:

300.29 (F40.218) **Animal** (e.g., spiders, insects, dogs).

300.29 (F40.228) **Natural environment** (e.g., heights, storms, water).

300.29 (F40.23x) **Blood-injection-injury** (e.g., needles, invasive medical procedures).

Coding note: Select specific ICD-10-CM code as follows:

F40.230 fear of blood; F40.231 fear of injections and transfusions; F40.232 fear of other medical care; or F40.233 fear of injury.

300.29 (F40.248) **Situational** (e.g., airplanes, elevators, enclosed places).

300.29 (F40.298) **Other** (e.g., situations that may lead to choking or vomiting; in children, e.g., loud sounds or costumed characters).

Coding note: When more than one phobic stimulus is present, code all ICD-10-CM codes that apply (e.g., for fear of snakes and flying, F40.218 specific phobia, animal, and F40.248 specific phobia, situational).

Phobias have traditionally been classified according to specific fear by means of Greek or Latin prefixes, as indicated in Table 9.4-4. Other phobias that are related to changes in the society are the fear of electromagnetic fields, of microwaves, and of society as a whole (amorphobia).

 **Table 9.4-4**
Phobias

Acrophobia	Fear of heights
Agoraphobia	Fear of open places
Ailurophobia	Fear of cats
Hydrophobia	Fear of water
Claustrophobia	Fear of closed spaces
Cynophobia	Fear of dogs
Mysophobia	Fear of dirt and germs
Pyrophobia	Fear of fire
Xenophobia	Fear of strangers
Zoophobia	Fear of animals

Mr. S was a successful lawyer who presented for treatment after his firm, to which he had previously been able to walk from home, moved to a new location that he could only reach by driving. Mr. S reported that he was “terrified” of driving, particularly on highways. Even the thought of getting into a car led him to worry that he would die in a fiery crash. His thoughts were associated with intense fear and numerous somatic symptoms, including a racing heart, nausea, and sweating. Although the thought of driving was terrifying in and of itself, Mr. S became nearly incapacitated when he drove on busy roads, often having to pull over to vomit. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

CLINICAL FEATURES

Phobias are characterized by the arousal of severe anxiety when patients are exposed to specific situations or objects or when patients even anticipate exposure to the situations or objects. Exposure to the phobic stimulus or anticipation of it almost invariably results in a panic attack in a person who is susceptible to them.

Persons with phobias, by definition, try to avoid the phobic stimulus; some go to great trouble to avoid anxiety-provoking situations. For example, a patient with a phobia may take a bus across the United States, rather than fly, to avoid contact with the object of the patient's phobia, an airplane. Perhaps as another way to avoid the stress of the phobic stimulus, many patients have substance-related disorders, particularly alcohol use disorders. Moreover, an estimated one-third of patients with social phobia have major depressive disorder.

The major finding on the mental status examination is the presence of an irrational and ego-dystonic fear of a specific situation, activity, or object; patients are able to describe how they avoid contact with the phobia. Depression is commonly found on the mental status examination and may be present in as many as one-third of all patients with phobia.

Differential Diagnosis

Nonpsychiatric medical conditions that can result in the development of a phobia include the use of substances (particularly hallucinogens and sympathomimetics), CNS tumors, and cerebrovascular diseases. Phobic symptoms in these instances are unlikely in the absence of additional suggestive findings on physical, neurological, and mental status examinations. Schizophrenia is also in the differential diagnosis of specific phobia because patients with schizophrenia can have phobic symptoms as part of their psychoses. Unlike patients with schizophrenia, however, patients with phobia have insight into the irrationality of their fears and lack the bizarre quality and other psychotic symptoms that accompany schizophrenia.

In the differential diagnosis of specific phobia, clinicians must consider panic disorder, agoraphobia, and avoidant personality disorder. Differentiation among panic disorder, agoraphobia, social phobia, and specific phobia can be difficult in individual cases. In general, however, patients with specific phobia tend to experience anxiety immediately when presented with the phobic stimulus. Furthermore, the anxiety or panic is limited to the identified situation; patients are not abnormally anxious when they are neither confronted with the phobic stimulus nor caused to anticipate the stimulus.

Other diagnoses to consider in the differential diagnosis of specific phobia are hypochondriasis, OCD, and paranoid personality disorder. Whereas hypochondriasis is the fear of having a disease, specific phobia of the illness type is the fear of contracting the disease. Some patients with OCD manifest behavior indistinguishable from that of a patient with specific phobia. For example, whereas patients with OCD may avoid knives because they have compulsive thoughts about killing their children, patients with specific phobia about knives may avoid them for fear of cutting themselves. Patients with paranoid personality disorder have generalized fear that distinguishes them from those with specific phobia.

COURSE AND PROGNOSIS

Specific phobia exhibits a bimodal age of onset, with a childhood peak for animal phobia, natural environment phobia, and blood-injection-injury phobia and an early adulthood peak for other phobias, such as situational phobia. Limited prospective epidemiological data are available that chart the natural course of specific phobia. Because patients with isolated specific phobia rarely present for treatment, there is also little research on the course of the disorder in the clinic. The limited information that is available suggests that most specific phobias that begin in childhood and persist into adulthood will continue to persist for many years. The severity of the condition is believed to remain relatively constant, which contrasts with the waxing and waning course seen in other anxiety disorders.

TREATMENT

Phobias

Behavior Therapy. The most studied and most effective treatment for phobias is probably behavior therapy. The key aspects of successful treatment are (1) the patient's commitment to treatment; (2) clearly identified problems and objectives; and (3) available alternative strategies for coping with the feelings. A variety of behavioral treatment techniques have been used, the most common being systematic desensitization, a method pioneered by Joseph Wolpe. In this method, the patient is exposed serially to a predetermined list of anxiety-provoking stimuli graded in a hierarchy from the least to the most frightening. Through the use of antianxiety drugs, hypnosis, and instruction in muscle relaxation, patients are taught how to induce in themselves both mental and physical repose. After they have mastered the techniques, patients are taught to use them to induce relaxation in the face of each anxiety-provoking stimulus. As they become desensitized to each stimulus in the scale, the patients move up to the next stimulus until, ultimately, what previously produced the most anxiety no longer elicits the painful affect.

Other behavioral techniques that have been used more recently involve intensive exposure to the phobic stimulus through either imagery or desensitization in vivo. In imaginal flooding, patients are exposed to the phobic stimulus for as long as they can tolerate the fear until they reach a point at which they can no longer feel it. Flooding (also known as implosion) in vivo requires patients to experience similar anxiety through exposure to the actual phobic stimulus.

Insight-Oriented Psychotherapy. Early in the development of psychoanalysis and the dynamically oriented psychotherapies, theorists believed that these methods were the treatments of choice for phobic neurosis, which was then thought to stem from oedipal-genital conflicts. Soon, however, therapists recognized that, despite progress in uncovering and analyzing unconscious conflicts, patients frequently failed to lose their phobic symptoms. Moreover, by continuing to avoid phobic situations, patients excluded a significant degree of anxiety and its related associations from the analytic process. Both Freud and his pupil Sandor Ferenczi recognized that if progress in analyzing these symptoms was to be made, therapists had to go beyond their analytic roles and actively urge patients with phobia to seek the phobic situation and experience the anxiety and resultant insight. Since then, psychiatrists have generally agreed that a measure of activity on the therapist's part is often required to treat phobic anxiety successfully. The decision to apply the techniques of psychodynamic insight-oriented therapy should be based not on the presence of phobic symptoms alone but on positive indications from the patient's ego structure and life patterns for the use of this method of treatment. Insight-oriented therapy enables patients to understand the origin of the phobia, the phenomenon of secondary gain, and the role of resistance and enables them to seek healthy ways of dealing with anxiety-provoking stimuli.

Virtual Therapy. A number of computer-generated simulations of phobic disorders have been developed. Patients are exposed to or interact with the phobic object or situation on the computer screen. Countless numbers of such programs are available, and others are in continual development. Variable success rates have been reported, but virtual therapy for phobic disorder is on the cutting edge of using computers to treat mental illness.

Other Therapeutic Modalities. Hypnosis, supportive therapy, and family therapy may be useful in the treatment of phobic disorders. Hypnosis is used to enhance the therapist's suggestion that the phobic object is not dangerous, and self-hypnosis can be taught to

the patient as a method of relaxation when confronted with the phobic object. Supportive psychotherapy and family therapy are often useful in helping the patient actively confront the phobic object during treatment. Not only can family therapy enlist the aid of the family in treating the patient, but it may also help the family understand the nature of the patient's problem.

Specific Phobia

A common treatment for specific phobia is exposure therapy. In this method, therapists desensitize patients by using a series of gradual, self-paced exposures to the phobic stimuli, and they teach patients various techniques to deal with anxiety, including relaxation, breathing control, and cognitive approaches. The cognitive-behavioral approaches include reinforcing the realization that the phobic situation is, in fact, safe. The key aspects of successful behavior therapy are the patient's commitment to treatment, clearly identified problems and objectives, and alternative strategies for coping with the patient's feelings. In the special situation of blood-injection-injury phobia, some therapists recommend that patients tense their bodies and remain seated during the exposure to help avoid the possibility of fainting from a vasovagal reaction to the phobic stimulation. β -adrenergic receptor antagonists may be useful in the treatment of specific phobia, especially when the phobia is associated with panic attacks. Pharmacotherapy (e.g., benzodiazepines), psychotherapy, or combined therapy directed to the attacks may also be of benefit.

9.5 Social Anxiety Disorder (Social Phobia)

Social anxiety disorder (also referred to as social phobia) involves the fear of social situations, including situations that involve scrutiny or contact with strangers. The term *social anxiety* reflects the distinct differentiation of social anxiety disorder from specific phobia, which is the intense and persistent fear of an object or situation. Persons with social anxiety disorder are fearful of embarrassing themselves in social situations (i.e., social gatherings, oral presentations, meeting new people). They may have specific fears about performing specific activities such as eating or speaking in front of others, or they may experience a vague, nonspecific fear of "embarrassing oneself." In either case, the fear in social anxiety disorder is of the embarrassment that may occur in the situation, not of the situation itself.

EPIDEMIOLOGY

Various studies have reported a lifetime prevalence ranging from 3 to 13 percent for social anxiety disorder. The 6-month prevalence is about 2 to 3 per 100 persons (Table 9.5-1). In epidemiological studies, females are affected more often than males, but in clinical samples, the reverse is often true. The reasons for these varying observations are unknown. The peak age of onset for social anxiety disorder is in the teens, although onset is common as young as 5 years of age and as old as 35 years.

Table 9.5-1
Lifetime Prevalence Rates of Social Anxiety Disorder

Site	Men (%)	Women (%)	Total (%)
United States (National Comorbidity Survey)	11.1	15.5	13.3
United States (Epidemiological Catchment Area Study)	2.1	3.1	2.6
Edmonton, Canada	1.3	2.1	1.7
Puerto Rico	0.8	1.1	1.0
Korea	0.1	1.0	0.5
Zurich, Switzerland	3.7	7.3	5.6
Taiwan	0.2	1.0	0.6
The Netherlands	5.9	9.7	7.8

COMORBIDITY

Persons with social anxiety disorder may have a history of other anxiety disorders, mood disorders, substance-related disorders, and bulimia nervosa.

ETIOLOGY

Several studies have reported that some children possibly have a trait characterized by a consistent pattern of behavioral inhibition. This trait may be particularly common in the children of parents who are affected with panic disorder, and it may develop into severe shyness as the children grow older. At least some persons with social anxiety disorder may have exhibited behavioral inhibition during childhood. Perhaps associated with this trait, which is thought to be biologically based, are the psychologically based data indicating that the parents of persons with social anxiety disorder, as a group, were less caring, more rejecting, and more overprotective of their children than were other parents. Some social anxiety disorder research has referred to the spectrum from dominance to submission observed in the animal kingdom. For example, whereas dominant humans may tend to walk with their chins in the air and to make eye contact, submissive humans may tend to walk with their chins down and to avoid eye contact.

Neurochemical Factors

The success of pharmacotherapies in treating social anxiety disorder has generated two specific neurochemical hypotheses about two types of social anxiety disorder. Specifically, the use of β -adrenergic receptor antagonists—for example, propranolol (Inderal)—for performance phobias (e.g., public speaking) has led to the development of an adrenergic theory for these phobias. Patients with performance phobias may release more norepinephrine or epinephrine, both centrally and peripherally, than do nonphobic persons, or such patients may be sensitive to a normal level of adrenergic stimulation. The observation that MAOIs may be more effective than tricyclic drugs in the treatment of generalized social anxiety disorder, in combination with preclinical data, has led some investigators to hypothesize that dopaminergic activity is related to the pathogenesis of the disorder. One study has shown significantly lower homovanillic acid concentrations. Another study using SPECT demonstrated decreased striatal dopamine reuptake site density. Thus, some evidence suggests dopaminergic dysfunction in social anxiety disorder.

Genetic Factors

First-degree relatives of persons with social anxiety disorder are about three times more likely to be affected with social anxiety disorder than are first-degree relatives of those without mental disorders. And some preliminary data indicate that monozygotic twins are more often concordant than are dizygotic twins, although in social anxiety disorder, it is particularly important to study twins reared apart to help control for environmental factors.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-5 diagnostic criteria for social anxiety disorder is listed in [Table 9.5-2](#). The clinician should recognize that at least some degree of social anxiety or self-consciousness is common in the general population. Community studies suggest that roughly one-third of all persons consider themselves to be far more anxious than other people in social situations. Moreover, such concerns may appear particularly heightened during certain developmental stages, such as adolescence, or after life transitions, such as marriage or occupation changes, associated with new demands for social interaction. Such anxiety only becomes social anxiety disorder when the anxiety either prevents an individual from participating in desired activities or causes marked distress during such activities. DSM-5 also includes a performance only diagnostic specifier for persons who have extreme social phobia specifically about speaking or performing in public.

Table 9.5-2
DSM-5 Diagnostic Criteria for Social Anxiety Disorder

- A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).
 Note: In children, the anxiety must occur in peer settings and just during interactions with adults.
- B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
- C. The social situations almost always provoke fear or anxiety.
 Note: In children, the fear of anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.
- D. The social situations are avoided or endured with intense fear or anxiety.
- E. The fear of anxiety is out of proportion to the actual threat posed by the social situations and to the sociocultural context.
- F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
- G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
- J. If another medical condition (e.g., Parkinson's disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if:

Performance only: If the fear is restricted to speaking or performing in public.

Ms. B was a 29-year-old computer programmer who presented for treatment after she was offered promotion to a managerial position at her firm. Although she wanted the raise and the increased responsibility that would come with the new job, which she had agreed to try on a probationary basis, Ms. B reported that she was reluctant to accept the position because it required frequent interactions with employees from other divisions of the company, as well as occasional public speaking. She stated that she had always felt nervous around new people, whom she worried would ridicule her for “saying stupid things” or committing social faux pas. She also reported feeling “terrified” to speak before groups. These fears had not previously interfered with her social life and job performance. However, since starting her probationary job, Ms. B reported that they had become problematic. She noted that when she had to interact with others, her heart started racing, her mouth became dry, and she felt sweaty. At meetings, she had sudden thoughts that she would say something very foolish or commit a terrible social gaffe that would cause people to laugh. As a consequence, she had skipped several important meetings and left others early. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

DIFFERENTIAL DIAGNOSIS

Social anxiety disorder needs to be differentiated from appropriate fear and normal shyness, respectively. Differential diagnostic considerations for social anxiety disorder are agoraphobia, panic disorder, avoidant personality disorder, major depressive disorder, and schizoid personality disorder. A patient with agoraphobia is often comforted by the presence of another person in an anxiety-provoking situation, but a patient with social anxiety disorder is made more anxious by the presence of other people. Whereas breathlessness, dizziness, a sense of suffocation, and a fear of dying are common in panic disorder and agoraphobia, the symptoms associated with social anxiety disorder usually involve blushing, muscle twitching, and anxiety about scrutiny. Differentiation between social anxiety disorder and avoidant personality disorder can be difficult and can require extensive interviews and psychiatric histories.

The avoidance of social situations can often be a symptom in depression, but a psychiatric interview with the patient is likely to elicit a broad constellation of depressive symptoms. In patients with schizoid personality disorder, the lack of interest in socializing, not the fear of socializing, leads to the avoidant social behavior.

COURSE AND PROGNOSIS

Social anxiety disorder tends to have its onset in late childhood or early adolescence. Existing prospective epidemiological findings indicate that social anxiety disorder is typically chronic, although patients whose symptoms do remit tend to stay well. Both retrospective epidemiological studies and prospective clinical studies suggest that the disorder can profoundly disrupt the life of an individual over many years. This can include disruption in school or academic achievement and interference with job performance and social development.

TREATMENT

Both psychotherapy and pharmacotherapy are useful in treating social anxiety disorder. Some studies indicate that the use of both

pharmacotherapy and psychotherapy produces better results than either therapy alone, although the finding may not be applicable to all situations and patients.

Effective drugs for the treatment of social anxiety disorder include (1) SSRIs, (2) the benzodiazepines, (3) venlafaxine (Effexor), and (4) buspirone (BuSpar). Most clinicians consider SSRIs the first-line treatment choice for patients with more generalized forms of social anxiety disorder. The benzodiazepines alprazolam (Xanax) and clonazepam (Klonopin) are also efficacious in social anxiety disorder. Buspirone has shown additive effects when used to augment treatment with SSRIs.

In severe cases, successful treatment of social anxiety disorder with both irreversible MAOIs such as phenelzine (Nardil) and reversible inhibitors of monoamine oxidase such as moclobemide (Aurorix) and brofaromine (Consonar), which are not available in the United States, has been reported. Therapeutic dosages of phenelzine range from 45 to 90 mg a day, with response rates ranging from 50 to 70 percent; approximately 5 to 6 weeks is needed to assess the efficacy.

The treatment of social anxiety disorder associated with performance situations frequently involves the use of β -adrenergic receptor antagonists shortly before exposure to a phobic stimulus. The two compounds most widely used are atenolol (Tenormin) 50 to 100 mg taken about 1 hour before the performance, or propranolol, 20 to 40 mg. Another option to help with performance anxiety is a relatively short- or intermediate-acting benzodiazepine, such as lorazepam or alprazolam. Cognitive, behavioral, and exposure techniques are also useful in performance situations.

Psychotherapy for social anxiety disorder usually involves a combination of behavioral and cognitive methods, including cognitive retraining, desensitization, rehearsal during sessions, and a range of homework assignments.

9.6 Generalized Anxiety Disorder

Anxiety can be conceptualized as a normal and adaptive response to threat that prepares the organism for flight or fight. Persons who seem to be anxious about almost everything, however, are likely to be classified as having generalized anxiety disorder. Generalized anxiety disorder is defined as excessive anxiety and worry about several events or activities for most days during at least a 6-month period. The worry is difficult to control and is associated with somatic symptoms, such as muscle tension, irritability, difficulty sleeping, and restlessness. The anxiety is not focused on features of another disorder, is not caused by substance use or a general medical condition, and does not occur only during a mood or psychiatric disorder. The anxiety is difficult to control, is subjectively distressing, and produces impairment in important areas of a person's life.

EPIDEMIOLOGY

Generalized anxiety disorder is a common condition; reasonable estimates for its 1-year prevalence range from 3 to 8 percent. The ratio of women to men with the disorder is about 2 to 1, but the ratio of women to men who are receiving inpatient treatment for the disorder is about 1 to 1. A lifetime prevalence is close to 5 percent with the Epidemiological Catchment Area (ECA) study suggesting a lifetime prevalence as high as 8 percent. In anxiety disorder clinics, about 25 percent of patients have generalized anxiety disorder. The disorder usually has its onset in late adolescence or early adulthood, although cases are commonly seen in older adults. Also, some evidence suggests that the prevalence of generalized anxiety disorder is particularly high in primary care settings.

COMORBIDITY

Generalized anxiety disorder is probably the disorder that most often coexists with another mental disorder, usually social phobia, specific phobia, panic disorder, or a depressive disorder. Perhaps 50 to 90 percent of patients with generalized anxiety disorder have another mental disorder. As many as 25 percent of patients eventually experience panic disorder. Generalized anxiety disorder is differentiated from panic disorder by the absence of spontaneous panic attacks. An additional high percentage of patients are likely to have major depressive disorder. Other common disorders associated with generalized anxiety disorder are dysthymic disorder and substance-related disorders.

ETIOLOGY

The cause of generalized anxiety disorder is not known. As currently defined, generalized anxiety disorder probably affects a heterogeneous group of persons. Perhaps because a certain degree of anxiety is normal and adaptive, differentiating normal anxiety from pathological anxiety and differentiating biological causative factors from psychosocial factors are difficult. Biological and psychological factors probably

work together.

Biological Factors

The therapeutic efficacies of benzodiazepines and the azapirones (e.g., buspirone [BuSpar]) have focused biological research efforts on the γ -aminobutyric acid and serotonin neurotransmitter systems. Whereas benzodiazepines (which are benzodiazepine receptor agonists) are known to reduce anxiety, flumazenil (Romazicon) (a benzodiazepine receptor antagonist) and the β -carbolines (benzodiazepine receptor reverse agonists) are known to induce anxiety. Although no convincing data indicate that the benzodiazepine receptors are abnormal in patients with generalized anxiety disorder, some researchers have focused on the occipital lobe, which has the highest concentrations of benzodiazepine receptors in the brain. Other brain areas hypothesized to be involved in generalized anxiety disorder are the basal ganglia, the limbic system, and the frontal cortex. Because buspirone is an agonist at the serotonin 5-HT_{1A} receptor, there is the hypothesis that the regulation of the serotonergic system in generalized anxiety disorder is abnormal. Other neurotransmitter systems that have been the subject of research in generalized anxiety disorder include the norepinephrine, glutamate, and cholecystokinin systems. Some evidence indicates that patients with generalized anxiety disorder may have subsensitivity of their α_2 -adrenergic receptors, as indicated by a blunted release of growth hormone after clonidine (Catapres) infusion.

Brain imaging studies of patients with generalized anxiety disorder have revealed significant findings. One PET study reported a lower metabolic rate in basal ganglia and white matter in patients with generalized anxiety disorder than in normal control subjects. A few genetic studies have also been conducted in the field. One study found that a genetic relation might exist between generalized anxiety disorder and major depressive disorder in women. Another study showed a distinct, but difficult-to-quantitate, genetic component in generalized anxiety disorder. About 25 percent of first-degree relatives of patients with generalized anxiety disorder are also affected. Male relatives are likely to have an alcohol use disorder. Some twin studies report a concordance rate of 50 percent in monozygotic twins and 15 percent in dizygotic twins. Table 9.6-1 lists relative genetic risks in selected anxiety disorders.

 **Table 9.6-1**
Familial Relative Risks in Selected Anxiety Disorders

Disorder	Population Prevalence (%)	Familial Relative Risk ^a
Panic disorder	1–3	2–20
Generalized anxiety disorder	3–5	6
Obsessive-compulsive disorder	1–3	3–5

^aRatio of risk to relatives of cases versus risk to relatives of controls.

A variety of electroencephalogram (EEG) abnormalities has been noted in alpha rhythm and evoked potentials. Sleep EEG studies have reported increased sleep discontinuity, decreased delta sleep, decreased stage 1 sleep, and reduced rapid eye movement sleep. These changes in sleep architecture differ from the changes seen in depressive disorders.

Psychosocial Factors

The two major schools of thought about psychosocial factors leading to the development of generalized anxiety disorder are the cognitive-behavioral school and the psychoanalytic school. According to the cognitive-behavioral school, patients with generalized anxiety disorder respond to incorrectly and inaccurately perceived dangers. The inaccuracy is generated by selective attention to negative details in the environment, by distortions in information processing, and by an overly negative view of the person's own ability to cope. The psychoanalytic school hypothesizes that anxiety is a symptom of unresolved, unconscious conflicts. Sigmund Freud first presented this psychological theory in 1909 with his description of Little Hans; before then, Freud had conceptualized anxiety as having a physiological basis. An example of Freudian theory as applied to general anxiety can be seen in the following case:

Mrs. B, a 26-year-old married woman, was admitted to the hospital for the evaluation of persistent anxiety that had begun 8 months earlier and was becoming increasingly disabling. Especially disturbing to the patient was the spontaneous intrusion of intermittent images in her mind's eye of her father and herself locked in a naked sexual embrace. The images were not only frightening, but they puzzled her greatly because she had always disliked her father intensely. Not only was he "poison" to her, but she tried to avoid any contact with him and found it difficult to talk to him if she was forced to be in his company.

As the patient described the difficulty of her relationship with her father, she suddenly recalled that her anxiety had begun at a time when her father was seemingly being more intrusive than ever as he tried to help her and her husband over a period of financial difficulty.

As the patient continued to revile her father, she suddenly commented that her mother had told her that her father "had been good to me when I was little and he used to sing songs to me and take me on his lap, but I don't remember. I only remember when he was mean to me. I just am glad when he keeps on talking mean to me the way he always has. I just wouldn't know what to do if he was nice to me." When asked by the interviewer if there might have been a time when she had wanted him to be nice to her, the patient replied, "When I was little, I just wanted to know that he did love me a little. I guess I always wanted him to be nice to me. But when I stop to think about it, I guess I didn't want him to be nice to me." The doctor then commented, "It sounds as if a part of you wants to be close to your father." In response, the patient burst into agitated sobs and blurted out, "I don't know how to be close to my father! I am too old to care about my father now!"

When the patient regained her composure, she recalled the memory of an event she had not thought of since it had occurred 15 years earlier. When she was 11 years old, she reported, while in the living room with her father, she had suddenly had the mental image of being in a sexual embrace with him. Terrified, she had run into the kitchen to find her mother. There had been no recurrence of that image until the onset of the current illness, and the incident had remained forgotten until its recall during the interview. Its emergence into consciousness amplified the history of the patient's illness and disclosed an earlier transient outbreak of the same symptoms she had experienced as an adult. After the patient had recovered her composure, she recalled further hitherto forgotten memories. She had slept in her parents' bedroom until she was 6, during which period her father, on one occasion, had taken her into bed and told her stories and, on another, had yelled at her very angrily as she lay in her crib.

During a clinical interview the next day, the patient revealed a fact that she had forgotten in her earlier account of her illness: At the end of the period during which her father had been making the friendly overtures that had so deeply troubled her, and the night before the sudden onset of her symptoms, she had had a nightmare. She was, she dreamed, at a zoo. It was night, and she heard strange noises in the darkness. She asked an attendant standing next to her what the noises were. "Oh," the attendant replied casually, "that's only the animals mating." She then noticed a large, gray elephant lying on its right side in the grass in front of her. As she watched, she noticed the

creature moving its left hind leg up and down as if it were trying to get to its feet. At that point she awoke from the dream with a feeling of terror and, afterward, during the morning, experienced the first episode of the frightening imagery of sexual activity with her father.

In direct association to the dream, the patient recalled a long-forgotten childhood memory of an incident that had occurred during her fourth or fifth year. She had awoken one night while in her crib in her parents' bedroom to observe her parents having sexual intercourse. They suddenly became aware of her watching them and sprang apart. The patient remembered seeing her mother hastily pulling up the bedclothes around her to cover her nakedness. Her father, meanwhile, rolled over half on his back, half on his left side. The patient noticed his erection and then saw him lift up his left leg as he sat up and yelled at her angrily to go to sleep.

It was not easy for the patient to communicate these memories. She spoke haltingly in a low voice and was visibly ashamed and anxious throughout the whole recital of the dream and its associations. She discharged a great quantity of affect, but after doing so, appeared considerably relaxed, relieved, and composed. On her return to the psychiatric ward, she was observed to be cheerful and outgoing with the ward personnel and other patients. Of particular note was that she no longer experienced any anxiety and had no recurrence of the sexual images involving her father that had previously been so deeply distressing. The patient was discharged a short while later after a further series of psychotherapeutic interviews, and when seen for a follow-up visit 2 months later, she reported continued emotional calm and comfort, without recurrence of psychiatric symptoms.

DIAGNOSIS

Generalized anxiety disorder is characterized by a pattern of frequent, persistent worry and anxiety that is out of proportion to the impact of the event or circumstance that is the focus of the worry. The distinction between generalized anxiety disorder and normal anxiety is emphasized by the use of the word “excessive” in the criteria and by the specification that the symptoms cause significant impairment or distress. DSM-5 diagnostic criteria for generalized anxiety disorder are listed in [Table 9.6-2](#).

 **Table 9.6-2**
DSM-5 Diagnostic Criteria for Generalized Anxiety Disorder

- A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
- B. The individual finds it difficult to control the worry.
- C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):
 - Note: Only one item is required in children.
 - 1. Restlessness or feeling keyed up or on edge.
 - 2. Being easily fatigued.
 - 3. Difficulty concentrating or mind going blank.
 - 4. Irritability.
 - 5. Muscle tension.
 - 6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).
- D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other areas of functioning.
- E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
- F. The disturbance is not better explained by another medical disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

CLINICAL FEATURES

The essential characteristics of generalized anxiety disorder are sustained and excessive anxiety and worry accompanied by either motor tension or restlessness. The anxiety is excessive and interferes with other aspects of a person's life. This pattern must occur more days than not for at least 3 months. The motor tension is most commonly manifested as shakiness, restlessness, and headaches.

Patients with generalized anxiety disorder usually seek out a general practitioner or internist for help with a somatic symptom. Alternatively, the patients go to a specialist for a specific symptom (e.g., chronic diarrhea). A specific nonpsychiatric medical disorder is rarely found, and patients vary in their doctor-seeking behavior. Some patients accept a diagnosis of generalized anxiety disorder and the appropriate treatment; others seek additional medical consultations for their problems.

Mr. G was a successful, married, 28-year-old teacher who presented for a psychiatric evaluation to treat mounting symptoms of worry and anxiety. Mr. G noted that for the preceding year, he had become more and more worried about his job performance. For example, although he had always been a respected and popular lecturer, he found himself worrying more and more about his ability to engage students and convey material effectively. Similarly, although he had always been financially secure, he increasingly worried that he was

going to lose his wealth due to unexpected expenses. Mr. G noted frequent somatic symptoms that accompanied his worries. For example, he often felt tense and irritable while he worked and spent time with his family, and he had difficulty distracting himself from worries about the upcoming challenges for the next day. He reported feeling increasingly restless, especially at night, when his worries kept him from falling asleep. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

DIFFERENTIAL DIAGNOSIS

As with other anxiety disorders, generalized anxiety disorder must be differentiated from both medical and psychiatric disorders. Neurological, endocrinological, metabolic, and medication-related disorders similar to those considered in the differential diagnosis of panic disorder must be considered in the differential diagnosis of generalized anxiety disorder. Common co-occurring anxiety disorders also must be considered, including panic disorder, phobias, OCD, and PTSD. To meet criteria for generalized anxiety disorder, patients must both exhibit the full syndrome, and their symptoms also cannot be explained by the presence of a comorbid anxiety disorder. To diagnose generalized anxiety disorder in the context of other anxiety disorders, it is most important to document anxiety or worry related to circumstances or topics that are either unrelated, or only minimally related, to other disorders. Proper diagnosis involves both definitively establishing the presence of generalized anxiety disorder and properly diagnosing other anxiety disorders. Patients with generalized anxiety disorder frequently develop major depressive disorder. As a result, this condition must also be recognized and distinguished. The key to making a correct diagnosis is documenting anxiety or worry that is unrelated to the depressive disorder.

COURSE AND PROGNOSIS

The age of onset is difficult to specify; most patients with the disorder report that they have been anxious for as long as they can remember. Patients usually come to a clinician's attention in their 20s, although the first contact with a clinician can occur at virtually any age. Only one-third of patients who have generalized anxiety disorder seek psychiatric treatment. Many go to general practitioners, internists, cardiologists, pulmonary specialists, or gastroenterologists, seeking treatment for the somatic component of the disorder. Because of the high incidence of comorbid mental disorders in patients with generalized anxiety disorder, the clinical course and prognosis of the disorder are difficult to predict. Nonetheless, some data indicate that life events are associated with the onset of generalized anxiety disorder: The occurrence of several negative life events greatly increases the likelihood that the disorder will develop. By definition, generalized anxiety disorder is a chronic condition that may well be lifelong.

TREATMENT

The most effective treatment of generalized anxiety disorder is probably one that combines psychotherapeutic, pharmacotherapeutic, and supportive approaches. The treatment may take a significant amount of time for the involved clinician, whether the clinician is a psychiatrist, a family practitioner, or another specialist.

Psychotherapy

The major psychotherapeutic approaches to generalized anxiety disorder are cognitive-behavioral, supportive, and insight oriented. Data are still limited on the relative merits of those approaches, although the most sophisticated studies have examined cognitive-behavioral techniques, which seem to have both short-term and long-term efficacy. Cognitive approaches address patients' hypothesized cognitive distortions directly, and behavioral approaches address somatic symptoms directly. The major techniques used in behavioral approaches are relaxation and biofeedback. Some preliminary data indicate that the combination of cognitive and behavioral approaches is more effective than either technique used alone. Supportive therapy offers patients reassurance and comfort, although its long-term efficacy is doubtful. Insight-oriented psychotherapy focuses on uncovering unconscious conflicts and identifying ego strengths. The efficacy of insight-oriented psychotherapy for generalized anxiety disorder is found in many anecdotal case reports, but large controlled studies are lacking.

Most patients experience a marked lessening of anxiety when given the opportunity to discuss their difficulties with a concerned and sympathetic physician. If clinicians discover external situations that are anxiety provoking, they may be able—alone or with the help of the patients or their families—to change the environment and thus reduce the stressful pressures. A reduction in symptoms often allows patients to function effectively in their daily work and relationships and thus gain new rewards and gratification that are themselves therapeutic.

In the psychoanalytic perspective, anxiety sometimes signals unconscious turmoil that deserves investigation. The anxiety can be normal, adaptive, maladaptive, too intense, or too mild, depending on the circumstances. Anxiety appears in numerous situations over the course of the life cycle; in many cases, symptom relief is not the most appropriate course of action.

For patients who are psychologically minded and motivated to understand the sources of their anxiety, psychotherapy may be the treatment of choice. Psychodynamic therapy proceeds with the assumption that anxiety can increase with effective treatment. The goal of the dynamic approach may be to increase the patient's anxiety tolerance (a capacity to experience anxiety without having to discharge it), rather than to eliminate anxiety. Empirical research indicates that many patients who have successful psychotherapeutic treatment may continue to experience anxiety after termination of the psychotherapy, but their increased ego mastery allows them to use the anxiety symptoms as a signal to reflect on internal struggles and to expand their insight and understanding. A psychodynamic approach to patients with generalized anxiety disorder involves a search for the patient's underlying fears.

B, a 28-year-old man with a history of a generalized anxiety disorder, was a former adolescent alcohol abuser now involved in Alcoholics Anonymous (AA). Because of sexual side effects, he was unwilling to take SSRI antidepressants, buspirone (BuSpar) had been ineffective, and gabapentin (Neurontin) was too sedating. Clonazepam (Klonopin) was effective, but B's continued participation in AA led to pressures from AA peers to give up benzodiazepines. Partly because of these pressures, B sought psychodynamic therapy with a psychiatrist. When the psychiatrist suggested that he begin tapering clonazepam, B balked, worried that he would become more anxious. The therapist suggested that it might be useful to bring his anxiety to sessions if their task really was going to be to learn more about his anxiety.

On a tapering dose of clonazepam B's anxiety increased. He complained that his male therapist was unempathic, making B suffer with anxiety while the therapist watched and did nothing. As the treatment unfolded, the therapist learned B had been especially close to his mother, who, with B, had been the target of criticism from his often absent, short-tempered, mean-spirited alcoholic father. B's mother had surgery and chemotherapy for breast cancer when B was 10 years old. It was shortly after this that B's anxiety symptoms began.

When clonazepam was discontinued, there was an outburst of anger at the therapist for making B suffer so much. The therapist quietly accepted B's anger at him, noting that he had asked B to endure more anxiety, while leaving him alone and on his own most of the week. When he suggested that B had found in the therapist his absent and sadistic father, B thought this made sense, and he began to trust the therapist more. B said he realized that the therapist could endure and understand his anger without needing to retaliate and that he was sticking to a treatment plan they had agreed to from the outset. As the alliance deepened, B struggled to put words to his experience of anxiety. B spoke more of his attachment to his mother and to the way he would cling to her to support her, pressing himself against her ample bosom, while his father would rage at them both while drunk, sometimes suggesting that B's clinging to her was unnatural and

inspired by lust.

B reported a dream in one session in which he watched passively, frozen with fear and guilt and unable to move, as a man murdered and dismembered a naked woman. B's associations to the dream led to painful memories of his mother's disfiguring surgery and to his guilt about not having been able to stop his father from angrily criticizing her both before and after the surgery. B then added there was another part of the dream he had left out because of shame. He had been sexually aroused during the dream. B suddenly reported an intrusive thought that upset him—a thought that the breast cancer had come because he had been unable to protect his mother—and because he had been aroused by her breasts. B wept for the first time in the therapy. Over time the therapist and patient explored the dream and his intrusive thoughts, learning that B felt guilty about having caused his mother's illness and disfiguring surgery not only because he could not protect her from father's rages but also because he felt guilty and ashamed about his attraction to his mother's breasts. He spoke of the way his father's drunken accusation of lust toward his mother was right. He feared, too, that he would be disfigured because of a disease or accident, perhaps by castration, for what he had done to his mother. It was not easy for B to explore these feelings, but as he did, his anxiety diminished. (Courtesy of Eric M. Plakun, M.D.)

Pharmacotherapy

The decision to prescribe an anxiolytic to patients with generalized anxiety disorder should rarely be made on the first visit. Because of the long-term nature of the disorder, a treatment plan must be carefully thought out. The three major drugs to be considered for the treatment of generalized anxiety disorder are benzodiazepines, the SSRIs, buspirone (BuSpar), and venlafaxine (Effexor). Other drugs that may be useful are the tricyclic drugs (e.g., imipramine [Tofranil]), antihistamines, and the β -adrenergic antagonists (e.g., propranolol [Inderal]) (Table 9.6-3).

Table 9.6-3
Common Medications for the Treatment of Recurrent Anxiety

Medication	Brand Name	Recommended Initial Dose	Daily Dose (mg) ^a
Antidepressants^b			
Fluoxetine	Prozac	5 mg/day	20–80
Fluvoxamine	Luvox	50 mg/day	100–300
Paroxetine	Paxil	10 mg/day	20–50
	Paxil CR	12.5 mg/day	25–75
Sertraline	Zoloft	25–50 mg/day	50–200
Citalopram	Celexa	10 mg/day	20–60
Escitalopram	Lexapro	5 mg/day	10–30
Venlafaxine	Effexor XR	37.5 mg/day	75–225
Phenelzine	Nardil	15 mg/day	45–90
Benzodiazepines^c			
Alprazolam	Xanax	0.25 mg tid	1–4 ^e
Clonazepam	Klonopin	0.25 mg bid	1–3
Lorazepam	Ativan	0.5 mg tid	2–6 ^e
Azapirone^d			
Buspirone	BuSpar	7.5 mg bid	30–60

bid, twice daily; tid, three times daily.

All except phenelzine are useful as a primary treatment for obsessive-compulsive disorder.

^aSome individuals will require higher or lower doses than those listed here.

^bUseful as a primary treatment for panic disorder (in which lower starting doses are usually used) with or without agoraphobia, generalized anxiety disorder, generalized social anxiety disorder, and posttraumatic stress disorder.

^cUseful as a primary treatment for panic disorder with or without agoraphobia, generalized anxiety disorder, and generalized social anxiety disorder.

May be a useful adjunct to antidepressants in the treatment of posttraumatic stress disorder or obsessive-compulsive disorder.

^dUseful as a primary treatment for generalized anxiety disorder.

^eTotal daily dose is divided across two to four doses per day.

Although drug treatment of generalized anxiety disorder is sometimes seen as a 6- to 12-month treatment, some evidence indicates that treatment should be long term, perhaps lifelong. About 25 percent of patients relapse in the first month after the discontinuation of therapy, and 60 to 80 percent relapse over the course of the next year. Although some patients become dependent on the benzodiazepines, tolerance rarely develops to the therapeutic effects of the benzodiazepines, buspirone, venlafaxine, or the SSRIs.

Benzodiazepines. Benzodiazepines have been the drugs of choice for generalized anxiety disorder. They can be prescribed on an as-needed basis, so that patients take a rapidly acting benzodiazepine when they feel particularly anxious. The alternative approach is to prescribe benzodiazepines for a limited period, during which psychosocial therapeutic approaches are implemented.

Several problems are associated with the use of benzodiazepines in generalized anxiety disorder. About 25 to 30 percent of all patients fail to respond, and tolerance and dependence can occur. Some patients also experience impaired alertness while taking the drugs and therefore are at risk for accidents involving automobiles and machinery.

The clinical decision to initiate treatment with a benzodiazepine should be considered and specific. The patient's diagnosis, the specific target symptoms, and the duration of treatment should all be defined, and the information should be shared with the patient. Treatment for most anxiety conditions lasts for 2 to 6 weeks followed by 1 or 2 weeks of tapering drug use before it is discontinued. The most common clinical mistake with benzodiazepine treatment is to continue treatment indefinitely.

For the treatment of anxiety, it is usual to begin giving a drug at the low end of its therapeutic range and to increase the dosage to achieve a therapeutic response. The use of a benzodiazepine with an intermediate half-life (8 to 15 hours) will likely avoid some of the adverse effects associated with the use of benzodiazepines with long half-lives, and the use of divided doses prevents the development of adverse effects associated with high peak plasma levels. The improvement produced by benzodiazepines may go beyond a simple antianxiety effect.

For example, the drugs may cause patients to regard various occurrences in a positive light. The drugs can also have a mild disinhibiting action, similar to that observed after ingesting modest amounts of alcohol.

Buspirone. Buspirone is a 5-HT_{1A} receptor partial agonist and is most likely effective in 60 to 80 percent of patients with generalized anxiety disorder. Data indicate that buspirone is more effective in reducing the cognitive symptoms of generalized anxiety disorder than in reducing the somatic symptoms. Evidence also indicates that patients who have previously had treatment with benzodiazepines are not likely to respond to treatment with buspirone. The lack of response may be caused by the absence, with buspirone treatment, of some of the nonanxiolytic effects of benzodiazepines (e.g., muscle relaxation and the additional sense of well-being). The major disadvantage of buspirone is that its effects take 2 to 3 weeks to become evident, in contrast to the almost immediate anxiolytic effects of the benzodiazepines. One approach is to initiate benzodiazepine and buspirone use simultaneously and then taper off the benzodiazepine use after 2 to 3 weeks, at which point the buspirone should have reached its maximal effects. Some studies have also reported that long-term combined treatment with benzodiazepine and buspirone may be more effective than either drug alone. Buspirone is not an effective treatment for benzodiazepine withdrawal.

Venlafaxine. Venlafaxine is effective in treating the insomnia, poor concentration, restlessness, irritability, and excessive muscle tension associated with generalized anxiety disorder. Venlafaxine is a nonselective inhibitor of the reuptake of three biogenic amines—serotonin; norepinephrine; and, to a lesser extent, dopamine.

Selective Serotonin Reuptake Inhibitors. SSRIs may be effective, especially for patients with comorbid depression. The prominent disadvantage of SSRIs, especially fluoxetine (Prozac), is that they can transiently increase anxiety and cause agitated states. For this reason, the SSRIs sertraline (Zoloft), citalopram (Celexa), or paroxetine (Paxil) are better choices in patients with high anxiety disorder. It is reasonable to begin treatment with sertraline, citalopram, or paroxetine plus a benzodiazepine and then to taper benzodiazepine use after 2 to 3 weeks. Further studies are needed to determine whether SSRIs are as effective for generalized anxiety disorder as they are for panic disorder and OCD.

Other Drugs. If conventional pharmacological treatment (e.g., with buspirone or a benzodiazepine) is ineffective or not completely effective, then a clinical reassessment is indicated to rule out comorbid conditions, such as depression, or to better understand the patient's environmental stresses. Other drugs that have proved useful for generalized anxiety disorder include the tricyclic and tetracyclic drugs. The β -adrenergic receptor antagonists may reduce the somatic manifestations of anxiety but not the underlying condition, and their use is usually limited to situational anxieties, such as performance anxiety.

9.7 Other Anxiety Disorders

ANXIETY DISORDER ATTRIBUTABLE TO ANOTHER MEDICAL CONDITION

Many medical disorders are associated with anxiety. Symptoms can include panic attacks, generalized anxiety, and other signs of distress. In all cases, the signs and symptoms will be due to the direct physiological effects of the medical condition.

Epidemiology

The occurrence of anxiety symptoms related to general medical conditions is common, although the incidence of the disorder varies for each specific general medical condition.

Etiology

A wide range of medical conditions can cause symptoms similar to those of anxiety disorders (Table 9.7-1). Hyperthyroidism, hypothyroidism, hypoparathyroidism, and vitamin B₁₂ deficiency are frequently associated with anxiety symptoms. A pheochromocytoma produces epinephrine, which can cause paroxysmal episodes of anxiety symptoms. Other medical conditions, such as cardiac arrhythmia, can produce physiological symptoms of panic disorder. Hypoglycemia can also mimic the symptoms of an anxiety disorder. The diverse medical conditions that can cause symptoms of anxiety disorder may do so through a common mechanism that involves both the noradrenergic system and the serotonergic system. Each of these conditions is characterized by prominent anxiety that arises as the direct result of some underlying physiological perturbation.

Table 9.7-1
Disorders Associated with Anxiety

- Neurological disorders
 - Cerebral neoplasms
 - Cerebral trauma and postconcussive syndromes
 - Cerebrovascular disease
 - Subarachnoid hemorrhage
 - Migraine
 - Encephalitis
 - Cerebral syphilis
 - Multiple sclerosis
 - Wilson's disease
 - Huntington's disease
 - Epilepsy
- Systemic conditions
 - Hypoxia
 - Cardiovascular disease
 - Cardiac arrhythmias
 - Pulmonary insufficiency
 - Anemia
- Endocrine disturbances
 - Pituitary dysfunction
 - Thyroid dysfunction
 - Parathyroid dysfunction
 - Adrenal dysfunction
 - Pheochromocytoma
 - Virilization disorders of females
- Inflammatory disorders
 - Lupus erythematosus
 - Rheumatoid arthritis
 - Polyarteritis nodosa
 - Temporal arteritis
- Deficiency states
 - Vitamin B₁₂ deficiency
 - Pellagra
- Miscellaneous conditions
 - Hypoglycemia
 - Carcinoid syndrome
 - Systemic malignancies
 - Premenstrual syndrome
 - Febrile illnesses and chronic infections
 - Porphyria
 - Infectious mononucleosis
 - Posthepatitic syndrome
 - Uremia
- Toxic conditions
 - Alcohol and drug withdrawal
 - Amphetamines
 - Sympathomimetic agents
 - Vasopressor agents
 - Caffeine and caffeine withdrawal
 - Penicillin
 - Sulfonamides
 - Cannabis
 - Mercury
 - Arsenic
 - Phosphorus
 - Organophosphates
 - Carbon disulfide
 - Benzene
 - Aspirin intolerance

Diagnosis

The diagnosis of anxiety disorder attributable to another medical condition requires the presence of symptoms of an anxiety disorder caused by one or more medical illnesses. The DSM-5 suggests that clinicians to specify whether the disorder is characterized by symptoms of generalized anxiety or panic attacks.

Clinicians should have an increased level of suspicion for the diagnosis when chronic or paroxysmal anxiety is associated with a physical disease known to cause such symptoms in some patients. Paroxysmal bouts of hypertension in an anxious patient may indicate that a workup for a pheochromocytoma is appropriate. A general medical workup may reveal diabetes, an adrenal tumor, thyroid disease, or a neurological condition. For example, some patients with complex partial epilepsy have extreme episodes of anxiety or fear as their only manifestation of the epileptic activity.

Clinical Features

The symptoms of anxiety disorder due to a general medical condition can be identical to those of the primary anxiety disorders. A syndrome similar to panic disorder is the most common clinical picture, and a syndrome similar to a phobia is the least common.

Panic Attacks. Patients who have cardiomyopathy may have the highest incidence of panic disorder secondary to a general medical condition. One study reported that 83 percent of patients with cardiomyopathy awaiting cardiac transplantation had panic disorder symptoms. Increased noradrenergic tone in these patients may be the provoking stimulus for the panic attacks. In some studies, about 25 percent of patients with Parkinson's disease and chronic obstructive pulmonary disease have symptoms of panic disorder. Other medical disorders associated with panic disorder include chronic pain, primary biliary cirrhosis, and epilepsy, particularly when the focus is in the right parahippocampal gyrus.

Generalized Anxiety. A high prevalence of generalized anxiety disorder symptoms has been reported in patients with Sjögren's syndrome, and this rate may be related to the effects of Sjögren's syndrome on cortical and subcortical functions and thyroid function. The highest prevalence of generalized anxiety disorder symptoms in a medical disorder seems to be in Graves' disease (hyperthyroidism), in which as many as two-thirds of all patients meet the criteria for generalized anxiety disorder.

A 86-year-old retired chemical engineer sought help for the onset of a series of attacks over the preceding 4 months in which he experienced marked apprehension, restlessness, a sense that the "walls were caving in," and the need to "get air" to relieve his sense of discomfort. These events typically occurred during the night and awakened him from sound sleep. To feel better, he would need to stick his head out of an open window, regardless of how cold it was outside. His symptoms would gradually improve over 15 to 20 minutes, but complete resolution of these symptoms took a full day. In response to pointed questioning, the patient reported sweating, dizziness, and shortness of breath during these episodes. He imagined that he would die if he could not open the window. He denied palpitations, choking sensations, paresthesia, and nausea. The patient recalled a similar series of attacks almost 30 years earlier during a period of time in which he frequently needed to travel and hence was away from home because of work obligations. The patient denied depressed mood, anhedonia, recent sleep dysfunctions, change in appetite or weight, decreased energy, and feelings of worthlessness. His medical history was notable for a right basal ganglia stroke 6 months earlier. He had a history of hypertension, borderline diabetes, and benign prostatic hypertrophy. Laboratory study results were unremarkable.

A diagnosis of anxiety disorder due to stroke, with panic attacks, was made. The patient was prescribed alprazolam (Xanax), 0.5 mg orally twice a day as needed for panic attacks, and started on escitalopram (Lexapro), 10 mg per day. At a follow-up visit, the patient reported complete resolution of his anxiety symptoms. He remained taking the escitalopram but no longer required the alprazolam. (Courtesy of LL Lavery, M.D., and EM Whyte, M.D.)

Phobias. Symptoms of phobias appear to be uncommon, although one study reported a 17 percent prevalence of symptoms of social phobia in patients with Parkinson's disease. Older persons with balance difficulties often complain of a fear of falling, which may express itself by their being unwilling or fearful of walking.

Laboratory Examination

A targeted work-up is required when an anxiety disorder due to another medical condition is being considered as part of the differential diagnosis. If possible, tests should be selected to rule in specific diagnoses suggested by the patient's somatic symptoms (if present).

Test to consider include complete blood count, electrolytes, glucose, blood urea nitrogen, creatinine, liver function tests, calcium, magnesium, phosphorus, thyroid function tests, and urine toxicology. Occasionally, additional studies may be indicated to rule out a pheochromocytoma (e.g., urinary catecholamines), a seizure disorder (e.g., EEG), cardiac arrhythmia (e.g., Holter monitoring), and pulmonary disease (pulse oximetry, arterial blood gases). Brain imaging may be useful in ruling out demyelinating disorder, tumor, stroke, or hydrocephalus and is especially important if the anxious individual reports neurological symptoms (e.g., headache, motor or sensory changes, and dizziness), although such complaints may represent somatic manifestations of primary anxiety disorders. Lumbar puncture may be appropriate if an inflammatory or infectious cause is suspected.

Differential Diagnosis

Anxiety, as a symptom, can be associated with many psychiatric disorders in addition to the anxiety disorders themselves. A mental status examination is necessary to determine the presence of mood symptoms or psychotic symptoms that may suggest another psychiatric diagnosis. For a clinician to conclude that a patient has an anxiety disorder caused by a general medical condition, the patient should clearly have anxiety as the predominant symptom and should have a specific causative nonpsychiatric medical disorder. To ascertain the degree to which a general medical condition is causative for the anxiety, the clinician should evaluate the timeline between the medical condition and the anxiety symptoms, the age of onset (primary anxiety disorders usually have their onset before age 35 years), and the patient's family history of both anxiety disorders and relevant general medical conditions (e.g., hyperthyroidism). A diagnosis of adjustment disorder with anxiety must also be considered in the differential diagnosis.

Course and Prognosis

The unremitting experience of anxiety can be disabling and can interfere with every aspect of life, including social, occupational, and psychological functioning. A sudden increase in anxiety level may prompt an affected person to seek medical or psychiatric help more quickly than when the onset is insidious. The treatment or the removal of the primary medical cause of the anxiety usually initiates a clear course of improvement in the anxiety disorder symptoms. In some cases, however, the anxiety disorder symptoms continue even after the primary medical condition is treated (e.g., after an episode of encephalitis). Some symptoms linger for a longer time than other anxiety disorder symptoms. When anxiety disorder symptoms are present for a significant period after the medical disorder has been treated, the remaining symptoms should probably be treated as if they were primary—that is, with psychotherapy, pharmacotherapy, or both.

Treatment

The primary treatment for anxiety disorder due to a general medical condition is to treat the underlying medical condition. If a patient also has an alcohol or other substance use disorder, this disorder must also be addressed therapeutically to gain control of the anxiety disorder symptoms. If the removal of the primary medical condition does not reverse the anxiety disorder symptoms, treatment of these symptoms should follow the treatment guidelines for the specific mental disorder. In general, behavioral modification techniques, anxiolytic agents, and serotonergic antidepressants have been the most effective treatment modalities.

SUBSTANCE-INDUCED ANXIETY DISORDER

Substance-induced disorder is the direct result of a toxic substance, including drugs of abuse, medication, poison, and alcohol, among others.

Epidemiology

Substance-induced anxiety disorder is common, both as the result of the ingestion of so-called recreational drugs and as the result of prescription drug use.

Etiology

A wide range of substances can cause symptoms of anxiety that can mimic any of the DSM-5 anxiety disorders. Although sympathomimetics, such as amphetamine, cocaine, and caffeine, have been most associated with the production of anxiety disorder symptoms, many serotonergic drugs (e.g., LSD and MDMA) can also cause both acute and chronic anxiety syndromes in users. A wide range of prescription medications is also associated with the production of anxiety disorder symptoms in susceptible persons.

Diagnosis

The diagnostic criteria for substance-induced anxiety disorder require the presence of prominent anxiety or panic attacks. The DSM-5 guidelines state that the symptoms should have developed during the use of the substance or within 1 month of the cessation of substance use; however, clinicians may have difficulty determining the relation between substance exposure and anxiety symptoms. The structure of the diagnosis includes specification of (1) the substance (e.g., cocaine), (2) the appropriate state during the onset (e.g., intoxication), and (3) the specific symptom pattern (e.g., panic attacks).

Clinical Features

The associated clinical features of substance-induced anxiety disorder vary with the particular substance involved. Even infrequent use of psychostimulants can result in anxiety disorder symptoms in some persons. Cognitive impairments in comprehension, calculation, and memory can be associated with anxiety disorder symptoms. These cognitive deficits are usually reversible when the substance use is stopped.

Virtually everyone who drinks alcohol, on at least a few occasions, has used it to reduce anxiety, most often social anxiety. In contrast, carefully controlled studies have found that the effects of alcohol on anxiety are variable and can be significantly affected by gender, the amount of alcohol ingested, and cultural attitudes. Nevertheless, alcohol use disorders and other substance-related disorders are commonly associated with anxiety disorders. Alcohol use disorders are about four times more common among patients with panic disorder than among the general population and about two and a half times more common among patients with phobias. Several studies have reported data indicating that genetic diatheses for both anxiety disorders and alcohol use disorders can exist in some families.

Differential Diagnosis

The differential diagnosis for substance-induced anxiety disorder includes the primary anxiety disorders; anxiety disorder due to a general medical condition (for which the patient may be receiving an implicated drug); and mood disorders, which are frequently accompanied by symptoms of anxiety disorders. Personality disorders and malingering must be considered in the differential diagnosis, particularly in some urban emergency departments.

Course and Prognosis

The course and prognosis generally depend on removal of the causally involved substance and the long-term ability of the affected person to limit use of the substance. The anxiogenic effects of most drugs are reversible. When the anxiety does not reverse with cessation of the drug, clinicians should reconsider the diagnosis of substance-induced anxiety disorder or consider the possibility that the substance caused irreversible brain damage.

Treatment

The primary treatment for substance-induced anxiety disorder is the removal of the causally involved substance. Treatment then must focus on finding an alternative treatment if the substance was a medically indicated drug, on limiting the patient's exposure if the substance was introduced through environmental exposure, or on treating the underlying substance-related disorder. If anxiety disorder symptoms continue even after stopping substance use, treatment of the anxiety disorder symptoms with appropriate psychotherapeutic or pharmacotherapeutic modalities may be appropriate.

MIXED ANXIETY-DEPRESSIVE DISORDER

Mixed anxiety-depressive disorder describes patients with both anxiety and depressive symptoms who do not meet the diagnostic criteria for either an anxiety disorder or a mood disorder. The combination of depressive and anxiety symptoms results in significant functional impairment for the affected person. The condition may be particularly prevalent in primary care practices and outpatient mental health clinics. Opponents have argued that the availability of the diagnosis may discourage clinicians from taking the necessary time to obtain a complete psychiatric history to differentiate true depressive disorders from true anxiety disorders. In Europe and especially in China, many of these patients are given a diagnosis of neurasthenia.

Epidemiology

The coexistence of major depressive disorder and panic disorder is common. As many as two-thirds of all patients with depressive symptoms have prominent anxiety symptoms, and one-third may meet the diagnostic criteria for panic disorder. Researchers have reported that 20 to 90 percent of all patients with panic disorder have episodes of major depressive disorder. These data suggest that the coexistence of depressive and anxiety symptoms, neither of which meets the diagnostic criteria for other depressive or anxiety disorders, may be common. Presently, however, formal epidemiological data on mixed anxiety-depressive disorder are not available. Nevertheless, some clinicians and researchers have estimated that the prevalence of the disorder in the general population is as high as 10 percent and as high as 50 percent in primary care clinics, although conservative estimates suggest a prevalence of about 1 percent in the general population.

Etiology

Four principal lines of evidence suggest that anxiety symptoms and depressive symptoms are causally linked in some affected patients. First, several investigators have reported similar neuroendocrine findings in depressive disorders and anxiety disorders, particularly panic disorder, including blunted cortisol response to adrenocorticotrophic hormone, blunted growth hormone response to clonidine (Catapres), and blunted thyroid-stimulating hormone and prolactin responses to thyrotropin-releasing hormone. Second, several investigators have reported data indicating that hyperactivity of the noradrenergic system is causally relevant to some patients with depressive disorders and with panic disorder. Specifically, these studies have found elevated concentrations of the norepinephrine metabolite (MHPG) in the urine, the plasma,

or the CSF of depressed patients and patients with panic disorder who were actively experiencing a panic attack. As with other anxiety and depressive disorders, serotonin and GABA may also be causally involved in mixed anxiety-depressive disorder. Third, many studies have found that serotonergic drugs, such as fluoxetine (Prozac) and clomipramine (Anafranil), are useful in treating both depressive and anxiety disorders. Fourth, a number of family studies have reported data indicating that anxiety and depressive symptoms are genetically linked in at least some families.

Diagnosis

The diagnostic criteria for mixed anxiety-depressive disorder require the presence of subsyndromal symptoms of both anxiety and depression and the presence of some autonomic symptoms, such as tremor, palpitations, dry mouth, and the sensation of a churning stomach. Some preliminary studies have indicated that the sensitivity of general practitioners to a syndrome of mixed anxiety-depressive disorder is low, although this lack of recognition may reflect the lack of an appropriate diagnostic label for the patients.

Clinical Features

The clinical features of mixed anxiety-depressive disorder combine symptoms of anxiety disorders and some symptoms of depressive disorders. In addition, symptoms of autonomic nervous system hyperactivity, such as gastrointestinal complaints, are common and contribute to the high frequency with which the patients are seen in outpatient medical clinics.

Differential Diagnosis

The differential diagnosis includes other anxiety and depressive disorders and personality disorders. Among the anxiety disorders, generalized anxiety disorder is most likely to overlap with mixed anxiety-depressive disorder. Among the mood disorders, dysthymic disorder and minor depressive disorder are most likely to overlap with mixed anxiety-depressive disorder. Among the personality disorders, avoidant, dependent, and obsessive-compulsive personality disorders may have symptoms that resemble those of mixed anxiety-depressive disorder. A diagnosis of a somatoform disorder should also be considered. Only a psychiatric history, a mental status examination, and a working knowledge of the specific criteria can help clinicians differentiate among these conditions. The prodromal signs of schizophrenia may show itself as a mixed picture of mounting anxiety and depression with eventual onset of psychotic symptoms.

Course and Prognosis

On the basis of clinical data to date, patients seem to be equally likely to have prominent anxiety symptoms, prominent depressive symptoms, or an equal mixture of the two symptoms at onset. During the course of the illness, anxiety or depressive symptoms may alternate in their predominance. The prognosis is not known.

Treatment

Because adequate studies comparing treatment modalities for mixed anxiety-depressive disorder are not available, clinicians are probably most likely to provide treatment based on the symptoms present, their severity, and the clinician's own level of experience with various treatment modalities. Psychotherapeutic approaches may involve time-limited approaches, such as cognitive therapy or behavior modification, although some clinicians use a less structured psychotherapeutic approach, such as insight-oriented psychotherapy. Pharmacotherapy for mixed anxiety-depressive disorder can include antianxiety drugs, antidepressant drugs, or both. Among the anxiolytic drugs, some data indicate that the use of triazolobenzodiazepines (e.g., alprazolam [Xanax]) may be indicated because of their effectiveness in treating depression associated with anxiety. A drug that affects the serotonin 5-HT_{1A} receptor, such as buspirone (BuSpar), may also be indicated. Among the antidepressants, despite the noradrenergic theories linking anxiety disorders and depressive disorders, the serotonergic antidepressants may be most effective in treating mixed anxiety-depressive disorder. Venlafaxine (Effexor) is an effective antidepressant that has been approved by the FDA for the treatment of depression as well as generalized anxiety disorder and is a drug of choice in the combined disorder.

Obsessive-Compulsive and Related Disorders

10.1 Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is represented by a diverse group of symptoms that include intrusive thoughts, rituals, preoccupations, and compulsions. These recurrent obsessions or compulsions cause severe distress to the person. The obsessions or compulsions are time-consuming and interfere significantly with the person's normal routine, occupational functioning, usual social activities, or relationships. A patient with OCD may have an obsession, a compulsion, or both.

An obsession is a recurrent and intrusive thought, feeling, idea, or sensation. In contrast to an obsession, which is a mental event, a compulsion is a behavior. Specifically, a compulsion is a conscious, standardized, recurrent behavior, such as counting, checking, or avoiding. A patient with OCD realizes the irrationality of the obsession and experiences both the obsession and the compulsion as ego-dystonic (i.e., unwanted behavior).

Although the compulsive act may be carried out in an attempt to reduce the anxiety associated with the obsession, it does not always succeed in doing so. The completion of the compulsive act may not affect the anxiety, and it may even increase the anxiety. Anxiety is also increased when a person resists carrying out a compulsion. A variety of OCD conditions are described in this section and those that follow (Sections 10.2–10.5).

EPIDEMIOLOGY

The rates of OCD are fairly consistent, with a lifetime prevalence in the general population estimated at 2 to 3 percent. Some researchers have estimated that the disorder is found in as many as 10 percent of outpatients in psychiatric clinics. These figures make OCD the fourth most common psychiatric diagnosis after phobias, substance-related disorders, and major depressive disorder. Epidemiological studies in Europe, Asia, and Africa have confirmed these rates across cultural boundaries.

Among adults, men and women are equally likely to be affected, but among adolescents, boys are more commonly affected than girls. The mean age of onset is about 20 years, although men have a slightly earlier age of onset (mean about 19 years) than women (mean about 22 years). Overall, the symptoms of about two thirds of affected persons have an onset before age 25, and the symptoms of fewer than 15 percent have an onset after age 35. The onset of the disorder can occur in adolescence or childhood, in some cases as early as 2 years of age. Single persons are more frequently affected with OCD than are married persons, although this finding probably reflects the difficulty that persons with the disorder have maintaining a relationship. OCD occurs less often among blacks than among whites, although access to health care rather than differences in prevalence may explain the variation.

COMORBIDITY

Persons with OCD are commonly affected by other mental disorders. The lifetime prevalence for major depressive disorder in persons with OCD is about 67 percent and for social phobia about 25 percent. Other common comorbid psychiatric diagnoses in patients with OCD include alcohol use disorders, generalized anxiety disorder, specific phobia, panic disorder, eating disorders, and personality disorders. OCD exhibits a superficial resemblance to obsessive-compulsive personality disorder, which is associated with an obsessive concern for details, perfectionism, and other similar personality traits. The incidence of Tourette's disorder in patients with OCD is 5 to 7 percent, and 20 to 30 percent of patients with OCD have a history of tics.

ETIOLOGY

Biological Factors

Neurotransmitters

SEROTONERGIC SYSTEM. The many clinical drug trials that have been conducted support the hypothesis that dysregulation of serotonin is involved in the symptom formation of obsessions and compulsions in the disorder. Data show that serotonergic drugs are more effective in treating OCD than drugs that affect other neurotransmitter systems, but whether serotonin is involved in the cause of OCD is not clear. Clinical studies have assayed cerebrospinal fluid (CSF) concentrations of serotonin metabolites (e.g., 5-hydroxyindoleacetic acid [5-HIAA]) and affinities and numbers of platelet-binding sites of tritiated imipramine (Tofranil), which binds to serotonin reuptake sites, and have reported variable findings of these measures in patients with OCD. In one study, the CSF concentration of 5-HIAA decreased after treatment with clomipramine (Anafranil), focusing attention on the serotonergic system.

NORADRENERGIC SYSTEM. Currently, less evidence exists for dysfunction in the noradrenergic system in OCD. Anecdotal reports show some improvement in OCD symptoms with use of oral clonidine (Catapres), a drug that lowers the amount of norepinephrine released from the presynaptic nerve terminals.

NEUROIMMUNOLOGY. Some interest exists in a positive link between streptococcal infection and OCD. Group A β -hemolytic streptococcal infection can cause rheumatic fever, and approximately 10 to 30 percent of the patients develop Sydenham's chorea and show obsessive-compulsive symptoms.

Brain-Imaging Studies. Neuroimaging in patients with OCD has produced converging data implicating altered function in the neurocircuitry between orbitofrontal cortex, caudate, and thalamus. Various functional brain-imaging studies—for example, positron emission tomography (PET)—have shown increased activity (e.g., metabolism and blood flow) in the frontal lobes, the basal ganglia (especially the caudate), and the cingulum of patients with OCD. The involvement of these areas in the pathology of OCD appears more associated with corticostriatal pathways than with the amygdala pathways, which are the current focus of much anxiety disorder research. Pharmacological and behavioral treatments reportedly reverse these abnormalities (Fig. 10.1-1). Data from functional brain-imaging studies are consistent with data from structural brain-imaging studies. Both computed tomographic (CT) and magnetic resonance imaging (MRI) studies have found bilaterally smaller caudates in patients with OCD. Both functional and structural brain-imaging study results are also compatible with the observation that neurological procedures involving the cingulum are sometimes effective in the treatment of OCD. One recent MRI study reported increased T1 relaxation times in the frontal cortex, a finding consistent with the location of abnormalities discovered in PET studies.

FIGURE 10.1-1

Brain regions implicated in the pathophysiology of obsessive-compulsive disorder. (From Rosenberg DR, MacMillan SN, Moore GJ. Brain anatomy and chemistry may predict treatment response in paediatric obsessive-compulsive disorder. *In J Neuropsychopharmacol.* 2001; 4:179, with permission.)

Genetics. Available genetic data on OCD support the hypothesis that the disorder has a significant genetic component. Relatives of probands with OCD consistently have a threefold to fivefold higher probability of having OCD or obsessive-compulsive features than families of control probands. The data, however, do not yet distinguish the heritable factors from the influence of cultural and behavioral effects on the transmission of the disorder. Studies of concordance for the disorder in twins have consistently found a significantly higher concordance rate for monozygotic twins than for dizygotic twins. Some studies also demonstrate increased rates of a variety of conditions among relatives of OCD probands, including generalized anxiety disorder, tic disorders, body dysmorphic disorder, hypochondriasis, eating disorders, and habits such as nail-biting.

Other Biological Data. Electrophysiological studies, sleep electroencephalogram (EEG) studies, and neuroendocrine studies have contributed data that indicate some commonalities between depressive disorders and OCD. A higher than usual incidence of nonspecific EEG abnormalities occurs in patients with OCD. Sleep EEG studies have found abnormalities similar to those in depressive disorders, such as decreased rapid eye movement latency. Neuroendocrine studies have also produced some analogies to depressive disorders, such as nonsuppression on the dexamethasone-suppression test in about one-third of patients and decreased growth hormone secretion with clonidine infusions.

As mentioned, studies have suggested a possible link between a subset of OCD cases and certain types of motor tic syndromes (i.e., Tourette's disorder and chronic motor tics). A higher rate of OCD, Tourette's disorder, and chronic motor tics are found in relatives of patients with Tourette's disorder than in relatives of controls, whether or not they had OCD. Most family studies of probands with OCD have found increased rates of Tourette's disorder and chronic motor tics only among the relatives of probands with OCD who also have some form of tic disorder. Evidence also suggests cotransmission of Tourette's disorder, OCD, and chronic motor tics within families.

Behavioral Factors

According to learning theorists, obsessions are conditioned stimuli. A relatively neutral stimulus becomes associated with fear or anxiety through a process of respondent conditioning by being paired with events that are noxious or anxiety producing. Thus, previously neutral objects and thoughts become conditioned stimuli capable of provoking anxiety or discomfort.

Compulsions are established in a different way. When a person discovers that a certain action reduces anxiety attached to an obsessional thought, he or she develops active avoidance strategies in the form of compulsions or ritualistic behaviors to control the anxiety. Gradually, because of their efficacy in reducing a painful secondary drive (anxiety), the avoidance strategies become fixed as learned patterns of compulsive behaviors. Learning theory provides useful concepts for explaining certain aspects of obsessive-compulsive phenomena—for example, the anxiety-provoking capacity of ideas not necessarily frightening in themselves and the establishment of compulsive patterns of behavior.

Psychosocial Factors

Personality Factors. OCD differs from obsessive-compulsive personality disorder, which is associated with an obsessive concern for details, perfectionism, and other similar personality traits. Most persons with OCD do not have premorbid compulsive symptoms, and such personality traits are neither necessary nor sufficient for the development of OCD. Only about 15 to 35 percent of patients with OCD have had premorbid obsessional traits.

Psychodynamic Factors. Psychodynamic insight may be of great help in understanding problems with treatment compliance, interpersonal difficulties, and personality problems accompanying the Axis I disorder. Many patients with OCD may refuse to cooperate

with effective treatments such as selective serotonin reuptake inhibitors (SSRIs) and behavior therapy. Even though the symptoms of OCD may be biologically driven, psychodynamic meanings may be attached to them. Patients may become invested in maintaining the symptomatology because of secondary gains. For example, a male patient, whose mother stays home to take care of him, may unconsciously wish to hang on to his OCD symptoms because they keep the attention of his mother.

Another contribution of psychodynamic understanding involves the interpersonal dimensions. Studies have shown that relatives will accommodate the patient through active participation in rituals or significant modifications of their daily routines. This form of family accommodation is correlated with stress in the family, rejecting attitudes toward the patient, and poor family functioning. Often, the family members are involved in an effort to reduce the patient's anxiety or to control the patient's expressions of anger. This pattern of relatedness may become internalized and be re-created when the patient enters a treatment setting. By looking at recurring patterns of interpersonal relationships from a psychodynamic perspective, patients may learn how their illness affects others.

Finally, one other contribution of psychodynamic thinking is recognition of the precipitants that initiate or exacerbate symptoms. Often, interpersonal difficulties increase the patient's anxiety and, thus, increase the patient's symptomatology as well. Research suggests that OCD may be precipitated by a number of environmental stressors, especially those involving pregnancy, childbirth, or parental care of children. An understanding of the stressors may assist the clinician in an overall treatment plan that reduces the stressful events themselves or their meaning to the patient.

SIGMUND FREUD. In classic psychoanalytic theory, OCD was termed *obsessive-compulsive neurosis* and was considered a regression from the oedipal phase to the anal psychosexual phase of development. When patients with OCD feel threatened by anxiety about retaliation for unconscious impulses or by the loss of a significant object's love, they retreat from the oedipal position and regress to an intensely ambivalent emotional stage associated with the anal phase. The ambivalence is connected to the unraveling of the smooth fusion between sexual and aggressive drives characteristic of the oedipal phase. The coexistence of hatred and love toward the same person leaves patients paralyzed with doubt and indecision.

An example of how Freud viewed OCD symptoms is described by Otto Fenichel in the case study presented here.

A patient, who was not analyzed, complained in the first interview that he suffered from the compulsion to look backward constantly, from fear that he might have overlooked something important behind him. These ideas were predominant; he might overlook a coin lying on the ground; he might have injured an insect by stepping on it; or an insect might have fallen on its back and need his help. The patient was also afraid of touching anything, and whenever he had touched an object he had to convince himself that he had not destroyed it. He had no vocation because the severe compulsions disturbed all his working activity; however, he had one passion: housecleaning. He liked to visit his neighbors and clean their houses, just for fun. Another symptom was described by the patient as his "clothes consciousness"; he was constantly preoccupied with the question whether or not his suit fitted. He, too, stated that sexuality did not play an important part in his life. He had sexual intercourse two or three times a year only, and exclusively with girls in whom he had no personal interest. Later on, he mentioned another symptom. As a child, he had felt his mother to be disgusting and had been terribly afraid of touching her. There was no real reason whatsoever for such a disgust, for the mother had been a nice person.

In the clinical picture for this case study, Freud believed the need to be clean and not to touch is related to anal sexuality, and the disgust for the mother is a reaction against incestuous fears.

One of the striking features of patients with OCD is the degree to which they are preoccupied with aggression or cleanliness, either overtly in the content of their symptoms or in the associations that lie behind them. The psychogenesis of OCD, therefore, may lie in disturbances in normal growth and development related to the anal-sadistic phase of development.

Ambivalence. Ambivalence is an important feature of normal children during the anal-sadistic developmental phase; children feel both love and murderous hate toward the same object, sometimes simultaneously. Patients with OCD often consciously experience both love and hate toward an object. This conflict of opposing emotions is evident in a patient's doing and undoing patterns of behavior and in paralyzing doubt in the face of choices.

Magical Thinking. In magical thinking, regression uncovers early modes of thought rather than impulses; that is, ego functions as well as id functions are affected by regression. Inherent in magical thinking is omnipotence of thought. Persons believe that merely by thinking about an event in the external world they can cause the event to occur without intermediate physical actions. This feeling causes them to fear having an aggressive thought (Fig. 10.1-2).

FIGURE 10.1-2

In magical thinking, one believes that the thought is equal to the deed, that wishing a person dead will make it happen, as symbolized in this illustration. (Courtesy of Arthur Tress.)

DIAGNOSIS AND CLINICAL FEATURES

As part of the diagnostic criteria for OCD, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) allows clinicians to indicate whether the patient's OCD is characterized by good or fair insight, poor insight, or absent insight (Table 10.1-1). Patients with good or fair insight recognize that their OCD beliefs are definitely or probably not true or may or may not be true. Patients with poor insight believe their OCD beliefs are probably true, and patients with absent insight are convinced that their beliefs are true.

 **Table 10.1-1**
DSM-5 Diagnostic Criteria for Obsessive-Compulsive Disorder

- A. Presence of obsessions, compulsions, or both:
Obsessions are defined by (1) and (2):
1. Recurrent and persistent thoughts, urges, or images that are experienced, at some time during the disturbance, as intrusive and unwanted, and that in most individuals cause marked anxiety or distress.
 2. The individual attempts to ignore or suppress such thoughts, urges, or images, or to neutralize them with some other thought or action (i.e., by performing a compulsion).
- Compulsions are defined by (1) and (2):
1. Repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the individual feels driven to perform in response to an obsession or according to rules that must be applied rigidly.
 2. The behaviors or mental acts are aimed at preventing or reducing anxiety or distress, or preventing some dreaded event or situation; however, these behaviors or mental acts are not connected in a realistic way with what they are designed to neutralize or prevent, or are clearly excessive.
- Note:** Young children may not be able to articulate the aims of these behaviors or mental acts.
- B. The obsessions or compulsions are time-consuming (e.g., take more than 1 hour per day) or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The obsessive-compulsive symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- D. The disturbance is not better explained by the symptoms of another mental disorder (e.g., excessive worries, as in generalized anxiety disorder; preoccupation with appearance, as in body dysmorphic disorder; difficulty discarding or parting with possessions, as in hoarding disorder; hair pulling, as in trichotillomania [hair-pulling disorder]; skin-picking, as in excoriation [skin-picking] disorder; stereotypies, as in stereotypic movement disorder; ritualized eating behavior, as in eating disorders; preoccupation with substances or gambling, as in substance-related and addictive disorders; preoccupation with having an illness, as in illness anxiety disorder; sexual urges or fantasies, as in paraphilic disorders; impulses, as in disruptive, impulse-control, and conduct disorders; guilty ruminations, as in major depressive disorder; thought insertion or delusional preoccupations, as in schizophrenia spectrum and other psychotic disorders; or repetitive patterns of behavior, as in autism spectrum disorder).
- Specify if:**
- With good or fair insight:** The individual recognizes that obsessive-compulsive disorder beliefs are definitely or probably not true or that they may not be true.
- With poor insight:** The individual thinks obsessive-compulsive disorder beliefs are probably true.
- With absent insight/delusional beliefs:** The individual is completely convinced that obsessive-compulsive disorder beliefs are true.
- Specify if:**
- Tic-related:** The individual has a current or past history of a tic disorder.

Patients with OCD often take their complaints to physicians rather than psychiatrists (Table 10.1-2). Most patients with OCD have both obsessions and compulsions—up to 75 percent in some surveys. Some researchers and clinicians believe that the number may be much closer to 100 percent if patients are carefully assessed for the presence of mental compulsions in addition to behavioral compulsions. For example, an obsession about hurting a child may be followed by a mental compulsion to repeat a specific prayer a specific number of times. Other researchers and clinicians, however, believe that some patients do have only obsessive thoughts without compulsions. Such patients are likely to have repetitious thoughts of a sexual or aggressive act that is reprehensible to them. For clarity, it is best to conceptualize obsessions as thoughts and compulsions as behavior.

 **Table 10.1-2**
Nonpsychiatric Clinical Specialists Likely to See Obsessive-Compulsive Disorder Patients

Specialist	Presenting Problem
Dermatologist	Chapped hands, eczematoid appearance
Family practitioner	Family member washing excessively, may mention counting or checking compulsions
Oncologist, infectious disease internist	Insistent belief that person has acquired immune deficiency syndrome
Neurologist	Obsessive-compulsive disorder associated with Tourette's disorder, head injury, epilepsy, choreas, other basal ganglia lesions or disorders
Neurosurgeon	Severe, intractable obsessive-compulsive disorder
Obstetrician	Postpartum obsessive-compulsive disorder
Pediatrician	Parent's concern about child's behavior, usually excessive washing
Pediatric cardiologist	Obsessive-compulsive disorder secondary to Sydenham's chorea
Plastic surgeon	Repeated consultations for "abnormal" features
Dentist	Gum lesions from excessive teeth cleaning

(From Rapoport JL. The neurobiology of obsessive-compulsive disorder. *JAMA*. 1988;260:2889, with permission.)

Obsessions and compulsions are the essential features of OCD. An idea or an impulse intrudes itself insistently and persistently into a person's conscious awareness. Typical obsessions associated with OCD include thoughts about contamination ("My hands are dirty") or doubts ("I forgot to turn off the stove").

A feeling of anxious dread accompanies the central manifestation, and the key characteristic of a compulsion is that it reduces the anxiety associated with the obsession. The obsession or the compulsion is ego-alien; that is, it is experienced as foreign to the person's experience of himself or herself as a psychological being. No matter how vivid and compelling the obsession or compulsion, the person usually recognizes it as absurd and irrational. The person suffering from obsessions and compulsions usually feels a strong desire to resist them. Nevertheless, about half of all patients offer little resistance to compulsions, although about 80 percent of all patients believe that the compulsion is irrational. Sometimes, patients overvalue obsessions and compulsions—for example, they may insist that compulsive cleanliness is morally correct, even though they have lost their jobs because of time spent cleaning.

Symptom Patterns

The presentation of obsessions and compulsions is heterogeneous in adults (Table 10.1-3) and in children and adolescents (Table 10.1-4). The symptoms of an individual patient can overlap and change with time, but OCD has four major symptom patterns.

Table 10.1-3
Obsessive-Compulsive Symptoms in Adults

Variable	%
Obsessions (<i>N</i> = 200)	
Contamination	45
Pathological doubt	42
Somatic	36
Need for symmetry	31
Aggressive	28
Sexual	26

 **Table 10.1-4**
Reported Obsessions and Compulsions for 70 Consecutive Child and Adolescent Patients

Major Presenting Symptom	No. (%) Reporting Symptom at Initial Interview ^a
Obsession	
Concern or disgust with bodily wastes or secretions (urine, stool, saliva), dirt, germs, environmental toxins	30 (43)
Fear something terrible may happen (fire, death or illness of loved one, self, or others)	18 (24)
Concern or need for symmetry, order, or exactness	12 (17)
Scrupulosity (excessive praying or religious concerns out of keeping with patient's background)	9 (13)
Lucky and unlucky numbers	6 (8)
Forbidden or perverse sexual thoughts, images, or impulses	3 (4)
Intrusive nonsense sounds, words, or music	1 (1)
Compulsion	
Excessive or ritualized hand washing, showering, bathing, tooth brushing, or grooming	60 (85)
Repeating rituals (e.g., going in and out of door, up and down from chair)	36 (51)
Checking doors, locks, stove, appliances, car brakes	32 (46)
Cleaning and other rituals to remove contact with contaminants	16 (23)
Touching	14 (20)
Ordering and arranging	12 (17)
Measures to prevent harm to self or others (e.g., hanging clothes a certain way)	11 (16)
Counting	13 (18)
Hoarding and collecting	8 (11)
Miscellaneous rituals (e.g., licking, spitting, special dress pattern)	18 (26)

^aMultiple symptoms recorded, so total exceeds 70.
(From Rapoport JL. The neurobiology of obsessive-compulsive disorder. *JAMA*. 1988;260:2889, with permission.)

Contamination. The most common pattern is an obsession of contamination, followed by washing or accompanied by compulsive avoidance of the presumably contaminated object. The feared object is often hard to avoid (e.g., feces, urine, dust, or germs). Patients may literally rub the skin off their hands by excessive hand washing or may be unable to leave their homes because of fear of germs. Although anxiety is the most common emotional response to the feared object, obsessive shame and disgust are also common. Patients with contamination obsessions usually believe that the contamination is spread from object to object or person to person by the slightest contact.

Pathological Doubt. The second most common pattern is an obsession of doubt, followed by a compulsion of checking. The obsession often implies some danger of violence (e.g., forgetting to turn off the stove or not locking a door). The checking may involve multiple trips back into the house to check the stove, for example. These patients have an obsessional self-doubt and always feel guilty about having forgotten or committed something.

Intrusive Thoughts. In the third most common pattern, there are intrusive obsessional thoughts without a compulsion. Such obsessions are usually repetitious thoughts of a sexual or aggressive act that is reprehensible to the patient. Patients obsessed with thoughts of aggressive or sexual acts may report themselves to police or confess to a priest. Suicidal ideation may also be obsessive; but a careful suicidal assessment of actual risk must always be done.

Symmetry. The fourth most common pattern is the need for symmetry or precision, which can lead to a compulsion of slowness. Patients can literally take hours to eat a meal or shave their faces.

Other Symptom Patterns. Religious obsessions and compulsive hoarding are common in patients with OCD. Compulsive hair pulling and nail biting are behavioral patterns related to OCD. Masturbation may also be compulsive.

Mental Status Examination

On mental status examinations, patients with OCD may show symptoms of depressive disorders. Such symptoms are present in about 50 percent of all patients. Some patients with OCD have character traits suggesting obsessive-compulsive personality disorder (e.g., excessive need for preciseness and neatness), but most do not. Patients with OCD, especially men, have a higher than average celibacy rate. Married patients have a greater than usual amount of marital discord.

Ms. K was referred for psychiatric evaluation by her general practitioner. On interview, Ms. K described a long history of checking rituals that had caused her to lose several jobs and had damaged numerous relationships. She reported, for example, that because she often had the thought that she had not locked the door to the car, it was difficult for her to leave that car until she had checked repeatedly that it was secure. She had broken several car door handles with the vigor of her checking and had been up to an hour late to

work because she spent so much time checking her car door. Similarly, she had recurrent thoughts that she had left the door to her apartment unlocked, and she returned several times daily to check her door before she left for work. She reported that checking doors decreased her anxiety about security. Although Ms. K reported that she had occasionally tried to leave her car or apartment without checking the door (e.g., when she was already late for work), she found that she became so worried about her car being stolen or her apartment being broken into that she had difficulty going anywhere. Ms. K reported that her obsessions about security had become so extreme over the past 3 months that she had lost her job due to recurrent tardiness. She recognized the irrational nature of her obsessive concerns but could not bring herself to ignore them. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

DIFFERENTIAL DIAGNOSIS

Medical Conditions

A number of primary medical disorders can produce syndromes bearing a striking resemblance to OCD. The current conceptualization of OCD as a disorder of the basal ganglia derives from the phenomenological similarity between idiopathic OCD and OCD-like disorders that are associated with basal ganglia diseases, such as Sydenham's chorea and Huntington's disease. Neurological signs of such basal ganglia pathology must be assessed when considering the diagnosis of OCD in a patient presenting for psychiatric treatment. It should also be noted that OCD frequently develops before age 30 years, and new-onset OCD in an older individual should raise questions about potential neurological contributions to the disorder.

Tourette's Disorder

OCD is closely related to Tourette's disorder, as the two conditions frequently co-occur, both in individuals over time and within families. About 90 percent of persons with Tourette's disorder have compulsive symptoms, and as many as two thirds meet the diagnostic criteria for OCD.

In its classic form, Tourette's disorder is associated with a pattern of recurrent vocal and motor tics that bears only a slight resemblance to OCD. The premonitory urges that precede tics often strikingly resemble obsessions, however, and many of the more complicated motor tics are very similar to compulsions.

Other Psychiatric Conditions

Obsessive-compulsive behavior is found in a host of other psychiatric disorders, and the clinician must also rule out these conditions when diagnosing OCD. OCD exhibits a superficial resemblance to obsessive-compulsive personality disorder, which is associated with an obsessive concern for details, perfectionism, and other similar personality traits. The conditions are easily distinguished in that only OCD is associated with a true syndrome of obsessions and compulsions.

Psychotic symptoms often lead to obsessive thoughts and compulsive behaviors that can be difficult to distinguish from OCD with poor insight, in which obsessions border on psychosis. The keys to distinguishing OCD from psychosis are (1) patients with OCD can almost always acknowledge the unreasonable nature of their symptoms, and (2) psychotic illnesses are typically associated with a host of other features that are not characteristic of OCD. Similarly, OCD can be difficult to differentiate from depression because the two disorders often occur comorbidly, and major depression is often associated with obsessive thoughts that, at times, border on true obsessions such as those that characterize OCD. The two conditions are best distinguished by their courses. Obsessive symptoms associated with depression are only found in the presence of a depressive episode, whereas true OCD persists despite remission of depression.

COURSE AND PROGNOSIS

More than half of patients with OCD have a sudden onset of symptoms. The onset of symptoms for about 50 to 70 percent of patients occurs after a stressful event, such as a pregnancy, a sexual problem, or the death of a relative. Because many persons manage to keep their symptoms secret, they often delay 5 to 10 years before coming to psychiatric attention, although the delay is probably shortening with increased awareness of the disorder. The course is usually long but variable; some patients experience a fluctuating course, and others experience a constant one.

About 20 to 30 percent of patients have significant improvement in their symptoms, and 40 to 50 percent have moderate improvement. The remaining 20 to 40 percent of patients either remain ill or their symptoms worsen.

About one-third of patients with OCD have major depressive disorder, and suicide is a risk for all patients with OCD. A poor prognosis is indicated by yielding to (rather than resisting) compulsions, childhood onset, bizarre compulsions, the need for hospitalization, a coexisting major depressive disorder, delusional beliefs, the presence of overvalued ideas (i.e., some acceptance of obsessions and compulsions), and the presence of a personality disorder (especially schizotypal personality disorder). A good prognosis is indicated by good social and occupational adjustment, the presence of a precipitating event, and an episodic nature of the symptoms. The obsessional content does not seem to be related to the prognosis.

TREATMENT

With mounting evidence that OCD is largely determined by biological factors, classic psychoanalytic theory has fallen out of favor. Moreover, because OCD symptoms appear to be largely refractory to psychodynamic psychotherapy and psychoanalysis, pharmacological and behavioral treatments have become common. But psychodynamic factors may be of considerable benefit in understanding what precipitates exacerbations of the disorder and in treating various forms of resistance to treatment, such as noncompliance with medication.

Many patients with OCD tenaciously resist treatment efforts. They may refuse to take medication and may resist carrying out therapeutic homework assignments and other activities prescribed by behavior therapists. The obsessive-compulsive symptoms themselves, no matter how biologically based, may have important psychological meanings that make patients reluctant to give them up. Psychodynamic exploration of a patient's resistance to treatment may improve compliance.

Well-controlled studies have found that pharmacotherapy, behavior therapy, or a combination of both is effective in significantly reducing the symptoms of patients with OCD. The decision about which therapy to use is based on the clinician's judgment and experience and the patient's acceptance of the various modalities.

Pharmacotherapy

The efficacy of pharmacotherapy in OCD has been proved in many clinical trials and is enhanced by the observation that the studies find a placebo response rate of only about 5 percent.

The drugs, some of which are used to treat depressive disorders or other mental disorders, can be given in their usual dosage ranges. Initial effects are generally seen after 4 to 6 weeks of treatment, although 8 to 16 weeks are usually needed to obtain maximal therapeutic benefit. Treatment with antidepressant drugs is still controversial, and a significant proportion of patients with OCD who respond to treatment with antidepressant drugs seem to relapse if the drug therapy is discontinued.

The standard approach is to start treatment with an SSRI or clomipramine and then move to other pharmacological strategies if the

serotonin-specific drugs are not effective. The serotonergic drugs have increased the percentage of patients with OCD who are likely to respond to treatment to the range of 50 to 70 percent.

Selective Serotonin Reuptake Inhibitors. Each of the SSRIs available in the United States—fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), sertraline (Zoloft), citalopram (Celexa)—has been approved by the US Food and Drug Administration (FDA) for the treatment of OCD. Higher dosages have often been necessary for a beneficial effect, such as 80 mg a day of fluoxetine. Although the SSRIs can cause sleep disturbance, nausea and diarrhea, headache, anxiety, and restlessness, these adverse effects are often transient and are generally less troubling than the adverse effects associated with tricyclic drugs, such as clomipramine. The best clinical outcomes occur when SSRIs are used in combination with behavioral therapy.

Clomipramine. Of all the tricyclic and tetracyclic drugs, clomipramine is the most selective for serotonin reuptake versus norepinephrine reuptake and is exceeded in this respect only by the SSRIs. The potency of serotonin reuptake of clomipramine is exceeded only by sertraline and paroxetine. Clomipramine was the first drug to be FDA approved for the treatment of OCD. Its dosing must be titrated upward over 2 to 3 weeks to avoid gastrointestinal adverse effects and orthostatic hypotension, and as with other tricyclic drugs, it causes significant sedation and anticholinergic effects, including dry mouth and constipation. As with SSRIs, the best outcomes result from a combination of drug and behavioral therapy.

Other Drugs. If treatment with clomipramine or an SSRI is unsuccessful, many therapists augment the first drug by the addition of valproate (Depakene), lithium (Eskalith), or carbamazepine (Tegretol). Other drugs that can be tried in the treatment of OCD are venlafaxine (Effexor), pindolol (Visken), and the monoamine oxidase inhibitors (MAOIs), especially phenelzine (Nardil). Other pharmacological agents for the treatment of unresponsive patients include buspirone (BuSpar), 5-hydroxytryptamine (5-HT), L-tryptophan, and clonazepam (Klonopin). Adding an atypical antipsychotic such as risperidone (Risperdal) has helped in some cases.

Behavior Therapy

Although few head-to-head comparisons have been made, behavior therapy is as effective as pharmacotherapies in OCD, and some data indicate that the beneficial effects are longer lasting with behavior therapy. Many clinicians, therefore, consider behavior therapy the treatment of choice for OCD. Behavior therapy can be conducted in both outpatient and inpatient settings. The principal behavioral approaches in OCD are exposure and response prevention. Desensitization, thought stopping, flooding, implosion therapy, and aversive conditioning have also been used in patients with OCD. In behavior therapy, patients must be truly committed to improvement.

Psychotherapy

In the absence of adequate studies of insight-oriented psychotherapy for OCD, any valid generalizations about its effectiveness are hard to make, although there are anecdotal reports of successes. Individual analysts have seen striking and lasting changes for the better in patients with obsessive-compulsive personality disorder, especially when they are able to come to terms with the aggressive impulses underlying their character traits. Likewise, analysts and dynamically oriented psychiatrists have observed marked symptomatic improvement in patients with OCD in the course of analysis or prolonged insight psychotherapy.

Mr. P, a passive, emotionally vacant, exceedingly polite and quiet man in his 30s, had obsessive-compulsive disorder and sought psychodynamic psychotherapy because he was having difficulty functioning at work or in relationships. Mr. P had counting rituals and a compulsion to keep checking that there were no sharp knives left with their blades exposed and no shoes not properly hung on shoetrees or aligned in closets. In sessions he often spoke endlessly about seemingly empty details of his work life. The therapist became drowsy at one point as he listened to Mr. P, who noticed this and, with uncharacteristic affect in his voice, asked, "Doctor, excuse me, but are you listening?" To this the therapist replied, "No, I guess not. Are you?" Mr. P apologized for having been boring.

This incident led to a direct discussion between them about the way Mr. P's obsessive, circumstantial, and emotionally empty recounting of details was a form of resistance and one in which his therapist had joined him by becoming drowsy in the session. Were they going to do the work of therapy together or not?

In subsequent sessions Mr. P made efforts to speak more about the origin of his symptoms, which began with a ritual of kissing his parents each goodnight nine times lest he be unable to sleep. On one occasion, while explaining this, Mr. P made a slip of speech about having to kiss his father nine times, instead substituting the word "kick" for "kiss." When he heard this, the therapist asked Mr. P if he had noticed the slip. Mr. P insisted he could not have made such a mistake, escalated his protests about this for a minute or two as he became sadder, then burst into sobs. While weeping Mr. P accused the therapist of pretending there had been a slip of speech to make him look bad, and then, with an outburst of anger, recalled the hurt and injury he had felt when the therapist had become drowsy in the session.

Surprised at the intensity of his feelings, Mr. P recalled when his need to kiss his parents goodnight in a ritualized way had begun. It was after he had gotten a new puppy. His controlling and intrusive father had kicked Mr. P's beloved new puppy after the latter had a series of toileting accidents in the house. Mr. P wept as he recalled his revulsion and rage at his father and the way he had later comforted his dog when alone. Mr. P recalled having repeatedly unfolded and refolded the blade of his jackknife to show his dog his weapon and swore to his dog that he would use it on his father if the latter ever tried to hurt him again. Soon after the kicking incident Mr. P's father decided he had had enough of this messy puppy and sent the dog away while Mr. P was at school. Mr. P was bereft for a while, but soon settled into an affectless, timid, and passive way of being.

Mr. P responded to what he had learned about his compulsions by actively trying to suppress them and became more anxious. As his anxiety was explored, memories emerged of Mr. P's earlier struggle with his parents around toileting before the puppy came into his life, when he had received regular enemas from his father to control the frequency of bowel movements. Despite loving his father, Mr. P was also enraged at him for taking his dog away without a chance to say goodbye and for the intrusive and terrifying experience of the enemas, while he was also furious at his mother for not stopping his father. Mr. P also felt humiliated that he had experienced this kind of intrusion into his body and that he had let his dog be given away by his father after swearing that he would protect the puppy from his father.

The meaning of Mr. P's specific rituals about knives and shoes became apparent in the course of his therapy as a result of his reaction to his therapist's lapse in becoming drowsy and a slip of speech that revealed aggression hidden beneath passivity and compliance. Mr. P needed to be sure that no knife blades were exposed because such blades represented the threat of a terrifying assault on his father or an equally terrifying failure to protect the puppy that he loved but lost. Similarly, Mr. P's compulsive need to put shoes properly and safely on shoetrees was linked to an effort to put away the memory of and prevent any recurrence of his beloved puppy being kicked and injured by a shod foot. After these were clarified and Mr. P tried to control his rituals, signal anxiety emerged, and with it the recovery of memories of an earlier struggle with his parents about intrusive control of his toileting behavior. (Courtesy of E. M. Plakun, M.D.)

Supportive psychotherapy undoubtedly has its place, especially for those patients with OCD who, despite symptoms of varying degrees of severity, are able to work and make social adjustments. With continuous and regular contact with an interested, sympathetic, and

encouraging professional person, patients may be able to function by virtue of this help, without which their symptoms would incapacitate them. Occasionally, when obsessional rituals and anxiety reach an intolerable intensity, it is necessary to hospitalize patients until the shelter of an institution and the removal from external environmental stresses diminish symptoms to a tolerable level.

A patient's family members are often driven to the verge of despair by the patient's behavior. Any psychotherapeutic endeavors must include attention to the family members through provision of emotional support, reassurance, explanation, and advice on how to manage and respond to the patient.

Other Therapies

Family therapy is often useful in supporting the family, helping reduce marital discord resulting from the disorder, and building a treatment alliance with the family members for the good of the patient. Group therapy is useful as a support system for some patients.

For extreme cases that are treatment resistant and chronically debilitating, electroconvulsive therapy (ECT) and psychosurgery are considerations. ECT should be tried before surgery. A psychosurgical procedure for OCD is cingulotomy, which may be successful in treating otherwise severe and treatment-unresponsive patients. Other surgical procedures (e.g., subcaudate tractotomy, also known as *capsulotomy*) have also been used for this purpose.

Deep Brain Stimulation (DBS)

Nonablative surgical techniques involving indwelling electrodes in various basal ganglia nuclei are under investigation to treat both OCD and Tourette's disorder. DBS is performed using MRI-guided stereotactic techniques in which electrodes are implanted in the brain. Complications of DBS include infection, bleeding, or the development of seizures, which are almost always controlled by treatment with phenytoin (Dilantin). Some patients who do not respond to psychosurgery alone and who do not respond to pharmacotherapy or behavior therapy before the operation do respond to pharmacotherapy or behavior therapy after psychosurgery.

OBSESSIVE-COMPULSIVE OR RELATED DISORDER DUE TO ANOTHER MEDICAL CONDITION

Many medical condition can result in obsessive-compulsive symptoms (i.e., hair pulling, skin-picking). The diagnosis of obsessive-compulsive or related disorder attributable to another medical condition is used when obsessive-compulsive symptoms develop in the context of an identifiable medical condition.

OCD-like symptoms have been reported in children following group A β -hemolytic streptococcal infection and have been called *pediatric autoimmune neuropsychiatric disorders associated with streptococcus* (PANDAS). They are believed to result from an autoimmune process that leads to inflammation of the basal ganglia that disrupts cortical-striatal-thalamic axis functioning. For more information, see [Section 31.14](#) OCD in childhood and adolescence.

SUBSTANCE-INDUCED OBSESSIVE-COMPULSIVE OR RELATED DISORDER

Substance-induced obsessive-compulsive or related disorder is characterized by the emergence of obsessive-compulsive or related symptoms as a result of a substance, including drugs, medications, and alcohol. Symptoms present either during use or within a month after substance use, intoxication, or withdrawal. The symptoms cannot be better accounted for by a specific obsessive-compulsive or related disorder or another medical condition. The disturbance cannot occur exclusively during the course of delirium.

OTHER SPECIFIED OBSESSIVE-COMPULSIVE OR RELATED DISORDER

This category is for patients who have symptoms characteristic of obsessive-compulsive and related disorder but do not meet the full criteria for any specific obsessive-compulsive or related disorder. This diagnosis is appropriate under three situations: (1) an atypical presentation, (2) another specific syndrome not listed in DSM-5, and (3) the information presented is insufficient to make a full diagnosis of a obsessive-compulsive or related disorder.

Olfactory Reference Syndrome

Olfactory reference syndrome is characterized by a false belief by the patient that he or she has a foul body odor that is not perceived by others. The preoccupation leads to repetitive behaviors such as washing the body or changing clothes. The patient may have good, fair, poor, or absent insight into the behavior. The syndrome is predominant in males and single status. The mean age of onset is 25 years of age. The belief of a subjective sense of smell that does not exist externally may rise to the level of a somatic delusion, in which case a diagnosis of delusional disorder should be considered. The syndrome has been well documented in the psychiatric literature, usually classified as a delusion of perception. Whether or not it deserves a special diagnostic category is open to question.

In assessing a patient with olfactory reference syndrome, it is important to exclude somatic causes. Some patients with temporal lobe epilepsy may complain of smelling foul odors. Local irritations of the hippocampus from pituitary tumors may also cause olfactory sensations. Patients with inflammation of the frontal, ethmoidal, or sphenoidal sinuses may also have a subjective sense of offensive odors. Olfactory reference syndrome is included in the "other specified" designation for obsessive-compulsive and related disorder of DSM-5.

10.2 Body Dysmorphic Disorder

Body dysmorphic disorder is characterized by a preoccupation with an imagined defect in appearance that causes clinically significant distress or impairment in important areas of functioning. If a slight physical anomaly is actually present, the person's concern with the anomaly is excessive and bothersome.

The disorder was recognized and named *dysmorphophobia* more than 100 years ago by Emil Kraepelin, who considered it a compulsive neurosis; Pierre Janet called it *obsession de la honte du corps* (obsession with shame of the body). Freud wrote about the condition in his description of the Wolf-Man, who was excessively concerned about his nose. Although dysmorphophobia was widely recognized and studied in Europe, it was not until the publication of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) in 1980 that dysmorphophobia, as an example of a typical somatoform disorder, was specifically mentioned in the US diagnostic criteria. In the fourth text revision of DSM (DSM-IV-TR), the condition was known as body dysmorphic disorder, because the DSM editors believed that the term *dysmorphophobia* inaccurately implied the presence of a behavioral pattern of phobic avoidance. In the fifth edition of DSM (DSM-5), body dysmorphic disorder is included in the obsessive-compulsive spectrum disorders due to its similarities to obsessive-compulsive disorder (OCD).

EPIDEMIOLOGY

Body dysmorphic disorder is a poorly studied condition, partly because patients are more likely to go to dermatologists, internists, or plastic surgeons than to psychiatrists for this condition. One study of a group of college students found that more than 50 percent had at least some preoccupation with a particular aspect of their appearance, and in about 25 percent of the students, the concern had at least some significant effect on their feelings and functioning. DSM-5 reports a point prevalence in the United States of 2.4 percent.

Available data indicate that the most common age of onset is between 15 and 30 years and that women are affected somewhat more often than men. Affected patients are also likely to be unmarried. Body dysmorphic disorder commonly coexists with other mental disorders. One study found that more than 90 percent of patients with body dysmorphic disorder had experienced a major depressive episode in their lifetimes; about 70 percent had experienced an anxiety disorder; and about 30 percent had experienced a psychotic disorder.

ETIOLOGY

The cause of body dysmorphic disorder is unknown. The high comorbidity with depressive disorders, a higher-than-expected family history of mood disorders and OCD, and the reported responsiveness of the condition to serotonin-specific drugs indicate that, in at least some patients, the pathophysiology of the disorder may involve serotonin and may be related to other mental disorders. Stereotyped concepts of beauty emphasized in certain families and within the culture at large may significantly affect patients with body dysmorphic disorder. In psychodynamic models, body dysmorphic disorder is seen as reflecting the displacement of a sexual or emotional conflict onto a nonrelated body part. Such an association occurs through the defense mechanisms of repression, dissociation, distortion, symbolization, and projection.

DIAGNOSIS

The DSM-5 diagnostic criteria for body dysmorphic disorder stipulate preoccupation with a perceived defect in appearance or overemphasis of a slight defect. It also stipulates that at some point during the course of the disorder, the patient performs compulsive behaviors (i.e., mirror checking, excessive grooming) or mental acts (e.g., comparing their appearance to that of others). The preoccupation causes patients significant emotional distress or markedly impairs their ability to function in important areas.

CLINICAL FEATURES

The most common concerns (Table 10.2-1) involve facial flaws, particularly those involving specific parts (e.g., the nose). Sometimes the concern is vague and difficult to understand, such as extreme concern over a “scrunchy” chin. One study found that, on average, patients had concerns about four body regions during the course of the disorder. Other body parts of concern are hair, breasts, and genitalia. A proposed variant of dysmorphic disorder among men is the desire to “bulk up” and develop large muscle mass, which can interfere with ordinary living, holding a job, or staying healthy. The specific body part may change during the time a patient is affected with the disorder. Common associated symptoms include ideas or frank delusions of reference (usually about persons' noticing the alleged body flaw), either excessive mirror checking or avoidance of reflective surfaces, and attempts to hide the presumed deformity (with makeup or clothing). The effects on a person's life can be significant; almost all affected patients avoid social and occupational exposure. As many as one-third of patients may be housebound because of worry about being ridiculed for the alleged deformities; and approximately one-fifth of patients attempt suicide. As discussed, comorbid diagnoses of depressive disorders and anxiety disorders are common, and patients may also have traits of OCD, schizoid, and narcissistic personality disorders.

Table 10.2-1
Location of Imagined Defects in 30 Patients with Body Dysmorphic Disorder^a

Location	N	%
Hair ^b	19	63
Nose	15	50
Skin ^c	15	50
Eyes	8	27
Head, face ^d	6	20
Overall body build, bone structure	6	20
Lips	5	17
Chin	5	17
Stomach, waist	5	17
Teeth	4	13
Legs, knees	4	13
Breasts, pectoral muscles	3	10
Ugly face (general)	3	10
Ears	2	7
Cheeks	2	7
Buttocks	2	7
Penis	2	7
Arms, wrists	2	7
Neck	1	3
Forehead	1	3
Facial muscles	1	3
Shoulders	1	3
Hips	1	3

^aTotal is greater than 100 percent because most patients had “defects” in more than one location.

^bInvolves head hair in 15 cases, beard growth in 2 cases, and other body hair in 3 cases.

^cInvolves acne in 7 cases, facial lines in 3 cases, and other skin concerns in 7 cases.

^dInvolves concerns with shape in 5 cases and size in 1 case.

(From Phillips KA, McElroy SL, Keck PE Jr, Pope HG, Hudson JL. Body dysmorphic disorder: 30 cases of imagined ugliness. *Am J Psychiatry*. 1993;150:303, with permission.)

Ms. R, a 28-year-old single woman, presented with the complaint that she is “ugly” and that she feels others are laughing at her because of her ugliness. In reality, Ms. R was an attractive woman. She first became preoccupied with her appearance when she was 13, when she became obsessed with her “facial defects” (e.g., her nose was too fat, her eyes were too far apart). Up until this point, Ms. R was confident, a good student, and socially active. However, her fixation on her face caused her to socially withdraw and have difficulty concentrating in school, which in turn had a negative effect on her grades.

Ms. R dropped out of high school and went for her GED due to her preoccupation. She began to frequently pick at “blemishes” and hairs on her face. She frequently checked herself in mirrors and other reflectively surfaces (e.g., spoons, windows). She found herself thinking about her defects almost all day every day. Despite reassuring comments from family and others, Ms. R could not be convinced that there was nothing wrong with her appearance.

DIFFERENTIAL DIAGNOSIS

The diagnosis of body dysmorphic disorder should not be made if the excessive bodily preoccupation is better accounted for by another psychiatric disorder. Excessive bodily preoccupation is generally restricted to concerns about being fat in anorexia nervosa; to discomfort with, or a sense of wrongness about, his or her primary and secondary sex characteristics occurring in gender identity disorder; and to mood-congruent cognitions involving appearance that occur exclusively during a major depressive episode. Individuals with avoidant personality disorder or social phobia may worry about being embarrassed by imagined or real defects in appearance, but this concern is usually not prominent, persistent, distressing, or impairing. Taijin kyofusho, a diagnosis in Japan, is similar to social phobia but has some features that are more consistent with body dysmorphic disorder, such as the belief that the person has an offensive odor or body parts that are offensive to others. Although individuals with body dysmorphic disorder have obsessional preoccupations about their appearance and may have associated compulsive behaviors (e.g., mirror checking), a separate or additional diagnosis of OCD is made only when the obsessions or compulsions are not restricted to concerns about appearance and are ego-dystonic. An additional diagnosis of delusional disorder, somatic type, can be made in people with body dysmorphic disorder only if their preoccupation with the imagined defect in appearance is held with a delusional intensity. Unlike normal concerns about appearance, the preoccupation with appearance and specific imagined defects in body dysmorphic disorder and the changed behavior because of the preoccupation are excessively time-consuming and are associated with significant distress or impairment.

COURSE AND PROGNOSIS

Body dysmorphic disorder usually begins during adolescence, although it may begin later after a protracted dissatisfaction with the body. Age of onset is not well understood because variably a long delay occurs between symptom onset and treatment seeking. The onset can be gradual or abrupt. The disorder usually has a long and undulating course with few symptom-free intervals. The part of the body on which concern is focused may remain the same or may change over time.

TREATMENT

Treatment of patients with body dysmorphic disorder with surgical, dermatological, dental, and other medical procedures to address the alleged defects is almost invariably unsuccessful. Although tricyclic drugs, monoamine oxidase inhibitors (MAOIs), and pimozide (Orap) have reportedly been useful in individual cases, other data indicate that serotonin-specific drugs—for example, clomipramine (Anafranil)

and fluoxetine (Prozac)—reduce symptoms in at least 50 percent of patients. In any patient with a coexisting mental disorder, such as a depressive disorder or an anxiety disorder, the coexisting disorder should be treated with the appropriate pharmacotherapy and psychotherapy. How long treatment should be continued after the symptoms of body dysmorphic disorder have remitted is unknown. Augmentation of the selective serotonin reuptake inhibitor (SSRI) with clomipramine (Anafranil), buspirone (BuSpar), lithium (Eskalith), methylphenidate (Ritalin), or antipsychotics may improve the response rate.

RELATION TO PLASTIC SURGERY

Few data exist about the number of patients seeking plastic surgery who have body dysmorphic disorder. One study found that only 2 percent of the patients in a plastic surgery clinic had the diagnosis, but DSM-5 reports the figure to be 7 to 8 percent. The overall percentage may be much higher, however. Surgical requests are varied: removal of facial sags, jowls, wrinkles, or puffiness; rhinoplasty; breast reduction or enhancement; and penile enlargement. Men who request penile enlargements and women who request cosmetic surgery of the labia of the vagina or the lips of the mouth often are suffering from this disorder. Commonly associated with the belief about appearance is an unrealistic expectation of how much surgery will correct the defect. As reality sets in, the person realizes that life's problems are not solved by altering the perceived cosmetic defect. Ideally, such patients will seek out psychotherapy to understand the true nature of their neurotic feelings of inadequacy. Absent that, patients may take out their unfulfilled expectations and anger by suing their plastic surgeons—who have one of highest malpractice-suit rates of any specialty—or by developing a clinical depression.

10.3 Hoarding Disorder

Compulsive hoarding is a common and often disabling phenomenon associated with impairment in such functions as eating, sleeping, and grooming. Hoarding may result in health problems and poor sanitation, particularly when hoarding of animals is involved, and may lead to death from fire or falling.

The disorder is characterized by acquiring and not discarding things that are deemed to be of little or no value, resulting in excessive clutter of living spaces. Hoarding was originally considered a subtype of obsessive-compulsive disorder (OCD), but is now considered to be a separate diagnostic entity. It is commonly driven by an obsessive fear of losing important items that the person believes may be of use at some point in the future, by distorted beliefs about the importance of possessions, and by extreme emotional attachment to possessions.

EPIDEMIOLOGY

Hoarding is believed to occur in approximately 2 to 5 percent of the population, although some studies have found lifetime prevalence as high as 14 percent. It occurs equally among men and women, is more common in single persons, and is associated with social anxiety, withdrawal, and dependent personality traits. Hoarding usually begins in early adolescence and persists throughout the lifespan.

COMORBIDITY

The most significant comorbidity is found between hoarding disorder and OCD, with as many as 30 percent of OCD patients showing hoarding behavior.

Studies have found an association between hoarding and compulsive buying. Buying or acquiring needless things (including receiving gifts) may be a source of comfort for hoarders, many of whom find themselves with extra items for a perceived but irrational future need. Approximately half of compulsive buyers display a high level of hoarding; however, up to 20 percent of hoarders do not show signs of excessive buying.

Hoarding is associated with high rates of personality disorders in addition to OCD. These include dependent, avoidant, schizotypal, and paranoid types.

Deficits in attention and executive function that occur in hoarding may resemble those seen in attention-deficit/hyperactivity disorder (ADHD). In one study, 20 percent of hoarding patients met the criteria for ADHD. This finding correlates with the fact that OCD patients with hoarding symptoms had a ten times higher rate of developing ADHD than those without.

Hoarding behaviors are relatively common among schizophrenic patients and have been noted in dementia and other neurocognitive disorders. One study found hoarding in 20 percent of dementia patients and 14 percent of brain injury patients. Onset of hoarding has been reported in cases of frontotemporal dementia and may follow surgery resulting in structural defects in prefrontal and orbitofrontal cortex. In a study of patients with focal lesions of the telencephalon, 15 percent exhibited a sudden onset of severe and persistent collecting and saving behavior.

Other disorders associated with hoarding include eating disorders, depression, anxiety disorders, substance use disorders (particularly alcohol dependence), kleptomania, and compulsive gambling. Among anxiety disorders, hoarding is most associated with generalized anxiety disorder (27 percent) and social anxiety disorder (14 percent).

ETIOLOGY

Little is known about the etiology of hoarding disorder. Research has shown a familial aspect to hoarding disorder, with about 80 percent of

hoarders reporting at least one first-degree relative with hoarding behavior. Biological research has shown a lower metabolism in the posterior cingulate cortex and the occipital cortex of hoarders, which may also account for various cognitive impairments within hoarders such as attention and decision-making deficits. One study of the molecular genetics for hoarding found a link between hoarding behavior and markers on chromosomes 4q, 5q, and 17q. Another study found that the catecholamine-O-methyltransferase (*COMT*) gene on chromosome 22q11.21 might contribute to the genetic susceptibility to hoarding.

DIAGNOSIS

Hoarding disorder is characterized by (1) the acquiring of and failure to discard a large amount of possessions that are deemed useless or of little value; (2) greatly cluttered living areas precluding normal activities; and (3) significant distress and impairment in functioning due to hoarding. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* includes diagnostic specifiers that relate to insight, which may be rated poor, fair, or good. Some patients are completely unaware of the full extent of the problem and totally resistant to treatment. At times, delusional beliefs about hoarded items are present.

CLINICAL FEATURES

Hoarding is driven by the fear of losing items that the patient believes will be needed later and a distorted belief about or an emotional attachment to possessions. Most hoarders do not perceive their behavior to be a problem. In fact, many perceive their behavior to be reasonable and part of their identity. Most hoarding patients accumulate possessions passively rather than intentionally, thus clutter accumulates gradually over time. Common hoarded items include newspapers, mail, magazines, old clothes, bags, books, lists, and notes. Hoarding poses risks to not only the patient, but also to those around them. Clutter accumulated from hoarding has been attributed to deaths from fire or patients being crushed by their possessions. It can also attract pest infestations that can pose a health risk both to the patient and residents around them. Many sufferers have been evicted from their home or threatened with eviction as a result of their hoarding. In severe cases, hoarding can interfere with work, social interaction, and basic activities such as eating or sleeping.

The pathological nature of hoarding comes from the inability to organize possessions and keep them organized. Many hoard to avoid making decisions about discarding items. Patients with hoarding disorder also overemphasize the importance of recalling information and possessions. For example, a hoarder will keep old newspapers and magazines because they believe that if discarded the information will be forgotten and will never be retrieved again. In addition, patients believe that forgetting information will lead to serious consequences and prefer to keep possessions in sight so as not to forget them.

Ms. T, a 55-year-old single woman, presented to a therapist accompanied by her adult son, who expressed concern about Ms. T's inability to "throw things away." He reported that Ms. T's home was extremely cluttered with "needless things." Whenever he attempted to help her "organize things," however, Ms. T would become agitated and argumentative. Ms. T confirmed her son's complaint and reported having this difficulty for as long as she could remember, but never really viewed it as a problem.

Over the past 5 years, Ms. T's home had become increasingly cluttered to the point that it became more and more difficult to move around within it. She was able to keep the kitchen and bathroom relatively clutter free, but the rest of her home was filled with boxes and bags filled with papers, magazines, clothes, and miscellaneous gifts and trinkets. Her living room was the most affected. Her son reported no longer being able to visit his mother because it was so difficult to move around and there were very few places for them to sit comfortably. This, Ms. T admits, has been a major source of depression for her. Ms. T used to enjoy entertaining family and friends, especially on holidays, but has not had any guests over in years because she felt that her home was no longer "suitable for company." She had made a few attempts to clean out her home, but was unable to discard most items. When asked why she was keeping them, she replied "I may need them later."

DIFFERENTIAL DIAGNOSIS

The diagnosis of hoarding disorder should not be made if the excessive acquisition and inability to discard possessions is better accounted for by another medical or psychiatric condition. Until recently, hoarding was considered to be a symptom of OCD and obsessive-compulsive personality disorder. However, there are some major differences. Hoarding disorder patients do not display some of the classic symptoms of OCD such as recurring intrusive thoughts or compulsive rituals. Unlike symptoms of OCD, symptoms of hoarding worsen with time, rituals are not fixed, and obsessions about dirt or contamination are absent. OCD patients have better insight into their condition. Symptoms are usually ego-dystonic, whereas in hoarding disorder they are ego-syntonic. Hoarding behavior is seldom repetitive and is not viewed as intrusive or distressing to the hoarder. Distress mainly comes at the prospect of discarding items, and it manifests more as guilt and anger than anxiety. Hoarding disorder also tends to be less responsive to classic treatments for OCD such as exposure therapy, cognitive-behavioral therapy (CBT), and selective serotonin reuptake inhibitors (SSRIs).

Some case reports show the onset of this behavior in patients after suffering brain lesions. Hoarding associated with brain lesions is more purposeless than hoarding that is motivated by emotional attachment or high intrinsic value of possessions. It is a common symptom in moderate to severe dementia. In cases of dementia, hoarding is often associated with a higher prevalence of hiding, rummaging, repetitive behavior, pilfering, and hyperphagia. Onset of the behavior usually coincides with onset of the dementia, starting in an organized manner, and becomes more disorganized as the disease progresses. The onset of dementia in a patient who has hoarded throughout his or her lifetime can aggravate the hoarding behavior.

Hoarding behavior can be associated with schizophrenia. It is mostly associated with severe cases and is seen as a repetitive behavior associated with delusions, self-neglect, and squalor. Bipolar disorder is ruled out by the absence of severe mood swings.

COURSE AND PROGNOSIS

The disorder is a chronic condition with a treatment-resistant course. Treatment seeking does not usually occur until patients are in their 40s or 50s, even if the hoarding began during adolescence. Symptoms may fluctuate throughout the course of the disorder, but full remission is rare. Patients have very little insight into their behavior and usually seek treatment under pressure from others. Some patients begin hoarding in response to a stressful event, while others report a slow and steady progression throughout life. Those who report onset due to a stressful event have a later age of onset than those who do not. Those with an earlier age of onset run a longer and more chronic course.

TREATMENT

Hoarding disorder is difficult to treat. Although it shows similarities to OCD, effective treatments for OCD have shown little benefit for patients with hoarding disorder. In one study, only 18 percent of patients responded to medication and CBT. The challenges posed by hoarding patients to typical CBT treatment include poor insight to the behavior and low motivation and resistance to treatment.

The most effective treatment for the disorder is a cognitive behavioral model that includes training in decision making and categorizing; exposure and habituation to discarding; and cognitive restructuring. This includes both office and in-home sessions. The role of the therapist in this model is to assist in the development of decision-making skills, to provide feedback about normal saving behavior, and to identify

and challenge the patient's erroneous beliefs about possessions. The goal in treatment is to get rid of a significant amount of possessions, thereby making the living space livable, and to provide the patient with the skills to maintain a positive balance between the amount of possessions and livable space. Studies have shown a 25 to 34 percent reduction in hoarding behaviors using this method. Restructuring of this method for group and web-based interventions are currently under study and show promise.

Pharmacological treatment studies using SSRIs have shown mixed results. Some studies have shown a negative response to SSRI treatment in hoarding patients compared with nonhoarders, while others have found no significant difference between the two groups.

10.4 Hair-Pulling Disorder (Trichotillomania)

Hair-pulling disorder is a chronic disorder characterized by repetitive hair pulling, leading to variable hair loss that may be visible to others. It is also known as *trichotillomania*, a term coined by a French dermatologist Francois Hallopeau in 1889. The disorder was once deemed rare and little about it was described beyond phenomenology. It is now regarded as more common. The disorder is similar to obsessive-compulsive disorder and impulse control in that there is increased tension prior to the hair pulling and a relief of tension or gratification after the hair pulling.

EPIDEMIOLOGY

The prevalence of hair-pulling disorder may be underestimated because of accompanying shame and secretiveness. The diagnosis encompasses at least two categories of hair pulling that differ in incidence, severity, age of presentation, and gender ratio. Other subsets may exist.

The most serious, chronic form of the disorder usually begins in early to mid-adolescence, with a lifetime prevalence ranging from 0.6 percent to as high as 3.4 percent in general populations and with female to male ratio as high as 10 to 1. The number of men may actually be higher, because men are even more likely than women to conceal hair pulling. A patient with chronic hair-pulling disorder is likely to be the only or oldest child in the family.

A childhood type of hair-pulling disorder occurs approximately equally in girls and boys. It is said to be more common than the adolescent or young adult syndrome and is generally far less serious dermatologically and psychologically.

An estimated 35 to 40 percent of patients with hair-pulling disorder chew or swallow the hair that they pull out at one time or another. Of this group, approximately one-third develop potentially hazardous bezoars—hairballs accumulating in the alimentary tract.

COMORBIDITY

Significant comorbidity is found between hair-pulling disorder and obsessive-compulsive disorder (OCD); anxiety disorders; Tourette's disorder; depressive disorders; eating disorders; and various personality disorders—particularly obsessive-compulsive, borderline, and narcissistic personality disorders. Comorbid substance abuse disorder is not encountered as frequently as it is in pathological gambling, kleptomania, and other impulse disorders.

ETIOLOGY

Although hair-pulling disorder is regarded as multidetermined, its onset has been linked to stressful situations in more than one-fourth of all cases. Disturbances in mother-child relationships, fear of being left alone, and recent object loss are often cited as critical factors contributing to the condition. Substance abuse may encourage development of the disorder. Depressive dynamics are often cited as predisposing factors, but no particular personality trait or disorder characterizes patients. Some see self-stimulation as the primary goal of hair pulling.

Family members of hair-pulling disorder patients often have a history of tics, impulse-control disorders, and obsessive-compulsive symptoms, further supporting a possible genetic predisposition.

One study looked at the neurobiology of hair-pulling disorder and found a smaller volume of the left putamen and left lenticulate areas. More recently, a study of the genetics of trichotillomania reported a relationship between a serotonin 2A (5-HT_{2A}) receptor gene polymorphism (T102C) and trichotillomania. However, because these studies examined relatively few subjects, these findings need to be replicated in a larger sample to be able to determine the role of basal ganglia abnormalities and serotonin in the etiology of trichotillomania.

DIAGNOSIS AND CLINICAL FEATURES

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes diagnostic criteria from hair-pulling disorder. Before engaging in the behavior, patients with hair-pulling disorder may experience an increasing sense of tension and achieve a sense of release or gratification from pulling out their hair. All areas of the body may be affected, most commonly the scalp (Fig. 10.4-1). Other areas involved are eyebrows, eyelashes, and beard; trunk, armpits, and pubic area are less commonly involved (Fig. 10.4-2).

FIGURE 10.4-1

Hair-pulling disorder (trichotillomania). Note the typical findings of an area of incomplete alopecia involving the frontal and vertex scalp. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

FIGURE 10.4-2

Example of plucking of the pubic hair because of hair-pulling disorder.

Two types of hair pulling have been described. *Focused pulling* is the use of an intentional act to control unpleasant personal experiences, such as an urge, bodily sensation (e.g., itching or burning), or thought. In contrast, *automatic pulling* occurs outside the person's awareness and most often during sedentary activities. Most patients have a combination of these types of hair pulling.

Hair loss is characterized by short, broken strands appearing together with long, normal hairs in the affected areas. No abnormalities of the skin or scalp are present. Hair pulling is not reported as being painful, although pruritus and tingling may occur in the involved area. Trichophagy, mouthing of the hair, may follow the hair plucking. Complications of trichophagy include trichobezoars, malnutrition, and intestinal obstruction. Patients usually deny the behavior and often try to hide the resultant alopecia. Head banging, nail biting, scratching, gnawing, excoriation, and other acts of self-mutilation may be present.

Ms. C, a 27-year-old single woman, came to a local clinic complaining of persistent hair pulling. She first started at age 11, when she began to pick the hairs at the nape of her neck. She would persistently pick at the hair until there was almost none left. Fortunately, her hair was long, so no one noticed the lack of hair at the back of her neck. Over the years, her hair picking progressed until she began picking hair from her entire head, leaving noticeable small bald patches. She strategically hid the bald patches by brushing over the remainder of her hair or with carefully placed scarves and hats. Despite her habit, Ms. C was pretty normal. She got good grades in school and was a year away from getting her master's degree.

Ms. C's habit was constant, occurring every day, often without her noticing it. She could simply be reading an assignment for school and eventually her hand would find its way into her hair to find a hair to pull. Soon she would notice a small pile of hairs in her book or on her lap, indicating that she had been pulling her hair out for a while. Whenever she tried to stop herself from pulling her hair, she would become increasingly nervous and anxious until she resumed the hair pulling. Her hair pulling sessions lasted anywhere from 10 minutes to an hour.

PATHOLOGY AND LABORATORY EXAMINATION

If necessary, the clinical diagnosis of hair-pulling disorder can be confirmed by punch biopsy of the scalp. In patients with a trichobezoar, blood count may reveal a mild leukocytosis and hypochromic anemia due to blood loss. Appropriate chemistries and radiological studies should also be performed, depending on the bezoar's suspected location and impact on the gastrointestinal (GI) tract.

DIFFERENTIAL DIAGNOSIS

Hair pulling may be a wholly benign condition or it may occur in the context of several mental disorders. The phenomenology of hair-pulling disorder and OCD overlap. As with OCD, hair-pulling disorder is often chronic and recognized by patients as undesirable. Unlike

those with OCD, patients with hair-pulling disorder do not experience obsessive thoughts, and the compulsive activity is limited to one act, hair pulling. Patients with factitious disorder actively seek medical attention and the patient role and deliberately simulate illness toward these ends. Patients who malingering or who have factitious disorder may mutilate themselves to get medical attention, but they do not acknowledge the self-inflicted nature of the lesions. Patients with stereotypic movement disorder have stereotypical and rhythmic movements, and they usually do not seem distressed by their behavior. A biopsy may be necessary to distinguish hair-pulling disorder from alopecia areata and trichotillomania.

COURSE AND PROGNOSIS

The mean age at onset of hair-pulling disorder is in the early teens, most frequently before age 17, but onset has been reported much later in life. The course of the disorder is not well known; both chronic and remitting forms occur. An early onset (before age 6) tends to remit more readily and responds to suggestions, support, and behavioral strategies. Late onset (after age 13) is associated with an increased likelihood of chronicity and poorer prognosis than the early-onset form. About a third of persons presenting for treatment report a duration of 1 year or less, whereas in some cases, the disorder has persisted for more than two decades.

TREATMENT

No consensus exists on the best treatment modality for hair-pulling disorder. Treatment usually involves psychiatrists and dermatologists in a joint endeavor. Psychopharmacological methods that have been used to treat psychodermatological disorders include topical steroids and hydroxyzine hydrochloride (Vistaril), an anxiolytic with antihistamine properties; antidepressants; and antipsychotics. Initial case reports showed efficacy of selective serotonin reuptake inhibitors (SSRIs) for hair-pulling disorder. Patients who respond poorly to SSRIs may improve with augmentation with pimozide (Orap), a dopamine receptor antagonist. Other medications that have been reported to have some efficacy for hair-pulling disorder include fluvoxamine (Luvox), citalopram (Celexa), venlafaxine (Effexor), naltrexone (ReVia), and lithium (Eskalith). A report of successful lithium treatment cited the possible effect of the drug on aggression, impulsivity, and mood instability as an explanation. In one study, patients taking naltrexone had a reduction in symptom severity. Case reports also indicate successful treatment with buspirone (BuSpar), clonazepam (Klonopin), and trazodone (Desyrel).

Successful behavioral treatments, such as biofeedback, self-monitoring, desensitization, and habit reversal, have been reported, but most studies have been based on individual cases or a small series of cases with relatively short follow-up periods. Chronic hair-pulling disorder has been treated successfully with insight-oriented psychotherapy. Hypnotherapy has been mentioned as potentially effective in the treatment of dermatological disorders in which psychological factors may be involved; the skin has been shown to be susceptible to hypnotic suggestion.

10.5 Excoriation (Skin-Picking) Disorder

Excoriation or skin-picking disorder is characterized by the compulsive and repetitive picking of the skin. It can lead to severe tissue damage and result in the need for various dermatological treatments. Throughout history, skin-picking disorder has had many names: skin-picking syndrome, emotional excoriation, nervous scratching artifact, epidermotillomania, and para-artificial excoriation.

EPIDEMIOLOGY

Skin-picking disorder has lifetime prevalence between 1 to 5 percent in the general population, about 12 percent in the adolescent psychiatric population, and occurs in 2 percent of patients with other dermatologic disorders. It is more prevalent in women than in men.

COMORBIDITY

The repetitive nature of skin-picking behavior is similar to the repetitive compulsive rituals found in obsessive-compulsive disorder (OCD), and skin-picking disorder is associated with high rates of OCD. In addition, patients with OCD may have obsessions about contamination and skin abnormalities or may be preoccupied with having smooth skin, flawless complexion, and cleanliness. Other comorbid conditions include hair-pulling disorder (trichotillomania, 38 percent), substance dependence (38 percent), major depressive disorder (32 to 58 percent), anxiety disorders (23 to 56 percent), and body dysmorphic disorder (27 to 45 percent). One study reported an association of both borderline and obsessive-compulsive personality disorder (71 percent) in patients with skin-picking disorder.

ETIOLOGY

The cause of skin-picking is unknown, however, several theories have been postulated. Some theorists speculate that skin-picking behavior is a manifestation of repressed rage at authoritarian parents. These patients pick at their skin and perform other self-destructive acts to assert themselves. Patients may pick as a means to relieve stress. For example, skin-picking has been associated with marital conflicts, passing of

loved ones, and unwanted pregnancies. According to psychoanalytic theory, the skin is an erotic organ, and picking at the skin or scratching the skin leading to excoriations may be a source of erotic pleasure. In that sense it has been considered a masturbatory equivalent. Patients may be unaware of these affects presumed to be in the unconscious. Many patients begin picking at the onset of dermatological conditions such as acne and continue to pick after the condition has cleared.

Abnormalities in serotonin, dopamine, and glutamate metabolism have been theorized to be an underlying neurochemical cause of the disorder, but further research is needed.

DIAGNOSIS

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) it was called trichotillomania. It was also known as skin-picking syndrome. DSM-5 diagnostic criteria for skin-picking disorder requires recurrent skin-picking resulting in skin lesions and repeated attempts to decrease or stop picking. The skin-picking must cause clinically relevant distress or impairment in functioning. The skin-picking behavior cannot be attributed to another medical or mental condition and cannot be a result of a substance use disorder (e.g., cocaine or methamphetamine use).

CLINICAL FEATURES

The face is the most common site of skin-picking (Fig. 10.5-1). Other common sites are legs, arms, torso, hands, cuticles, fingers, and scalp. Although most patients report having a primary picking area, many times they pick other areas of the body in order for the primary area to heal. In severe cases, skin-picking can result in physical disfigurement and medical consequences that require medical or surgical interventions (e.g., skin grafts or radiosurgery).

FIGURE 10.5-1

Skin-picking disorder. Multiple erythematous and pigmented maculae and crusted erosions on chin. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Patients may experience tension prior to picking and a relief and gratification after picking. Many report picking as a means to relieve stress, tension, and other negative feelings. In spite of the relief felt from picking, patients often feel guilty or embarrassed at their behavior. Up to 87 percent of patients report feeling embarrassed by the picking and 58 percent report avoiding social situations. Many patients use bandages, makeup, or clothing to hide their picking. Of skin-picking patients, 15 percent report suicidal ideation due to their behavior and about 12 percent have attempted suicide.

Ms. J, a 22-year-old single woman, presented to a psychiatrist at the urging of her dermatologist because of compulsive picking at the skin on her face. She picked at it every day up to three times a day in sessions lasting from 20 minutes to over an hour. She had massive scarring and lesions on her face. She went to a physician 6 months prior when one of the lesions had become infected.

Ms. J began picking her face at age 11 at the onset of puberty. At first, she only picked at acne that formed on her face, but as the urge to pick became greater, she started picking at clear patches of skin as well. Due to the scarring and lesions, Ms. J became increasingly withdrawn and avoided all social engagements. She reported feeling great tension prior to picking and only after she began picking did she feel relief.

DIFFERENTIAL DIAGNOSIS

The diagnosis of skin-picking disorder cannot be made if the behavior can be better accounted for by another medical or psychological condition. Many medical and dermatological conditions may result in urges to itch and pick at the skin. Conditions include eczema, psoriasis, diabetes, liver or kidney disease, Hodgkin's disease, polycythemia vera, or systemic lupus. Skin-picking can also be seen in Prader-Willi syndrome (97 percent). A thorough physical examination is crucial prior to psychiatric diagnosis.

Skin-picking disorder is similar to OCD and it is associated with high rates of comorbid OCD. The disorders differ in a few ways. Skin-picking disorder is prevalent in females while OCD is equal between genders. The compulsions associated with OCD are usually driven by intrusive thoughts, while the compulsion to pick the skin is usually not. Although skin-picking generally decreases anxiety, it can also entice pleasure in the patient, which is rarely the case in OCD. Skin-picking in OCD patients is usually the result of obsessions about contamination or skin abnormalities.

Skin-picking is commonly seen in body dysmorphic disorder. In one study, 45 percent of body dysmorphic patients report lifetime skin-picking disorder and 37 percent report having skin-picking disorder secondary to body dysmorphic disorder. The skin-picking in body dysmorphic disorder is primarily centered on removing or minimizing believed imperfection in the patient's appearance.

Substance use disorders often co-occur with skin-picking disorder. Methamphetamine and cocaine use may result in the sensation that something is crawling on the body or under the skin (formication), which can result in skin-picking. In order to make the diagnosis of skin-picking disorder, however, skin-picking cannot be a physiological effect of substance use.

Factitious Dermatitis

Factitious dermatitis or *dermatitis artefacta* is a disorder in which skin-picking is the target of self-inflicted injury and the patient uses more elaborate methods than simple excoriation to self-induce skin lesions. It is seen in 0.3 percent of dermatology patients and has a female to male ratio of 8 to 1. It can present at any age, but occurs most frequently in adolescents and young adults. It can present as an aggravation of dermatosis, targeting a variety of skin lesions including blisters, ulcers, erythema, edema, purpura, and sinuses. The morphology of factitious dermatitis lesions is often bizarre and linear, with clear-cut, angulated, or geometric edges. Presence of completely normal, unaffected skin adjacent to the horrific-looking lesions is a clue to the diagnosis of factitious dermatitis (Fig. 10.5-2). In addition, the patient's description of history of the skin lesions is usually vague and lacks detail about the appearance and evolution of the lesions.

FIGURE 10.5-2

Typical self-produced lesions with scabbing. (From Douthwaite AH, ed. *French's Index of Differential Diagnosis*. 7th ed. Baltimore: Williams & Wilkins; 1954, with permission.)

COURSE AND PROGNOSIS

The onset of skin-picking disorder is either in early adulthood or between 30 and 45 years of age. Onset in children before age 10 years has also been seen. The mean age of onset is between 12 to 16 years of age. There may be a lag of time between onset and actual diagnosis. Because little is known about the disorder, many are unaware that it can be treated. Many times patients do not seek treatment until a severe dermatological or medical condition has developed.

Typically, symptoms wax and wane over the course of the patient's life. Approximately 44 percent of women report that the amount of picking coincides with their menstrual cycle.

TREATMENT

Skin-picking disorder is difficult to treat and there are few data on effective treatments. Most patients do not actively seek treatment due to embarrassment or because they believe their condition is untreatable. There is support for the use of selective serotonin reuptake inhibitors (SSRIs). Studies comparing fluoxetine (Prozac) against placebo has shown fluoxetine to be superior in reducing skin-picking. The opioid antagonist naltrexone (Revia) has proven to reduce the urge to pick, particularly in patients who experience pleasure from the behavior. Glutamatergic agents and lamotrigine (Lamictal) have also shown efficacy. Nonpharmacological treatments include habit reversal and brief cognitive-behavioral therapy (CBT).

Effective therapy requires both psychological and somatic treatment. In some cases mechanical prevention of skin-picking by different protective measures may be of use in an effort to break the cycle. Psychotherapy at the same time deals with the underlying emotional factors.

Trauma- and Stressor-Related Disorders

11.1 Posttraumatic Stress Disorder and Acute Stress Disorder

Both posttraumatic stress disorder (PTSD) and acute stress disorder are marked by increased stress and anxiety following exposure to a traumatic or stressful event. Traumatic or stressful events may include being a witness to or being involved in a violent accident or crime, military combat, or assault, being kidnapped, being involved in a natural disaster, being diagnosed with a life-threatening illness, or experiencing systematic physical or sexual abuse. The person reacts to the experience with fear and helplessness, persistently relives the event, and tries to avoid being reminded of it. The event may be relived in dreams and waking thoughts (flashbacks).

The stressors causing both acute stress disorder and PTSD are sufficiently overwhelming to affect almost everyone. They can arise from experiences in war, torture (discussed in detail below), natural catastrophes, assault, rape, and serious accidents, for example, in cars and in burning buildings. Persons reexperience the traumatic event in their dreams and their daily thoughts; they are determined to avoid anything that brings the event to mind and they undergo a numbing of responsiveness along with a state of hyperarousal. Other symptoms are depression, anxiety, and cognitive difficulties such as poor concentration.

A link between acute mental syndromes and traumatic events has been recognized for more than 200 years. Observations of trauma-related syndromes were documented following the Civil War, and early psychoanalytic writers, including Sigmund Freud, noted a relation between neurosis and trauma. Considerable interest in posttraumatic mental disorders was stimulated by observations of “battle fatigue,” “shell shock,” and “soldier’s heart” in both World Wars I and II. Moreover, increasing documentation of mental reactions to the Holocaust, to a series of natural disasters, and to assault contributed to the growing recognition of a close relation between trauma and psychopathology.

EPIDEMIOLOGY

The lifetime incidence of PTSD is estimated to be 9 to 15 percent and the lifetime prevalence of PTSD is estimated to be about 8 percent of the general population, although an additional 5 to 15 percent may experience subclinical forms of the disorder. The lifetime prevalence rate is 10 percent in women and 4 percent in men. According to the National Vietnam Veterans Readjustment Study (NVVRS), 30 percent of men develop full-blown PTSD after having served in the war and an additional 22.5 percent develop partial PTSD, falling just short of qualifying for the disorder. Among veterans of the Iraq and Afghanistan wars, 13 percent received the diagnosis of PTSD.

Although PTSD can appear at any age, it is most prevalent in young adults, because they tend to be more exposed to precipitating situations. Children can also have the disorder (see [Section 31.11b](#)). Men and women differ in the types of traumas to which they are exposed. Historically, men’s trauma was usually combat experience, and women’s trauma was most commonly assault or rape. The disorder is most likely to occur in those who are single, divorced, widowed, socially withdrawn, or of low socioeconomic level, but anyone can be effected, no one is immune. The most important risk factors, however, for this disorder are the severity, duration, and proximity of a person’s exposure to the actual trauma. A familial pattern seems to exist for this disorder, and first-degree biological relatives of persons with a history of depression have an increased risk for developing PTSD following a traumatic event.

COMORBIDITY

Comorbidity rates are high among patients with PTSD, with about two thirds having at least two other disorders. Common comorbid conditions include depressive disorders, substance-related disorders, anxiety disorders, and bipolar disorders. Comorbid disorders make persons more vulnerable to develop PTSD.

ETIOLOGY

Stressor

By definition, a stressor is the prime causative factor in the development of PTSD. Not everyone experiences the disorder after a traumatic event, however. The stressor alone does not suffice to cause the disorder. Clinicians must also consider individual’s preexisting biological and psychosocial factors and events that happened before and after the trauma. For example, a member of a group who lived through a disaster can sometimes better deal with trauma because others have also shared the experience. The stressor’s subjective meaning to a person is also important. For example, survivors of a catastrophe may experience guilt feelings (survivor guilt) that can predispose to, or exacerbate, PTSD.

Three weeks after a train derailment, a 42-year-old budget analyst presented to the mental health clinic. He noted that he was embarrassed to seek care, as he was previously a firefighter, but he felt he needed “some reassurance that what I’m experiencing is normal.” He reported that, since the wreck, he had been feeling nervous and on edge. He experienced some difficulty focusing his attention at work, and he had occasional intrusive recollections of “the way the ground just shook; the tremendous ‘bang’ and then the screaming when the train rolled over.” He noted that he had spoken with five business colleagues who were also on the train, and three acknowledged similar symptoms. However, they said that they were improving. He was more concerned about the frequency of tearful episodes, sometimes brought on by hearing the name of a severely injured friend, but, at other times, occurring “for no particular reason.” In addition, he noted that, when he evacuated the train, rescue workers gave him explicit directions about where to report, and, although he complied, he now felt extremely guilty about not returning to the train to assist in the rescue of others. He reported a modest decrease in appetite and denied weight loss but noted that he had stopped jogging during his lunch break. He had difficulty initiating sleep, so he had begun consuming a “glass or two” of wine before bed to help with this. He did not feel rested on awakening. He denied suicidal ideation or any psychotic symptoms. His sister had taken an antidepressant several years ago, but he did not desire medication. He feared that side effects could further diminish his ability to function at the workplace and could cause him to gain weight. (Courtesy of D. M. Benedek, M.D., R. J. Ursano, M.D., and H. C. Holloway, M.D.)

Risk Factors

Even when faced with overwhelming trauma, most persons do not experience PTSD symptoms. The National Comorbidity Study found that 60 percent of males and 50 percent of females had experienced some significant trauma, whereas the reported lifetime prevalence of PTSD, as mentioned earlier, was only about 8 percent. Similarly, events that may appear mundane or less than catastrophic to most persons can produce PTSD in some. Evidence indicates of a dose–response relationship between the degree of trauma and the likelihood of symptoms. [Table 11.1-1](#) summarizes vulnerability factors that appear to play etiological roles in the disorder.

 **Table 11.1-1**
Predisposing Vulnerability Factors in Posttraumatic Stress Disorder

Presence of childhood trauma
Borderline, paranoid, dependent, or antisocial personality disorder traits
Inadequate family or peer support system
Being female
Genetic vulnerability to psychiatric illness
Recent stressful life changes
Perception of an external locus of control (natural cause) rather than an internal one (human cause)
Recent excessive alcohol intake

Psychodynamic Factors

The psychoanalytic model of the PTSD hypothesizes that the trauma has reactivated a previously quiescent, yet unresolved psychological conflict. The revival of the childhood trauma results in regression and the use of the defense mechanisms of repression, denial, reaction formation, and undoing. According to Freud, a splitting of consciousness occurs in patients who reported a history of childhood sexual trauma. A preexisting conflict might be symbolically reawakened by the new traumatic event. The ego relives and thereby tries to master and reduce the anxiety. Psychodynamic themes in PTSD are summarized in [Table 11.1-2](#). Persons who suffer from alexithymia, the inability to identify or verbalize feeling states, are incapable of soothing themselves when under stress.

 **Table 11.1-2**
Psychodynamic Themes in Posttraumatic Stress Disorder

-
- ▶ The subjective meaning of a stressor may determine its traumatogenicity.
 - ▶ Traumatic events can resonate with childhood traumas.
 - ▶ Inability to regulate affect can result from trauma.
 - ▶ Somatization and alexithymia may be among the after effects of trauma.
 - ▶ Common defenses used include denial, minimization, splitting, projective disavowal, dissociation, and guilt (as a defense against underlying helplessness).
 - ▶ Mode of object relatedness involves projection and introjection of the following roles: omnipotent rescuer, abuser, and victim.
-

Cognitive-Behavioral Factors

The cognitive model of PTSD posits that affected persons cannot process or rationalize the trauma that precipitated the disorder. They continue to experience the stress and attempt to avoid experiencing it by avoidance techniques. Consistent with their partial ability to cope cognitively with the event, persons experience alternating periods of acknowledging and blocking the event. The attempt of the brain to process the massive amount of information provoked by the trauma is thought to produce these alternating periods. The behavioral model of PTSD emphasizes two phases in its development. First, the trauma (the unconditioned stimulus) that produces a fear response is paired, through classic conditioning, with a conditioned stimulus (physical or mental reminders of the trauma, such as sights, smells, or sounds). Second, through instrumental learning, the conditioned stimuli elicit the fear response independent of the original unconditioned stimulus, and persons develop a pattern of avoiding both the conditioned stimulus and the unconditioned stimulus. Some persons also receive secondary gains from the external world, commonly monetary compensation, increased attention or sympathy, and the satisfaction of dependency needs. These gains reinforce the disorder and its persistence.

Biological Factors

The biological theories of PTSD have developed both from preclinical studies of animal models of stress and from measures of biological variables in clinical populations with the disorder. Many neurotransmitter systems have been implicated by both sets of data. Preclinical models of learned helplessness, kindling, and sensitization in animals have led to theories about norepinephrine, dopamine, endogenous opioids, and benzodiazepine receptors and the hypothalamic-pituitary-adrenal (HPA) axis. In clinical populations, data have supported hypotheses that the noradrenergic and endogenous opiate systems, as well as the HPA axis, are hyperactive in at least some patients with PTSD. Other major biological findings are increased activity and responsiveness of the autonomic nervous system, as evidenced by elevated heart rates and blood pressure readings and by abnormal sleep architecture (e.g., sleep fragmentation and increased sleep latency). Some researchers have suggested a similarity between PTSD and two other psychiatric disorders: major depressive disorder and panic disorder.

Noradrenergic System. Soldiers with PTSD-like symptoms exhibit nervousness, increased blood pressure and heart rate, palpitations, sweating, flushing, and tremors—symptoms associated with adrenergic drugs. Studies found increased 24-hour urine epinephrine concentrations in veterans with PTSD and increased urine catecholamine concentrations in sexually abused girls. Further, platelet α_2 - and lymphocyte β -adrenergic receptors are downregulated in PTSD, possibly in response to chronically elevated catecholamine concentrations. About 30 to 40 percent of patients with PTSD report flashbacks after yohimbine (Yocon) administration. Such findings are strong evidence for altered function in the noradrenergic system in PTSD.

Opioid System. Abnormality in the opioid system is suggested by low plasma β -endorphin concentrations in PTSD. Combat veterans with PTSD demonstrate a naloxone (Narcan)-reversible analgesic response to combat-related stimuli, raising the possibility of opioid system hyperregulation similar to that in the HPA axis. One study showed that nalmefene (Revex), an opioid receptor antagonist, was of use in reducing symptoms of PTSD in combat veterans.

Corticotropin-Releasing Factor and the HPA Axis. Several factors point to dysfunction of the HPA axis. Studies have demonstrated low plasma and urinary free cortisol concentrations in PTSD. More glucocorticoid receptors are found on lymphocytes, and challenge with exogenous corticotropin-releasing factor (CRF) yields a blunted corticotropin (ACTH) response. Further, suppression of cortisol by challenge with low-dose dexamethasone (Decadron) is enhanced in PTSD. This indicates hyperregulation of the HPA axis in PTSD. Also, some studies have revealed cortisol hypersuppression in trauma-exposed patients who develop PTSD, compared with patients

exposed to trauma who do not develop PTSD, indicating that it might be specifically associated with PTSD and not just trauma. Overall, this hyperregulation of the HPA axis differs from the neuroendocrine activity usually seen during stress and in other disorders such as depression. Recently, the role of the hippocampus in PTSD has received increased attention, although the issue remains controversial. Animal studies have shown that stress is associated with structural changes in the hippocampus, and studies of combat veterans with PTSD have revealed a lower average volume in the hippocampal region of the brain. Structural changes in the amygdala, an area of the brain associated with fear, have also been demonstrated.

DIAGNOSIS

The 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) criteria for PTSD (Table 11.1-3) specify that the symptoms of intrusion, avoidance, alternations of mood and cognition, and hyperarousal must have lasted more than 1 month. The DSM-5 diagnosis of PTSD allows the physician to specify if the symptoms occur in preschool-aged children or with dissociative (depersonalization/derealization) symptoms. For patients whose symptoms have been present less than 1 month, the appropriate diagnosis may be acute stress disorder (Table 11.1-4).

Table 11.1-3
DSM-5 Diagnostic Criteria for Posttraumatic Stress Disorder

Note: The following criteria apply to adults, adolescents, and children older than 6 years. For children 6 years and younger, see corresponding criteria below.

- A. Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:
1. Directly experiencing the traumatic event(s).
 2. Witnessing, in person, the event(s) as it occurred to others.
 3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental.
 4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse).
- Note:** Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related.
- B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:
1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).
Note: In children older than 6 years, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.
 2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).
Note: In children, there may be frightening dreams without recognizable content.
 3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)
Note: In children, trauma-specific reenactment may occur in play.
 4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect the traumatic event(s).
 5. Marked physiological reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
- C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:
1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
 2. Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
- D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).
 2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous," "My whole nervous system is permanently ruined").
 3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others.
 4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).
 5. Markedly diminished interest or participation in significant activities.
 6. Feelings of detachment or estranged from others.
 7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).
- E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.
 2. Reckless or self-destructive behavior.
 3. Hypervigilance.
 4. Exaggerated startle response.
 5. Problems with concentration.
 6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).
- F. Duration of the disturbance (Criteria B, C, D, and E) is more than 1 month.
- G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. The disturbance is not attributable to the physiological effects of a substance (e.g., medication, alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for posttraumatic stress disorder, and in addition, in response to the stressor, the individual experiences persistent or recurrent symptoms of either of the following:

1. **Depersonalization:** Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time slowly).
2. **Derealization:** Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts, behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

Specify if:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

Posttraumatic Stress Disorder for Children 6 Years and Younger

A. In children 6 years and younger, exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:

1. Directly experiencing the traumatic event(s).
2. Witnessing, in person, the event(s) as it occurred to others, especially primary caregivers.
Note: Witnessing does not include events that are witnessed only in electronic media, television, movies, or pictures.
3. Learning that the traumatic event(s) occurred to a parent or caregiving figure.

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).
Note: Spontaneous and intrusive memories may not necessarily appear distressing and may be expressed as play reenactment.
2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).
Note: It may not be possible to ascertain that the frightening content is related to the traumatic event.
3. Dissociative reactions (e.g., flashbacks) in which the child feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.) Such trauma-specific reenactment may occur in play.
4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
5. Marked physiological reactions to reminders of the traumatic event(s).

C. One (or more) of the following symptoms, representing either persistent avoidance of stimuli associated with the traumatic event(s) or negative alterations in cognitions and mood associated with the traumatic event(s), must be present, beginning after the event(s) or worsening after the event(s):

Persistent Avoidance of Stimuli

1. Avoidance of or efforts to avoid activities, places, or physical reminders that arouse recollections of the traumatic event(s).
2. Avoidance of or efforts to avoid people, conversations, or interpersonal situations that arouse recollections of the traumatic event(s).

Negative Alterations in Cognitions

3. Substantially increased frequency of negative emotional states (e.g., fear, guilt, sadness, shame, confusion).
 4. Markedly diminished interest or participation in significant activities, including constriction of play.
 5. Socially withdrawn behavior.
 6. Persistent reduction in expression of positive emotions.
- D. Alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects (including extreme temper tantrums).
 2. Hypervigilance.
 3. Exaggerated startle response.
 4. Problems with concentration.
 5. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).
- E. The duration of the disturbance is more than 1 month.
- F. The disturbance causes clinically significant distress or impairment in relationships with parents, siblings, peers, or other caregivers or with school behavior.
- G. The disturbance is not attributable to the physiological effects of a substance (e.g., medication or alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for posttraumatic stress disorder, and the individual experiences persistent or recurrent symptoms of either of the following:

1. **Depersonalization:** Persistent or recurrent experiences or feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly).
2. **Derealization:** Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts) or another medical condition (e.g. complex partial seizures).

Specify if:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

Table 11.1-4
DSM-5 Diagnostic Criteria for Acute Stress Disorder

- A. Exposure to actual or threatened death, serious injury, or sexual violation in one (or more) of the following ways:
1. Directly experiencing the traumatic event(s).
 2. Witnessing, in person, the event(s) as it occurred to others.
 3. Learning that the event(s) occurred to a close family member or close friend. **Note:** In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental.
 4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains, police officer repeatedly exposed to details of child abuse).
Note: This does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related.
- B. Presence of nine (or more) of the following symptoms from any of the five categories of intrusion, negative mood, dissociation, avoidance, and arousal, beginning or worsening after the traumatic event(s) occurred:
- Intrusion Symptoms**
1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s). **Note:** In children, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.
 2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the event(s). **Note:** In children, there may be frightening dreams without recognizable content.
 3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.) **Note:** In children, trauma-specific reenactment may occur in play.
 4. Intense or prolonged psychological distress or marked physiological reactions in response to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
- Negative Mood**
5. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).
- Dissociative Symptoms**
6. An altered sense of the reality of one's surroundings or oneself (e.g., seeing oneself from another's perspective, being in a daze, time slowing).
 7. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).
- Avoidance Symptoms**
8. Efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
 9. Efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
- Arousal Symptoms**
10. Sleep disturbance (e.g., difficulty falling or staying asleep, restless sleep).
 11. Irritable behavior and angry outbursts (with little or no provocation), typically expressed as verbal or physical aggression toward people or objects.
 12. Hypervigilance.
 13. Problems with concentration.
 14. Exaggerated startle response.
- C. Duration of the disturbance (symptoms in Criterion B) is 3 days to 1 month after trauma exposure.
Note: Symptoms typically begin immediately after the trauma, but persistence for at least 3 days and up to a month is needed to meet disorder criteria.
- D. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The disturbance is not attributable to the physiological effects of a substance (e.g., medication or alcohol) or another medical condition (e.g., mild traumatic brain injury) and is not better explained by brief psychotic disorder.

Mrs. M sought treatment for symptoms that she developed in the wake of an assault that had occurred about 6 weeks prior to her psychiatric evaluation. While leaving work late one evening, Mrs. M was attacked in a parking lot next to the hospital in which she worked. She was raped and badly beaten but was able to escape and call for help. On referral, Mrs. M reported frequent intrusive thoughts about the assault, including nightmares about the event and recurrent intrusive visions of her assailant. She reported that she now took the bus to work to avoid the scene of the attack and that she had to change her work hours so that she did not have to leave the building after dark. In addition, she reported that she had difficulty interacting with men, particularly those who resembled her attacker, and that she consequently avoided such interactions whenever possible. Mrs. M described increased irritability, difficulty staying asleep at night, poor concentration, and an increased focus on her environment, particularly after dark. (Courtesy of Erin B. McClure-Tone, Ph.D., and Daniel S. Pine, M.D.)

CLINICAL FEATURES

Individuals with PTSD show symptoms in three domains: intrusion symptoms following the trauma, avoiding stimuli associated with the trauma, and experiencing symptoms of increased automatic arousal, such as an enhanced startle. Flashbacks, in which the individual may act and feel as if the trauma were reoccurring, represent a classic intrusion symptom. Other intrusion symptoms include distressing recollections or dreams and either physiological or psychological stress reactions to exposure to stimuli that are linked to the trauma. An individual must exhibit at least one intrusion symptom to meet the criteria for PTSD. Symptoms of avoidance associated with PTSD include efforts to avoid thoughts or activities related to the trauma, anhedonia, reduced capacity to remember events related to the trauma, blunted affect, feelings of detachment or derealization, and a sense of a foreshortened future. Symptoms of increased arousal include insomnia, irritability, hypervigilance, and exaggerated startle.

A 40-year-old man watched the September 11, 2001, terrorist attack on the World Trade Center on television. Immediately thereafter he developed feelings of panic associated with thoughts that he was going to die. The panic disappeared within a few hours; however, for the next few nights he had nightmares with obsessive thoughts about dying. He sought consultation and reported to the psychiatrist that his wife had been killed in a plane crash 20 years earlier. He described having adapted to the loss "normally" and was aware that his current symptoms were probably related to that traumatic event. On further exploration in brief psychotherapy, he realized that his reactions to his wife's death were muted and that his relationship with her was ambivalent. At the time of her death, he was contemplating divorce and frequently had wished her dead. He had never fully worked through the mourning process for his wife, and

his catastrophic reaction to the terrorist attack was related, in part, to those suppressed feelings. He was able to recognize his feelings of guilt related to his wife and his need for punishment manifested by thinking he was going to die.

Gulf War Syndrome

In the Persian Gulf War against Iraq, which began in 1990 and ended in 1991, approximately 700,000 American soldiers served in the coalition forces. Upon their return, more than 100,000 US veterans reported a vast array of health problems, including irritability, chronic fatigue, shortness of breath, muscle and joint pain, migraine headaches, digestive disturbances, rash, hair loss, forgetfulness, and difficulty concentrating. Collectively, these symptoms were called the *Gulf War syndrome*. The US Department of Defense acknowledges that up to 20,000 troops serving in the combat area may have been exposed to chemical weapons, and the best evidence indicates that the condition is a disorder that in some cases may have been precipitated by exposure to an unidentified toxin (Table 11.1-5). One study of loss of memory found structural change in the right parietal lobe and damage to the basal ganglia with associated neurotransmitter dysfunction. A significant number of veterans have developed amyotrophic lateral sclerosis (ALS), thought to be the result of genetic mutations.

 **Table 11.1-5**
Syndromes Associated with Toxic Exposure^a

Syndrome	Characteristics	Possible Toxins
1	Impaired cognition	Insect repellent containing N,N'-diethyl-m-toluamide (DEET ^b) absorbed through skin
2	Confusion-ataxia	Exposure to chemical weapons (e.g., sarin)
3	Arthromyoneuropathy	Insect repellent containing DEET in combination with oral pyridostigmine ^c

^aThe three syndromes involved a relatively small group ($N = 249$) of veterans and are based on self-reported descriptions and selection. (Data are from R. W. Haley and T. L. Kurt.)

^bDEET is a carbonate compound used as an insect repellent. Concentrations above 30 percent DEET are neurotoxic in children. The military repellent contains 75 percent. (DEET is available in 100 percent concentrations as an unregulated over-the-counter preparation usually sold in sport stores.)

^cMost US troops took low-dose pyridostigmine (Mestinon, 30 mg every 8 hours) for about 5 days in 1991 to protect against exposure to the nerve agent soman.

In a 1997 editorial in the *Journal of the American Medical Association*, the relationship of the Persian Gulf War syndrome and stress was stated as follows:

Physicians need to acknowledge that many Gulf War veterans are experiencing stress-related disorders and the physical consequences of stress. These conditions should not be hidden or denied, but rather are well-recognized entities that have been studied extensively in survivors of past wars, most notably the Vietnam conflict. As physicians, we should not accept a diagnosis of stress-related disorder in veterans prior to excluding treatable physical factors, but at the same time, we need to recognize the pervasive presence of stress-related illness such as hypertension, fibromyalgia, and chronic fatigue among Persian Gulf War veterans and manage these illnesses appropriately. As a nation, we need to get beyond the fallacious idea that diseases of the mind either are not real or are shameful and to better recognize that the mind and the body are inextricably linked.

In addition, thousands of Gulf War veterans developed PTSD and the differentiation between the two disorders has proved difficult. PTSD is caused by psychological stress, and Gulf War syndrome is presumed to be caused by environmental biological stressors. Signs and symptoms often overlap and both conditions may exist at the same time.

9/11/01

On September 11, 2001, terrorist activity destroyed the World Trade Center in New York City and damaged the Pentagon in Washington (Fig. 11.1-1). It resulted in more than 3,500 deaths and injuries and left many citizens in need of therapeutic intervention. One survey found a prevalence rate of 11.4 percent for PTSD and 9.7 percent for depression in US citizens 1 month after 9/11. It is estimated that more than 25,000 people suffer symptoms of PTSD related to the 9/11 attacks beyond the 1-year mark.

FIGURE 11.1-1

Iraq and Afghanistan

In October 2001, the United States, along with Australia, Canada, and the United Kingdom, began the invasion of Afghanistan in the wake of the September 11, 2001, attacks. US forces are scheduled to withdraw by the end of 2014. On March 20, 2003, US forces, along with their allies, invaded Iraq, marking the beginning of the Iraq War, which officially ended on December 15, 2011.

Both wars caused an estimated 17 percent of returning soldiers to develop PTSD. The rate of PTSD is higher in women soldiers. Women account for 11 percent of those who served in Iraq and Afghanistan and for 14 percent of patients at Veterans Administration (VA) hospitals and clinics. Women soldiers are more likely to seek help than men soldiers. The rate of suicide for active duty personnel in both of these wars have assumed epidemic proportions, with the likelihood of suicide being double that of the general population.

Traumatic brain injury (TBI), the result of direct or indirect trauma to the brain, causes changes in either the gross or microscopic structure of the brain with associated signs and symptoms depending on the location of the lesion. In most cases of TBI there will be signs and symptoms of PTSD as well, complicating the picture. According to the Department of Veterans Affairs, 19 percent of veterans may have TBI.

Natural Disasters

Tsunami. On December 26, 2004, a massive tsunami struck the shores of Indonesia, Sri Lanka, South India, and Thailand and caused serious damage and deaths as far west as the coast of Africa and South Africa. The tsunami caused nearly 300,000 deaths and left more than 1 million people without homes. Many survivors continue to live in fear and show signs of PTSD; fishermen fear venturing out to sea, children fear playing at beaches they once enjoyed, and many families have trouble sleeping for fear of another tsunami.

Hurricane. In August 2005, a category 5 hurricane, Hurricane Katrina, ravaged the Gulf of Mexico, the Bahamas, South Florida, Louisiana, Mississippi, and Alabama. Its high winds and torrential rainfall breached the levee system that protected New Orleans, Louisiana, causing major flooding. More than 1,300 people were killed and tens of thousands were left stranded. In October 2012, Hurricane Sandy landed on the eastern coast of the United States and in the New York–New Jersey metropolitan area caused almost 150 deaths with an estimated 650,000 homes damaged or destroyed. Over 50,000 persons were believed to have developed full blown PTSD as a result.

Earthquake. On January 12, 2010, a 7.0 magnitude earthquake hit Port-au-Prince, the capital of the Republic of Haiti, which had a population of approximately 3 million people. Approximately 316,000 people died, 300,000 were injured, and 1 million were made homeless. The government of Haiti also estimated that 250,000 residences and 30,000 commercial buildings had collapsed or were severely damaged, leaving 10 million cubic meters of rubble.

On March 11, 2011, a 9.0 magnitude earthquake hit northeastern Japan, causing a 10-meter tsunami that reached as far as the western coast of the United States, making it the fifth largest earthquake since 1900. Approximately 15,700 people were killed, 4,700 were missing, and 5,700 were injured. It also brought Japan into its second recession in 3 years and triggered the world's biggest nuclear disaster since Chernobyl in 1986.

PTSD developed among those who experienced these disasters, the full extent of which remains to be determined. Some estimates range from 50 to 75 percent of survivors experienced some or all of the signs and symptoms of PTSD.

Torture

The intentional physical and psychological torture of one human by another can have emotionally damaging effects comparable to, and possibly worse than, those seen with combat and other types of trauma. As defined by the United Nations, torture is any deliberate infliction of severe mental pain or suffering, usually through cruel, inhuman, or degrading treatment or punishment. This broad definition includes various forms of interpersonal violence, from chronic domestic abuse to broad-scale genocide. According to Amnesty International, torture is common and widespread in most of the 150 countries worldwide where human rights violations have been documented. Recent figures estimate that between 5 and 35 percent of the world's 14 million refugees have had at least one torture experience, and these numbers do

not even account for the consequences of the current political, regional, and religious disputes in various parts of the world where torture is still practiced.

DIFFERENTIAL DIAGNOSIS

Because patients often exhibit complex reactions to trauma, the clinician must be careful to exclude other syndromes as well when evaluating patients presenting in the wake of trauma. It is particularly important to recognize potentially treatable medical contributors to posttraumatic symptomatology, especially head injury during the trauma. Medical contributors can usually be detected through a careful history and physical examination. Other organic considerations that can both cause and exacerbate the symptoms are epilepsy, alcohol-use disorders, and other substance-related disorders. Acute intoxication or withdrawal from some substances may also present a clinical picture that is difficult to distinguish from the disorder until the effects of the substance have worn off.

Symptoms of PTSD can be difficult to distinguish from both panic disorder and generalized anxiety disorder, because all three syndromes are associated with prominent anxiety and autonomic arousal. Keys to correctly diagnosing PTSD involve a careful review of the time course relating the symptoms to a traumatic event. PTSD is also associated with re-experiencing and avoidance of a trauma, features typically not present in panic or generalized anxiety disorder. Major depression is also a frequent concomitant of PTSD. Although the two syndromes are not usually difficult to distinguish phenomenologically, it is important to note the presence of comorbid depression, because this can influence treatment of PTSD. PTSD must be differentiated from a series of related disorders that can exhibit phenomenological similarities, including borderline personality disorder, dissociative disorders, and factitious disorders. Borderline personality disorder can be difficult to distinguish from PTSD. The two disorders can coexist or even be causally related. Patients with dissociative disorders do not usually have the degree of avoidance behavior, the autonomic hyperarousal, or the history of trauma that patients with PTSD report.

COURSE AND PROGNOSIS

PTSD usually develops some time after the trauma. The delay can be as short as 1 week or as long as 30 years. Symptoms can fluctuate over time and may be most intense during periods of stress. Untreated, about 30 percent of patients recover completely, 40 percent continue to have mild symptoms, 20 percent continue to have moderate symptoms, and 10 percent remain unchanged or become worse. After 1 year, about 50 percent of patients will recover. A good prognosis is predicted by rapid onset of the symptoms, short duration of the symptoms (less than 6 months), good premorbid functioning, strong social supports, and the absence of other psychiatric, medical, or substance-related disorders or other risk factors.

In general, the very young and the very old have more difficulty with traumatic events than do those in midlife. For example, about 80 percent of young children who sustain a burn injury show symptoms of PTSD 1 or 2 years after the initial injury; only 30 percent of adults who suffer such an injury have symptoms of PTSD after 1 year. Presumably, young children do not yet have adequate coping mechanisms to deal with the physical and emotional insults of the trauma. Likewise, older persons are likely to have more rigid coping mechanisms than younger adults and to be less able to muster a flexible approach to dealing with the effects of trauma. Furthermore, the traumatic effects can be exacerbated by physical disabilities characteristic of late life, particularly disabilities of the nervous system and the cardiovascular system, such as reduced cerebral blood flow, failing vision, palpitations, and arrhythmias. Preexisting psychiatric disability, whether a personality disorder or a more serious condition, also increases the effects of particular stressors. PTSD that is comorbid with other disorders is often more severe and perhaps more chronic and may be difficult to treat. The availability of social supports may also influence the development, severity, and duration of PTSD. In general, patients who have a good network of social support are less likely to have the disorder and to experience it in its severe forms and are more likely to recover faster.

TREATMENT

When a clinician is faced with a patient who has experienced a significant trauma, the major approaches are support, encouragement to discuss the event, and education about a variety of coping mechanisms (e.g., relaxation). In encouraging persons to talk about the event it is imperative that the clinician allow the person to proceed at his or her own pace. Some patients will not be willing to talk until well after the event has passed, and those wishes should be respected. To press a person who is reluctant to talk about a trauma into doing so is likely to increase rather than decrease the risk of developing PTSD. The use of sedatives and hypnotics can also be helpful in some cases. When a patient has experienced a traumatic event in the past and has now developed PTSD, the emphasis should be on education about the disorder and its treatment, both pharmacological and psychotherapeutic. The clinician should also work to destigmatize the notion of mental illness and PTSD. Additional support for the patient and the family can be obtained through local and national support groups for patients with PTSD.

Pharmacotherapy

Selective serotonin reuptake inhibitors (SSRIs), such as sertraline (Zoloft) and paroxetine (Paxil), are considered first-line treatments for PTSD, owing to their efficacy, tolerability, and safety ratings. SSRIs reduce symptoms from all PTSD symptom clusters and are effective in improving symptoms unique to PTSD, not just symptoms similar to those of depression or other anxiety disorders. Bupropion (BuSpar) is serotonergic and may also be of use.

The efficacy of imipramine (Tofranil) and amitriptyline (Elavil), two tricyclic drugs, in the treatment of PTSD is supported by a number of well-controlled clinical trials. Although some trials of the two drugs have had negative findings, most of these trials had serious design flaws, including too short a duration. Dosages of imipramine and amitriptyline should be the same as those used to treat depressive disorders, and an adequate trial should last at least 8 weeks. Patients who respond well should probably continue the pharmacotherapy for at least 1 year before an attempt is made to withdraw the drug. Some studies indicate that pharmacotherapy is more effective in treating the depression, anxiety, and hyperarousal than in treating the avoidance, denial, and emotional numbing.

Other drugs that may be useful in the treatment of PTSD include the monoamine oxidase inhibitors (MAOIs) (e.g., phenelzine [Nardil]), trazodone (Desyrel), and the anticonvulsants (e.g., carbamazepine [Tegretol], valproate [Depakene]). Some studies have also revealed improvement in PTSD in patients treated with reversible monoamine oxidase inhibitors (RIMAs). Use of clonidine (Catapres) and propranolol (Inderal), which are antiadrenergic agents, is suggested by the theories about noradrenergic hyperactivity in the disorder. There are almost no positive data concerning the use of antipsychotic drugs in the disorder, so the use of drugs such as haloperidol (Haldol) should be reserved for the short-term control of severe aggression and agitation. Research is ongoing about the use of opioid receptor agonists during traumatic events as a preventative against developing PTSD.

Psychotherapy

Psychodynamic psychotherapy may be useful in the treatment of many patients with PTSD. In some cases, reconstruction of the traumatic events with associated abreaction and catharsis may be therapeutic, but psychotherapy must be individualized because reexperiencing the trauma overwhelms some patients.

Psychotherapeutic interventions for PTSD include behavior therapy, cognitive therapy, and hypnosis. Many clinicians advocate time-limited psychotherapy for the victims of trauma. Such therapy usually takes a cognitive approach and also provides support and security. The short-term nature of psychotherapy minimizes the risk of dependence and chronicity, but issues of suspicion, paranoia, and trust often

adversely affect compliance. Therapists should overcome patients' denial of the traumatic event, encourage them to relax, and remove them from the source of the stress. Patients should be encouraged to sleep, using medication if necessary. Support from persons in their environment (e.g., friends and relatives) should be provided. Patients should be encouraged to review and abreact emotional feelings associated with the traumatic event and to plan for future recovery. Abreaction—experiencing the emotions associated with the event—may be helpful for some patients. The amobarbital (Amytal) interview has been used to facilitate this process.

Psychotherapy after a traumatic event should follow a model of crisis intervention with support, education, and the development of coping mechanisms and acceptance of the event. When PTSD has developed, two major psychotherapeutic approaches can be taken. The first is exposure therapy, in which the patient re-experiences the traumatic event through imaging techniques or in vivo exposure. The exposures can be intense, as in implosive therapy, or graded, as in systematic desensitization. The second approach is to teach the patient methods of stress management, including relaxation techniques and cognitive approaches, to coping with stress. Some preliminary data indicate that, although stress management techniques are effective more rapidly than exposure techniques, the results of exposure techniques last longer.

Another psychotherapeutic technique that is relatively novel and somewhat controversial is eye movement desensitization and reprocessing (EMDR), in which the patient focuses on the lateral movement of the clinician's finger while maintaining a mental image of the trauma experience. The general belief is that symptoms can be relieved as patients work through the traumatic event while in a state of deep relaxation. Proponents of this treatment state it is as effective, and possibly more effective, than other treatments for PTSD and that it is preferred by both clinicians and patients who have tried it.

In addition to individual therapy techniques, group therapy and family therapy have been reported to be effective in cases of PTSD. The advantages of group therapy include sharing of traumatic experiences and support from other group members. Group therapy has been particularly successful with Vietnam veterans and survivors of catastrophic disasters such as earthquakes. Family therapy often helps sustain a marriage through periods of exacerbated symptoms. Hospitalization may be necessary when symptoms are particularly severe or when a risk of suicide or other violence exists.

UNSPECIFIED TRAUMA- OR STRESSOR-RELATED DISORDER

In DSM-5, the category of “unspecified trauma- or stressor-related disorder” is used for patients who develop emotional or behavioral symptoms in response to an identifiable stressor but do not meet the full criteria of any other specified trauma- or stressor-related disorder (e.g., acute stress disorder, PTSD, or adjustment disorder). The symptoms cannot meet the criteria for another mental, medical disorder and is not an exacerbation of a preexisting mental disorder. The symptoms also cannot be attributed to the direct physiological effects of a substance. See [Section 11.2](#) for a discussion of adjustment disorders.

11.2 Adjustment Disorders

The diagnostic category of adjustment disorders is widely used among clinicians in practice. Adjustment disorders are characterized by an emotional response to a stressful event. It is one of the few diagnostic entities in which an external stressful event is linked to the development of symptoms. Typically, the stressor involves financial issues, a medical illness, or relationship problem. The symptom complex that develops may involve anxious or depressive affect or may present with a disturbance of conduct. By definition, the symptoms must begin within 3 months of the stressor. A variety of subtypes of adjustment disorder are identified in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). These include adjustment disorder with depressed mood, mixed anxiety and depressed mood, disturbance of conduct, mixed disturbance of emotions and conduct, features of acute stress disorder or posttraumatic stress disorder (PTSD), bereavement, and unspecified type.

EPIDEMIOLOGY

The prevalence of the disorder is estimated to be from 2 to 8 percent of the general population. Women are diagnosed with the disorder twice as often as men, and single women are generally overly represented as most at risk. In children and adolescents, boys and girls are equally diagnosed with adjustment disorders. The disorders can occur at any age but are most frequently diagnosed in adolescents. Among adolescents of either sex, common precipitating stresses are school problems, parental rejection and divorce, and substance abuse. Among adults, common precipitating stresses are marital problems, divorce, moving to a new environment, and financial problems.

Adjustment disorders are one of the most common psychiatric diagnoses for disorders of patients hospitalized for medical and surgical

problems. In one study, 5 percent of persons admitted to a hospital over a 3-year period were classified as having an adjustment disorder. Up to 50 percent of persons with specific medical problems or stressors have been diagnosed with adjustment disorders. Furthermore, 10 to 30 percent of mental health outpatients and up to 50 percent of general hospital inpatients referred for mental health consultations have been diagnosed with adjustment disorders.

ETIOLOGY

By definition, an adjustment disorder is precipitated by one or more stressors. The severity of the stressor or stressors does not always predict the severity of the disorder; the stressor severity is a complex function of degree, quantity, duration, reversibility, environment, and personal context. For example, the loss of a parent is different for a child 10 years of age than for a person 40 years of age. Personality organization and cultural or group norms and values also contribute to the disproportionate responses to stressors.

Stressors may be single, such as a divorce or the loss of a job, or multiple, such as the death of a person important to a patient, which coincides with the patient's own physical illness and loss of a job. Stressors may be recurrent, such as seasonal business difficulties, or continuous, such as chronic illness or poverty. A discordant intrafamilial relationship can produce an adjustment disorder that affects the entire family system, or the disorder may be limited to a patient who was perhaps the victim of a crime or who has a physical illness. Sometimes, adjustment disorders occur in a group or community setting, and the stressors affect several persons, as in a natural disaster or in racial, social, or religious persecution. Specific developmental stages, such as beginning school, leaving home, getting married, becoming a parent, failing to achieve occupational goals, having the last child leave home, and retiring, are often associated with adjustment disorders.

Psychodynamic Factors

Pivotal to understanding adjustment disorders is an understanding of three factors: the nature of the stressor, the conscious and unconscious meanings of the stressor, and the patient's preexisting vulnerability. A concurrent personality disorder or organic impairment may make a person vulnerable to adjustment disorders. Vulnerability is also associated with the loss of a parent during infancy or being reared in a dysfunctional family. Actual or perceived support from key relationships can affect behavioral and emotional responses to stressors.

Several psychoanalytic researchers have pointed out that the same stress can produce a range of responses in various persons. Throughout his life, Sigmund Freud remained interested in why the stresses of ordinary life produce illness in some and not in others, why an illness takes a particular form, and why some experiences and not others predispose a person to psychopathology. He gave considerable weight to constitutional factors and viewed them as interacting with a person's life experiences to produce fixation.

Psychoanalytic research has emphasized the role of the mother and the rearing environment in a person's later capacity to respond to stress. Particularly important was Donald Winnicott's concept of the good-enough mother, a person who adapts to the infant's needs and provides sufficient support to enable the growing child to tolerate the frustrations in life.

Clinicians must undertake a detailed exploration of a patient's experience of the stressor. Certain patients commonly place all the blame on a particular event when a less obvious event may have had more significant psychological meaning for the patient. Current events may reawaken past traumas or disappointments from childhood, so patients should be encouraged to think about how the current situation relates to similar past events.

Throughout early development, each child develops a unique set of defense mechanisms to deal with stressful events. Because of greater amounts of trauma or greater constitutional vulnerability, some children have less mature defensive constellations than other children. This disadvantage may cause them as adults to react with substantially impaired functioning when they are faced with a loss, a divorce, or a financial setback; those who have developed mature defense mechanisms are less vulnerable and bounce back more quickly from the stressor. Resilience is also crucially determined by the nature of children's early relationships with their parents. Studies of trauma repeatedly indicate that supportive, nurturing relationships prevent traumatic incidents from causing permanent psychological damage.

Psychodynamic clinicians must consider the relation between a stressor and the human developmental life cycle. When adolescents leave home for college, for example, they are at high developmental risk for reacting with a temporary symptomatic picture. Similarly, if the young person who leaves home is the last child in the family, the parents may be particularly vulnerable to a reaction of adjustment disorder. Moreover, middle-aged persons who are confronting their own mortality may be especially sensitive to the effects of loss or death.

Family and Genetic Factors

Some studies suggest that certain persons appear to be at increased risk both for the occurrence of these adverse life events and for the development of pathology once they occur. Findings from a study of more than 2,000 twin pairs indicate that life events and stressors are modestly correlated in twin pairs, with monozygotic twins showing greater concordance than dizygotic twins. Family environmental and genetic factors each accounted for approximately 20 percent of the variance in that study. Another twin study that examined genetic contributions to the development of PTSD symptoms (not necessarily at the level of full disorder and, therefore, relevant to adjustment disorders) also concluded that the likelihood of developing symptoms in response to traumatic life events is partially under genetic control.

DIAGNOSIS AND CLINICAL FEATURES

Although by definition adjustment disorders follow a stressor, the symptoms do not necessarily begin immediately. Up to 3 months may elapse between a stressor and the development of symptoms. Symptoms do not always subside as soon as the stressor ceases; if the stressor continues, the disorder may be chronic. The disorder can occur at any age, and its symptoms vary considerably, with depressive, anxious, and mixed features most common in adults. Physical symptoms, which are most common in children and the elderly, can occur in any age group. Manifestations may also include assaultive behavior and reckless driving, excessive drinking, defaulting on legal responsibilities, withdrawal, vegetative signs, insomnia, and suicidal behavior.

The clinical presentations of adjustment disorder can vary widely. DSM-5 lists six adjustment disorders, including an unspecified category (Table 11.2-1).

Table 11.2-1
DSM-5 Diagnostic Criteria for Adjustment Disorders

- A. The development of emotional or behavioral symptoms in response to an identifiable stressor(s) occurring within 3 months of the onset of the stressor(s).
- B. These symptoms or behavior are clinically significant, as evidenced by one or both of the following:
 1. Marked distress that is out of proportion to the severity or intensity of the stressor, taking into account the external context and the cultural factors that might influence symptom severity and presentation.
 2. Significant impairment in social, occupational, or other areas of functioning.
- C. The stress-related disturbance does not meet the criteria for another mental disorder and is not merely an exacerbation of a preexisting mental disorder.
- D. The symptoms do not represent normal bereavement.
- E. Once the stressor or its consequences have terminated, the symptoms do not persist for more than an additional 6 months.

Specify whether:

- 309.0 (F43.21) With depressed mood:** Low mood, tearfulness, or feelings of hopelessness are predominant.
- 309.24 (F43.22) With anxiety:** Nervousness, worry, jitteriness, or separation anxiety is predominant.
- 309.28 (F43.23) With mixed anxiety and depressed mood:** A combination of depression and anxiety is predominant.
- 309.3 (F43.24) With disturbance of conduct:** Disturbance of conduct is predominant.
- 309.4 (F43.25) With mixed disturbance of emotions and conduct:** Both emotional symptoms (e.g., depression, anxiety) and a disturbance of conduct are predominant.
- 309.9 (F43.20) Unspecified:** For maladaptive reactions that are not classifiable as one of the specific subtypes of adjustment disorder.

Adjustment Disorder with Depressed Mood

In adjustment disorder with depressed mood, the predominant manifestations are depressed mood, tearfulness, and hopelessness. This type must be distinguished from major depressive disorder and uncomplicated bereavement. Adolescents with this type of adjustment disorder are at increased risk for major depressive disorder in young adulthood.

Adjustment Disorder with Anxiety

Symptoms of anxiety, such as palpitations, jitteriness, and agitation, are present in adjustment disorder with anxiety, which must be differentiated from anxiety disorders.

Adjustment Disorder with Mixed Anxiety and Depressed Mood

In adjustment disorder with mixed anxiety and depressed mood, patients exhibit features of both anxiety and depression that do not meet the criteria for an already established anxiety disorder or depressive disorder.

A 48-year-old married woman, in good health, with no previous psychiatric difficulties, presented to the emergency room reporting that she had overdosed on a handful of antihistamines shortly before she arrived. She described her problems as having started 2 months earlier, soon after her husband unexpectedly requested a divorce. She felt betrayed after having devoted much of her 20-year marriage to being a wife, mother, and homemaker. She was sad and tearful at times, and she occasionally had difficulty sleeping. Otherwise, she had no vegetative symptoms and enjoyed time with family and friends. She felt desperate and suicidal after she realized that “he no longer loved me.” After crisis intervention in the emergency setting, she responded well to individual psychotherapy over a 3-month period. She occasionally required benzodiazepines for anxiety during the period of treatment. By the time of discharge, she had returned to her baseline function. She came to terms with the possibility of life after divorce and was exploring her best options under the circumstances. (Courtesy of Jeffrey W. Katzman, M.D., and Cynthia M. A. Geppert, M.D., Ph.D., M.P.H.)

Adjustment Disorder with Disturbance of Conduct

In adjustment disorder with disturbance of conduct, the predominant manifestation involves conduct in which the rights of others are violated or age-appropriate societal norms and rules are disregarded. Examples of behavior in this category are truancy, vandalism, reckless driving, and fighting. The category must be differentiated from conduct disorder and antisocial personality disorder.

Adjustment Disorder with Mixed Disturbance of Emotions and Conduct

A combination of disturbances of emotions and of conduct sometimes occurs. Clinicians are encouraged to try to make one or the other diagnosis in the interest of clarity.

Adjustment Disorder Unspecified

Adjustment disorder unspecified is a residual category for atypical maladaptive reactions to stress. Examples include inappropriate responses to the diagnosis of physical illness, such as massive denial, severe noncompliance with treatment, and social withdrawal, without significant depressed or anxious mood.

DIFFERENTIAL DIAGNOSIS

Although uncomplicated bereavement often produces temporarily impaired social and occupational functioning, the person's dysfunction remains within the expectable bounds of a reaction to the loss of a loved one and, thus, is not considered adjustment disorder. See [Section 34.1](#) for a further discussion of bereavement.

Other disorders from which adjustment disorder must be differentiated include major depressive disorder, brief psychotic disorder, generalized anxiety disorder, somatic symptom disorder, substance-related disorder, conduct disorder, and PTSD. These diagnoses should be given precedence in all cases that meet their criteria, even in the presence of a stressor or group of stressors that served as a precipitant. Patients with an adjustment disorder are impaired in social or occupational functioning and show symptoms beyond the normal and expectable reaction to the stressor. Because no absolute criteria help to distinguish an adjustment disorder from another condition, clinical judgment is necessary. Some patients may meet the criteria for both an adjustment disorder and a personality disorder. If the adjustment disorder follows a physical illness, the clinician must make sure that the symptoms are not a continuation or another manifestation of the illness or its treatment.

Acute and Posttraumatic Stress Disorders

The presence of a stressor is a requirement in the diagnosis of adjustment disorder, PTSD, and acute stress disorder. PTSD and acute stress disorder have the nature of the stressor better characterized and are accompanied by a defined constellation of affective and autonomic symptoms. In contrast, the stressor in adjustment disorder can be of any severity, with a wide range of possible symptoms. When the response to an extreme stressor does not meet the acute stress or posttraumatic disorder threshold, the adjustment disorder diagnosis would be appropriate. PTSD is discussed fully in [Section 11.1](#).

COURSE AND PROGNOSIS

With appropriate treatment, the overall prognosis of an adjustment disorder is generally favorable. Most patients return to their previous level of functioning within 3 months. Some persons (particularly adolescents) who receive a diagnosis of an adjustment disorder later have mood disorders or substance-related disorders. Adolescents usually require a longer time to recover than adults.

Research over the past 5 years has disclosed a risk for suicide, especially in adolescent patients with adjustment disorder, not previously fully appreciated. A recent study of 119 patients with adjustment disorder indicated that 60 percent had documented suicide attempts in the hospital. Fifty percent had attempted suicide immediately prior to their hospital admission. Comorbid diagnoses of substance abuse and personality disorder contributed to the suicide risk profile. A study of the background, pathology, and treatment-related factors of suicidal adolescents found that those with adjustment disorder and suicidality were more likely to have made attempts (up to 25 percent), to exhibit psychomotor restlessness and dysphoric mood, to have experienced a suicide of another person as a stressor, to have poor psychosocial functioning upon treatment entry, and to have received prior psychiatric care.

A 16-year-old high school senior experienced rejection in his first serious relationship. In the weeks after the end of the relationship, he began to exhibit dysphoric mood accompanied by anxiety and psychomotor agitation. He had received counseling in junior high school when his parents divorced and he began using alcohol and marijuana and had been suspended during his freshman year for fighting. A month after the breakup, he began to tell his parents that life was no longer worth living without his former girlfriend. Two months later his parents came home from work and found him hanging in the garage with a note stating he could not go on alone. (Courtesy of J. W. Katzman, M.D., and C. M. A. Geppert, M.D., Ph.D., M.P.H.)

TREATMENT

Psychotherapy

Psychotherapy remains the treatment of choice for adjustment disorders. Group therapy can be particularly useful for patients who have had similar stresses—for example, a group of retired persons or patients having renal dialysis. Individual psychotherapy offers the opportunity to explore the meaning of the stressor to the patient so that earlier traumas can be worked through. After successful therapy, patients sometimes emerge from an adjustment disorder stronger than in the premorbid period, although no pathology was evident during that period. Because a stressor can be clearly delineated in adjustment disorders, it is often believed that psychotherapy is not indicated and that the disorder will remit spontaneously. This viewpoint, however, ignores the fact that many persons exposed to the same stressor experience different symptoms, and in adjustment disorders, the response is pathological. Psychotherapy can help persons adapt to stressors that are not reversible or time limited and can serve as a preventive intervention if the stressor does remit.

Psychiatrists treating adjustment disorders must be particularly aware of problems of secondary gain. The illness role may be rewarding to some normally healthy persons who have had little experience with illness's capacity to free them from responsibility. Thus, patients can find therapists' attention, empathy, and understanding, which are necessary for success, rewarding in their own right, and therapists may thereby reinforce patients' symptoms. Such considerations must be weighed before intensive psychotherapy is begun; when a secondary gain has already been established, therapy is difficult. Patients with an adjustment disorder that includes a conduct disturbance may have difficulties with the law, authorities, or school. Psychiatrists should not attempt to rescue such patients from the consequences of their actions. Too often, such kindness only reinforces socially unacceptable means of tension reduction and hinders the acquisition of insight and subsequent emotional growth. In these cases, family therapy can help.

Crisis Intervention

Crisis intervention and case management are short-term treatments aimed at helping persons with adjustment disorders resolve their situations quickly by supportive techniques, suggestion, reassurance, environmental modification, and even hospitalization, if necessary. The frequency and length of visits for crisis support vary according to patients' needs; daily sessions may be necessary, sometimes two or three times each day. Flexibility is essential in this approach.

Pharmacotherapy

No studies have assessed the efficacy of pharmacological interventions in individuals with adjustment disorder, but it may be reasonable to use medication to treat specific symptoms for a brief time. The judicious use of medications can help patients with adjustment disorders, but they should be prescribed for brief periods. Depending on the type of adjustment disorder, a patient may respond to an anti-anxiety agent or to an antidepressant. Patients with severe anxiety bordering on panic can benefit from anxiolytics such as diazepam (Valium), and those in withdrawn or inhibited states may be helped by a short course of psychostimulant medication. Antipsychotic drugs may be used if there are signs of decompensation or impending psychosis. Selective serotonin reuptake inhibitors have been found useful in treating symptoms of traumatic grief. Recently, there has been an increase in antidepressant use to augment psychotherapy in patients with adjustment disorders. Pharmacological intervention in this population is most often used, however, to augment psychosocial strategies rather than serving as the

primary modality.

In psychiatry, *dissociation* is defined as an unconscious defense mechanism involving the segregation of any group of mental or behavioral processes from the rest of the person's psychic activity. Dissociative disorders involve this mechanism so that there is a disruption in one or more mental functions, such as memory, identity, perception, consciousness, or motor behavior. The disturbance may be sudden or gradual, transient or chronic, and the signs and symptoms of the disorder are often caused by psychological trauma.

Amnesia brought on by intrapsychic conflict is coded differently from amnesia brought on by a medical condition such as encephalitis. In the latter case, according to the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), a diagnosis of neurocognitive disorder due to a medical condition would be made; whereas in the former condition, a diagnosis of dissociative amnesia would be made. (See [Section 21.4](#) which discusses neurocognitive disorders brought on by another medical condition [amnesic disorder] for a further discussion of this topic.)

DISSOCIATIVE AMNESIA

The DSM-5 diagnostic criteria for dissociative amnesia are listed in [Table 12-1](#). The main feature of dissociative amnesia is an inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by normal forgetfulness. And, as mentioned above, the disorder does not result from the direct physiological effects of a substance or a neurological or other general medical condition. The different types of dissociative amnesia are listed in [Table 12-2](#).

 **Table 12-1**
DSM-5 Diagnostic Criteria for Dissociative Amnesia

- A. An inability to recall important autobiographical information, usually of a traumatic or stressful nature, that is inconsistent with ordinary forgetting.
Note: Dissociative amnesia most often consists of localized or selective amnesia for a specific event or events; or generalized amnesia for identity and life history.
 - B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
 - C. The disturbance is not attributable to the physiological effects of a substance (e.g., alcohol or other drug of abuse, a medication) or a neurological or other medical condition (e.g., partial complex seizures, transient global amnesia, sequelae of a closed head injury/traumatic brain injury, other neurological condition).
 - D. The disturbance is not better explained by dissociative identity disorder, posttraumatic stress disorder, acute stress disorder, somatic symptom disorder, or major or mild neurocognitive disorder.
- Coding Note:** The code for dissociative amnesia without dissociative fugue is 300.12 (F44.0). The code for dissociative amnesia with dissociative fugue is 300.13 (F44.1).

Specify if:

300.13 (F44.1) With dissociative fugue: Apparently purposeful travel or bewildered wandering that is associated with amnesia for identity or for other important autobiographical information.

 **Table 12-2**
Types of Dissociative Amnesia

Localized amnesia: Inability to recall events related to a circumscribed period of time

Selective amnesia: Ability to remember some, but not all, of the events occurring during a circumscribed period of time

Generalized amnesia: Failure to recall one's entire life

Continuous amnesia: Failure to recall successive events as they occur

Systematized amnesia: Failure to remember a category of information, such as all memories relating to one's family or to a particular person

A 45-year-old, divorced, left-handed, male bus dispatcher was seen in psychiatric consultation on a medical unit. He had been admitted with an episode of chest discomfort, light-headedness, and left-arm weakness. He had a history of hypertension and had a medical admission in the past year for ischemic chest pain, although he had not suffered a myocardial infarction. Psychiatric consultation was called, because the patient complained of memory loss for the previous 12 years, behaving and responding to the environment as if it were 12 years previously (e.g., he did not recognize his 8-year-old son, insisted that he was unmarried, and denied recollection of current events, such as the name of the current president). Physical and laboratory findings were unchanged from the patient's usual baseline.

Brain computed tomography (CT) scan was normal.

On mental status examination, the patient displayed intact intellectual function but insisted that the date was 12 years earlier, denying recall of his entire subsequent personal history and of current events for the past 12 years. He was perplexed by the contradiction between his memory and current circumstances. The patient described a family history of brutal beatings and physical discipline. He was a decorated combat veteran, although he described amnesic episodes for some of his combat experiences. In the military, he had been a champion golden glove boxer noted for his powerful left hand.

He was educated about his disorder and given the suggestion that his memory could return as he could tolerate it, perhaps overnight during sleep or perhaps over a longer time. If this strategy was unsuccessful, hypnosis or an amobarbital (Amytal) interview was proposed. (Adapted from a case of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Epidemiology

Dissociative amnesia has been reported in a range of approximately 2 to 6 percent of the general population. No known difference is seen in incidence between men and women. Cases generally begin to be reported in late adolescence and adulthood. Dissociative amnesia can be especially difficult to assess in preadolescent children because of their more limited ability to describe subjective experience.

Etiology

In many cases of acute dissociative amnesia, the psychosocial environment out of which the amnesia develops is massively conflictual, with the patient experiencing intolerable emotions of shame, guilt, despair, rage, and desperation. These usually result from conflicts over unacceptable urges or impulses, such as intense sexual, suicidal, or violent compulsions. Traumatic experiences such as physical or sexual abuse can induce the disorder. In some cases the trauma is caused by a betrayal by a trusted, needed other (betrayal trauma). This betrayal is thought to influence the way in which the event is processed and remembered.

Diagnosis and Clinical Features

Classic Presentation. The classic disorder is an overt, florid, dramatic clinical disturbance that frequently results in the patient being brought quickly to medical attention, specifically for symptoms related to the dissociative disorder. It is frequently found in those who have experienced extreme acute trauma. It also commonly develops, however, in the context of profound intrapsychic conflict or emotional stress. Patients may present with intercurrent somatoform or conversion symptoms, alterations in consciousness, depersonalization, derealization, trance states, spontaneous age regression, and even ongoing anterograde dissociative amnesia. Depression and suicidal ideation are reported in many cases. No single personality profile or antecedent history is consistently reported in these patients, although a prior personal or family history of somatoform or dissociative symptoms has been shown to predispose individuals to develop acute amnesia during traumatic circumstances. Many of these patients have histories of prior adult or childhood abuse or trauma. In wartime cases, as in other forms of combat-related posttraumatic disorders, the most important variable in the development of dissociative symptoms, however, appears to be the intensity of combat. [Table 12-3](#) presents the mental status evaluation of dissociative amnesia.

 **Table 12-3**
Mental Status Examination Questions for Dissociative Amnesia

If answers are positive, ask the patient to describe the event.

Make sure to specify that the symptom does not occur during an episode of intoxication.

- (1) Do you ever have blackouts? Blank spells? Memory lapses?
- (2) Do you lose time? Have gaps in your experience of time?
- (3) Have you ever traveled a considerable distance without recollection of how you did this or where you went exactly?
- (4) Do people tell you of things you have said and done that you do not recall?
- (5) Do you find objects in your possession (such as clothes, personal items, groceries in your grocery cart, books, tools, equipment, jewelry, vehicles, weapons, and so on) that you do not remember acquiring? Out-of-character items? Items that a child might have? Toys? Stuffed animals?
- (6) Have you ever been told or found evidence that you have talents and abilities that you did not know that you had? For example, musical, artistic, mechanical, literary, athletic, or other talents? Do your tastes seem to fluctuate a lot? For example, food preference, personal habits, taste in music or clothes, and so forth.
- (7) Do you have gaps in your memory of your life? Are you missing parts of your memory for your life history? Are you missing memories of some important events in your life? For example, weddings, birthdays, graduations, pregnancies, birth of children, and so on.
- (8) Do you lose track of or tune out conversations or therapy sessions as they are occurring? Do you find that, while you are listening to someone talk, you did not hear all or part of what was just said?
- (9) What is the longest period of time that you have lost? Minutes? Hours? Days? Weeks? Months? Years? Describe.

(Adapted from Loewenstein RJ. An office mental status examination for chronic complex dissociative symptoms and multiple personality disorder. *Psychiatr Clin North Am.* 1991;14:567-604, with permission.)

Nonclassic Presentation. These patients frequently come to treatment for a variety of symptoms, such as depression or mood swings, substance abuse, sleep disturbances, somatoform symptoms, anxiety and panic, suicidal or self-mutilating impulses and acts, violent outbursts, eating problems, and interpersonal problems. Self-mutilation and violent behavior in these patients may also be accompanied by amnesia. Amnesia may also occur for flashbacks or behavioral re-experiencing episodes related to trauma.

Differential Diagnosis

The differential diagnosis of dissociative amnesia is listed in Table 12-4.

Table 12-4
Differential Diagnosis of Dissociative Amnesia

Ordinary forgetfulness	Acute stress disorder
Age-related cognitive decline	Posttraumatic stress disorder
Nonpathological forms of amnesia	Somatization disorder
Infantile and childhood amnesia	Psychotic episode
Amnesia for sleep and dreaming	Lack of memory for psychotic episode when returns to nonpsychotic state
Hypnotic amnesia	Mood disorder episode
Dementia	Lack of memory for aspects of episode of mania when depressed and vice versa or when euthymic
Delirium	Factitious disorder
Amnesic disorders	Malingering
Neurological disorders with discrete memory loss episodes	Psychophysiological symptoms or disorders
Posttraumatic amnesia	Asthma and breathing problems
Transient global amnesia	Perimenstrual disorders
Amnesia related to seizure disorders	Irritable bowel syndrome
Substance-related amnesia	Gastroesophageal reflux disease
Alcohol	Somatic memory
Sedative-hypnotics	Affective symptoms
Anticholinergic agents	Depressed mood, dysphoria, or anhedonia
Steroids	Brief mood swings or mood lability
Marijuana	Suicidal thoughts and attempts or self-mutilation
Narcotic analgesics	Guilt and survivor guilt
Psychedelics	Helpless and hopeless feelings
Phencyclidine	Obsessive-compulsive symptoms
Methyldopa (Aldomet)	Ruminations about trauma
Pentazocine (Talwin)	Obsessive counting, singing
Hypoglycemic agents	Arranging
β -blockers	Washing
Lithium carbonate	Checking
Many others	
Other dissociative disorders	
Dissociative fugue	
Dissociative identity disorder	
Dissociative disorder not otherwise specified	

Ordinary Forgetfulness and Nonpathological Amnesia. Ordinary forgetfulness is a phenomenon that is benign and unrelated to stressful events. In dissociative amnesia, the memory loss is more extensive than in nonpathological amnesia. Other nonpathological forms of amnesia have been described, such as infantile and childhood amnesia, amnesia for sleep and dreaming, and hypnotic amnesia.

Dementia, Delirium, and Amnesic Disorders due to Medical Conditions. In patients with dementia, delirium, and amnesic disorders due to medical conditions, the memory loss for personal information is embedded in a far more extensive set of cognitive, language, attentional, behavioral, and memory problems. Loss of memory for personal identity is usually not found without evidence of a marked disturbance in many domains of cognitive function. Causes of organic amnesic disorders include Korsakoff's psychosis, cerebral vascular accident (CVA), postoperative amnesia, postinfectious amnesia, anoxic amnesia, and transient global amnesia. Electroconvulsive therapy (ECT) may also cause a marked temporary amnesia, as well as persistent memory problems in some cases. Here, however, memory loss for autobiographical experience is unrelated to traumatic or overwhelming experiences and seems to involve many different types of personal experiences, most commonly those occurring just before or during the ECT treatments.

Posttraumatic Amnesia. In posttraumatic amnesia caused by brain injury, a history of a clear-cut physical trauma, a period of unconsciousness or amnesia, or both is usually seen, and there is objective clinical evidence of brain injury.

Seizure Disorders. In most seizure cases, the clinical presentation differs significantly from that of dissociative amnesia, with clear-cut ictal events and sequelae. Patients with pseudoepileptic seizures may also have dissociative symptoms, such as amnesia and an antecedent history of psychological trauma. Rarely, patients with recurrent, complex partial seizures present with ongoing bizarre behavior, memory problems, irritability, or violence, leading to a differential diagnostic puzzle. In some of these cases, the diagnosis can be clarified only by telemetry or ambulatory electroencephalographic (EEG) monitoring.

Substance-Related Amnesia. A variety of substances and intoxicants have been implicated in the production of amnesia. Common offending agents are listed in Table 12-4.

Transient Global Amnesia. Transient global amnesia can be mistaken for a dissociative amnesia, especially because stressful life events may precede either disorder. In transient global amnesia, however, there is the sudden onset of complete anterograde amnesia and learning abilities; pronounced retrograde amnesia; preservation of memory for personal identity; anxious awareness of memory loss with repeated, often perseverative, questioning; overall normal behavior; lack of gross neurological abnormalities in most cases; and rapid return of baseline cognitive function, with a persistent short retrograde amnesia. The patient usually is older than 50 years of age and shows risk factors for cerebrovascular disease, although epilepsy and migraine have been etiologically implicated in some cases.

Dissociative Identity Disorders. Patients with dissociative identity disorder can present with acute forms of amnesia and fugue episodes. These patients, however, are characterized by a plethora of symptoms, only some of which are usually found in patients with

dissociative amnesia. With respect to amnesia, most patients with dissociative identity disorder and those with dissociative disorder not otherwise specified with dissociative identity disorder features report multiple forms of complex amnesia, including recurrent blackouts, fugues, unexplained possessions, and fluctuations in skills, habits, and knowledge.

Acute Stress Disorder, Posttraumatic Stress Disorder, and Somatic Symptom Disorder. Most forms of dissociative amnesia are best conceptualized as part of a group of trauma spectrum disorders that includes acute stress disorder, posttraumatic stress disorder (PTSD), and somatic symptom disorder. Many patients with dissociative amnesia meet full or partial diagnostic criteria for those acute stress disorders or a combination of the three. Amnesia is a criterion symptom of each of the latter disorders.

Malingering and Factitious Amnesia. No absolute way exists to differentiate dissociative amnesia from factitious or malingering amnesia. Malingerers have been noted to continue their deception even during hypnotically or barbiturate-facilitated interviews. A patient who presents to psychiatric attention seeking to recover repressed memories as a chief complaint most likely has a factitious disorder or has been subject to suggestive influences. Most of these individuals actually do not describe bona fide amnesia when carefully questioned, but are often insistent that they must have been abused in childhood to explain their unhappiness or life dysfunction.

Course and Prognosis

Little is known about the clinical course of dissociative amnesia. Acute dissociative amnesia frequently spontaneously resolves once the person is removed to safety from traumatic or overwhelming circumstances. At the other extreme, some patients do develop chronic forms of generalized, continuous, or severe localized amnesia and are profoundly disabled and require high levels of social support, such as nursing home placement or intensive family caretaking. Clinicians should try to restore patients' lost memories to consciousness as soon as possible; otherwise, the repressed memory may form a nucleus in the unconscious mind around which future amnesic episodes may develop.

Treatment

Cognitive Therapy. Cognitive therapy may have specific benefits for individuals with trauma disorders. Identifying the specific cognitive distortions that are based in the trauma may provide an entrée into autobiographical memory for which the patient experiences amnesia. As the patient becomes able to correct cognitive distortions, particularly about the meaning of prior trauma, more detailed recall of traumatic events may occur.

Hypnosis. Hypnosis can be used in a number of different ways in the treatment of dissociative amnesia. In particular, hypnotic interventions can be used to contain, modulate, and titrate the intensity of symptoms; to facilitate controlled recall of dissociated memories; to provide support and ego strengthening for the patient; and, finally, to promote working through and integration of dissociated material.

In addition, the patient can be taught self-hypnosis to apply containment and calming techniques in his or her everyday life. Successful use of containment techniques, whether hypnotically facilitated or not, also increases the patient's sense that he or she can more effectively be in control of alternations between intrusive symptoms and amnesia.

Somatic Therapies. No known pharmacotherapy exists for dissociative amnesia other than pharmacologically facilitated interviews. A variety of agents have been used for this purpose, including sodium amobarbital, thiopental (Pentothal), oral benzodiazepines, and amphetamines.

Pharmacologically facilitated interviews using intravenous amobarbital or diazepam (Valium) are used primarily in working with acute amnesias and conversion reactions, among other indications, in general hospital medical and psychiatric services. This procedure is also occasionally useful in refractory cases of chronic dissociative amnesia when patients are unresponsive to other interventions. The material uncovered in a pharmacologically facilitated interview needs to be processed by the patient in his or her usual conscious state.

Group Psychotherapy. Time-limited and longer-term group psychotherapies have been reported to be helpful for combat veterans with PTSD and for survivors of childhood abuse. During group sessions, patients may recover memories for which they have had amnesia. Supportive interventions by the group members or the group therapist, or both, may facilitate integration and mastery of the dissociated material.

DEPERSONALIZATION/DEREALIZATION DISORDER

Depersonalization is defined as the persistent or recurrent feeling of detachment or estrangement from one's self. The individual may report feeling like an automaton or watching himself or herself in a movie (Fig. 12-1). Derealization is somewhat related and refers to feelings of unreality or of being detached from one's environment. The patient may describe his or her perception of the outside world as lacking lucidity and emotional coloring, as though dreaming or dead (Fig. 12-2).

FIGURE 12-1 Dissociative states are characterized by feelings of unreality, as evoked in this photograph. (Courtesy of Arthur Tress.)

FIGURE 12-2 Depersonalization/derealization is experienced as a sense of unreality in one's environment or sense of self, as evoked in this double-exposure photograph. (Courtesy of Hayley R. Weinberg.)

The current DSM-5 definition of depersonalization disorder is found in [Table 12-5](#).

 **Table 12-5**
DSM-5 Diagnostic Criteria for Depersonalization/Derealization Disorder

- A. The presence of persistent or recurrent experiences of depersonalization, derealization, or both:
1. **Depersonalization:** Experiences of unreality, detachment, or being an outside observer with respect to one's thoughts, feelings, sensations, body, or actions (e.g., perceptual alterations, distorted sense of time, unreal or absent self, emotional and physical numbing).
 2. **Derealization:** Experiences of unreality or detachment with respect to surroundings (e.g., individuals or objects are experienced as unreal, dreamlike, foggy, lifeless, or visually distorted).
- B. During the depersonalization or derealization experiences, reality testing remains intact.
- C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, medication) or another medical condition (e.g., seizures).
- E. The disturbance is not better explained by another mental disorder, such as schizophrenia, panic disorder, major depressive disorder, acute stress disorder, posttraumatic stress disorder, or another dissociative disorder.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Epidemiology

Transient experiences of depersonalization and derealization are extremely common in normal and clinical populations. They are the third most commonly reported psychiatric symptoms, after depression and anxiety. One survey found a 1-year prevalence of 19 percent in the general population. It is common in seizure patients and migraine sufferers; they can also occur with use of psychedelic drugs, especially marijuana, lysergic acid diethylamide (LSD), and mescaline, and less frequently as a side effect of some medications, such as anticholinergic agents. They have been described after certain types of meditation, deep hypnosis, extended mirror or crystal gazing, and sensory deprivation experiences. They are also common after mild to moderate head injury, wherein little or no loss of consciousness occurs, but they are significantly less likely if unconsciousness lasts for more than 30 minutes. They are also common after life-threatening experiences, with or without serious bodily injury. Depersonalization is found two to four times more in women than in men.

Etiology

Psychodynamic. Traditional psychodynamic formulations have emphasized the disintegration of the ego or have viewed depersonalization as an affective response in defense of the ego. These explanations stress the role of overwhelming painful experiences or conflictual impulses as triggering events.

Traumatic Stress. A substantial proportion, typically one third to one half, of patients in clinical depersonalization case series report histories of significant trauma. Several studies of accident victims find as many as 60 percent of those with a life-threatening experience report at least transient depersonalization during the event or immediately thereafter. Military training studies find that symptoms of depersonalization and derealization are commonly evoked by stress and fatigue and are inversely related to performance.

Neurobiological Theories. The association of depersonalization with migraines and marijuana, its generally favorable response to selective serotonin reuptake inhibitors (SSRIs), and the increase in depersonalization symptoms seen with the depletion of L-tryptophan, a serotonin precursor, point to serotonergic involvement. Depersonalization is the primary dissociative symptom elicited by the drug-challenge studies described in the section on neurobiological theories of dissociation. These studies strongly implicate the *N*-methyl-D-aspartate (NMDA) subtype of the glutamate receptor as central to the genesis of depersonalization symptoms.

Diagnosis and Clinical Features

A number of distinct components comprise the experience of depersonalization, including a sense of (1) bodily changes, (2) duality of self as observer and actor, (3) being cut off from others, and (4) being cut off from one's own emotions. Patients experiencing depersonalization often have great difficulty expressing what they are feeling. Trying to express their subjective suffering with banal phrases, such as "I feel dead," "Nothing seems real," or "I'm standing outside of myself," depersonalized patients may not adequately convey to the examiner the distress they experience. While complaining bitterly about how this is ruining their life, they may nonetheless appear remarkably undistressed.

Ms. R was a 27-year-old, unmarried, graduate student with a master's degree in biology. She complained about intermittent episodes of "standing back," usually associated with anxiety-provoking social situations. When asked about a recent episode, she described presenting in a seminar course. "All of a sudden, I was talking, but it didn't feel like it was me talking. It was very disconcerting. I had this feeling, 'who's doing the talking?' I felt like I was just watching someone else talk. Listening to words come out of my mouth, but I wasn't saying them. It wasn't me. It went on for a while. I was calm, even sort of peaceful. It was as if I was very far away. In the back of the room somewhere—just watching myself. But the person talking didn't even seem like me really. It was like I was watching someone else." The feeling lasted the rest of that day and persisted into the next, during which time it gradually dissipated. She thought that she remembered having similar experiences during high school, but was certain that they occurred at least once a year during college and graduate school.

As a child, Ms. R reported frequent intense anxiety from overhearing or witnessing the frequent violent arguments and periodic physical fights between her parents. In addition, the family was subject to many unpredictable dislocations and moves owing to the patient's father's intermittent difficulties with finances and employment. The patient's anxieties did not abate when the parents divorced when she was a late adolescent. Her father moved away and had little further contact with her. Her relationship with her mother became increasingly angry, critical, and contentious. She was unsure if she experienced depersonalization during childhood while listening to her parents' fights. (Adapted from a case of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Differential Diagnosis

The variety of conditions associated with depersonalization complicate the differential diagnosis of depersonalization disorder. Depersonalization can result from a medical condition or neurological condition, intoxication or withdrawal from illicit drugs, as a side effect of medications, or can be associated with panic attacks, phobias, PTSD, or acute stress disorder, schizophrenia, or another dissociative disorder. A thorough medical and neurological evaluation is essential, including standard laboratory studies, an EEG, and any indicated drug screens. Drug-related depersonalization is typically transient, but persistent depersonalization can follow an episode of intoxication with a variety of substances, including marijuana, cocaine, and other psychostimulants. A range of neurological conditions, including seizure disorders, brain tumors, postconcussive syndrome, metabolic abnormalities, migraine, vertigo, and Ménière's disease, have been reported as causes. Depersonalization caused by organic conditions tends to be primarily sensory without the elaborated descriptions and personalized meanings common to psychiatric etiologies.

Course and Prognosis

Depersonalization after traumatic experiences or intoxication commonly remits spontaneously after removal from the traumatic circumstances or ending of the episode of intoxication. Depersonalization accompanying mood, psychotic, or other anxiety disorders commonly remits with definitive treatment of these conditions.

Depersonalization disorder itself may have an episodic, relapsing and remitting, or chronic course. Many patients with chronic depersonalization may have a course characterized by severe impairment in occupational, social, and personal functioning. Mean age of onset is thought to be in late adolescence or early adulthood in most cases.

Treatment

Clinicians working with patients with depersonalization/derealization disorder often find them to be a singularly clinically refractory group. Some systematic evidence indicates that SSRI antidepressants, such as fluoxetine (Prozac), may be helpful to patients with depersonalization disorder. Two recent, double-blind, placebo-controlled studies, however, found no efficacy for fluvoxamine (Luvox) and lamotrigine (Lamictal), respectively, for depersonalization disorder. Some patients with depersonalization disorder respond at best sporadically and partially to the usual groups of psychiatric medications, singly or in combination: antidepressants, mood stabilizers, typical and atypical neuroleptics, anticonvulsants, and so forth.

Many different types of psychotherapy have been used to treat depersonalization disorder: psychodynamic, cognitive, cognitive-behavioral, hypnotherapeutic, and supportive. Many such patients do not have a robust response to these specific types of standard psychotherapy. Stress management strategies, distraction techniques, reduction of sensory stimulation, relaxation training, and physical exercise may be somewhat helpful in some patients.

DISSOCIATIVE FUGUE

Dissociative fugue was deleted as a major diagnostic category in DSM-5 and is now diagnosed on a subtype (specifier) of dissociative amnesia. Dissociative fugue can be seen in patients with both dissociative amnesia and dissociative identity disorder. The disorder remains a distinct diagnosis in the *International Statistical Classification of Diseases and Related Health Problems* tenth edition (ICD-10) and is discussed as a discrete entity in *Synopsis* because of its clinical relevance.

Dissociative fugue is described as sudden, unexpected travel away from home or one's customary place of daily activities, with inability to recall some or all of one's past. This is accompanied by confusion about personal identity or even the assumption of a new identity. The disturbance is not due to the direct physiological effects of a substance or a general medical condition. The symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Etiology

Traumatic circumstances (i.e., combat, rape, recurrent childhood sexual abuse, massive social dislocations, natural disasters), leading to an altered state of consciousness dominated by a wish to flee, are the underlying cause of most fugue episodes. In some cases a similar antecedent history is seen, although a psychological trauma is not present at the onset of the fugue episode. In these cases, instead of, or in addition to, external dangers or traumas, the patients are usually struggling with extreme emotions or impulses (i.e., overwhelming fear, guilt, shame, or intense incestuous, sexual, suicidal, or violent urges) that are in conflict with the patient's conscience or ego ideals.

Epidemiology

The disorder is thought to be more common during natural disasters, wartime, or times of major social dislocation and violence, although no systematic data exist on this point. No adequate data exist to demonstrate a gender bias to this disorder; however, most cases describe men, primarily in the military. Dissociative fugue is usually described in adults.

Diagnosis and Clinical Features

Dissociative fugues have been described to last from minutes to months. Some patients report multiple fugues. In most cases in which this was described, a more chronic dissociative disorder, such as dissociative identity disorder, was not ruled out.

In some extremely severe cases of PTSD, nightmares may be terminated by a waking fugue in which the patient runs to another part of the house or runs outside. Children or adolescents may be more limited than adults in their ability to travel. Thus, fugues in this population may be brief and involve only short distances.

A teenage girl was continually sexually abused by her alcoholic father and another family friend. She was threatened with perpetration of sexual abuse on her younger siblings if she told anyone about the abuse. The girl became suicidal but felt that she had to stay alive to protect her siblings. She precipitously ran away from home after being raped by her father and several of his friends as a "birthday present" for one of them. She traveled to a part of the city where she had lived previously with the idea that she would find her grandmother with whom she had lived before the abuse began. She traveled by public transportation and walked the streets, apparently without attracting attention. After approximately 8 hours, she was stopped by the police in a curfew check. When questioned, she could not recall recent events or give her current address, insisting that she lived with her grandmother. On initial psychiatric examination, she was aware of her identity, but she believed that it was 2 years earlier, giving her age as 2 years younger and insisting that none of the events of recent years had occurred. (Courtesy of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

After the termination of a fugue, the patient may experience perplexity, confusion, trance-like behaviors, depersonalization, derealization, and conversion symptoms, in addition to amnesia. Some patients may terminate a fugue with an episode of generalized dissociative

amnesia.

As the patient with dissociative fugue begins to become less dissociated, he or she may display mood disorder symptoms, intense suicidal ideation, and PTSD or anxiety disorder symptoms. In the classic cases, an alter identity is created under whose auspices the patient lives for a period of time. Many of these latter cases are better classified as dissociative identity disorder or, if using DSM-5, as other specified dissociative disorder with features of dissociative identity disorder.

Differential Diagnosis

Individuals with dissociative amnesia may engage in confused wandering during an amnesia episode. In dissociative fugue, however, there is *purposeful* travel away from the individual's home or customary place of daily activities, usually with the individual preoccupied by a single idea that is accompanied by a wish to run away.

Patients with dissociative identity disorder may have symptoms of dissociative fugue, usually recurrently throughout their lives. Patients with dissociative identity disorder have multiple forms of complex amnesias and, usually, multiple alter identities that develop, starting in childhood.

In complex partial seizures, patients have been noted to exhibit wandering or semipurposeful behavior, or both, during seizures or in postictal states, for which subsequent amnesia occurs. Seizure patients in an epileptic fugue often exhibit abnormal behavior, however, including confusion, perseveration, and abnormal or repetitive movements. Other features of seizures are typically reported in the clinical history, such as an aura, motor abnormalities, stereotyped behavior, perceptual alterations, incontinence, and a postictal state. Serial or telemetric EEGs, or both, usually show abnormalities associated with behavioral pathology.

Wandering behavior during a variety of general medical conditions, toxic and substance-related disorders, delirium, dementia, and organic amnesic syndromes could theoretically be confused with dissociative fugue. In most cases, however, the somatic, toxic, neurological, or substance-related disorder can be ruled in by the history, physical examination, laboratory tests, or toxicological and drug screening. Use of alcohol or substances may be involved in precipitating an episode of dissociative fugue.

Wandering and purposeful travel can occur during the manic phase of bipolar disorder or schizoaffective disorder. Patients who are manic may not recall behavior that occurred in the euthymic or depressed state and vice versa. In purposeful travel owing to mania, however, the patient is usually preoccupied with grandiose ideas and often calls attention to himself or herself because of inappropriate behavior. Assumption of an alternate identity does not occur.

Similarly, peripatetic behavior can occur in some patients with schizophrenia. Memory for events during wandering episodes in such patients may be difficult to ascertain owing to the patient's thought disorder. Patients with dissociative fugue, however, do not demonstrate a psychotic thought disorder or other symptoms of psychosis.

Malingering of dissociative fugue can occur in individuals who are attempting to flee a situation involving legal, financial, or personal difficulties, as well as in soldiers who are attempting to avoid combat or unpleasant military duties. No test, battery of tests, or set of procedures exist that invariably distinguish true dissociative symptoms from those that are malingered. Malingering of dissociative symptoms, such as reports of amnesia for purposeful travel during an episode of antisocial behavior, can be maintained even during hypnotic or pharmacologically facilitated interviews. Many malingerers confess spontaneously or when confronted. In the forensic context, the examiner should always carefully consider the diagnosis of malingering when fugue is claimed.

Course and Prognosis

Most fugues are relatively brief, lasting from hours to days. Most individuals appear to recover, although refractory dissociative amnesia may persist in rare cases. Some studies have described recurrent fugues in most individuals presenting with an episode of dissociative fugue. No systematic modern data exist that attempt to differentiate dissociative fugue from dissociative identity disorder with recurrent fugues.

Treatment

Dissociative fugue is usually treated with an eclectic, psychodynamically oriented psychotherapy that focuses on helping the patient recover memory for identity and recent experience. Hypnotherapy and pharmacologically facilitated interviews are frequently necessary adjunctive techniques to assist with memory recovery. Patients may need medical treatment for injuries sustained during the fugue as well as food and sleep.

Clinicians should be prepared for the emergence of suicidal ideation or self-destructive ideas and impulses as the traumatic or stressful prelude circumstances are revealed. Psychiatric hospitalization may be indicated if the patient is an outpatient.

Family, sexual, occupational, or legal problems that were part of the original matrix that generated the fugue episode may be substantially exacerbated by the time the patient's original identity and life situation are detected. Thus, family treatment and social service interventions may be necessary to help resolve such complex difficulties.

When dissociative fugue involves assumption of a new identity, it is useful to conceptualize this entity as psychologically vital to protecting the person. Traumatic experiences, memories, cognitions, identifications, emotions, strivings, self-perceptions, or a combination of these have become so conflicting and, yet, so peremptory that the person can resolve them only by embodying them in an alter identity. The therapeutic goal in such cases is neither suppression of the new identity nor fascinated explication of all its attributes. As in dissociative identity disorder, the clinician should appreciate the importance of the psychodynamic information contained within the alter personality state and the intensity of the psychological forces that necessitated its creation. In these cases, the most desirable therapeutic outcome is fusion of the identities, with the person working through and integrating the memories of the experiences that precipitated the fugue.

DISSOCIATIVE IDENTITY DISORDER

Dissociative identity disorder, previously called multiple personality disorder, has been the most extensively researched of all the dissociative disorders. It is characterized by the presence of two or more distinct identities or personality states. The identities or personality states, sometimes called *alters*, *self-states*, *alter identities*, or *parts*, among other terms, differ from one another in that each presents as having its own pattern of perceiving, relating to, and thinking about the environment and self, in short, its own personality. It is the paradigmatic dissociative psychopathology in that the symptoms of all the other dissociative disorders are commonly found in patients with dissociative identity disorder: amnesia, fugue, depersonalization, derealization, and similar symptoms.

Until about 1800, patients with dissociative identity disorder were mainly seen as suffering from various states of possession. In the early 1800s, Benjamin Rush built on the clinical reports of others and provided a clinical description of the phenomenology of dissociative identity disorder. Subsequently, both Jean-Martin Charcot and Pierre Janet described the symptoms of the disorder and recognized the dissociative nature of the symptoms. Both Sigmund Freud and Eugen Bleuler recognized the symptoms, although Freud attributed psychodynamic mechanisms to the symptoms and Bleuler considered the symptoms to be reflective of schizophrenia. Perhaps because of an increased appreciation of the problem of child sexual and physical abuse and perhaps because of the cases described in the popular media (*The Three Faces of Eve*, *Sybil*), awareness of dissociative identity disorder has increased.

Epidemiology

Few systematic epidemiological data exist for dissociative identity disorder. Clinical studies report female to male ratios between 5 to 1 and

9 to 1 for diagnosed cases.

Etiology

Dissociative identity disorder is strongly linked to severe experiences of early childhood trauma, usually maltreatment. The rates of reported severe childhood trauma for child and adult patients with dissociative identity disorder range from 85 to 97 percent of cases. Physical and sexual abuse are the most frequently reported sources of childhood trauma. The contribution of genetic factors is only now being systematically assessed, but preliminary studies have not found evidence of a significant genetic contribution.

Diagnosis and Clinical Features

The key feature in diagnosing this disorder is the presence of two or more distinct personality states. There are many other signs and symptoms, however, that define the disorder, and because of great diversity, this makes the diagnosis difficult. These are listed in [Table 12-6](#), which describes the many other associated symptoms commonly found in patients with dissociative personality disorder.

 **Table 12-6**
Dissociative Identity Disorder-Associated Symptoms Commonly Found in Dissociative Identity Disorder

Posttraumatic stress disorder symptoms

- Intrusive symptoms

- Hyperarousal

- Avoidance and numbing symptoms

Somatic symptoms

- Conversion and pseudoneurological symptoms

- Seizure-like episodes

- Pain symptoms

- Headache, abdominal, musculoskeletal, pelvic pain

- Psychophysiological symptoms or disorders

- Asthma and breathing problems

- Perimenstrual disorders

- Irritable bowel syndrome

- Gastroesophageal reflux disease

- Somatic memory

Affective symptoms

- Depressed mood, dysphoria, or anhedonia

- Brief mood swings or mood lability

- Suicidal thoughts and attempts of self-mutilation

- Helpless and hopeless feelings

Obsessive-compulsive symptoms

- Ruminations about trauma

- Obsessive counting, singing

- Arranging

- Washing

- Checking

Mental Status. A careful and detailed mental status is essential in making the diagnosis. It is easy to mistake patients with this disorder as suffering from schizophrenia, borderline personality disorder, or of outright malingering. [Table 12-7](#) lists the questions clinicians should ask in order to make the proper diagnosis.

 **Table 12-7**
Mental Status Examination Questions for Dissociative Identity Disorder Process Symptoms

If answers are positive, ask the patient to describe the event.

Make sure to specify that the symptom does not occur during an episode of intoxication

- (1) Do you act so differently in one situation compared to another situation that you feel almost like you were two different people?
- (2) Do you feel that there is more than one of you? More than one part of you? Side of you? Do they seem to be in conflict or in a struggle?
- (3) Does that part (those parts) of you have its (their) own independent way(s) of thinking, perceiving, and relating to the world and the self? Have its (their) own memories, thoughts, and feelings?
- (4) Does more than one of these entities take control of your behavior?
- (5) Do you ever have thoughts or feelings, or both, that come from inside you (outside you) that you cannot explain? That do not feel like thoughts or feelings that you would have? That seem like thoughts or feelings that are not under your control (passive influence)?
- (6) Have you ever felt that your body was engaged in behavior that did not seem to be under your control? For example, saying things, going places, buying things, writing things, drawing or creating things, hurting yourself or others, and so forth? That your body does not seem to belong to you?
- (7) Do you ever feel that you have to struggle against another part of you that seems to want to do or to say something that you do not wish to do or to say?
- (8) Do you ever feel that there is a force (pressure, part) inside you that tries to stop you from doing or saying something?
- (9) Do you ever hear voices, sounds, or conversations in your mind? That seem to be discussing you? Commenting on what you do? Telling you to do or not do certain things? To hurt yourself or others? That seem to be warning you or trying to protect you? That try to comfort, support, or soothe you? That provide important information about things to you? That argue or say things that have nothing to do with you? That have names? Men? Women? Children?
- (10) I would like to talk with that part (side, aspect, facet) of you (of the mind) that is called the "angry one" (the Little Girl, Janie, that went to Atlantic City last weekend and spend lots of money, etc.). Can that part come forward now, please?
- (11) Do you frequently have the experience of feeling like you are outside yourself? Inside yourself? Beside yourself, watching yourself as if you were another person?
- (12) Do you ever feel disconnected from yourself or your body as if you (your body) were not real?
- (13) Do you frequently experience the world around you as unreal? As if you are in a fog or daze? As if it were painted? Two-dimensional?
- (14) Do you ever looking in the mirror and not recognize who you see? See someone else there?

(Adapted from Loewenstein RJ. An office mental status examination for a chronic complex dissociative symptoms and multiple personality disorder. *Psychiatr Clin North Am.* 1991;14:567, with permission.)

Memory and Amnesia Symptoms. Dissociative disturbances of memory are manifest in several basic ways and are frequently observable in clinical settings. As part of the general mental status examination, clinicians should routinely inquire about experiences of losing time, blackout spells, and major gaps in the continuity of recall for personal information. Dissociative time loss experiences are too extensive to be explained by normal forgetting and typically have sharply demarcated onsets and offsets.

Patients with dissociative disorder often report significant gaps in autobiographical memory, especially for childhood events. Dissociative gaps in autobiographical recall are usually sharply demarcated and do not fit the normal decline in autobiographical recall for younger ages.

Ms. A, a 33-year-old married woman employed as a librarian in a school for disturbed children, presented to psychiatric attention after discovering her 5-year-old daughter "playing doctor" with several neighborhood children. Although this event was of little consequence, the patient began to become fearful that her daughter would be molested. The patient was seen by her internist and was treated with antianxiety agents and antidepressants, but with little improvement. She sought psychiatric consultation from several clinicians, but repeated, good trials of antidepressants, antianxiety agents, and supportive psychotherapy resulted in limited improvement. After the death of her father from complications of alcoholism, the patient became more symptomatic. He had been estranged from the family since the patient was approximately 12 years of age, owing to his drinking and associated antisocial behavior.

Psychiatric hospitalization was precipitated by the patient's arrest for disorderly conduct in a nearby city. She was found in a hotel, in revealing clothing, engaged in an altercation with a man. She denied knowledge of how she had come to the hotel, although the man insisted that she had come there under a different name for a voluntary sexual encounter.

On psychiatric examination, the patient described dense amnesia for the first 12 years of her life, with the feeling that her "life started at 12 years old." She reported that, for as long as she could remember, she had an imaginary companion, an elderly black woman, who advised her and kept her company. She reported hearing other voices in her head: several women and children, as well as her father's voice repeatedly speaking to her in a derogatory way. She reported that much of her life since 12 years of age was also punctuated by episodes of amnesia: for work, for her marriage, for the birth of her children, and for her sex life with her husband. She reported

perplexing changes in skills; for example, she was often told that she played the piano well but had no conscious awareness that she could do so. Her husband reported that she had always been “forgetful” of conversations and family activities. He also noted that, at times, she would speak like a child; at times, she would adopt a southern accent; and, at other times, she would be angry and provocative. She frequently had little recall of these episodes.

Questioned more closely about her early life, the patient appeared to enter a trance and stated, “I just don’t want to be locked in the closet” in a child-like voice. Inquiry about this produced rapid shifts in state between alter identities who differed in manifested age, facial expression, voice tone, and knowledge of the patient’s history. One spoke in an angry, expletive-filled manner and appeared irritable and preoccupied with sexuality. She discussed the episode with the man in the hotel and stated that it was she who had arranged it. Gradually, the alters described a history of family chaos, brutality, and neglect during the first 12 years of the patient’s life, until her mother, also alcoholic, achieved sobriety and fled her husband, taking her children with her. The patient, in the alter identities, described episodes of physical abuse, sexual abuse, and emotional torment by the father, her siblings, and her mother.

After assessment of family members, the patient’s mother also met diagnostic criteria for dissociative identity disorder, as did her older sister, who also had been molested. A brother met diagnostic criteria for PTSD, major depression, and alcohol dependence. (Adapted from a case of Richard J. Loewenstein, M.D., and Frank W. Putnam, M.D.)

Dissociative Alterations in Identity. Clinically, dissociative alterations in identity may first be manifested by odd first-person plural or third-person singular or plural self-references. In addition, patients may refer to themselves using their own first names or make depersonalized self-references, such as “the body,” when describing themselves and others. Patients often describe a profound sense of concretized internal division or personified internal conflicts between parts of themselves. In some instances, these parts may have proper names or may be designated by their predominate affect or function, for example, “the angry one” or “the wife.” Patients may suddenly change the way in which they refer to others, for example, “the son” instead of “my son.”

Other Associated Symptoms. Most patients with dissociative identity disorder meet criteria for a mood disorder, usually one of the depression spectrum disorders. Frequent, rapid mood swings are common, but these are usually caused by posttraumatic and dissociative phenomena, not a true cyclic mood disorder. Considerable overlap may exist between PTSD symptoms of anxiety, disturbed sleep, and dysphoria and mood disorder symptoms.

Obsessive-compulsive personality traits are common in dissociative identity disorder, and intercurrent obsessive-compulsive disorder (OCD) symptoms are regularly found in patients with dissociative identity disorder, with a subgroup manifesting severe OCD symptoms. OCD symptoms commonly have a posttraumatic quality: checking repeatedly to be sure that no one can enter the house or the bedroom, compulsive washing to relieve a feeling of being dirty because of abuse, and repetitive counting or singing in the mind to distract from anxiety over being abused, for example.

Child and Adolescent Presentations. Children and adolescents manifest the same core dissociative symptoms and secondary clinical phenomena as adults. Age-related differences in autonomy and lifestyle, however, may significantly influence the clinical expression of dissociative symptoms in youth. Younger children, in particular, have a less linear and less continuous sense of time and often are not able to self-identify dissociative discontinuities in their behavior. Often additional informants, such as teachers and relatives, are available to help document dissociative behaviors.

A number of normal childhood phenomena, such as imaginary companionship and elaborated daydreams, must be carefully differentiated from pathological dissociation in younger children. The clinical presentation may be that of an elaborated or autonomous imaginary companionship, with the imaginary companions taking control of the child’s behavior, often experienced through passive influence experiences or auditory pseudohallucinations, or both, that command the child to behave in certain ways.

Differential Diagnosis

Table 12-8 lists the most common disorders that must be differentiated from dissociative identity disorder.

 **Table 12-8**
Differential Diagnosis of Dissociative Identity Disorder

Comorbidity versus differential diagnosis

Affective disorders

Psychotic disorders

Anxiety disorders

Posttraumatic stress disorder

Personality disorders

Neurocognitive disorders

Neurological and seizure disorders

Somatic symptom disorders

Factitious disorders

Malingering

Other dissociative disorders

Deep-trance phenomena

Factitious, Imitative, and Malingered Dissociative Identity Disorder. Indicators of falsified or *imitative dissociative identity disorder* are reported to include those typical of other factitious or malingering presentations. These include symptom exaggeration, lies, use of symptoms to excuse antisocial behavior (e.g., amnesia only for bad behavior), amplification of symptoms when under observation, refusal to allow collateral contacts, legal problems, and pseudologia fantastica. Patients with genuine dissociative identity disorder are usually confused, conflicted, ashamed, and distressed by their symptoms and trauma history. Those with nongenuine disorder frequently show little dysphoria about their disorder.

Course and Prognosis

Little is known about the natural history of untreated dissociative identity disorder. Some individuals with untreated dissociative identity disorder are thought to continue involvement in abusive relationships or violent subcultures, or both, that may result in the traumatization of their children, with the potential for additional family transmission of the disorder. Many authorities believe that some percentage of patients with undiagnosed or untreated dissociative identity disorder die by suicide or as a result of their risk-taking behaviors.

Prognosis is poorer in patients with comorbid organic mental disorders, psychotic disorders (*not* dissociative identity disorder pseudopsychosis), and severe medical illnesses. Refractory substance abuse and eating disorders also suggest a poorer prognosis. Other factors that usually indicate a poorer outcome include significant antisocial personality features, current criminal activity, ongoing perpetration of abuse, and current victimization, with refusal to leave abusive relationships. Repeated adult traumas with recurrent episodes of acute stress disorder may severely complicate the clinical course.

Treatment

Psychotherapy. Successful psychotherapy for the patient with dissociative identity disorder requires the clinician to be comfortable with a range of psychotherapeutic interventions and be willing to actively work to structure the treatment. These modalities include psychoanalytic psychotherapy, cognitive therapy, behavioral therapy, hypnotherapy, and a familiarity with the psychotherapy and psychopharmacological management of the traumatized patient. Comfort with family treatment and systems theory is helpful in working with a patient who subjectively experiences himself or herself as a complex system of selves with alliances, family-like relationships, and intragroup conflict. A grounding in work with patients with somatoform disorders may also be helpful in sorting through the plethora of somatic symptoms with which these patients commonly present.

Cognitive Therapy. Many cognitive distortions associated with dissociative identity disorder are only slowly responsive to cognitive therapy techniques, and successful cognitive interventions may lead to additional dysphoria. A subgroup of patients with dissociative identity disorder does not progress beyond a long-term supportive treatment entirely directed toward stabilization of their multiple multiaxial difficulties. To the extent that they can be engaged in treatment at all, these patients require a long-term treatment focus on symptom containment and management of their overall life dysfunction, as would be the case with any other severely and persistently ill psychiatric patient.

Hypnosis. Hypnotherapeutic interventions can often alleviate self-destructive impulses or reduce symptoms, such as flashbacks, dissociative hallucinations, and passive-influence experiences. Teaching the patient self-hypnosis may help with crises outside of sessions. Hypnosis can be useful for accessing specific alter personality states and their sequestered affects and memories. Hypnosis is also used to create relaxed mental states in which negative life events can be examined without overwhelming anxiety. Clinicians using hypnosis should be trained in its use in general and in trauma populations. Clinicians should be aware of current controversies over the impact of hypnosis on accurate reporting of recollections and should use appropriate informed consent for its use.

Psychopharmacological Interventions. Antidepressant medications are often important in the reduction of depression and stabilization of mood. A variety of PTSD symptoms, especially intrusive and hyperarousal symptoms, are partially medication responsive. Clinicians report some success with SSRI, tricyclic, and monoamine oxidase (MAO) antidepressants, β -blockers, clonidine (Catapres), anticonvulsants, and benzodiazepines in reducing intrusive symptoms, hyperarousal, and anxiety in patients with dissociative identity disorder. Recent research suggests that the α_1 -adrenergic antagonist prazosin (Minipress) may be helpful for PTSD nightmares. Case reports suggest that aggression may respond to carbamazepine (Tegretol) in some individuals if EEG abnormalities are present. Patients with obsessive-compulsive symptoms may respond to antidepressants with antiobsessive efficacy. Open-label studies suggest that naltrexone (ReVia) may be helpful for amelioration of recurrent self-injurious behaviors in a subset of traumatized patients.

The atypical neuroleptics, such as risperidone (Risperdal), quetiapine (Seroquel), ziprasidone (Geodon), and olanzapine (Zyprexa), may be more effective and better tolerated than typical neuroleptics for overwhelming anxiety and intrusive PTSD symptoms in patients with dissociative identity disorder. Occasionally, an extremely disorganized, overwhelmed, chronically ill patient with dissociative identity disorder, who has not responded to trials of other neuroleptics, responds favorably to a trial of clozapine (Clozaril).

Electroconvulsive Therapy. For some patients, ECT is helpful in ameliorating refractory mood disorders and does not worsen dissociative memory problems. Clinical experience in tertiary care settings for severely ill patients with dissociative identity disorder suggests that a clinical picture of major depression with persistent, refractory melancholic features across all alter states may predict a positive response to ECT. This response is usually only partial, however, as is typical for most successful somatic treatments in the dissociative identity disorder population.

Target symptoms and somatic treatments for dissociative identity disorder are listed in [Table 12-9](#).

Table 12-9
Medications for Associated Symptoms in Dissociative Identity Disorder

Medications and somatic treatments for posttraumatic stress disorder (PTSD), affective disorders, anxiety disorders, and obsessive-compulsive disorder (OCD)

Selective serotonin reuptake inhibitors (no preferred agent, except for OCD symptoms)

Fluvoxamine (Luvox) (for OCD presentations)

Clomipramine (Anafranil) (for OCD presentations)

Tricyclic antidepressants

Monoamine oxidase inhibitors (if patient can reliably maintain diet safely)

Electroconvulsive therapy (for refractory depression with persistent melancholic features across all dissociative identity disorder alters)

Mood stabilizers (more useful for PTSD and anxiety than mood swings)

Divalproex (Depakote)

Lamotrigine (Lamictal)

Oral or intramuscular benzodiazepines

Medications for sleep problems

Low-dose trazodone (Desyrel)

Low-dose mirtazapine (Remeron)

Low-dose tricyclic antidepressants

Low-dose neuroleptics

Benzodiazepines (often less helpful for sleep problems in this population)

Zolpidem (Ambien)

Anticholinergic agents (diphenhydramine [Benadryl], hydroxyzine [Vistaril])

Medications for self-injury, addictions

Naltrexone (ReVia)

Adjunctive Treatments

Group Therapy. In therapy groups including general psychiatric patients, the emergence of alter personalities can be disruptive to the group process by eliciting excess fascination or by frightening other patients. Therapy groups composed only of patients with dissociative identity disorder are reported to be more successful, although the groups must be carefully structured, must provide firm limits, and should generally focus only on here-and-now issues of coping and adaptation.

Family Therapy. Family or couples therapy is often important for long-term stabilization and to address pathological family and marital processes that are common in patients with dissociative identity disorder and their family members. Education of family and concerned others about dissociative identity disorder and its treatment may help family members cope more effectively with dissociative identity disorder and PTSD symptoms in their loved ones. Group interventions for education and support of family members have also been found helpful. Sex therapy may be an important part of couples' treatment, because patients with dissociative identity disorder may become intensely phobic of intimate contact for periods of time, and spouses may have little idea how to deal with this in a helpful way.

Self-Help Groups. Patients with dissociative identity disorder usually have a negative outcome to self-help groups or 12-step groups for incest survivors. A variety of problematic issues occur in these settings, including intensification of PTSD symptoms because of discussion of trauma material without clinical safeguards, exploitation of the patient with dissociative identity disorder by predatory group members, contamination of that patient's recall by group discussions of trauma, and a feeling of alienation even from these other reputed sufferers of trauma and dissociation.

Expressive and Occupational Therapies. Expressive and occupational therapies, such as art and movement therapy, have proved particularly helpful in treatment of patients with dissociative identity disorder. Art therapy may be used to help with containment and structuring of severe dissociative identity disorder and PTSD symptoms, as well as to permit these patients safer expression of thoughts, feelings, mental images, and conflicts that they have difficulty verbalizing. Movement therapy may facilitate normalization of body sense and body image for these severely traumatized patients. Occupational therapy may help the patient with focused, structured activities that can be completed successfully and may help with grounding and symptom management.

Eye Movement Desensitization and Reprocessing (EMDR). EMDR is a treatment that has recently been advocated for adjunctive treatment of PTSD. There are disagreements in the literature about the usefulness and efficacy of this modality of treatment, and published efficacy studies are discrepant. No systematic studies have been done in dissociative identity disorder patients using EMDR. Case reports suggest that some dissociative identity disorder patients may be destabilized by EMDR procedures, especially those with acutely increased PTSD and dissociative symptoms. Some authorities believe that EMDR can be used as a helpful adjunct for later phases of treatment in well-stabilized dissociative identity disorder outpatients. The International Society for the Study of Trauma and Dissociation dissociative identity disorder treatment guidelines suggest that EMDR only be used in this patient population by clinicians who have taken advanced EMDR training, are knowledgeable and skilled in phasic trauma treatment for dissociative disorders, and have received supervision in the use of EMDR in dissociative identity disorder.

OTHER SPECIFIED OR UNSPECIFIED DISSOCIATIVE DISORDER

The category of dissociative disorder covers all of the conditions characterized by a primary dissociative response that do not meet diagnostic criteria for one of the other DSM-5 dissociative disorders.

Dissociative Trance Disorder

Dissociative trance disorder is manifest by a temporary, marked alteration in the state of consciousness or by loss of the customary sense of

personal identity without the replacement by an alternate sense of identity. A variant of this, possession trance, involves single or episodic alternations in the state of consciousness, characterized by the exchange of the person's customary identity with a new identity usually attributed to a spirit, divine power, deity, or another person. In this possessed state, the individual exhibits stereotypical and culturally determined behaviors or experiences being controlled by the possessing entity. There must be partial or full amnesia for the event. The trance or possession state must not be a normally accepted part of a cultural or religious practice and must cause significant distress or functional impairment in one or more of the usual domains. Finally, the dissociative trance state must not occur exclusively during the course of a psychotic disorder and is not the result of any substance use or general medical condition.

Brainwashing

DSM-5 describes this dissociative disorder as “identity disturbance due to prolonged and intense coercive persuasion.” Brainwashing occurs largely in the setting of political reform, as has been described at length with the Cultural Revolution in communist China, war imprisonment, torture of political dissidents, terrorist hostages, and, more familiarly in Western culture, totalitarian cult indoctrination. It implies that under conditions of adequate stress and duress, individuals can be made to comply with the demands of those in power, thereby undergoing major changes in their personality, beliefs, and behaviors. Persons subjected to such conditions can undergo considerable harm, including loss of health and life, and they typically manifest a variety of posttraumatic and dissociative symptoms.

The first stage in coercive processes has been likened to the artificial creation of an identity crisis, with the emergence of a new pseudoidentity that manifests characteristics of a dissociative state. Under circumstances of extreme and malignant dependency, overwhelming vulnerability, and danger to one's existence, individuals develop a state characterized by extreme idealization of their captors, with ensuing identification with the aggressor and externalization of their superego, regressive adaptation known as *traumatic infantilism*, paralysis of will, and a state of frozen fright. The coercive techniques that are typically used to induce such a state in the victim have been amply described and include isolation of the subject, degradation, control over all communications and basic daily functions, induction of fear and confusion, peer pressure, assignment of repetitive and monotonous routines, unpredictability of environmental supplies, renunciation of past relationships and values, and various deprivations. Even though physical or sexual abuse, torture, and extreme sensory deprivation and physical neglect can be part of this process, they are not required to define a coercive process. As a result, victims manifest extensive posttraumatic and dissociative symptomatology, including drastic alteration of their identity, values, and beliefs; reduction of cognitive flexibility with regression to simplistic perceptions of good versus evil and dominance versus submission; numbing of experience and blunting of affect; trance-like states and diminished environmental responsiveness; and, in some cases, more severe dissociative symptoms such as amnesia, depersonalization, and shifts in identity.

The treatment of victims of coercion can vary considerably, depending on their particular background, the circumstances involved, and the setting in which help is sought. Although no systematic studies exist in this domain, basic principles involve validation of the traumatic experience and coercive techniques used, cognitive reframing of the events that transpired, exploration of preexisting psychopathology and vulnerabilities (when applicable), and general techniques used in treating posttraumatic and dissociative states. In addition, family interventions and therapy may be required, at least in cases of cult indoctrination, because significant family duress and disruption commonly occur.

Recovered Memory Syndrome

Under hypnosis or during psychotherapy, a patient may recover a memory of a painful experience or conflict—particularly of sexual or physical abuse—that is etiologically significant. When the repressed material is brought back to consciousness, the person not only may recall the experience but may relive it, accompanied by the appropriate affective response (a process called *abreaction*). If the event recalled never really happened but the person believes it to be true and reacts accordingly, it is known as *false memory syndrome*.

The syndrome has led to lawsuits involving accusations of child abuse. However, Thomas E. Gutheil describes memory as a “slender reed—insufficiently strong to bear the weight of a court case.” Even if the memory of abuse is real, the perpetrator is not the present person, but the person of the past. Gutheil does not believe that litigation usually serves the patient's psychological goals. Clinical attention should probably be directed toward helping patients cast aside the limiting restrictive role of victim and transcend their past traumas, work through them, and try to get on with their lives.

Ganser Syndrome

Ganser syndrome is a poorly understood condition characterized by the giving of approximate answers (paralogia) together with a clouding of consciousness and is frequently accompanied by hallucinations and other dissociative, somatoform, or conversion symptoms.

Epidemiology. Cases have been reported in a variety of cultures, but the overall frequency of such reports has declined with time. Men outnumber women by approximately 2 to 1. Three of Ganser's first four cases were convicts, leading some authors to consider it to be a disorder of penal populations and, thus, an indicator of potential malingering.

Etiology. Some case reports identify precipitating stressors, such as personal conflicts and financial reverses, whereas others note organic brain syndromes, head injuries, seizures, and medical or psychiatric illness. Psychodynamic explanations are common in the older literature, but organic etiologies are stressed in more recent case studies. It is speculated that the organic insults may act as acute stressors, precipitating the syndrome in vulnerable individuals. Some patients have reported significant histories of childhood maltreatment and adversity.

Diagnosis and Clinical Features. The symptom of *passing over* (*vorbeigehen*) the correct answer for a related, but incorrect one, is the hallmark of Ganser syndrome. The approximate answers often just miss the mark but bear an obvious relation to the question, indicating that it has been understood. When asked how old she was, a 25-year-old woman answered, “I'm not five.” If asked to do simple calculations (e.g., $2 + 2 = 5$); for general information (the capital of the United States is New York); to identify simple objects (a pencil is a key); or to name colors (green is gray), the patient with Ganser syndrome gives erroneous but comprehensible answers.

A clouding of consciousness also occurs, usually manifest by disorientation, amnesias, loss of personal information, and some impairment of reality testing. Visual and auditory hallucinations occur in roughly one half of the cases. Neurological examination may reveal what Ganser called *hysterical stigmata*, for example, a nonneurological analgesia or shifting hyperalgesia. It must be accompanied by other dissociative symptoms, such as amnesias, conversion symptoms, or trance-like behaviors.

Differential Diagnosis. Given the reported frequent history of organic brain syndromes, seizures, head trauma, and psychosis in Ganser syndrome, a thorough neurological and medical evaluation is warranted. Differential diagnoses include organic dementia, depressive pseudodementia, the confabulation of Korsakoff's syndrome, organic dysphasias, and reactive psychoses. Patients with dissociative identity disorder occasionally may also exhibit Ganser-like symptoms.

Treatment. No systematic treatment studies have been conducted, given the rarity of this condition. In most case reports, the patient has been hospitalized and has been provided with a protective and supportive environment. In some instances, low doses of antipsychotic medications have been reported to be beneficial. Confrontation or interpretations of the patient's approximate answers are not productive,

but exploration of possible stressors may be helpful. Hypnosis and amobarbital narcosynthesis have also been used successfully to help patients reveal the underlying stressors that preceded the development of the syndrome, with concomitant cessation of the Ganser symptoms. Usually, a relatively rapid return to normal function occurs within days, although some cases may take a month or more to resolve. The individual is typically amnesic for the period of the syndrome.

13.1 Introduction and Overview

Psychosomatic medicine has been a specific area of concern within the field of psychiatry for more than 50 years. The term *psychosomatic* is derived from the Greek words *psyche* (soul) and *soma* (body). The term literally refers to how the mind affects the body. Unfortunately, it has come to be used, at least by the lay public, to describe an individual with medical complaints that have no physical cause and are “all in your head.” In part due to this misconceptualization, the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM), in 1980, deleted the nosological term psychophysiological (or psychosomatic) disorders and replaced it with psychological factors affecting physical conditions (see [Section 13.5](#)), nor has the term reappeared in subsequent editions, including the latest edition (DSM-5). Nonetheless, the term continues to be used by researchers and is in the title of major journals in the field (e.g., *Psychosomatic Medicine*, *Psychosomatics*, and *Journal of Psychosomatic Research*). It is also used by the two major national organizations in the field (the Academy of Psychosomatic Medicine and the American Psychosomatic Society) as well as international organizations (e.g., the European Association for Consultation Liaison Psychiatry and Psychosomatics). In 2003 the American Board of Medical Specialties and the American Board of Psychiatry and Neurology approved the specialty of psychosomatic medicine. That decision recognized the importance of the field and also brought the term *psychosomatic* back into common use.

HISTORY

As Edward Shorter discusses in detail in his summary of the history of psychosomatic illness, ways of presenting illness vary over history, because patients unconsciously select symptoms that are thought to represent true somatic illnesses. As a result, psychosomatic presentations have varied over the course of recent history. Prior to 1800, physicians did not conduct clinical evaluations and could not distinguish somatic from psychogenic illness. As a result, the diagnoses of hysteria and hypochondriasis could easily be made in the presence of true medical illnesses and did not suggest any specific disease presentations.

Sigmund Freud was the principal theoretician to bring psyche and soma together. He demonstrated the importance of the emotions in producing mental disturbances and somatic disorders. His early psychoanalytic formulations detailed the role of psychic determinism in somatic conversion reactions. Using Freud’s insight, a number of workers in the early decades of the 20th century tried to expand the understanding of the interrelationship of psyche and soma. The influence on adult organ tissue of various unresolved pregenital impulses was proposed by Karl Abraham in 1927, the application of the idea of conversion reaction to organs under the control of the autonomic nervous systems was described by Sándor Ferenczi in 1926, and the attaching of a symbolic meaning to fever and hemorrhage was suggested by Georg Groddeck in 1929.

In the 20th century, somatization symptoms changed from predominantly neurologic (e.g., hysterical paralysis) to other symptoms such as fatigue and chronic pain. Edward Shorter attributes this change to three causes: (1) improvements in medical diagnostic techniques made it easier to rule out organic causes for neurologic disease; (2) the central nervous system (CNS) paradigm faded; and (3) social roles changed (e.g., the disappearance of the historical notion that “weak” women would be expected to have fainting spells and paralysis).

Although hysterical neurologic symptoms have remained relatively less common in the 21st century, CNS explanations of chronic pain and fatigue are gaining prominence. For example, functional brain research has demonstrated brain dysfunction and possibly genetic contributions among some individuals with fibromyalgia and chronic fatigue syndrome. Those syndromes, while still thought by some to represent somatization variants, are currently established medical diagnoses. The major conceptual trends in the history of psychosomatic medicine are outlined in [Table 13.1-1](#).

 **Table 13.1-1**
Major Conceptual Trends in the History of Psychosomatic Medicine

- I. Psychoanalytic
- Sigmund Freud (1900): Somatic involvement occurs in conversion hysteria, which is psychogenic in origin—e.g., paralysis of an extremity. Conversion hysteria always has a primary psychic cause and meaning; i.e., it represents the symbolic substitutive expression of an unconscious conflict. It involves organs innervated only by the voluntary neuromuscular or the sensorimotor nervous system. Psychic energy that is dammed up is discharged through physiological outlets.
- Sándor Ferenczi (1910): The concept of conversion hysteria is applied to organs innervated by the autonomic nervous system; e.g., the bleeding of ulcerative colitis may be described as representing a specific psychic fantasy.
- Georg Groddeck (1910): Clearly organic diseases, such as fever and hemorrhage, are held to have primary psychic meanings; i.e., they are interpreted as conversion symptoms that represent the expression of unconscious fantasies.
- Franz Alexander (1934, 1968): Psychosomatic symptoms occur only in organs innervated by the autonomic nervous system and have no specific psychic meaning (as does conversion hysteria) but are end results of prolonged physiological states, which are the physiological accompaniments of certain specific unconscious repressed conflicts. Presented first conceptualization of the biopsychosocial model.
- Helen Flanders Dunbar (1936): Specific conscious personality pictures are associated with specific psychosomatic diseases, an idea similar to Meyer Friedman's 1959 theory of the type A coronary type.
- Peter Sifneos, John C. Nemiah (1970): Elaborated the concept of alexithymia. Developmental arrests in the capacity and the ability to express conflict-related affect result in psychosomatic symptom formation. Concept of "alexithymia" modified later by Stoudemire, who advocated the term "somatothymia" emphasizing cultural influences on use of somatic language and somatic symptom to express affective distress.
- II. Psychophysiological
- Walter Cannon (1927): Demonstrated the physiological concomitants of some emotions and the important role of the autonomic nervous system in producing those reactions. The concept is based on Pavlovian behavioral experimental designs.
- Harold Wolff (1943): Attempted to correlate life stress to physiological response, using objective laboratory tests. Physiological change, if prolonged, may lead to structural change. He established the basic research paradigm for the fields of psychoimmunology, psychocardiology, and psychoneuroendocrinology.
- Hans Selye (1945): Under stress, a general adaptation syndrome develops. Adrenal cortical hormones are responsible for the physiological reaction.
- Meyer Friedman (1959): Theory of type A personality as a risk factor for cardiovascular disease. The basic concept was introduced by Helen Flanders Dunbar as early as 1936.
- Robert Ader (2007): Beginning in the 1970s, established the basic concepts and the research methods for the field of psychoneuroimmunology.
- III. Sociocultural
- Karen Horney (1939), James Halliday (1948): Emphasized the influence of the culture in the development of psychosomatic illness. They thought that culture influences the mother, who, in turn, affects the child in her relationship with the child—e.g., nursing, child rearing, anxiety transmission.
- Thomas Holmes, Richard Rahe (1975): Correlated the severity and the number of recent stressful life events with the likelihood of disease.
- IV. Systems theory
- Adolph Meyer (1958): Formulated the psychobiological approach to patient assessment that emphasizes the integrated assessment of developmental, psychological, social, environmental, and biological aspects of the patient's condition. Basic concept of the biopsychosocial model is implicit in his approach.
- Zbigniew Lipowski (1970): A total approach to psychosomatic disease is necessary. External (ecological, infectious, cultural, environmental), internal (emotional), genetic, somatic, and constitutional factors as well as past and present history are important and should be studied by investigators working in the various fields in which they are trained.
- George Engel (1977): Coined the term "biopsychosocial" derived from general systems theory and based on conceptual ideas introduced much earlier by Alexander and Meyer.
- Leon Eisenberg (1995): Contemporary psychiatric research demonstrates that the mind-brain responds to biological and social vectors while being jointly constructed of both. Major brain pathways are specified in the genome; detailed connections are fashioned by, and consequently reflect, socially mediated experience in the world.

CURRENT TRENDS

The practice of psychosomatic medicine has evolved considerably since its early clinical origins and has come to focus on psychiatric illnesses that occur in the setting of physical health care. In large part this evolution has occurred as a result of the increased complexity of medicine, the increased understanding of the relationship of medical illness to psychiatric illness, and the greater appreciation of mind and body as one. A key outcome of this has been the granting of subspecialty status for psychosomatic medicine. Clinical care is now delivered in a variety of health care settings and utilizes an ever expanding set of diagnostic tools, as well as many effective somatic and psychotherapeutic interventions. Research in the area has progressed to include a greater understanding of the relationship between chronic medical conditions and psychiatric disorders and has examined the pathophysiologic relationships, the epidemiology of comorbid medical and psychiatric disorders, and the role specific interventions play in physiologic, clinical, and economic outcomes (Table 13.1-2).

 **Table 13.1-2**
Summary of Clinical Problems in Psychosomatic Medicine

Type of Clinical Problem	Example
Psychiatric symptoms secondary to a medical condition	Delirium, dementia
Psychiatric symptoms as a reaction to medical condition or treatments	Anxiety related to chemotherapy, depression related to limb amputation
Psychiatric complications of medical conditions and treatments	Depression secondary to interferon treatment
Psychological factors precipitating medical symptoms	Somatoform disorders
Medical complications of psychiatric conditions or treatment	Neuroleptic malignant syndrome, acute withdrawal from alcohol or other substance
Co-occurring medical and psychiatric conditions	Recurrence of depressive disorder in setting of cancer treatment (conditions occur independently); schizophrenia in a patient with end-stage renal disease
Psychiatric/psychosocial assessment	Capacity evaluation; evaluation prior to organ transplantation

Psychiatric morbidity is very common in patients with medical conditions, with a prevalence ranging from 20 to 67 percent, depending on the illness. Patients in the general hospital have the highest rate of psychiatric disorders when compared with community samples or patients in ambulatory primary care. For example, compared with community samples, depressive disorders in the general hospital are more than twice as common, and substance abuse is two to three times as common. Delirium occurs in 18 percent of patients. Similarly, increased rates are seen in primary and long-term care.

Psychiatric morbidity has serious effects on medically ill patients and is often a risk factor for their medical conditions. It is well established that depression is both a risk factor and a poor prognostic indicator in coronary artery disease. Psychiatric illness worsens cardiac morbidity and mortality in patients with a history of myocardial infarction, diminishes glycemic control in patients with diabetes, and decreases return to functioning in patients experiencing a stroke. Depressive and anxiety disorders compound the disability associated with stroke. In the context of neurodegenerative disease such as Parkinson's or Alzheimer's, depression, psychosis, and behavioral disturbances are significant predictors of functional decline, institutionalization, and caregiver burden. Hospitalized patients with delirium are significantly less likely to improve in function compared with patients without delirium. Delirium is associated with worse outcomes after surgery, even after controlling for severity of medical illness.

In addition, depression and other mental disorders significantly impact quality of life and the ability of patients to adhere to treatment regimens (e.g., in patients with diabetes mellitus). Psychiatric disorders are linked to nonadherence with antiretroviral therapy, adversely affecting the survival of human immunodeficiency virus (HIV)-infected patients. Psychiatric disorders worsen the prognosis and quality of life of cancer patients. Psychiatric disorders are also linked to nonadherence with safe sex guidelines and with use of sterile needles in HIV-infected injection drug users, thus having major public health implications.

EVALUATION PROCESS IN PSYCHOSOMATIC MEDICINE

Psychiatric assessment in the medical setting includes a standard psychiatric assessment as well as a particular focus on the medical history and context of physical health care. In addition to obtaining a complete psychiatric history, including past history, family history, developmental history, and a review of systems, the medical history and current treatment should be reviewed and documented. A full mental status examination, including a cognitive examination, should be completed, and components of a neurologic and physical examination may be indicated depending on the nature of the presenting problem.

Another important objective of the psychiatric evaluation is to gain an understanding of the patient's experience of his or her illness. In many cases, this becomes the central focus for both the psychiatric assessment and interventions. It is often helpful to develop an understanding of the patient's developmental and personal history as well as key dynamic conflicts, which in turn may help to make the patient's experience with illness more comprehensible. Such an evaluation can include use of the concepts of stress, personality traits, coping strategies, and defense mechanisms. Observations and hypotheses that are developed can help to guide a patient's psychotherapy aimed at diminishing distress and may also be helpful for the primary medical team in their interactions with the patient.

Finally, a full report synthesizing the information should be completed and include specific recommendations for additional evaluations and intervention. Ideally, the report should be accompanied by a discussion with the referring physician.

TREATMENTS USED IN PSYCHOSOMATIC MEDICINE

A host of interventions have been successfully utilized in psychosomatic medicine. Specific consideration must be given to medical illness and treatments when making recommendations for psychotropic medications. Psychotherapy also plays an important role in psychosomatic medicine and may vary in its structure and outcomes as compared with therapy that occurs in a mental health practice.

Psychopharmacologic recommendations need to consider several important factors. In addition to targeting a patient's active symptoms, considering the history of illness and treatments, and weighing the particular side-effect profile of a particular medication, there are several other factors that must be considered that relate to the patient's medical illness and treatment. It is critical to evaluate potential drug-drug interactions and contraindications to the use of potential psychotropic agents. Because the majority of psychotropic medications used are metabolized in the liver, awareness of liver function is important. General appreciation of side effects, such as weight gain, risk of development of diabetes, and cardiovascular risk, must be considered in the choice of medications. In addition, it is also important to incorporate knowledge of recent data that outline effectiveness and specific risks involved for patients with co-occurring psychiatric and physical disorders. For example, a greater understanding of the side effects of antipsychotic medications has raised concerns about the use of these medications in patients with dementia.

The use of psychosocial interventions also requires adaptation when used in this population. The methods and the goals of psychosocial interventions used in the medically ill are often determined by the consideration of disease onset, etiology, course, prognosis, treatment, and understanding of the nature of the presenting psychiatric symptoms in addition to an understanding of the patient's existing coping skills and social support networks. However, there are ample data that psychosocial interventions are effective in addressing a series of identified problems and that such interventions in many cases are associated with a variety of positive clinical outcomes.

13.2 Somatic Symptom Disorder

Somatic symptom disorder, also known as hypochondriasis, is characterized by 6 or more months of a general and nondelusional preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms. This preoccupation causes significant distress and impairment in one's life; it is not accounted for by another psychiatric or medical disorder; and a subset of individuals with somatic symptom disorder has poor insight about the presence of this disorder.

EPIDEMIOLOGY

In general medical clinic populations, the reported 6-month prevalence of this disorder is 4 to 6 percent, but it may be as high as 15 percent. Men and women are equally affected by this disorder. Although the onset of symptoms can occur at any age, the disorder most commonly appears in persons 20 to 30 years of age. Some evidence indicates that this diagnosis is more common among blacks than among whites, but social position, education level, gender, and marital status do not appear to affect the diagnosis. This disorder's complaints reportedly occur in about 3 percent of medical students, usually in the first 2 years, but they are generally transient.

ETIOLOGY

Persons with this disorder augment and amplify their somatic sensations; they have low thresholds for, and low tolerance of, physical discomfort. For example, what persons normally perceive as abdominal pressure, persons with somatic symptom disorder experience as abdominal pain. They may focus on bodily sensations, misinterpret them, and become alarmed by them because of a faulty cognitive scheme.

Somatic symptom disorder can also be understood in terms of a social learning model. The symptoms of this disorder are viewed as a request for admission to the sick role made by a person facing seemingly insurmountable and insoluble problems. The sick role offers an escape that allows a patient to avoid noxious obligations, to postpone unwelcome challenges, and to be excused from usual duties and obligations.

Somatic symptom disorder is sometimes a variant form of other mental disorders, among which depressive disorders and anxiety disorders are most frequently included. An estimated 80 percent of patients with this disorder may have coexisting depressive or anxiety disorders. Patients who meet the diagnostic criteria for somatic symptom disorder may be somatizing subtypes of these other disorders.

The psychodynamic school of thought holds that aggressive and hostile wishes toward others are transferred (through repression and displacement) into physical complaints. The anger of patients with this disorder originates in past disappointments, rejections, and losses, but the patients express their anger in the present by soliciting the help and concern of other persons and then rejecting them as ineffective.

This disorder is also viewed as a defense against guilt, a sense of innate badness, an expression of low self-esteem, and a sign of excessive self-concern. Pain and somatic suffering thus become means of atonement and expiation (undoing) and can be experienced as deserved punishment for past wrongdoing (either real or imaginary) and for a person's sense of wickedness and sinfulness.

DIAGNOSIS

According to the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), the diagnostic criteria for somatic symptom disorder require that patients be preoccupied with the false belief that they have a serious disease, based on their misinterpretation of physical signs or sensations (Table 13.2-1). The belief must last at least 6 months, despite the absence of pathological findings on medical and neurological examinations. The diagnostic criteria also require that the belief cannot have the intensity of a delusion (more appropriately diagnosed as delusional disorder) and cannot be restricted to distress about appearance (more appropriately diagnosed as body dysmorphic disorder). The symptoms of somatic symptom disorder must be sufficiently intense to cause emotional distress or impair the patient's ability to function in important areas of life. Clinicians may specify the presence of poor insight; patients do not consistently recognize that their concerns about disease are excessive.

 **Table 13.2-1**
DSM-5 Diagnostic Criteria for Somatic Symptom Disorder

- A. One or more somatic symptoms that are distressing or result in significant disruption of daily life.
- B. Excessive thoughts, feelings, or behaviors related to the somatic symptoms or associated health concerns as manifested by at least one of the following:
 - 1. Disproportionate and persistent thoughts about the seriousness of one's symptoms.
 - 2. Persistently high level of anxiety about health or symptoms.
 - 3. Excessive time and energy devoted to these symptoms or health concerns.
- C. Although any one somatic symptom may not be continuously present, the state of being symptomatic is persistent (typically more than 6 months).

Specify if:

With predominant pain (previously pain disorder): This specifier is for individuals whose somatic symptoms predominantly involve pain.

Specify if:

Persistent: A persistent course is characterized by severe symptoms, marked impairment, and long duration (more than 6 months).

Specify current severity:

Mild: Only one of the symptoms specified in Criterion B is fulfilled.

Moderate: Two or more of the symptoms specified in Criterion B are fulfilled.

Severe: Two or more of the symptoms specified in Criterion B are fulfilled, plus there are multiple somatic complaints (or one very severe somatic symptom).

CLINICAL FEATURES

Patients with somatic symptom disorder believe that they have a serious disease that has not yet been detected and they cannot be persuaded to the contrary. They may maintain a belief that they have a particular disease or, as time progresses, they may transfer their belief to another disease. Their convictions persist despite negative laboratory results, the benign course of the alleged disease over time, and appropriate reassurances from physicians. Yet, their beliefs are not sufficiently fixed to be delusions. Somatic symptom disorder is often accompanied by symptoms of depression and anxiety and commonly coexists with a depressive or anxiety disorder.

A severe case of somatic symptom disorder that highlights diagnostic, prognostic, and management issues is described in the case study.

Mr. K, a white man in his mid-30s, consulted a general medicine clinic complaining of gastrointestinal problems. Major presenting symptoms were a long list of physical symptoms and concerns mostly related to the gastrointestinal system. These included abdominal pain, left lower quadrant cramps, bloating, persistent sense of fullness in stomach hours after eating, intolerance to foods, constipation, decrease in physical stamina, heart palpitations, and feelings that “skin is getting yellow” and “not getting enough oxygen.” A review of systems disclosed disturbances from virtually every organ system, including tired eyes with blurred vision, sore throat and “lump” in throat, heart palpitations, irregular heartbeat, dizziness, trouble breathing, and general weakness.

The patient reported that symptoms started prior to the age of 30 years. For more than a decade, he had been seen by psychiatrists, general practitioners, and all kinds of medical specialists, including surgeons. He used the Internet constantly and traveled extensively in search of expert evaluations, seeking new procedures and diagnostic assessments. He had undergone repeated colonoscopies, sigmoidoscopies, and computed tomographic (CT) scans, magnetic resonance imaging (MRI) studies, and ultrasound examinations of the abdomen that had failed to disclose any pathology. He was on disability and had been unable to work for more than 2 years due to his condition.

About 3 years before his visit to the medicine clinic, his abdominal complaints and his fixed belief that he had an intestinal obstruction led to an exploratory surgical intervention for the first time, apparently with negative findings. However, according to the patient, the surgery “got things even worse,” and since then he had been operated on at least five other occasions. During these surgeries he has undergone subtotal colectomies and ileostomies due to possible “adhesions” to rule out “mechanical” obstruction. However, available records from some of the surgeries do not disclose any specific pathology other than “intractable constipation.” Pathological specimens were also inconclusive.

The physical examination showed a well-developed, well-nourished male, who was afebrile. A complete physical and neurological examination was normal except for examination of the abdomen, which revealed multiple abdominal scars. Right ileostomy was present, with soft stool in the bag and active bowel sounds. There was no point tenderness and no abdominal distension. During the examination, the patient kept pointing to an area of “hardness” in the left lower quadrant that he thought was a “tight muscle strangling his bowels.” However, the examination did not disclose any palpable mass. Skin and extremities were all within normal limits, and all joints had full range of motion and no swelling. Musculature was well developed. Neurological examination was within normal limits. The patient was scheduled for brief monthly visits by the primary care physician, during which the doctor performed brief physicals, reassured the patient, and allowed the patient to talk about “stressors.” The physician avoided invasive tests or diagnostic procedures, did not prescribe any medications, and avoided telling the patient that the symptoms were mental or “all in his head.” The primary care physician then referred the patient back to psychiatry.

The psychiatrist confirmed a long list of physical symptoms that started before the age of 30 years, most of which remained medically unexplained. The psychiatric examination revealed some anxiety symptoms, including apprehension, tension, uneasiness, and somatic components such as blushing and palpitations that seemed particularly prominent in front of social situations. Possible symptoms of depression included mild dysphoria, low energy, and sleep disturbance, all of which the patient blamed on his “medical” problems. The mental status examination showed that Mr. K's mood was rather somber and pessimistic, although he denied feeling sad or depressed. Affect was irritable. He was somatically focused and had little if any psychological insight. The examination revealed the presence of a few life stressors (unemployment, financial problems, and family issues) that the patient quickly discounted as unimportant. Although the

patient continued to deny having any psychiatric problems or any need for psychiatric intervention or treatment, he agreed to a few regular visits to continue to assess his situation. He refused to engage anyone from his family in this process. Efforts to engage the patient with formal therapy such as cognitive-behavioral therapy (CBT) or a medication trial were all futile, so he was seen only for “supportive psychotherapy,” with the hope of developing rapport and preventing additional iatrogenic complications.

During the follow-up period, the patient was operated on at least one more time and continued to complain of abdominal bloating and constipation and to rely on laxatives. The belief that there was a mechanical obstruction of the intestines continued to be firmly held by the patient and bordered on the delusional. However, he continued to refuse pharmacological treatment. The only medication he accepted was a low-dose benzodiazepine for anxiety. He continued to monitor his intestinal function 24 hours per day and to seek evaluation by prominent specialists, traveling to high-profile specialty centers far from home in search of solutions. (Courtesy of J. I. Escobar, M.D.)

Although DSM-5 specifies that the symptoms must be present for at least 6 months, transient manifestations can occur after major stresses, most commonly the death or serious illness of someone important to the patient or a serious (perhaps life-threatening) illness that has been resolved but that leaves the patient temporarily affected in its wake. Such states that last fewer than 6 months are diagnosed as “Other Specified Somatic Symptom and Related Disorders” in DSM-5. Transient somatic symptom disorder responses to external stress generally remit when the stress is resolved, but they can become chronic if reinforced by persons in the patient’s social system or by health professionals.

DIFFERENTIAL DIAGNOSIS

Somatic symptom disorder must be differentiated from nonpsychiatric medical conditions, especially disorders that show symptoms that are not necessarily easily diagnosed. Such diseases include acquired immunodeficiency syndrome (AIDS), endocrinopathies, myasthenia gravis, multiple sclerosis, degenerative diseases of the nervous system, systemic lupus erythematosus, and occult neoplastic disorders.

Somatic symptom disorder is differentiated from illness anxiety disorder (a new diagnosis in DSM-5 discussed in Section 13.3) by the emphasis in illness anxiety disorder on fear of having a disease rather than a concern about many symptoms. Patients with illness anxiety disorder usually complain about fewer symptoms than patients with somatic symptom disorder; they are primarily concerned about being sick.

Conversion disorder is acute and generally transient and usually involves a symptom rather than a particular disease. The presence or absence of *la belle indifférence* is an unreliable feature with which to differentiate the two conditions. Patients with body dysmorphic disorder wish to appear normal, but believe that others notice that they are not, whereas those with somatic symptom disorder seek out attention for their presumed diseases.

Somatic symptom disorder can also occur in patients with depressive disorders and anxiety disorders. Patients with panic disorder may initially complain that they are affected by a disease (e.g., heart trouble), but careful questioning during the medical history usually uncovers the classic symptoms of a panic attack. Delusional disorder beliefs occur in schizophrenia and other psychotic disorders, but can be differentiated from somatic symptom disorder by their delusional intensity and by the presence of other psychotic symptoms. In addition, schizophrenic patients’ somatic delusions tend to be bizarre, idiosyncratic, and out of keeping with their cultural milieu, as illustrated in the case below.

A 52-year-old man complained “my guts are rotting away.” Even after an extensive medical workup, he could not be reassured that he was not ill.

Somatic symptom disorder is distinguished from factitious disorder with physical symptoms and from malingering in that patients with somatic symptom disorder actually experience and do not simulate the symptoms they report.

COURSE AND PROGNOSIS

The course of the disorder is usually episodic; the episodes last from months to years and are separated by equally long quiescent periods. There may be an obvious association between exacerbations of somatic symptoms and psychosocial stressors. Although no well-conducted large outcome studies have been reported, an estimated one third to one half of all patients with somatic symptom disorder eventually improve significantly. A good prognosis is associated with high socioeconomic status, treatment-responsive anxiety or depression, sudden onset of symptoms, the absence of a personality disorder, and the absence of a related nonpsychiatric medical condition. Most children with the disorder recover by late adolescence or early adulthood.

TREATMENT

Patients with somatic symptom disorder usually resist psychiatric treatment, although some accept this treatment if it takes place in a medical setting and focuses on stress reduction and education in coping with chronic illness. Group psychotherapy often benefits such patients, in part because it provides the social support and social interaction that seem to reduce their anxiety. Other forms of psychotherapy, such as individual insight-oriented psychotherapy, behavior therapy, cognitive therapy, and hypnosis, may be useful.

Frequent, regularly scheduled physical examinations help to reassure patients that their physicians are not abandoning them and that their complaints are being taken seriously. Invasive diagnostic and therapeutic procedures should only be undertaken, however, when objective evidence calls for them. When possible, the clinician should refrain from treating equivocal or incidental physical examination findings.

Pharmacotherapy alleviates somatic symptom disorder only when a patient has an underlying drug-responsive condition, such as an anxiety disorder or depressive disorder. When somatic symptom disorder is secondary to another primary mental disorder, that disorder must be treated in its own right. When the disorder is a transient situational reaction, clinicians must help patients cope with the stress without reinforcing their illness behavior and their use of the sick role as a solution to their problems.

OTHER SPECIFIED OR UNSPECIFIED SOMATIC SYMPTOM DISORDER

This DSM-5 category is used to describe conditions characterized by one or more unexplained physical symptoms of at least 6 months’ duration, which are below the threshold for a diagnosis of somatic symptom disorder. The symptoms are not caused, or fully explained, by another medical, psychiatric, or substance abuse disorder, and they cause clinically significant distress or impairment.

Two types of symptom patterns may be seen in patients with other specified or unspecified somatic symptom disorder: those involving the autonomic nervous system and those involving sensations of fatigue or weakness. In what is sometimes referred to as *autonomic arousal disorder*, some patients are affected with symptoms that are limited to bodily functions innervated by the autonomic nervous system. Such patients have complaints involving the cardiovascular, respiratory, gastrointestinal, urogenital, and dermatological systems. Other patients complain of mental and physical fatigue, physical weakness and exhaustion, and inability to perform many everyday activities because of their symptoms. Some clinicians believe this syndrome is neurasthenia, a diagnosis used primarily in Europe and Asia. The syndrome may

overlap with chronic fatigue syndrome, which various research reports have hypothesized to involved psychiatric, virological, and immunological factors. (See [Chapter 14](#), which discusses chronic fatigue syndrome in depth.) Other conditions included in this unspecified category of somatic symptom disorder are pseudocyesis (discussed in [Chapter 27](#)) and conditions that may not have met the 6-month criterion of the other somatic symptom disorders.

13.3 Illness Anxiety Disorder

Illness anxiety disorder is a new diagnosis in the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) that applies to those persons who are preoccupied with being sick or with developing a disease of some kind. It is a variant of somatic symptom disorder (hypochondriasis) described in Section 13.2. As stated in DSM-5: Most individuals with hypochondriasis are now classified as having somatic symptom disorder; however, in a minority of cases, the diagnosis of illness anxiety disorder applies instead. In describing the differential diagnosis between the two, according to DSM-5, somatic symptom disorder is diagnosed when somatic symptoms are present, whereas in illness anxiety disorder, there are few or no somatic symptoms and persons are “primarily concerned with the idea they are ill.” The diagnosis may also be used for persons who do, in fact, have a medical illness but whose anxiety is out of proportion to their diagnosis and who assume the worst possible outcome imaginable.

EPIDEMIOLOGY

The prevalence of this disorder is unknown aside from using data that relate to hypochondriasis, which gives a prevalence of 4 to 6 percent in a general medical clinic population. In other surveys, up to 15 percent of persons in the general population worry about becoming sick and incapacitated as a result. One might expect the disorder to be diagnosed more frequently in older rather than younger persons. There is no evidence to date that the diagnosis is more common among different races or that gender, social position, education level, and marital status affect the diagnosis.

ETIOLOGY

The etiology is unknown. The social learning model described for somatic symptom disorder may apply to this disorder as well. In that construct, the fear of illness is viewed as a request to play the sick role made by someone facing seemingly insurmountable and insolvable problems. The sick role offers an escape that allows a patient to be excused from usual duties and obligations.

The psychodynamic school of thought is also similar to somatic symptom disorder. Aggressive and hostile wishes toward others are transferred into minor physical complaints or the fear of physical illness. The anger of patients with illness anxiety disorder, as in those with hypochondriasis, originates in past disappointments, rejections, and losses. Similarly, the fear of illness is also viewed as a defense against guilt, a sense of innate badness, an expression of low self-esteem, and a sign of excessive self-concern. The feared illness may also be seen as punishment for past either real or imaginary wrongdoing. The nature of the person’s relationships to significant others in his or her past life may also be significant. A parent who died from a specific illness, for example, might be the stimulus for the fear of developing that illness in the offspring of that parent. The type of the fear may also be symbolic of unconscious conflicts that are reflected in the type of illness of which the person is afraid or the organ system selected (e.g., heart, kidney).

DIAGNOSIS

The major DSM-5 diagnostic criteria for illness anxiety disorder are that patients be preoccupied with the false belief that they have or will develop a serious disease and there are few if any physical signs or symptoms ([Table 13.3-1](#)). The belief must last at least 6 months, and there are no pathological findings on medical or neurological examinations. The belief cannot have the fixity of a delusion (more appropriately diagnosed as delusional disorder) and cannot be distress about appearance (more appropriately diagnosed as body dysmorphic disorder). The anxiety about illness must be incapacitating and cause emotional distress or impair the patient’s ability to function in important areas of life. Some persons with the disorder may visit physicians (care-seeking type) while others may not (care-avoidant type). The majority of patients, however, make repeated visits to physicians and other health care providers.

 **Table 13.3-1**
DSM-5 Diagnostic Criteria for Illness Anxiety Disorder

- A. Preoccupation with having or acquiring a serious illness.
- B. Somatic symptoms are not present or, if present, are only mild in intensity. If another medical condition is present or there is a high risk for developing a medical condition (e.g., strong family history is present), the preoccupation is clearly excessive or disproportionate.
- C. There is a high level of anxiety about health, and the individual is easily alarmed about personal health status.
- D. The individual performs excessive health-related behaviors (e.g., repeatedly checks his or her body for signs of illness) or exhibits maladaptive avoidance (e.g., avoids doctor appointments and hospitals).
- E. Illness preoccupation has been present for at least 6 months, but the specific illness that is feared may change over that period of time.
- F. The illness-related preoccupation is not better explained by another mental disorder, such as somatic symptom disorder, panic disorder, generalized disorder, body dysmorphic disorder, obsessive-compulsive disorder, or delusional disorder, somatic type.

Specify whether:

Care-seeking type: Medical care, including physician visits or undergoing tests and procedures, is frequently used.

Care-avoidant type: Medical care is rarely used.

CLINICAL FEATURES

Patients with illness anxiety disorder, like those with somatic symptom disorder, believe that they have a serious disease that has not yet been diagnosed, and they cannot be persuaded to the contrary. They may maintain a belief that they have a particular disease or, as time progresses, they may transfer their belief to another disease. Their convictions persist despite negative laboratory results, the benign course of the alleged disease over time, and appropriate reassurances from physicians. Their preoccupation with illness interferes with their interaction with family, friends, and coworkers. They are often addicted to Internet searches about their feared illness, inferring the worst from information (or misinformation) they find there.

DIFFERENTIAL DIAGNOSIS

Illness anxiety disorder must be differentiated from other medical conditions. Too often these patients are dismissed as “chronic complainers” and careful medical examinations are not performed. Patients with illness anxiety disorder are differentiated from those with somatic symptom disorder by the emphasis in illness anxiety disorder on fear of having a disease versus the emphasis in somatic symptom disorder on concern about many symptoms; but both may exist to varying degrees in each disorder. Patients with illness anxiety disorder usually complain about fewer symptoms than patients with somatic symptom disorder. Somatic symptom disorder usually has an onset before age 30, whereas illness anxiety disorder has a less specific age of onset. Conversion disorder is acute, generally transient, and usually involves a symptom rather than a particular disease. Pain disorder is chronic, as is hypochondriasis, but the symptoms are limited to complaints of pain. The fear of illness can also occur in patients with depressive and anxiety disorders. If a patient meets the full diagnostic criteria for both illness anxiety disorder and another major mental disorder, such as major depressive disorder or generalized anxiety disorder, the patient should receive both diagnoses. Patients with panic disorder may initially complain that they are affected by a disease (e.g., heart trouble), but careful questioning during the medical history usually uncovers the classic symptoms of a panic attack. Delusional beliefs occur in schizophrenia and other psychotic disorders but can be differentiated from illness anxiety disorder by their delusional intensity and by the presence of other psychotic symptoms. In addition, schizophrenic patients’ somatic delusions tend to be bizarre, idiosyncratic, and out of keeping with their cultural milieu.

Illness anxiety disorder can be differentiated from obsessive-compulsive disorder by the singularity of their beliefs and by the absence of compulsive behavioral traits; but there is often an obsessive quality to the patients’ fear.

COURSE AND PROGNOSIS

Because the disorder is only recently described, there are no reliable data about the prognosis. One may extrapolate from the course of somatic symptom disorder, which is usually episodic; the episodes last from months to years and are separated by equally long quiescent periods. As with hypochondriasis, a good prognosis is associated with high socioeconomic status, treatment-responsive anxiety or depression, sudden onset of symptoms, the absence of a personality disorder, and the absence of a related nonpsychiatric medical condition.

TREATMENT

As with somatic symptom disorder, patients with illness anxiety disorder usually resist psychiatric treatment, although some accept this treatment if it takes place in a medical setting and focuses on stress reduction and education in coping with chronic illness. Group psychotherapy may be of help especially if the group is homogeneous with patients suffering from the same disorder. Other forms of psychotherapy, such as individual insight-oriented psychotherapy, behavior therapy, cognitive therapy, and hypnosis, may be useful.

The role of frequent, regularly scheduled physical examinations is controversial. Some patients may benefit from being reassured that their complaints are being taken seriously and that they do not have the illness of which they are afraid. Others, however, are resistant to seeing a doctor in the first place, or, if having done so, of accepting the fact that there is nothing to worry about. Invasive diagnostic and therapeutic procedures should only be undertaken when objective evidence calls for them. When possible, the clinician should refrain from treating equivocal or incidental physical examination findings.

Pharmacotherapy may be of help in alleviating the anxiety generated by the fear that the patient has about illness, especially if it is one that is life-threatening; but it is only ameliorative and cannot provide lasting relief. That can only come from an effective psychotherapeutic program that is acceptable to the patient and in which he or she is willing and able to participate.

13.4 Functional Neurological Symptom Disorder (Conversion Disorder)

Conversion disorder, also called functional neurological symptom disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), is an illness of symptoms or deficits that affect voluntary motor or sensory functions, which suggest another medical condition, but that is judged to be caused by psychological factors because the illness is preceded by conflicts or other stressors. The symptoms or deficits of conversion disorder are not intentionally produced, are not caused by substance use, are not limited to pain or sexual symptoms, and the gain is primarily psychological and not social, monetary, or legal (Table 13.4-1).

Table 13.4-1
Common Symptoms of Conversion Disorder

Motor Symptoms	Sensory Deficits
Involuntary movements	Anesthesia, especially of extremities
Tics	Midline anesthesia
Blepharospasm	Blindness
Torticollis	Tunnel vision
Opisthotonos	Deafness
Seizures	Visceral Symptoms
Abnormal gait	Psychogenic vomiting
Falling	Pseudocyesis
Astasia-abasia	Globus hystericus
Paralysis	Swooning or syncope
Weakness	Urinary retention
Aphonia	Diarrhea

(Courtesy of Frederick G. Guggenheim, M.D.)

The syndrome currently known as *conversion disorder* was originally combined with the syndrome known as *somatization disorder* and was referred to as hysteria, conversion reaction, or dissociative reaction. Paul Briquet and Jean-Martin Charcot contributed to the development of the concept of conversion disorder by noting the influence of heredity on the symptom and the common association with a traumatic event. The term conversion was introduced by Sigmund Freud, who, based on his work with Anna O, hypothesized that the symptoms of conversion disorder reflect unconscious conflicts.

EPIDEMIOLOGY

Some symptoms of conversion disorder that are not sufficiently severe to warrant the diagnosis may occur in up to one third of the general population sometime during their lives. Reported rates of conversion disorder vary from 11 of 100,000 to 300 of 100,000 in general population samples. Among specific populations, the occurrence of conversion disorder may be even higher than that, perhaps making conversion disorder the most common somatoform disorder in some populations. Several studies have reported that 5 to 15 percent of psychiatric consultations in a general hospital and 25 to 30 percent of admissions to a Veterans Administration hospital involve patients with conversion disorder diagnoses.

The ratio of women to men among adult patients is at least 2 to 1 and as much as 10 to 1; among children, an even higher predominance is seen in girls. Symptoms are more common on the left than on the right side of the body in women. Women who present with conversion symptoms are more likely subsequently to develop somatization disorder than women who have not had conversion symptoms. An association exists between conversion disorder and antisocial personality disorder in men. Men with conversion disorder have often been involved in occupational or military accidents. The onset of conversion disorder is generally from late childhood to early adulthood and is rare before 10 years of age or after 35 years of age, but onset as late as the ninth decade of life has been reported. When symptoms suggest a conversion disorder onset in middle or old age, the probability of an occult neurological or other medical condition is high. Conversion symptoms in children younger than 10 years of age are usually limited to gait problems or seizures.

Data indicate that conversion disorder is most common among rural populations, persons with little education, those with low intelligence quotients, those in low socioeconomic groups, and military personnel who have been exposed to combat situations. Conversion disorder is commonly associated with comorbid diagnoses of major depressive disorder, anxiety disorders, and schizophrenia and shows an increased frequency in relatives of probands with conversion disorder. Limited data suggest that conversion symptoms are more frequent in relatives of people with conversion disorder. An increased risk of conversion disorder in monozygotic, but not dizygotic, twin pairs has been reported.

COMORBIDITY

Medical and, especially, neurological disorders occur frequently among patients with conversion disorders. What is typically seen in these comorbid neurological or medical conditions is an elaboration of symptoms stemming from the original organic lesion.

Depressive disorders, anxiety disorders, and somatization disorders are especially noted for their association with conversion disorder. Conversion disorder in schizophrenia is reported, but it is uncommon. Studies of patients admitted to a psychiatric hospital for conversion disorder reveal, on further study, that one quarter to one half have a clinically significant mood disorder or schizophrenia.

Personality disorders also frequently accompany conversion disorder, especially the histrionic type (in 5 to 21 percent of cases) and the passive-dependent type (9 to 40 percent of cases). Conversion disorders can occur, however, in persons with no predisposing medical, neurological, or psychiatric disorder.

ETIOLOGY

Psychoanalytic Factors

According to psychoanalytic theory, conversion disorder is caused by repression of unconscious intrapsychic conflict and conversion of anxiety into a physical symptom. The conflict is between an instinctual impulse (e.g., aggression or sexuality) and the prohibitions against its expression. The symptoms allow partial expression of the forbidden wish or urge but disguise it, so that patients can avoid consciously confronting their unacceptable impulses; that is, the conversion disorder symptom has a symbolic relation to the unconscious conflict—for example, vaginismus protects the patient from expressing unacceptable sexual wishes. Conversion disorder symptoms also allow patients to communicate that they need special consideration and special treatment. Such symptoms may function as a nonverbal means of controlling or manipulating others.

Learning Theory

In terms of conditioned learning theory, a conversion symptom can be seen as a piece of classically conditioned learned behavior; symptoms of illness, learned in childhood, are called forth as a means of coping with an otherwise impossible situation.

Biological Factors

Increasing data implicate biological and neuropsychological factors in the development of conversion disorder symptoms. Preliminary brain-imaging studies have found hypometabolism of the dominant hemisphere and hypermetabolism of the nondominant hemisphere and have implicated impaired hemispheric communication in the cause of conversion disorder. The symptoms may be caused by an excessive cortical arousal that sets off negative feedback loops between the cerebral cortex and the brainstem reticular formation. Elevated levels of corticofugal output, in turn, inhibit the patient's awareness of bodily sensation, which may explain the observed sensory deficits in some patients with conversion disorder. Neuropsychological tests sometimes reveal subtle cerebral impairments in verbal communication, memory, vigilance, affective incongruity, and attention in these patients.

DIAGNOSIS

The DSM-5 limits the diagnosis of conversion disorder to those symptoms that affect a voluntary motor or sensory function, that is, neurological symptoms. Physicians cannot explain the neurological symptoms solely on the basis of any known neurological condition.

The diagnosis of conversion disorder requires that clinicians find a necessary and critical association between the cause of the neurological symptoms and psychological factors, although the symptoms cannot result from malingering or factitious disorder. The diagnosis of conversion disorder also excludes symptoms of pain and sexual dysfunction and symptoms that occur only in somatization disorder. DSM-5 allows specification of the type of symptom or deficit seen in conversion disorder, for example, with weakness or paralysis, with abnormal movements, or with attacks or seizures.

CLINICAL FEATURES

Paralysis, blindness, and mutism are the most common conversion disorder symptoms. Conversion disorder may be most commonly associated with passive-aggressive, dependent, antisocial, and histrionic personality disorders. Depressive and anxiety disorder symptoms often accompany the symptoms of conversion disorder, and affected patients are at risk for suicide.

Mr. J is a 28-year-old single man who is employed in a factory. He was brought to an emergency department by his father, complaining that he had lost his vision while sitting in the back seat on the way home from a family gathering. He had been playing volleyball at the gathering but had sustained no significant injury except for the volleyball hitting him in the head a few times. As was usual for this man, he had been reluctant to play volleyball because of the lack of his athletic skills and was placed on a team at the last moment. He recalls having some problems with seeing during the game, but his vision did not become ablated until he was in the car on the way home. By the time he got to the emergency department, his vision was improving, although he still complained of blurriness and mild diplopia. The double vision could be attenuated by having him focus on items at different distances.

On examination, Mr. J was fully cooperative, somewhat uncertain about why this would have occurred, and rather nonchalant. Pupillary, oculomotor, and general sensorimotor examinations were normal. After being cleared medically, the patient was sent to a mental health center for further evaluation.

At the mental health center, the patient recounts the same story as he did in the emergency department, and he was still accompanied by his father. He began to recount how his vision started to return to normal when his father pulled over on the side of the road and began to talk to him about the events of the day. He spoke with his father about how he had felt embarrassed and somewhat conflicted about playing volleyball and how he had felt that he really should play because of external pressures. Further history from the patient and his father revealed that this young man had been shy as an adolescent, particularly around athletic participation. He had never had another episode of visual loss. He did recount feeling anxious and sometimes not feeling well in his body during athletic activities.

Discussion with the patient at the mental health center focused on the potential role of psychological and social factors in acute vision loss. The patient was somewhat perplexed by this but was also amenable to discussion. He stated that he clearly recognized that he began seeing and feeling better when his father pulled off to the side of the road and discussed things with him. Doctors admitted that they did not know the cause of the vision loss and that it would likely not return. The patient and his father were satisfied with the medical and psychiatric evaluation and agreed to return for care if there were any further symptoms. The patient was appointed a follow-up time at the outpatient psychiatric clinic. (Courtesy of Michael A. Hollifield, M.D.)

Sensory Symptoms

In conversion disorder, anesthesia and paresthesia are common, especially of the extremities. All sensory modalities can be involved, and the

distribution of the disturbance is usually inconsistent with either central or peripheral neurological disease. Thus, clinicians may see the characteristic stocking-and-glove anesthesia of the hands or feet or the hemianesthesia of the body beginning precisely along the midline.

Conversion disorder symptoms may involve the organs of special sense and can produce deafness, blindness, and tunnel vision. These symptoms can be unilateral or bilateral, but neurological evaluation reveals intact sensory pathways. In conversion disorder blindness, for example, patients walk around without collisions or self-injury, their pupils react to light, and their cortical-evoked potentials are normal.

Motor Symptoms

The motor symptoms of conversion disorder include abnormal movements, gait disturbance, weakness, and paralysis. Gross rhythmical tremors, choreiform movements, tics, and jerks may be present. The movements generally worsen when attention is called to them. One gait disturbance seen in conversion disorder is *astasia-abasia*, which is a wildly ataxic, staggering gait accompanied by gross, irregular, jerky truncal movements and thrashing and waving arm movements. Patients with the symptoms rarely fall; if they do, they are generally not injured.

Other common motor disturbances are paralysis and paresis involving one, two, or all four limbs, although the distribution of the involved muscles does not conform to the neural pathways. Reflexes remain normal; the patients have no fasciculations or muscle atrophy (except after long-standing conversion paralysis); electromyography findings are normal.

Seizure Symptoms

Pseudoseizures are another symptom in conversion disorder. Clinicians may find it difficult to differentiate a pseudoseizure from an actual seizure by clinical observation alone. Moreover, about one third of the patient's pseudoseizures also have a coexisting epileptic disorder. Tongue-biting, urinary incontinence, and injuries after falling can occur in pseudoseizures, although these symptoms are generally not present. Pupillary and gag reflexes are retained after pseudoseizure, and patients have no postseizure increase in prolactin concentrations.

Other Associated Features

Several psychological symptoms have also been associated with conversion disorder.

Primary Gain. Patients achieve primary gain by keeping internal conflicts outside their awareness. Symptoms have symbolic value; they represent an unconscious psychological conflict.

Secondary Gain. Patients accrue tangible advantages and benefits as a result of being sick; for example, being excused from obligations and difficult life situations, receiving support and assistance that might not otherwise be forthcoming, and controlling other persons' behavior.

La Belle Indifférence. *La belle indifférence* is a patient's inappropriately cavalier attitude toward serious symptoms; that is, the patient seems to be unconcerned about what appears to be a major impairment. That bland indifference is also seen in some seriously ill medical patients who develop a stoic attitude. The presence or absence of *la belle indifférence* is not pathognomonic of conversion disorder, but it is often associated with the condition.

Identification. Patients with conversion disorder may unconsciously model their symptoms on those of someone important to them. For example, a parent or a person who has recently died may serve as a model for conversion disorder. During pathological grief reaction, bereaved persons commonly have symptoms of the deceased.

DIFFERENTIAL DIAGNOSIS

One of the major problems in diagnosing conversion disorder is the difficulty of definitively ruling out a medical disorder. Concomitant nonpsychiatric medical disorders are common in hospitalized patients with conversion disorder, and evidence of a current or previous neurological disorder or a systemic disease affecting the brain has been reported in 18 to 64 percent of such patients. An estimated 25 to 50 percent of patients classified as having conversion disorder eventually receive diagnoses of neurological or nonpsychiatric medical disorders that could have caused their earlier symptoms. Thus, a thorough medical and neurological workup is essential in all cases. If the symptoms can be resolved by suggestion, hypnosis, or parenteral amobarbital (Amytal) or lorazepam (Ativan), they are probably the result of conversion disorder.

Neurological disorders (e.g., dementia and other degenerative diseases), brain tumors, and basal ganglia disease must be considered in the differential diagnosis. For example, weakness may be confused with myasthenia gravis, polymyositis, acquired myopathies, or multiple sclerosis. Optic neuritis may be misdiagnosed as conversion disorder blindness. Other diseases that can cause confusing symptoms are Guillain-Barré syndrome, Creutzfeldt-Jakob disease, periodic paralysis, and early neurological manifestations of acquired immunodeficiency syndrome (AIDS). Conversion disorder symptoms occur in schizophrenia, depressive disorders, and anxiety disorders, but these other disorders are associated with their own distinct symptoms that eventually make differential diagnosis possible.

Sensorimotor symptoms also occur in somatization disorder. But somatization disorder is a chronic illness that begins early in life and includes symptoms in many other organ systems. In hypochondriasis, patients have no actual loss or distortion of function; the somatic complaints are chronic and are not limited to neurological symptoms, and the characteristic hypochondriacal attitudes and beliefs are present. If the patient's symptoms are limited to pain, pain disorder can be diagnosed. Patients whose complaints are limited to sexual function are classified as having a sexual dysfunction, rather than conversion disorder.

In both malingering and factitious disorder, the symptoms are under conscious, voluntary control. A malingeringer's history is usually more inconsistent and contradictory than that of a patient with conversion disorder, and a malingeringer's fraudulent behavior is clearly goal directed.

Table 13.4-2 lists examples of important tests that are relevant to conversion disorder symptoms.

 **Table 13.4-2**
Distinctive Physical Examination Findings in Conversion Disorder

Condition	Test	Conversion Findings
Anesthesia	Map dermatomes	Sensory loss does not conform to recognized pattern of distribution
Hemianesthesia	Check midline	Strict half-body split
Astasia-abasia	Walking, dancing	With suggestion, those who cannot walk may still be able to dance; alteration of sensory and motor findings with suggestion
Paralysis, paresis	Drop paralyzed hand onto face	Hand falls next to face, not on it
	Hoover test	Pressure noted in examiner's hand under paralyzed leg when attempting straight leg raising
	Check motor strength	Give-away weakness
Coma	Examiner attempts to open eyes	Resists opening; gaze preference is away from doctor
	Ocular cephalic maneuver	Eyes stare straight ahead, do not move from side to side
Aphonia	Request a cough	Essentially normal coughing sound indicates cords are closing
Intractable sneezing	Observe	Short nasal grunts with little or no sneezing on inspiratory phase; little or no aerosolization of secretions; minimal facial expression; eyes open; stops when asleep; abates when alone
Syncope	Head-up tilt test	Magnitude of changes in vital signs and venous pooling do not explain continuing symptoms
Tunnel vision	Visual fields	Changing pattern on multiple examinations
Profound monocular blindness	Swinging flashlight sign (Marcus Gunn)	Absence of relative afferent pupillary defect
	Binocular visual fields	Sufficient vision in "bad eye" precludes plotting normal physiological blind spot in good eye
Severe bilateral blindness	"Wiggle your fingers, I'm just testing coordination"	Patient may begin to mimic new movements before realizing the slip
	Sudden flash of bright light	Patient flinches
	"Look at your hand"	Patient does not look there
	"Touch your index fingers"	Even blind patients can do this by proprioception

(Courtesy of Frederick G. Guggenheim, M.D.)

COURSE AND PROGNOSIS

The onset of conversion disorder is usually acute, but a crescendo of symptomatology may also occur. Symptoms or deficits are usually of short duration, and approximately 95 percent of acute cases remit spontaneously, usually within 2 weeks in hospitalized patients. If symptoms have been present for 6 months or longer, the prognosis for symptom resolution is less than 50 percent and diminishes further the longer that conversion is present. Recurrence occurs in one fifth to one fourth of people within 1 year of the first episode. Thus, one episode is a predictor for future episodes. A good prognosis is heralded by acute onset, presence of clearly identifiable stressors at the time of onset, a short interval between onset and the institution of treatment, and above average intelligence. Paralysis, aphonia, and blindness are associated with a good prognosis, whereas tremor and seizures are poor prognostic factors.

TREATMENT

Resolution of the conversion disorder symptom is usually spontaneous, although it is probably facilitated by insight-oriented supportive or behavior therapy. The most important feature of the therapy is a relationship with a caring and confident therapist. With patients who are resistant to the idea of psychotherapy, physicians can suggest that the psychotherapy will focus on issues of stress and coping. Telling such patients that their symptoms are imaginary often makes them worse. Hypnosis, anxiolytics, and behavioral relaxation exercises are effective in some cases. Parenteral amobarbital or lorazepam may be helpful in obtaining additional historic information, especially when a patient has recently experienced a traumatic event. Psychodynamic approaches include psychoanalysis and insight-oriented psychotherapy, in which patients explore intrapsychic conflicts and the symbolism of the conversion disorder symptoms. Brief and direct forms of short-term psychotherapy have also been used to treat conversion disorder. The longer the duration of these patients' sick role and the more they have regressed, the more difficult the treatment.

13.5 Psychological Factors Affecting Other Medical Conditions

Psychosomatic medicine has been a specific area of study within the field of psychiatry. It is based on two basic assumptions: There is a unity of mind and body; and psychological factors must be taken into account when considering all disease states.

Concepts derived from the field of psychosomatic medicine influenced both the emergence of complementary and alternative medicine (CAM), which relies heavily on examining psychological factors in the maintenance of health, and the field of holistic medicine, with its emphasis on examining and treating the whole patient, not just his or her illness. The concepts of psychosomatic medicine also influenced the field of behavioral medicine, which integrates the behavioral sciences and the biomedical approach to the prevention, diagnosis, and treatment of disease. Psychosomatic concepts have contributed greatly to those approaches to medical care.

The concepts of psychosomatic medicine are subsumed in the diagnostic entity of “Psychological Factors Affecting Other Medical Conditions.” This category covers physical disorders caused by or adversely affected by emotional or psychological factors. A medical condition must always be present for the diagnosis to be made.

CLASSIFICATION

The diagnostic criteria for “Psychological Factors Affecting Other Medical Conditions” excluded (1) classic mental disorders that have physical symptoms as part of the disorder (e.g., conversion disorder, in which a physical symptom is produced by psychological conflict); (2) somatization disorder, in which the physical symptoms are not based on organic pathology; (3) hypochondriasis, in which patients have an exaggerated concern with their health; (4) physical complaints that are frequently associated with mental disorders (e.g., dysthymic disorder, which usually has such somatic accompaniments as muscle weakness, asthenia, fatigue, and exhaustion); and (5) physical complaints associated with substance-related disorders (e.g., coughing associated with nicotine dependence).

STRESS THEORY

Stress can be described as a circumstance that disturbs, or is likely to disturb, the normal physiological or psychological functioning of a person. In the 1920s, Walter Cannon (1871–1945) conducted the first systematic study of the relation of stress to disease. He demonstrated that stimulation of the autonomic nervous system, particularly the sympathetic system, readied the organism for the “fight-or-flight” response characterized by hypertension, tachycardia, and increased cardiac output. This was useful in the animal who could fight or flee; but in the person who could do neither by virtue of being civilized, the ensuing stress resulted in disease (e.g., produced a cardiovascular disorder).

In the 1950s, Harold Wolff (1898–1962) observed that the physiology of the gastrointestinal (GI) tract appeared to correlate with specific emotional states. Hyperfunction was associated with hostility and hypofunction with sadness. Wolff regarded such reactions as nonspecific, believing that the patient’s reaction is determined by the general life situation and perceptual appraisal of the stressful event. Earlier, William Beaumont (1785–1853), an American military surgeon, had a patient named Alexis St. Martin, who became famous because of a gunshot wound that resulted in a permanent gastric fistula. Beaumont noted that during highly charged emotional states, the mucosa could become either hyperemic or blanch, indicating that blood flow to the stomach was influenced by emotions.

Hans Selye (1907–1982) developed a model of stress that he called the *general adaptation syndrome*. It consisted of three phases: (1) the alarm reaction; (2) the stage of resistance, in which adaptation is ideally achieved; and (3) the stage of exhaustion, in which acquired adaptation or resistance may be lost. He considered stress a nonspecific bodily response to any demand caused by either pleasant or unpleasant conditions. Selye believed that stress, by definition, need not always be unpleasant. He called unpleasant stress *distress*. Accepting both types of stress requires adaptation.

The body reacts to stress—in this sense defined as anything (real, symbolic, or imagined) that threatens an individual’s survival—by putting into motion a set of responses that seeks to diminish the impact of the stressor and restore homeostasis. Much is known about the physiological response to acute stress, but considerably less is known about the response to chronic stress. Many stressors occur over a prolonged period of time or have long-lasting repercussions. For example, the loss of a spouse may be followed by months or years of loneliness, and a violent sexual assault may be followed by years of apprehension and worry. Neuroendocrine and immune responses to such events help explain why and how stress can have deleterious effects.

Neurotransmitter Responses to Stress

Stressors activate noradrenergic systems in the brain (most notably in the locus ceruleus) and cause release of catecholamines from the autonomic nervous system. Stressors also activate serotonergic systems in the brain, as evidenced by increased serotonin turnover. Recent evidence suggests that, although glucocorticoids tend to enhance overall serotonin functioning, differences may exist in glucocorticoid regulation of serotonin-receptor subtypes, which can have implications for serotonergic functioning in depression and related illnesses. For example, glucocorticoids can increase serotonin 5-hydroxytryptamine (5-HT₂)-mediated actions, thus contributing to the intensification of actions of these receptor types, which have been implicated in the pathophysiology of major depressive disorder. Stress also increases dopaminergic neurotransmission in mesoprefrontal pathways.

Amino acid and peptidergic neurotransmitters are also intricately involved in the stress response. Studies have shown that corticotropin-releasing factor (CRF) (as a neurotransmitter, not just as a hormonal regulator of hypothalamic-pituitary-adrenal [HPA] axis functioning), glutamate (through *N*-methyl-D-aspartate [NMDA] receptors), and γ -aminobutyric acid (GABA) all play important roles in generating the stress response or in modulating other stress-responsive systems, such as dopaminergic and noradrenergic brain circuitry.

Endocrine Responses to Stress

In response to stress, CRF is secreted from the hypothalamus into the hypophysial-pituitary-portal system. CRF acts at the anterior pituitary to trigger release of adrenocorticotrophic hormone (ACTH). Once ACTH is released, it acts at the adrenal cortex to stimulate the synthesis and release of glucocorticoids. Glucocorticoids themselves have myriad effects within the body, but their actions can be summarized in the short term as promoting energy use, increasing cardiovascular activity (in the service of the flight-or-fight response), and inhibiting functions such as growth, reproduction, and immunity.

This HPA axis is subject to tight negative feedback control by its own end products (i.e., ACTH and cortisol) at multiple levels, including the anterior pituitary, the hypothalamus, and such suprahypothalamic brain regions as the hippocampus. In addition to CRF, numerous secretagogues (i.e., substances that elicit ACTH release) exist that can bypass CRF release and act directly to initiate the glucocorticoid cascade. Examples of such secretagogues include catecholamines, vasopressin, and oxytocin. Interestingly, different stressors (e.g., cold stress vs. hypotension) trigger different patterns of secretagogue release, again demonstrating that the notion of a uniform stress response to a generic stressor is an oversimplification.

Immune Response to Stress

Part of the stress response consists of the inhibition of immune functioning by glucocorticoids. This inhibition may reflect a compensatory action of the HPA axis to mitigate other physiological effects of stress. Conversely, stress can also cause immune activation through a variety of pathways. CRF itself can stimulate norepinephrine release via CRF receptors located on the locus ceruleus, which activates the sympathetic nervous system, both centrally and peripherally, and increases epinephrine release from the adrenal medulla. In addition, direct links of norepinephrine neurons synapse on immune target cells. Thus, in the face of stressors, profound immune activation also occurs, including the release of humoral immune factors (cytokines) such as interleukin-1 (IL-1) and IL-6. These cytokines can themselves cause further release of CRF, which in theory serves to increase glucocorticoid effects and thereby self-limit the immune activation.

Life Events

A life event or situation, favorable or unfavorable (Selye's distress), often occurring by chance, generates challenges to which the person must adequately respond. Thomas Holmes and Richard Rahe constructed a social readjustment rating scale after asking hundreds of persons from varying backgrounds to rank the relative degree of adjustment required by changing life events. Holmes and Rahe listed 43 life events associated with varying amounts of disruption and stress in average persons' lives and assigned each of them a certain number of units: for example, the death of a spouse, 100 life-change units; divorce, 73 units; marital separations, 65 units; and the death of a close family member, 63 units. Accumulation of 200 or more life-change units in a single year increases the risk of developing a psychosomatic disorder in that year. Of interest, persons who face general stresses optimistically, rather than pessimistically, are less apt to experience psychosomatic disorders; if they do, they are more apt to recover easily (Table 13.5-1).

 **Table 13.5-1**
Social Readjustment Rating Scale

Life Event	Mean Value
1. Death of spouse	100
2. Divorce	73
3. Marital separation from mate	65
4. Detention in jail or other institution	63
5. Death of a close family member	63
6. Major personal injury or illness	53
7. Marriage	50
8. Being fired at work	47
9. Marital reconciliation with mate	45
10. Retirement from work	45
11. Major change in the health or behavior of a family member	44
12. Pregnancy	40
13. Sexual difficulties	39
14. Gaining a new family member (through birth, adoption, oldster moving in, etc.)	39
15. Major business readjustment (merger, reorganization, bankruptcy, etc.)	39

(From Holmes T. Life situations, emotions, and disease. *Psychosom Med.* 1978;9:747, with permission.)

Specific versus Nonspecific Stress Factors

In addition to life stresses such as a divorce or the death of a spouse, some investigators have suggested that specific personalities and conflicts are associated with certain psychosomatic diseases. A specific personality or a specific unconscious conflict may contribute to the development of a specific psychosomatic disorder. Researchers first identified specific personality types in connection with coronary disease. An individual with a coronary personality is a hard-driving, competitive, aggressive person who is predisposed to coronary artery disease. Meyer Friedman and Ray Rosenman first defined two types: (1) type A—similar to the coronary personality—and (2) type B personalities—calm, relaxed, and not susceptible to coronary disease.

Franz Alexander was a major proponent of the theory that specific unconscious conflicts are associated with specific psychosomatic disorders. For example, persons susceptible to having a peptic ulcer were believed to have strong ungratified dependency needs. Persons with essential hypertension were considered to have hostile impulses about which they felt guilty. Patients with bronchial asthma had issues with separation anxiety. The specific psychic stress theory is no longer considered a reliable indicator of who will develop which disorder; the nonspecific stress theory is more acceptable to most workers in the field today. Nevertheless, chronic stress, usually with the intervening variable of anxiety, predisposes certain persons to psychosomatic disorders. The vulnerable organ may be anywhere in the body. Some persons are “stomach reactors,” others are “cardiovascular reactors,” “skin reactors,” and so on. The diathesis or susceptibility of an organ system to react to stress is probably of genetic origin; but it may also result from acquired vulnerability (e.g., lungs weakened by smoking). According to psychoanalytic theory, the choice of the afflicted region is determined by unconscious factors, a concept known as *somatic compliance*. For example, Freud reported on a male patient with fears of homosexual impulses who developed pruritus ani and a woman with guilt over masturbation who developed vulvodynia.

Another nonspecific factor is the concept of alexithymia, developed by Peter Sifneos and John Nemiah, in which persons cannot express feelings because they are unaware of their mood. Such patients develop tension states that leave them susceptible to develop somatic diseases.

SPECIFIC ORGAN SYSTEMS

Gastrointestinal System

GI disorders rank high in medical illnesses associated with psychiatric consultation. This ranking reflects the high prevalence of GI disorders and the link between psychiatric disorders and GI somatic symptoms. A significant proportion of GI disorders are functional disorders. Psychological and psychiatric factors commonly influence onset, severity, and outcome in the functional GI disorders.

Functional Gastrointestinal Disorders. Table 13.5-2 outlines the spectrum of functional GI disorders, which can include symptoms identified throughout the GI tract.

 **Table 13.5-2**
Functional Gastrointestinal Disorders

Functional Esophageal Disorders

Globus	Lump in throat, common transient response to emotional distress
Rumination	Repetitive regurgitation of gastric contents
Noncardiac chest pain	Angina-like chest pain thought to be esophageal in origin; motor abnormalities include nonspecific high-amplitude esophageal contractions, especially in the distal esophagus (<i>nutcracker esophagus</i>) and diffuse esophageal motor spasms; symptoms particularly sensitive to emotional distress
Functional heartburn	Acid reflux without anatomical abnormality or esophagitis
Functional dysphagia	Difficulty swallowing solids or liquids in the absence of anatomical abnormality; intermittent esophageal motor disorder can be present
Unspecified functional esophageal disorder	Other nonspecific esophageal symptoms

Functional Gastrointestinal Disorder

Functional dyspepsia	Symptoms localized to epigastrium include pain, bloating, early satiety, nausea, or vomiting, often associated with heartburn
Aerophagia	Repetitive air swallowing and belching

Functional Bowel Disorder

Irritable bowel syndrome	See discussion in text.
Borbulence	Bloating, fullness, borborygmi, and flatulence
Functional constipation	A wide range of patterns that are difficult to categorize; generally fewer than three bowel movements a week with hardened stools, causing discomfort in defecation; abdominal pain is variably present; diarrhea suggests diagnosis of irritable bowel syndrome
Functional diarrhea	Loose or watery stools more than 75 percent of time, often with urgency or incontinence, which may or may not have pain, but lack other aspects of irritable bowel syndrome
Unspecified functional bowel disorder	Catch-all category for symptoms that are not sufficient to allow clear diagnosis of another functional disorder; includes isolated symptomatic abdominal pain with or without change in stool habits, mucus, urgency, runny or loose stools, distention, heartburn, or borborygmi

Functional Abdominal Pain

Functional abdominal pain	Diffuse abdominal pain without symptoms that are diagnostic of irritable bowel syndrome
Functional biliary pain	Right upper quadrant pain; sphincter of Oddi dyskinesia, fibrosis, or other anatomical abnormalities commonly identified

Functional Anorectal Disorder

Functional incontinence	Commonly associated with fecal impaction; must differentiate from anatomical (scarring) or neurological disorders of rectum
Functional anorectal pain	Chronic, severe, persistent rectal pain (levator syndrome) or intermittent sharp pain lasting seconds to minutes and disappearing completely (proctalgia fugax)
Obstructed defecation	Caused by spastic pelvic floor (pelvic floor dyssynergia; most common in young and middle-aged women)
Dyschezia	Difficulty with evacuation

(Adapted from Drossman DA, Thompson WG, Talley NJ, Funch-Jensen P, Janssens J, Whitehead WE. Identification of sub-groups of functional gastrointestinal disorders. *Gastroenterol Int.* 1990;3:159, with permission.)

The case history presented here illustrates the relationship between psychiatric illness, GI disease, and GI disorders.

A freshman, male, college cross-country athlete was referred for psychiatric consultation with complaints of frequent belching and anxiety. The patient had been a successful high school runner, but had struggled in his early adjustment to college athletics. His performance was below that of his high school level. Consultation with a gastroenterologist failed to find a physical cause for his complaints.

On psychiatric consultation, the patient noted anxiety about his ability to compete at the college level. Many more talented runners were in practice and meets than he had previously experienced. He reported an urge to belch frequently and feelings of abdominal fullness. When he tried to run, he reported difficulty breathing, and feeling excess gas in his stomach prohibited him from taking a full breath. He reported significant worry with insomnia and feeling "edgy" during the day. There was no history of alcohol or drug use and no previous psychiatric history.

Further interview information was consistent with aerophagia and adjustment disorder with anxious mood. He was referred for relaxation training and brief psychotherapy to address his target anxiety symptoms. The therapy focused on reducing his fear of failing as a college athlete and reducing dysfunctional cognitions about his performance. The therapist advised the coaching staff that performance anxiety significantly contributed to the patient's symptoms. Suggestions to reduce performance anxiety in this athlete were made to the coaching staff. Citalopram (Celexa), 20 mg, was prescribed.

Over the next 6 weeks, the patient reported significant improvement in his breathing, feelings of fullness, anxiety, and sleep disturbance. His running began to improve, but had not yet returned to the expected level of performance. His coaches, however, were happy with his improvement and optimistic about his probability of eventually making a contribution to the team. (Courtesy of William R. Yates, M.D.)

Extensive reports in the literature attest to the link between stress, anxiety, and physiological responsiveness of the GI system. Anxiety can produce disturbances in GI function through a central control mechanism or via humoral effects, such as the release of catecholamines. Electrical stimulation studies suggest that sympathetic autonomic responses can be generated in the lateral hypothalamus, a region with neural interactions within the limbic forebrain. Parasympathetic autonomic responses also influence GI function. Parasympathetic impulses originate in the periventricular and lateral hypothalamus and travel to the dorsal motor nucleus of the vagus, the main parasympathetic output pathway. The vagus is modulated by the limbic system linking an emotions-gut pathway of response.

Acute stress can induce physiological responses in several GI target organs. In the esophagus, acute stress increases resting tone of the upper esophageal sphincter and increases contraction amplitude in the distal esophagus. Such physiological responses may result in symptoms that are consistent with globus or esophageal spasm syndrome. In the stomach, acute stress induces decreased antral motor activity, potentially producing functional nausea and vomiting. In the small intestine, reduced migrating motor function can occur, whereas

in the large intestine, myoelectrical and motility activity can be increased under acute stress. These effects in the small and large intestine may be responsible for bowel symptoms associated with irritable bowel syndrome (IBS).

Patients with contraction abnormalities and functional esophageal syndromes demonstrate high rates of psychiatric comorbidity. Functional esophageal symptoms include globus, dysphagia, chest pain, and regurgitation. Such symptoms can occur in conjunction with esophageal smooth muscle contraction abnormalities in the esophagus. Not all patients with functional esophageal symptoms display contraction abnormalities. Anxiety disorders ranked highest in a study of psychiatric comorbidity in functional esophageal spasm, being present in 67 percent of subjects referred to a GI motility laboratory for testing. Generalized anxiety disorder topped the list of anxiety disorder diagnoses in this series. Many patients in this study had anxiety disorder symptoms before the onset of esophageal symptoms. This suggests that anxiety disorder may induce physiological changes in the esophagus that can produce functional esophageal symptoms.

Peptic Ulcer Disease. *Peptic ulcer* refers to mucosal ulceration involving the distal stomach or proximal duodenum. Symptoms of peptic ulcer disease include a gnawing or burning epigastric pain that occurs 1 to 3 hours after meals and is relieved by food or antacids. Accompanying symptoms can include nausea, vomiting, dyspepsia, or signs of GI bleeding, such as hematemesis or melena. Lesions generally are small, 1 cm or less in diameter.

Early theories identified excess gastric acid secretion as the most important etiological factor. Infection with the bacteria *Helicobacter pylori* has been associated with 95 to 99 percent of duodenal ulcers and 70 to 90 percent of gastric ulcers. Antibiotic therapy that targets *H. pylori* results in much higher healing and cure rates than antacid and histamine blocker therapy.

Early studies of peptic ulcer disease suggested a role of psychological factors in the production of ulcer vulnerability. This effect was believed to be mediated through the increased gastric acid excretion associated with psychological stress. Studies of prisoners of war during World War II documented rates of peptic ulcer formation twice as high as controls. Recent evidence for a primary role of *H. pylori* in peptic ulcer initiation suggests that psychosocial factors may play a primary role in the clinical expression of symptoms. Stressful life events may also reduce immune responses, resulting in a higher vulnerability to infection with *H. pylori*. No consensus exists on specific psychiatric disorders being related to peptic ulcer disease.

Ulcerative Colitis. Ulcerative colitis is an inflammatory bowel disease affecting primarily the large intestine. The cause of ulcerative colitis is unknown. The predominant symptom of ulcerative colitis is bloody diarrhea. Extracolonic manifestations can include uveitis, iritis, skin diseases, and primary sclerosing cholangitis. Diagnosis is made mainly by colonoscopy or proctoscopy. Surgical resection of portions of the large bowel or entire bowel can result in cure for some patients.

For individual patients, psychiatric factors may play a key role in the presentation and complexity of the disorders such as ulcerative colitis. Some workers have reported an increased prevalence of dependent personalities in these patients. No generalizations about psychological mechanisms for ulcerative colitis can be made, however.

Crohn's Disease. Crohn's disease is an inflammatory bowel disease affecting primarily the small intestine and colon. Common symptoms in Crohn's disease include diarrhea, abdominal pain, and weight loss.

Because Crohn's disease is a chronic illness, most studies of psychiatric comorbidity focus on psychiatric disorders occurring after the onset of the disorder. A study of psychiatric symptoms in patients with Crohn's disease before the onset of symptoms found high rates (23 percent) of preexisting panic disorder compared with control subjects and subjects with ulcerative colitis. No statistically significant preexisting psychiatric comorbidity in ulcerative colitis occurred in this study. Longitudinal studies and careful retrospective studies in chronic GI disorders can be helpful in sorting out psychiatric disorder as a risk factor, consequence, or chance association with specific GI disorder.

Psychotropic Drug Side Effects on Gastrointestinal Function. Psychotropic drugs can produce significant changes in GI function, resulting in adverse effects. These GI adverse effects can produce several clinical challenges. First, patients may elect to discontinue necessary treatment because of the GI side effects. Second, prescribers may need to consider the possibility of serious GI illness or exacerbation of functional GI disturbances when drug-induced symptoms develop. Clinicians may need to carefully consider the side-effect profile of specific psychotropic drugs when treating patients with GI disorders.

Serotonin is found in the gut and the selective serotonin reuptake inhibitors (SSRIs) can produce significant GI symptoms. These GI adverse effects tend to be noted at the initiation of therapy and to be dose related, with higher doses producing higher rates of adverse effects. Nausea and diarrhea are significant adverse effects in the profile of the SSRI compounds.

Standard tricyclic antidepressants (TCAs) can also produce GI effects, specifically, dry mouth and constipation. These effects appear to be primarily related to the anticholinergic effect of tricyclic compounds.

Treatment

PSYCHOTROPIC TREATMENT. Psychotropic drug use is common in the treatment of a variety of GI disorders. Psychotropic drug treatment in patients with GI disease is complicated by disturbances in gastric motility and absorption, and metabolism is related to the underlying GI disorder. Many GI effects of psychotropic drugs can be used for therapeutic effects with functional GI disorders. An example of a beneficial side effect would be using a TCA to reduce gastric motility in IBS with diarrhea. Psychotropic GI side effects, however, can exacerbate a GI disorder. An example of a potential adverse side effect would be prescribing a TCA to treat a depressed patient with gastroesophageal reflux.

Psychotropic drug treatment is complicated by acute and chronic liver disease. Most of the psychotropic agents are metabolized by the liver. Many of these agents can be associated with hepatotoxicity. When acute changes in liver function tests occur with TCAs, carbamazepine (Tegretol), or the antipsychotics, it may be necessary to discontinue the drugs. During periods of discontinuation, lorazepam (Ativan) or lithium (Eskalith) can be used, because they are excreted by the kidney. Electroconvulsive therapy (ECT) could also be used in the patient with liver disease, although the anesthesiologist needs to carefully choose anesthetic agents with minimal risk for hepatotoxicity.

PSYCHOTHERAPY. Psychotherapy can be a key component in the stepped-care approach to the treatment of IBS and other functional GI disorders. Multiple different models of psychotherapy have been used. These include short-term, dynamically oriented, individual psychotherapy; supportive psychotherapy; hypnotherapy; relaxation techniques; and cognitive therapy.

COMBINED PHARMACOTHERAPY AND PSYCHOTHERAPY MANAGEMENT. The combination of pharmacotherapy and psychotherapy is receiving increasing attention in effectiveness studies for a variety of disorders. Many GI disorders present opportunities for clinicians to consider combined therapy options. Because GI tolerability may be limited in these populations, psychotherapy augmentation strategies increase in importance.

Cardiovascular Disorders

Cardiovascular disorders are the leading cause of death in the United States and the industrialized world. Depression, anxiety, type A behavior, hostility, anger, and acute mental stress have been evaluated as risk factors for the development and expression of coronary disease. Negative affect in general, low socioeconomic status, and low social support have been shown to have significant relationships with each of these individual psychological factors, and some investigators have proposed these latter characteristics as more promising indices of

psychological risk. Data from the Normative Aging Study on 498 men with a mean age of 60 years demonstrate a dose-response relationship between negative emotions, a combination of anxiety and depression symptoms, and the incidence of coronary disease. At present, however, the strongest evidence available pertains to depression.

Studies of patients with preexisting coronary artery disease (CAD) also demonstrate a near doubling of risk for adverse coronary disease-related outcomes, including myocardial infarction (MI), revascularization procedures for unstable angina, and death, in association with depression. Severe depression 6 months after coronary artery bypass graft (CABG) surgery or persistence of even moderate depression symptoms beginning before surgery at 6-month postoperative follow-up predicts an increased risk of death over 5-year follow-up.

Type A Behavior Pattern, Anger, and Hostility. The relationship between a behavior pattern characterized by easily aroused anger, impatience, aggression, competitive striving, and time urgency (type A) and CAD found the type A pattern to be associated with a nearly twofold increased risk of incident MI and CAD-related mortality. Group therapy to modify a type A behavior pattern was associated with reduced reinfarction and mortality in a 4.5-year study of patients with prior MI. Type A behavior modification therapy has also been demonstrated to reduce episodes of silent ischemia seen on ambulatory electrocardiographic (ECG) monitoring.

Hostility is a core component of the type A concept. Low hostility is associated with low CAD risk in studies of workplace populations. High hostility is associated with increased risk of death in 16-year follow-up of survivors of a previous MI. In addition, hostility is associated with several physiological processes, which, in turn, are associated with CAD, such as reduced parasympathetic modulation of heart rate, increased circulating catecholamines, increased coronary calcification, and increased lipid levels during interpersonal conflict. Conversely, submissiveness has been found to be protective against CAD risk in women. Adrenergic receptor function is downregulated in hostile men, presumably an adaptive response to heightened sympathetic drive and chronic overproduction of catecholamines caused by chronic and frequent anger.

Stress Management. A recent meta-analysis of 23 randomized, controlled trials evaluated the additional impact of psychosocial treatment on rehabilitation from documented CAD. Relaxation training, stress management, and group social support were the predominant modalities of psychosocial intervention. Anxiety, depression, biological risk factors, mortality, and recurrent cardiac events were the clinical endpoints studied. These studies included a total of 2,024 patients in intervention groups and 1,156 control subjects. Patients having psychosocial treatment had greater reductions in emotional distress, systolic blood pressure, heart rate, and blood cholesterol level than comparison subjects. Patients who did not receive psychosocial intervention had 70 percent greater mortality and 84 percent higher cardiac recurrent event rates during 2 years of follow-up. Cardiac rehabilitation itself may reduce high levels of hostility, as well as anxiety and depression symptoms, in patients after MI. A meta-analytical review of psychoeducational programs for patients with CAD concluded that they led to a substantial improvement in blood pressure, cholesterol, body weight, smoking behavior, physical exercise, and eating habits and to a 29 percent reduction in MI and 34 percent reduction in mortality, without achieving significant effects on mood and anxiety. These programs included health education and stress management components.

Cardiac Arrhythmias and Sudden Cardiac Death. A comprehensive overview of cardiac arrhythmias is beyond the scope of this section. Among the many subtypes of cardiac arrhythmia, of greatest importance to psychiatrists are sinus node dysfunction and atrioventricular (AV) conduction disturbances resulting in bradyarrhythmias and tachyarrhythmias that may be lethal or symptomatic yet benign.

Because autonomic cardiac modulation is profoundly sensitive to acute emotional stress, such as intense anger, fear, or sadness, it is not surprising that acute emotions can stimulate arrhythmias. Indeed, instances of sudden cardiac death related to sudden emotional distress have been noted throughout history in all cultures. Two studies have demonstrated that, in addition to depression, a high level of anxiety symptoms raises the risk of further coronary events in patients after MI by two to five times that for nonanxious comparison patients. High anxiety symptom levels are associated with a tripling of risk of sudden cardiac death.

Heart Transplantation. Heart transplantation is available to approximately 2,500 patients annually in the United States. It provides approximately 75 percent 5-year survival for patients with severe heart failure, who would otherwise have a less than 50 percent 2-year survival. Candidates for heart transplantation typically experience a series of adaptive challenges as they proceed through the process of evaluation, waiting, perioperative management, postoperative recuperation, and long-term adaptation to life with a transplant. These stages of adaptation typically elicit anxiety, depression, elation, and working through of grief. Mood disorders are common in transplant recipients, in part because of chronic prednisone therapy.

Hypertension. Hypertension is a disease characterized by an elevated blood pressure of 140/90 mm Hg or above. It is primary (essential hypertension of unknown etiology) or secondary to a known medical illness. Some patients have labile blood pressure (e.g., "white coat" hypertension, in which elevations occur only in a physician's office and are related to anxiety). Personality profiles associated with essential hypertension include persons who have a general readiness to be aggressive, which they try to control, albeit unsuccessfully. The psychoanalyst Otto Fenichel observed that the increase in essential hypertension is probably connected to the mental situation of persons who have learned that aggressiveness is bad and must live in a world for which an enormous amount of aggressiveness is required.

Vasovagal Syncope. Vasovagal syncope is characterized by a sudden loss of consciousness (fainting) caused by a vasodepressor response decreasing cerebral perfusion. Sympathetic autonomic activity is inhibited, and parasympathetic vagal nerve activity is augmented; the result is decreased cardiac output, decreased vascular peripheral resistance, vasodilation, and bradycardia. This reaction decreases ventricular filling, lowers the blood supply to the brain, and leads to brain hypoxia and loss of consciousness. Because patients with vasomotor syncope normally put themselves, or fall into, a prone position, the decreased cardiac output is corrected. Raising the patient's legs also helps correct the physiological imbalance. When syncope is related to orthostatic hypotension, as an adverse effect of psychotropic medication, patients should be advised to shift slowly from a sitting to a standing position. The specific physiological triggers of vasovagal syncope have not been identified, but acutely stressful situations are known etiological factors.

Respiratory System

Psychological distress may become manifest in disrupted breathing, as in the tachypnea seen in anxiety disorders or sighing respirations in the depressed or anxious patient. Disturbances of breathing can likewise perturb any sense of psychic calm, as in the terror of any asthma patient with severe airway obstruction or marked hypoxemia.

Asthma. Asthma is a chronic, episodic illness characterized by extensive narrowing of the tracheobronchial tree. Symptoms include coughing, wheezing, chest tightness, and dyspnea. Nocturnal symptoms and exacerbations are common. Although patients with asthma are characterized as having excessive dependency needs, no specific personality type has been identified; however, up to 30 percent of persons with asthma meet the criteria for panic disorder or agoraphobia. The fear of dyspnea can directly trigger asthma attacks, and high levels of anxiety are associated with increased rates of hospitalization and asthma-associated mortality. Certain personality traits in patients with asthma are associated with greater use of corticosteroids and bronchodilators and longer hospitalizations than would be predicted from pulmonary function alone. These traits include intense fear, emotional lability, sensitivity to rejection, and lack of persistence in difficult

situations.

Family members of patients with severe asthma tend to have higher than predicted prevalence rates of mood disorders, posttraumatic stress disorder, substance use, and antisocial personality disorder. How these conditions contribute to the genesis or maintenance of asthma in an individual patient is unknown. The familial and current social environment may interact with a genetic predisposition for asthma to influence the timing and severity of the clinical picture. This interaction may be especially insidious in adolescents whose need for, and fear of, emotional separation from the family often becomes entangled in battles over medication adherence as well as other modes of diligent self-care.

Hyperventilation Syndrome. Patients with hyperventilation syndrome breathe rapidly and deeply for several minutes, often unaware that they are doing so. They soon complain of feelings of suffocation, anxiety, giddiness, and lightheadedness. Tetany, palpitations, chronic pain, and paresthesias about the mouth and in the fingers and toes are associated symptoms. Finally, syncope may occur. The symptoms are caused by an excessive loss of CO_2 resulting in respiratory alkalosis. Cerebral vasoconstriction results from low cerebral tissue PCO_2 .

The attack can be aborted by having patients breathe into a paper (not plastic) bag or hold their breath for as long as possible, which raises the plasma PCO_2 . Another useful treatment technique is to have patients deliberately hyperventilate for 1 or 2 minutes and then describe the syndrome to them. This can also be reassuring to patients who fear they have a progressive, if not fatal, disease.

Chronic Obstructive Pulmonary Disease. *Chronic obstructive pulmonary disease* (COPD) refers to a spectrum of disorders that are characterized by three pathophysiological aspects: (1) chronic cough and sputum production; (2) emphysema usually associated with smoking or α_1 -antitrypsin deficiency; and (3) inflammation, which produces fibrosis and narrowing of the airways. As for asthma, prevalence rates for panic disorder and anxiety disorders are increased among patients with COPD. Anxiety disorders occur at rates of 16 to 34 percent, which are greater than the rate of 15 percent for the general population. Panic disorder prevalence rates among patients with COPD range from 8 to 24 percent, higher than the general prevalence of 1.5 percent.

Patients with COPD can benefit from the use of inhaled sympathomimetic agents, but two points deserve emphasis. First, use of high doses can produce hypokalemia. Second, refractory symptoms can lead to the excessive use of oral α_2 -agonists, which have a high incidence of side effects, including tremor, anxiety, and interference with sleep.

A 59-year-old female smoker with known COPD presented to the emergency room with chronic fatigue and dyspnea and an acute syndrome of depressed mood, suicidal ideation, and confusion. She lived alone and had exhausted her tank of supplemental oxygen that she only occasionally used at a low flow rate. One week earlier, to more aggressively treat the patient's worsened sputum production, her pulmonary physician had changed the oral corticosteroid to 10 mg dexamethasone (Decadron) per day from 10 mg prednisone per day. Arterial blood gases revealed moderate hypoxemia and hypercapnia and a chronic compensated respiratory acidosis—all essentially unchanged from previous studies. On examination, the patient appeared agitated and could not specify the date, the weekday, or her physician's name. The consulting psychiatrist considered delirium likely and ordered serum electrolytes, which yielded a blood glucose of 580 mg/dL. The psychiatrist made a diagnosis of organic mental disorder and secondary mood disturbance due to severe hyperglycemia. The change to a high-potency corticosteroid with intense glucocorticoid activity had provoked the massive rise in blood sugar and, in this elderly patient with poor oxygenation, resulted in delirium and a severe mood disturbance. The patient was admitted and treated for the hyperglycemia with intravenous (IV) saline and small doses of insulin. By the next day, her mental status had returned to normal, and the suicidal ideation and depressed mood had disappeared. (Courtesy of Michael G. Moran, M.D.)

Endocrine System

An understanding of endocrine disorders is important, not only because they are widespread, but also because they can produce symptoms that are indistinguishable from psychiatric illnesses. Physical manifestations of endocrine disease provide clues to the diagnosis but are not always present. The effect of endocrinopathies on psychiatric symptomatology has been studied, particularly for disorders of the thyroid and adrenal glands. Less is known about psychiatric sequelae of other endocrine disorders, such as reproductive disturbances, acromegaly, prolactin (PRL)-secreting tumors, and hyperparathyroidism.

Hyperthyroidism. Hyperthyroidism, or thyrotoxicosis, results from overproduction of thyroid hormone by the thyroid gland. The most common cause is exophthalmic goiter, also called Graves' disease (see [Color Plate 13.5-1](#)). Toxic nodular goiter causes another 10 percent of cases among middle-aged and elderly patients. Physical signs of hyperthyroidism include increased pulse, arrhythmias, elevated blood pressure, fine tremor, heat intolerance, excessive sweating, weight loss, tachycardia, menstrual irregularities, muscle weakness, and exophthalmos. Psychiatric features include nervousness, fatigue, insomnia, mood lability, and dysphoria. Speech may be pressured, and patients may exhibit a heightened activity level. Cognitive symptoms include a short attention span, impaired recent memory, and an exaggerated startle response. Patients with severe hyperthyroidism may exhibit visual hallucinations, paranoid ideation, and delirium. Although some symptoms of hyperthyroidism resemble those of a manic episode, an association between hyperthyroidism and mania has rarely been observed; however, both disorders may exist in the same patient.

Treatments for Graves' disease are (1) propylthiouracil (PTU) and antithyroid drugs, (2) radioactive iodine (RAI), and (3) surgical thyroidectomy. β -Adrenergic receptor antagonists (e.g., propranolol [Inderal]) can provide symptomatic relief.

Treatment of thyroid nodular goiter consists of β -adrenergic receptor antagonists and RAI. Treatment of thyroiditis consists of a brief course (a few weeks) of β -adrenergic receptor antagonists, because this condition is short-lived. For patients with psychotic symptoms, medium-potency antipsychotics are preferable to low-potency drugs, because the latter can worsen tachycardia. Tricyclic drugs should be used with caution, if at all, for the same reason. Depressed patients often respond to SSRIs. In general, the psychiatric symptoms resolve with successful treatment of the hyperthyroidism.

Hypothyroidism. Hypothyroidism results from inadequate synthesis of thyroid hormone and is categorized as either overt or subclinical. In overt hypothyroidism, thyroid hormone concentrations are abnormally low, thyroid-stimulating hormone (TSH) levels are elevated, and patients are symptomatic; in subclinical hypothyroidism, patients have normal thyroid hormone concentrations but elevated TSH levels.

Psychiatric symptoms of hypothyroidism include depressed mood, apathy, impaired memory, and other cognitive defects. Also, hypothyroidism can contribute to treatment-refractory depression. A psychotic syndrome of auditory hallucinations and paranoia, *myxedema madness*, has been described in some patients. Urgent psychiatric treatment is necessary for patients presenting with severe psychiatric symptoms (e.g., psychosis or suicidal depression). Psychotropic agents should be given at low doses initially, because the reduced metabolic rate of patients with hypothyroidism may reduce breakdown and result in higher concentrations of medications in blood.

SUBCLINICAL HYPOTHYROIDISM. Subclinical hypothyroidism can produce depressive symptoms and cognitive deficits, although they are less severe than those produced by overt hypothyroidism. The lifetime prevalence of depression in patients with subclinical hypothyroidism is

approximately double that in the general population. These patients display a lower response rate to antidepressants and a greater likelihood of responding to lithium (Cytomel) augmentation than euthyroid patients with depression.

Diabetes Mellitus. Diabetes mellitus is a disorder of metabolism and the vascular system, manifested by disturbances in the body's handling of glucose, lipids, and protein. It results from impaired insulin secretion or action. It is also a serious long-term side effect of serotonin-dopamine antagonist drugs (SDAs) used to treat psychosis. Heredity and family history are important in the onset of diabetes; however, sudden onset is often associated with emotional stress, which disturbs the homeostatic balance in persons who are predisposed to the disorder. Psychological factors that seem significant are those provoking feelings of frustration, loneliness, and dejection. Patients with diabetes must usually maintain some dietary control over their diabetes. When they are depressed and dejected, they often overeat or overdrink self-destructively and cause their diabetes to get out of control. This reaction is especially common in patients with juvenile, or type 1, diabetes. Terms such as oral, dependent, seeking maternal attention, and excessively passive have been applied to persons with this condition.

Supportive psychotherapy helps achieve cooperation in the medical management of this complex disease. Therapists should encourage patients to lead as normal a life as possible, recognizing that they have a chronic but manageable disease. In patients with known diabetes, ketoacidosis can produce some violence and confusion. More commonly, hypoglycemia (often occurring when a patient with diabetes drinks alcohol) can produce severe anxiety states, confusion, and disturbed behavior. Inappropriate behavior caused by hypoglycemia must be distinguished from that caused by simple drunkenness.

Adrenal Disorders

Cushing's Syndrome. Spontaneous Cushing's syndrome results from adrenocortical hyperfunction and can develop from either excessive secretion of ACTH (which stimulates the adrenal gland to produce cortisol) or from adrenal pathology (e.g., a cortisol-producing adrenal tumor). Cushing's disease, the most common form of spontaneous Cushing's syndrome, results from excessive pituitary secretion of ACTH, usually from a pituitary adenoma.

The clinical features of Cushing's disease include a characteristic "moon facies," or rounded face, from accumulation of adipose tissue around the zygomatic arch. Truncal obesity, a "buffalo hump" appearance, results from cervicodorsal adipose tissue deposition. The catabolic effects of cortisol on protein produce muscle wasting, slow wound healing, easy bruising, and thinning of the skin, leading to abdominal striae (Fig. 13.5-2). Bones become osteoporotic, sometimes resulting in pathological fractures and loss of height. Psychiatric symptoms are common and vary from severe depression to elation with or without evidence of psychotic features.

FIGURE 13.5-2

Cushing's syndrome. Legs thin owing to atrophy of thigh muscles. Some abdominal obesity with marked striae. (From Douithwaite AH, ed. *Fench's Index of Differential Diagnosis*. 7th ed. Baltimore: Williams & Wilkins; 1954, with permission.)

The treatment of pituitary ACTH-producing tumors involves surgical resection or pituitary irradiation. Medications that antagonize cortisol production (e.g., metyrapone [Metopirone]) or suppress ACTH (e.g., serotonin antagonists such as cyproheptadine [Periactin]) are sometimes used but have met with limited success.

Hypercortisolism. Psychiatric symptoms are myriad. Most patients experience fatigue and approximately 75 percent report depressed mood. Of these, approximately 60 percent experience moderate or severe depression. Depression severity does not appear to be influenced by the etiology underlying the Cushing's syndrome. Depressive symptoms occur more commonly in female patients than in male patients with Cushing's syndrome.

Emotional lability, irritability, decreased libido, anxiety, and hypersensitivity to stimuli are common. Somatic symptoms and elevated neuroticism scores on the Eysenck Personality Inventory have also been reported, with significant improvement after normalization of cortisol levels. Social withdrawal may develop as a result of shame regarding one's physical appearance. Paranoia, hallucinations, and depersonalization are estimated to occur in 5 to 15 percent of cases. Cognitive changes are common, with approximately 83 percent of patients experiencing deficits in concentration and memory. The severity of these deficits correlates with plasma cortisol and ACTH levels.

Manic and psychotic symptoms occur much less frequently than depression, at a rate of approximately 3 to 8 percent of patients, but rising to as high as 40 percent in patients with adrenal carcinomas. In cases of iatrogenic hypercortisolism and adrenal carcinomas, however, mania and psychosis may predominate. The psychiatric disturbances in prednisone-treated patients tend to appear within the first 2 weeks of treatment and occur more commonly in women than in men.

The withdrawal of steroids can also produce psychiatric disturbances, particularly depression, weakness, anorexia, and arthralgia. Other steroid-induced withdrawal symptoms include emotional lability, memory impairment, and delirium. Withdrawal symptoms have been noted to persist for as long as 8 weeks after corticosteroid withdrawal.

Patients presenting with mood lability or depression in association with muscle weakness, obesity, diabetes, easy bruising, cutaneous striae, acne, hypertension, and, in women, hirsutism and oligomenorrhea or amenorrhea benefit from an endocrinological evaluation.

Hyperprolactinemia. Prolactin, produced by the anterior pituitary, stimulates milk production from the breast and modulates maternal behavior. Its production is inhibited by dopamine (also known as prolactin-inhibiting factor) produced by the tuberoinfundibular neurons of the arcuate nucleus of the hypothalamus. Normal concentrations (5 to 25 ng/mL in women and 5 to 15 ng/mL in men) fluctuate during the day, peaking during sleep. Exercise and emotional stress can increase prolactin concentration. Medications that block dopamine action (e.g., antipsychotics) raise prolactin concentrations up to 20 times. All antipsychotics appear equally likely to raise prolactin concentrations, with the exception of clozapine (Clozaril) and olanzapine (Zyprexa). Other medications that may increase prolactin concentrations include oral contraceptives, estrogens, tricyclic drugs, serotonergic antidepressants, and propranolol. Hypothyroidism raises prolactin concentration because thyrotropin-releasing hormone (TRH) stimulates prolactin release. Physiological hyperprolactinemia occurs in pregnant and breast-feeding women; nipple stimulation also increases prolactin concentrations.

Traumatic childhood experiences, such as separation from parents or living with an alcoholic father, have been reported to predispose to hyperprolactinemia. Stressful life events are also associated with galactorrhea, even in the absence of increased prolactin concentrations. Low prolactin levels are associated with decreased libido. Hyperprolactinemia can cause sexual dysfunction, such as erectile disorder and anorgasmia.

Skin Disorders

Psychocutaneous disorders encompass a wide variety of dermatological diseases that may be affected by the presence of psychiatric symptoms or stress and psychiatric illnesses in which the skin is the target of disordered thinking, behavior, or perception. Although the link between stress and several dermatological disorders has been suspected for years, few well-controlled studies of treatments of dermatological disorders have assessed whether stress reduction or treatment of psychiatric comorbidity improves their outcome. Although evidence of interactions between the nervous, immune, and endocrine systems has improved the understanding of psychocutaneous disorders, more study of these often disabling disorders and their treatment is needed.

Atopic Dermatitis. Atopic dermatitis (also called *atopic eczema* or *neurodermatitis*) is a chronic skin disorder characterized by pruritus and inflammation (eczema), which often begins as an erythematous, pruritic, maculopapular eruption. Patients with atopic dermatitis tend to be more anxious and depressed than clinical and disease-free control groups. Anxiety or depression exacerbates atopic dermatitis by eliciting scratching behavior, and depressive symptoms appear to amplify the itch perception. Studies of children with atopic dermatitis found that those with behavior problems had more severe illness. In families that encouraged independence, children had less severe symptoms, whereas parental overprotectiveness reinforced scratching.

Psoriasis. Psoriasis is a chronic, relapsing disease of the skin, with lesions characterized by silvery scales with a glossy, homogeneous erythema under the scales. It is difficult to control the adverse effect of psoriasis on quality of life. It can lead to stress that, in turn, can trigger more psoriasis. Patients who report that stress triggered psoriasis often describe disease-related stress resulting from the cosmetic disfigurement and social stigma of psoriasis, rather than stressful major life events. Psoriasis-related stress may have more to do with psychosocial difficulties inherent in the interpersonal relationships of patients with psoriasis than with the severity or chronicity of psoriasis activity.

Controlled studies have found that patients with psoriasis have high levels of anxiety and depression and significant comorbidity with a wide array of personality disorders including schizoid, avoidant, passive-aggressive, and obsessive-compulsive personality disorders. Patients' self-report of psoriasis severity correlated directly with depression and suicidal ideation, and comorbid depression reduced the threshold for pruritus in patients with psoriasis. Heavy alcohol consumption (more than 80 g of ethanol daily) by male patients with psoriasis may predict a poor treatment outcome.

Psychogenic Excoriation. Psychogenic excoriations (also called *psychogenic pruritus*) are lesions caused by scratching or picking in response to an itch or other skin sensation or because of an urge to remove an irregularity on the skin from preexisting dermatoses, such as acne. Lesions are typically found in areas that the patient can easily reach (e.g., the face, upper back, and the upper and lower extremities) and are a few millimeters in diameter and weeping, crusted, or scarred, with occasional postinflammatory hypopigmentation or hyperpigmentation. The behavior in psychogenic excoriation sometimes resembles obsessive-compulsive disorder in that it is repetitive, ritualistic, and tension reducing, and patients attempt (often unsuccessfully) to resist excoriating. The skin is an important erogenous zone, and Freud believed it susceptible to unconscious sexual impulses.

Localized Pruritus

PRURITUS ANI. The investigation of pruritus ani commonly yields a history of local irritation (e.g., threadworms, irritant discharge, fungal infection) or general systemic factors (e.g., nutritional deficiencies, drug intoxication). After running a conventional course, however, pruritus ani often fails to respond to therapeutic measures and acquires a life of its own, apparently perpetuated by scratching and superimposed inflammation. It is a distressing complaint that often interferes with work and social activity. Investigation of many patients with the disorder has revealed that personality deviations often precede the condition and that emotional disturbances often precipitate and maintain it.

PRURITUS VULVAE. As with pruritus ani, specific physical causes, either localized or generalized, may be demonstrable in pruritus vulvae, and the presence of glaring psychopathology in no way lessens the need for adequate medical investigation. In some patients, pleasure derived from rubbing and scratching is conscious—they realize it is a symbolic form of masturbation—but more often than not, the pleasure element is repressed. Some patients may give a long history of sexual frustration, which was frequently intensified at the time of the onset of the pruritus.

Hyperhidrosis. States of fear, rage, and tension can induce increased sweat secretion that appears primarily on the palms, the soles, and the axillae. The sensitivity of sweating in response to emotion serves as the basis for measurement of sweat by the galvanic skin response (an important tool of psychosomatic research), biofeedback, and the polygraph (lie detector test). Under conditions of prolonged emotional stress, excessive sweating (hyperhidrosis) can lead to secondary skin changes, rashes, blisters, and infections; therefore, hyperhidrosis may underlie several other dermatological conditions that are not primarily related to emotions. Basically, hyperhidrosis can be viewed as an anxiety phenomenon mediated by the autonomic nervous system, and it must be differentiated from drug-induced states of hyperhidrosis.

Urticaria. Psychiatric factors have been implicated in the development of some types of urticaria. Most psychiatric studies have focused on chronic idiopathic urticaria. Early psychodynamic theories about urticaria have been abandoned because no association between a specific personality conflict and urticaria could be proved. Patients with chronic idiopathic urticaria are frequently depressed and anxious, however, and women are more likely to experience significant psychiatric symptoms. Whether the psychiatric symptoms resulted from urticaria or were a contributing causal factor in its development or exacerbation is unclear, however. Controlled studies found an association between stressful life events and the onset of urticaria. Stress can lead to the secretion of such neuropeptides as vasoactive intestinal peptide and substance P, which can cause vasodilation and contribute to the development of urticarial wheals.

Musculoskeletal System

The musculoskeletal disorders are a diverse group of syndromes and diseases that have the presence of muscle and joint symptoms as their common denominator. The relevance of these disorders to the psychiatrist is the consistently observed correlation with psychiatric illness. Many patients with a musculoskeletal disorder exhibit additional symptoms and signs suggesting the presence of an accompanying psychiatric disorder. These comorbid psychiatric conditions may be a result of the patient's psychological response to the loss and discomfort imposed by the disease or may be produced by the effect of the disease process on the central nervous system (CNS).

Rheumatoid Arthritis. Rheumatoid arthritis is a disease characterized by chronic musculoskeletal pain arising from inflammation of the joints. The disorder's significant causative factors are hereditary, allergic, immunological, and psychological.

Stress can predispose patients to rheumatoid arthritis and other autoimmune diseases by immune suppression. Depression is comorbid with rheumatoid arthritis in about 20 percent of individuals. Those who get depressed are more likely to be unmarried, have a longer duration of illness, and have a higher occurrence of medical comorbidity. Individuals with rheumatoid arthritis and depression commonly demonstrate poorer functional status, and they report more often painful joints, pronounced experience of pain, health care use, bed days, and inability to work than do patients with similar objective measures of arthritic activity without depression.

Psychotropic agents may be of use in some patients. Sleep, which is often disrupted by pain, can be assisted by the combination of a nonsteroidal anti-inflammatory drug (NSAID) and trazodone (Desyrel) or mirtazapine (Remeron), with appropriate cautionary advice regarding orthostatic hypotension. Tricyclic drugs exert mild anti-inflammatory effects independent of their mood-altering benefit; however, anticholinergic effects (prominent among the tricyclic drugs and also present with some serotonergic agents) can aggravate dry oral and ocular membranes in some patients with the disorder.

Systemic Lupus Erythematosus. Systemic lupus erythematosus is a connective tissue disease of unclear etiology, characterized by recurrent episodes of destructive inflammation of several organs, including the skin, joints, kidneys, blood vessels, and CNS. This disorder is highly unpredictable, often incapacitating, and potentially disfiguring, and its treatment requires administration of potentially toxic drugs. The psychiatrist can assist in promoting positive interactions between patients and the program staff and ensuring a tolerant attitude on the part of these staff members. Supportive psychotherapy can help patients acquire the knowledge and maturity necessary to deal with the disorder as effectively as possible.

Low Back Pain. Low back pain affects almost 15 million Americans and is one of the major reasons for days lost from work and for disability claims paid to workers by insurance companies. Signs and symptoms vary from patient to patient, most often consisting of excruciating pain, restricted movement, paresthesias, and weakness or numbness, all of which may be accompanied by anxiety, fear, or even panic. The areas most affected are the lower lumbar, lumbosacral, and sacroiliac regions. It is often accompanied by sciatica, with pain radiating down one or both buttocks or following the distribution of the sciatic nerve. Although low back pain can be caused by a ruptured intervertebral disk, a fracture of the back, congenital defects of the lower spine, or a ligamentous muscle strain, many instances are psychosomatic. Examining physicians should be particularly alert to patients who give a history of minor back trauma followed by severe disabling pain. Patients with low back pain often report that the pain began at a time of psychological trauma or stress, but others (perhaps 50 percent) develop pain gradually over a period of months. Patients' reaction to the pain is disproportionately emotional, with excessive anxiety and depression. Furthermore, the pain distribution rarely follows a normal neuroanatomical distribution and may vary in location and intensity.

Treatment includes educating patients about the physiological component (vasospasm) and helping them understand the working of the unconscious mind and conflicts that arise from unconscious affects, especially that of rage. The patient understands that the mind is substituting physical pain for emotional pain so that the conscious mind does not have to deal with conflict. Physical activity should be resumed as quickly as possible, with treatments such as spinal manipulation and mandatory physical therapy sessions used minimally if at all.

Fibromyalgia. Fibromyalgia is characterized by pain and stiffness of the soft tissues, such as muscles, ligaments, and tendons. Local areas of tenderness are referred to as "trigger points." The cervical and thoracic areas are affected most often, but the pain may be located in the arms, shoulders, low back, or legs. It is more common in women than in men. The etiology is unknown; however, it is often precipitated by stress that causes localized arterial spasm that interferes with perfusion of oxygen in the affected areas. Pain results, with associated symptoms of anxiety, fatigue, and inability to sleep because of the pain. There are no pathognomonic laboratory findings. The diagnosis is made after excluding rheumatic disease or hypothyroidism. Fibromyalgia is often present in chronic fatigue syndrome and depressive disorders.

Analgesics, such as aspirin and acetaminophen, are useful for pain. Narcotics should be avoided. Some patients may respond to NSAIDs. Patients with more severe cases may respond to injections of an anesthetic (e.g., procaine) into the affected area; steroid injections are usually unwarranted. The relation between stress, spasms, and pain should be explained. Relaxation exercises and massage of the trigger points may also be of use. Antidepressants, especially sertraline (Zoloft), have shown encouraging results. Psychotherapy may be warranted for patients who are able to gain insight into the nature of the disorder and also to help them identify and deal with psychosocial stressors.

Headaches

Headaches are the most common neurological symptom and one of the most common medical complaints. Every year about 80 percent of the population has at least one headache, and 10 to 20 percent go to physicians with headache as their primary complaint. Headaches are also a major cause of absenteeism from work and avoidance of social and personal activities.

Most headaches are not associated with significant organic disease; many persons are susceptible to headaches at times of emotional stress. Moreover, in many psychiatric disorders, including anxiety and depressive disorders, headache is frequently a prominent symptom. Patients with headaches are often referred to psychiatrists by primary care physicians and neurologists after extensive biomedical workups, which often include magnetic resonance imaging (MRI) of the head. Most workups for common headache complaints have negative findings, and such results may be frustrating for both patient and physician. Physicians not well versed in psychological medicine may attempt to reassure such patients by telling them that they have no disease. But this reassurance may have the opposite effect—it may increase patients' anxiety and even escalate into a disagreement about whether the pain is real or imagined. Psychological stress usually exacerbates headaches, whether their primary underlying cause is physical or psychological.

Migraine (Vascular) and Cluster Headaches. Migraine (vascular) headache is a paroxysmal disorder characterized by recurrent unilateral headaches, with or without related visual and gastrointestinal disturbances (e.g., nausea, vomiting, and photophobia). They are probably caused by a functional disturbance in the cranial circulation. Migraines can be precipitated by cycling estrogen, which may account for their higher prevalence in women. Stress is also a precipitant, and many persons with migraine are overly controlled, perfectionists, and unable to suppress anger. Cluster headaches are related to migraines. They are unilateral, occur up to eight times a day, and are associated with miosis, ptosis, and diaphoresis.

Migraines and cluster headaches are best treated during the prodromal period with ergotamine tartrate (Cafergot) and analgesics.

Prophylactic administration of propranolol or verapamil (Isoptin) is useful when the headaches are frequent. Sumatriptan (Imitrex) is indicated for the short-term treatment of migraine and can abort attacks. SSRIs are also useful for prophylaxis. Psychotherapy to diminish the effects of conflict and stress and certain behavioral techniques (e.g., biofeedback) have been reported to be useful.

Tension (Muscle Contraction) Headaches. Emotional stress is often associated with prolonged contraction of head and neck muscles, which over several hours may constrict the blood vessels and result in ischemia. A dull, aching pain, sometimes feeling like a tightening band, often begins suboccipitally and may spread over the head. The scalp may be tender to the touch and, in contrast to a migraine, the headache is usually bilateral and not associated with prodromata, nausea, or vomiting. Tension headaches may be episodic or chronic and need to be differentiated from migraine headaches, especially with and without aura.

Tension headaches are frequently associated with anxiety and depression and occur to some degree in about 80 percent of persons during periods of emotional stress. Tense, high-strung, competitive personalities are especially susceptible to the disorder. In the initial stage, persons may be treated with anti-anxiety agents, muscle relaxants, and massage or heat application to the head and neck; antidepressants may be prescribed when an underlying depression is present. Psychotherapy is an effective treatment for persons chronically afflicted by tension headaches. Learning to avoid or cope better with tension is the most effective long-term management approach. Biofeedback using electromyogram (EMG) feedback from the frontal or temporal muscles may help some patients. Relaxation exercises and meditation also benefit some patients.

TREATMENT OF PSYCHOSOMATIC DISORDERS

A major role of psychiatrists and other physicians working with patients with psychosomatic disorders is mobilizing the patient to change behavior in ways that optimize the process of healing. This may require a general change in lifestyle (e.g., taking vacations) or a more specific behavioral change (e.g., giving up smoking). Whether or not this occurs depends in large measure on the quality of the relationship between doctor and patient. Failure of the physician to establish good rapport accounts for much of the ineffectiveness in getting patients to change.

Ideally, both physician and patient collaborate and decide on a course of action. At times this may resemble a negotiation in which doctor and patient discuss various options and reach a compromise about an agreed-upon goal.

Stress Management and Relaxation Therapy

Cognitive-behavioral therapy methods are increasingly used to help individuals better manage their responses to stressful life events. These treatment methods are based on the notion that cognitive appraisals about stressful events and the coping efforts related to these appraisals play a major role in determining stress responding. Cognitive-behavioral therapy approaches to stress management have three major aims: (1) to help individuals become more aware of their own cognitive appraisals of stressful events, (2) to educate individuals about how their appraisals of stressful events can influence negative emotional and behavioral responses and to help them reconceptualize their abilities to alter these appraisals, and (3) to teach individuals how to develop and maintain the use of a variety of effective cognitive and behavioral stress management skills.

Stress-Management Training. Five skills form the core of almost all stress-management programs: self-observation, cognitive restructuring, relaxation training, time management, and problem-solving.

SELF-OBSERVATION. A daily diary format is used, with patients being asked to keep a record of how they responded to challenging or stressful events that occurred each day. A particular stress (e.g., argument with spouse) may precipitate a sign or symptom (e.g., pain in the neck).

COGNITIVE RESTRUCTURING. This helps participants become aware of, and change, their maladaptive thoughts, beliefs, and expectations. Patients are taught to substitute negative assumptions with positive assumptions.

RELAXATION EXERCISES. Edmund Jacobson in 1938 developed a method called *progressive muscle relaxation* to teach relaxation without using instrumentation as is used in biofeedback. Patients were taught to relax muscle groups, such as those involved in “tension headaches.” When they encountered, and were aware of, situations that caused tension in their muscles, the patients were trained to relax. This method is a type of systematic desensitization—a type of behavior therapy.

Hypnosis. Hypnosis is effective in smoking cessation and dietary change augmentation. It is used in combination with aversive imagery (e.g., cigarettes taste obnoxious). Some patients exhibit a moderately high relapse rate and may require repeated programs of hypnotic therapy (usually three to four sessions).

Biofeedback. Neal Miller in 1969 published his pioneering paper “Learning of Visceral and Glandular Responses,” in which he reported that, in animals, various visceral responses regulated by the involuntary autonomic nervous system could be modified by learning operant conditioning carried out in the laboratory. This led to humans being able to learn to control certain involuntary physiological responses (called *biofeedback*) such as blood vessel vasoconstriction, cardiac rhythm, and heart rate. These physiological changes seem to play a significant role in the development and treatment or cure of certain psychosomatic disorders.

Biofeedback and related techniques have been useful in tension headaches, migraine headaches, and Raynaud’s disease. Although biofeedback techniques initially produced encouraging results in treating essential hypertension, relaxation therapy has produced more significant long-term effects than biofeedback.

TIME MANAGEMENT. Time-management methods are designed to help individuals restore a sense of balance to their lives. The first step in training in time-management skills is designed to enhance awareness of current patterns of time use. To accomplish this goal, individuals might be asked to keep a record of how they spend their time each day, noting the amount of time spent in important categories, such as work, family, exercise, or leisure activities. Alternatively, they may be asked to list the important areas in their lives and then asked to provide two time estimates: (1) the amount of time they currently spend engaging in these activities and (2) the amount of time they would like to spend engaging in these activities. Frequently, a substantial difference is seen in the time individuals would like to spend on important activities and the amount of time they actually spend on such activities. With awareness of this difference comes increased motivation to make changes.

PROBLEM-SOLVING. The final step is problem-solving, in which patients try to apply the best solution to the problem situation and then review their progress with the therapist.

13.6 Factitious Disorder

Patients with factitious disorder simulate, induce, or aggravate illness to receive medical attention, regardless of whether or not they are ill. Thus, they may inflict painful, deforming, or even life-threatening injury on themselves, their children, or other dependents. The primary motivation is not avoidance of duties, financial gain, or anything concrete. The motivation is simply to receive medical care and to partake in the medical system.

Factitious disorders can lead to significant morbidity or even mortality. Therefore, even though presenting complaints are falsified, the medical and psychiatric needs of these patients must be taken seriously. For example, an operating room technician, the daughter of a physician, repetitively injected herself with *Pseudomonas*, which caused multiple bouts of sepsis and bilateral renal failure that led to her death. Such deaths are not uncommon. In a 1951 article in *Lancet*, Richard Asher coined the term “Munchausen syndrome” to refer to a syndrome in which patients embellish their personal history, chronically fabricate symptoms to gain hospital admission, and move from hospital to hospital. The syndrome was named after Baron Hieronymus Friedrich Freiherr von Munchausen (1720–1797), a German cavalry officer (Fig. 13.6-1).

FIGURE 13.6-1

The Baron Karl Friedrich Hieronymus von Münchhausen (1720–1797). **Left:** The Baron wears military armor in this 1750 portrait by G. Bruckner. A nobleman who served the Russian army in the war against the Turks, the baron entertained friends with embellished stories of his war adventures in his retirement. His tales gained fame when published by Rudolph E. Raspe. **Right:** The baron appears as a caricature in this drawing by 19th-century artist Gustave Doré. Like the baron, patients with factitious disorders are real persons deserving of respect, even though they often present themselves as caricatures. (Portrait courtesy of Bernhard Wiebel, <http://www.Muenchhausen.ch>. The actual portrait was lost in World War II. Caricature from Gustave Doré. *The Adventures of Baron Munchausen, One Hundred and Sixty Illustrations by Gustave Doré*. New York: Pantheon Books; 1944.)

EPIDEMIOLOGY

No comprehensive epidemiological data on factitious disorder exist. Limited studies indicate that patients with factitious disorder may comprise approximately 0.8 to 1.0 percent of psychiatry consultation patients. Cases of feigned psychological signs and symptoms are reported much less commonly than those of physical signs and symptoms. A data bank of persons who feign illness has been established to alert hospitals about such patients, many of whom travel from place to place, seek admission under different names, or simulate different illnesses.

Approximately two thirds of patients with Munchausen syndrome are male. They tend to be white, middle-aged, unemployed, unmarried, and without significant social or family attachments. Patients diagnosed with factitious disorders with physical signs and symptoms are mostly women, who outnumber men 3 to 1. They are usually 20 to 40 years of age with a history of employment or education in nursing or a health care occupation. Factitious physical disorders usually begin for patients in their 20s or 30s, although the literature contains cases ranging from 4 to 79 years of age.

Factitious disorder by proxy (called factitious disorder imposed on another in the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5]) is most commonly perpetrated by mothers against infants or young children. Rare or underrecognized, it accounts for less than 0.04 percent, or 1,000 of 3 million cases of child abuse reported in the United States each year. Good epidemiological data are lacking, however. This disorder is discussed below.

COMORBIDITY

Many persons diagnosed with factitious disorder have comorbid psychiatric diagnoses (e.g., mood disorders, personality disorders, or substance-related disorders).

ETIOLOGY

Psychosocial Factors

The psychodynamic underpinnings of factitious disorders are poorly understood because the patients are difficult to engage in an exploratory psychotherapy process. They may insist that their symptoms are physical and that psychologically oriented treatment is therefore useless. Anecdotal case reports indicate that many of the patients suffered childhood abuse or deprivation, resulting in frequent hospitalizations during early development. In such circumstances, an inpatient stay may have been regarded as an escape from a traumatic home situation, and the patient may have found a series of caretakers (e.g., doctors, nurses, and hospital workers) to be loving and caring. In contrast, the patients' families of origin included a rejecting mother or an absent father. The usual history reveals that the patient perceives one or both parents as rejecting figures who are unable to form close relationships. The facsimile of genuine illness, therefore, is used to re-create the desired positive parent-child bond. The disorders are a form of repetitional compulsion, repeating the basic conflict of needing and seeking acceptance and love while expecting that they will not be forthcoming. Hence, the patient transforms the physicians and staff members into rejecting parents.

Patients who seek out painful procedures, such as surgical operations and invasive diagnostic tests, may have a masochistic personality makeup in which pain serves as punishment for past sins, imagined or real. Some patients may attempt to master the past and the early trauma of serious medical illness or hospitalization by assuming the role of the patient and reliving the painful and frightening experience over and over again through multiple hospitalizations. Patients who feign psychiatric illness may have had a relative who was hospitalized with the illness they are simulating. Through identification, patients hope to reunite with the relative in a magical way.

Many patients have the poor identity formation and disturbed self-image that is characteristic of someone with borderline personality disorder. Some patients are *as-if personalities* who have assumed the identities of those around them. If these patients are health professionals, they are often unable to differentiate themselves from the patients with whom they come in contact. The cooperation or encouragement of other persons in simulating a factitious illness occurs in a rare variant of the disorder. Although most patients act alone, friends or relatives participate in fabricating the illness in some instances.

Significant defense mechanisms are repression, identification with the aggressor, regression, and symbolization.

Biological Factors

Some researchers have proposed that brain dysfunction may be a factor in factitious disorders. It has been hypothesized that impaired information processing contributes to the *pseudologia fantastica* and aberrant behavior of patients with Munchausen disorder; however, no genetic patterns have been established, and electroencephalographic (EEG) studies noted no specific abnormalities in patients with factitious disorders.

DIAGNOSIS AND CLINICAL FEATURES

Factitious disorder is the faking of physical or psychological signs and symptoms. Clues that should trigger suspicion of the disorder are given in Table 13.6-1. The psychiatric examination should emphasize securing information from any available friends, relatives, or other informants, because interviews with reliable outside sources often reveal the false nature of the patient's illness. Although time-consuming and tedious, verifying all the facts presented by the patient about previous hospitalizations and medical care is essential.

 **Table 13.6-1**
Clues that Should Trigger Suspicion of Factitious Disorder

Unusual, dramatic presentation of symptoms that defy conventional medical or psychiatric understanding
Symptoms do not respond appropriately to usual treatment or medications
Emergence of new, unusual symptoms when other symptoms resolve
Eagerness to undergo procedures or testing or to recount symptoms
Reluctance to give access to collateral sources of information (i.e., refusing to sign releases of information or to give contact information for family and friends)
Extensive medical history or evidence of multiple surgeries
Multiple drug allergies
Medical profession
Few visitors
Ability to forecast unusual progression of symptoms or unusual response to treatment

(Table by Dora L. Wang, M.D., Seth Powsner, M.D., and Stuart J. Eisendrath, M.D.)

Psychiatric evaluation is requested on a consultation basis in about 50 percent of cases, usually after a simulated illness is suspected. The psychiatrist is often asked to confirm the diagnosis of factitious disorder. Under these circumstances, it is necessary to avoid pointed or accusatory questioning that may provoke truculence, evasion, or flight from the hospital. A danger may exist of provoking frank psychosis if vigorous confrontation is used; in some instances, the feigned illness serves an adaptive function and is a desperate attempt to ward off further disintegration.

Factitious disorder has been divided into two groups depending on the types of signs or symptoms feigned. There is one disorder marked by psychological symptoms and another marked by physical symptoms. Both may occur together. In DSM-5, no distinction is made between the two and the disorder is divided into that "imposed on self" and that "imposed on another" (factitious disorder by proxy). In the discussion that follows, the clinical picture of either psychological symptoms or physical symptoms is considered separately.

Factitious Disorder with Predominantly Psychological Signs and Symptoms

Some patients show psychiatric symptoms judged to be feigned. This determination can be difficult and is often made only after a prolonged investigation. The feigned symptoms frequently include depression, hallucinations, dissociative and conversion symptoms, and bizarre behavior. Because the patient's condition does not improve after routine therapeutic measures are administered, he or she may receive large doses of psychoactive drugs and may undergo electroconvulsive therapy.

Factitious psychological symptoms resemble the phenomenon of pseudomalingering, conceptualized as satisfying the need to maintain an intact self-image, which would be marred by admitting psychological problems that are beyond the person's capacity to master through conscious effort. In this case, deception is a transient ego-supporting device.

Recent findings indicate that factitious psychotic symptoms are more common than had previously been suspected. The presence of simulated psychosis as a feature of other disorders, such as mood disorders, indicates a poor overall prognosis.

Inpatients who are psychotic and found to have factitious disorder with predominantly psychological signs and symptoms—that is, exclusively simulated psychotic symptoms—generally have a concurrent diagnosis of borderline personality disorder. In these cases, the outcome appears to be worse than that of bipolar I disorder or schizoaffective disorder.

Patients may appear depressed and may explain their depression by offering a false history of the recent death of a significant friend or relative. Elements of the history that may suggest factitious bereavement include a violent or bloody death, a death under dramatic circumstances, and the dead person being a child or a young adult. Other patients may describe either recent and remote memory loss or both auditory and visual hallucinations.

Some patients may use psychoactive substances for the purpose of producing symptoms, such as stimulants to produce restlessness or insomnia, or hallucinogens to produce distortions of reality. Combinations of psychoactive substances can produce very unusual presentations.

Other symptoms, which also appear in the physical type of factitious disorder, include pseudologia fantastica and impostorship. In pseudologia fantastica, limited factual material is mixed with extensive and colorful fantasies. The listener's interest pleases the patient and, thus, reinforces the symptom. The history or the symptoms are not the only distortions of truth. Patients often give false and conflicting accounts about other areas of their lives (e.g., they may claim the death of a parent, to play on the sympathy of others). Imposture is commonly related to lying in these cases. Many patients assume the identity of a prestigious person. Men, for example, report being war heroes and attribute their surgical scars to wounds received during battle or in other dramatic and dangerous exploits. Similarly, they may say that they have ties to accomplished or renowned figures.

Table 13.6-2 lists various syndromes feigned by patients who want to be seen as having a mental illness.

Table 13.6-2
Presentations in Factitious Disorder with Predominantly Psychological Signs and Symptoms

Bereavement	Eating disorder
Depression	Amnesia
Posttraumatic stress disorder	Substance-related disorder
Pain disorder	Paraphillias
Psychosis	Hypersomnia
Bipolar I disorder	Transsexualism
Dissociative identity disorder	

(Adapted from Feldman MD, Eisendrath SJ. *The Spectrum of Factitious Disorders*. Washington, DC: American Psychiatric Press; 1996, with permission.)

Ms. MA was 24 years of age when she first presented in 1973 after an overdose. She gave a history of recurrent overdoses and wrist-slashing attempts since 1969, and, on admission, she stated that she was controlled by her dead sister who kept telling her to take her own life. Her family history was negative.

She was found to be carrying a list of Schneiderian first-rank symptoms in her handbag; she behaved bizarrely, picking imaginary objects out of the wastepaper basket and opening imaginary doors in the waiting room. She admitted to visual hallucinations and offered four of the first-rank symptoms on her list, but her mental state reverted to normal after 2 days. When she was presented at a case conference, the consensus view was that she had been simulating schizophrenia but had a gross personality disorder; however, the consultant in charge dissented from that general view, feeling that she was genuinely psychotic.

On follow-up, this turned out to be the case. She was readmitted in 1975 and was mute, catatonic, grossly thought disordered, and the diagnosis was changed to that of a schizophrenic illness. She has been followed up regularly since and now presents the picture of a mild schizophrenic defect state; she takes regular depot medication but still complains of auditory hallucinations, hearing her dead sister's voice. She is a day patient. (Courtesy of Dora Wang, M.D., Deepa N. Nadiga, M.D., and James J. Jenson, M.D.)

Chronic Factitious Disorder with Predominantly Physical Signs and Symptoms

Factitious disorder with predominantly physical signs and symptoms is the best-known type of Munchausen syndrome. The disorder has also been called hospital addiction, polysurgical addiction—producing the so-called washboard abdomen—and professional patient syndrome, among other names.

The essential feature of patients with the disorder is their ability to present physical symptoms so well that they can gain admission to, and stay in, a hospital. To support their history, these patients may feign symptoms suggesting a disorder involving any organ system. They are familiar with the diagnoses of most disorders that usually require hospital admission or medication and can give excellent histories capable of deceiving even experienced clinicians. Clinical presentations are myriad and include hematoma, hemoptysis, abdominal pain, fever, hypoglycemia, lupus-like syndromes, nausea, vomiting, dizziness, and seizures. Urine is contaminated with blood or feces; anticoagulants are taken to simulate bleeding disorders; insulin is used to produce hypoglycemia; and so on. Such patients often insist on surgery and claim adhesions from previous surgical procedures. They may acquire a “gridiron” or washboard-like abdomen from multiple procedures. Complaints of pain, especially that simulating renal colic, are common, with the patients wanting narcotics. In about half the reported cases, these patients demand treatment with specific medications, usually analgesics. Once in the hospital, they continue to be demanding and difficult. As each test is returned with a negative result, they may accuse doctors of incompetence, threaten litigation, and become generally abusive. Some may sign out abruptly shortly before they believe they are going to be confronted with their factitious behavior. They then go to another hospital in the same or another city and begin the cycle again. Specific predisposing factors are true physical disorders during childhood leading to extensive medical treatment, a grudge against the medical profession, employment as a medical paraprofessional, and an important relationship with a physician in the past. See Color Plate 13.6-2 for factitious skin disease.

Factitious Disorder with Combined Psychological and Physical Signs and Symptoms

In combined forms of factitious disorder, both psychological and physical signs and symptoms are present. In one representative report, a patient alternated between feigned dementia, bereavement, rape, and seizures.

Table 13.6-3 provides a comprehensive overview of a variety of signs and symptoms that may be faked and mistaken for genuine illness. The table also includes the means of simulation and possible methods of detection.

Table 13.6-3
Presentations of Factitious Disorder with Predominantly Physical Signs and Symptoms with Means of Simulation and Possible Methods of Detection

Presentation	Means of Simulation that Have Been Reported	Possible Methods of Detection
Autoimmune		
Goodpasture's syndrome	False history, adding blood to urine	Bronchoalveolar lavage negative for hemosiderin-laden cells
Systemic lupus erythematosus	Malar rash simulated through cosmetics, feigning joint pain	Negative antinuclear antibody test, removability of rash
Dermatological		
Burns	Chemical agents such as oven cleaner	Unnatural shape of lesions, streaks left by chemicals, minor injury to fingers
Excoriations	Self-infliction	Found on accessible parts of the body, or a preponderance of left-sided lesions in a right-handed person
Lesions	Injection of exogenous material such as talc, milk, or gasoline	Puncture marks left by needles, discovery of syringes
Endocrine		
Cushing's syndrome	Steroid ingestion	Evidence of exogenous steroid use
Hyperthyroidism	Thyroxine or L-iodothyronine ingestion	The 24-hour I-131 uptake is suppressed in factitious disease and increased in Graves' disease
Hypoglycemia or insulinoma	(1) Insulin injection (2) Ingestion of oral hypoglycemics	(1) Insulin to C-peptide ratio greater than 1, detection of serum insulin antibodies (2) Serum levels of hypoglycemic medication
Pheochromocytomy	Epinephrine or metaraminol injection	Analysis of urinary catecholamines may reveal epinephrine only or other suspicious findings
Gastrointestinal		
Diarrhea	Phenolphthalein or castor oil ingestion	Testing of stool for laxatives, increased stool weight
Hemoptysis	Contamination of sputum sample, self-induced trauma such as cuts to tongue	Collect specimen under observation, examine mouth
Ulcerative colitis	Laceration of colon with knitting needle	
Hematological		
Aplastic anemia	Self-administration of chemotherapeutic agents to suppress bone marrow	Hematology/oncology consultation
Anemia	Self-induced phlebotomy	Blood studies
Coagulopathy	Ingestion of warfarin or other anticoagulants	
Infectious Disease		
Abdominal abscess	Injection of feces into abdominal wall	Unusual pathogens in microbiology tests
Acquired immunodeficiency syndrome (AIDS)	False history	Collateral information
Neoplastic		
Cancer	False medical and family history, shaving head to simulate chemotherapy	Collateral information, examination
Neurologic		
Paraplegia or quadriplegia	Feigning, fictitious history	Imaging studies, electromyography
Seizures	Feigning, fictitious history	Video electroencephalogram
Obstetrics/gynecology		
Antepartum hemorrhage	Vaginal puncture wounds, use of fake blood	Examination, test blood
Ectopic pregnancy	Feigning abdominal pain while self-injecting human chorionic gonadotropin	Ultrasound
Menorrhagia	Using stolen blood	Type blood
Placenta previa	Intravaginal use of hat pin	Examination
Premature labor	Feigned uterine contractions, manipulation of tocodynamometer	Examination
Premature rupture of membranes	Voiding urine into vagina	Examine fluid
Trophoblastic disease	Addition of human chorionic gonadotropin to urine	
Vaginal bleeding	Self-mutilation with fingernails, nail files, bleach, knives, tweezers, nupticks, glass, pencils	Examination
Vaginal discharge	Applying cigarette ash to underwear	Examination

Systemic		
Fever	Warming thermometer against a lightbulb or other heat source, drinking hot fluids, friction from mouth or anal sphincter, false recordings, injection of pyrogens such as feces, vaccines, thyroid hormone, or tetanus toxoid	Simultaneous taking of temperature from two different locals (orally and rectally), recording the temperature of freshly voided urine, the appearance of cool skin despite high thermometer readings, normal white blood cell count, unusually high or inconsistent temperatures
Urinary		
Bacteriuria	Contamination of urethra or specimen	Unusual pathogen
Hematuria	Contamination of specimen with blood or meat, warfarin ingestion, foreign bodies in bladder (pins)	Collect specimen under observation
Proteinuria	Inserting egg protein into urethra	
Stones	Feigning of renal colic pain, bringing in stones made of exogenous materials or inserting them into urethra	Pathology report

(Table by Dora L. Wang, M.D., Seth Powsner, M.D., and Stuart J. Eisendrath, M.D.)

Factitious Disorder by Proxy

In this diagnosis, a person intentionally produces physical signs or symptoms in another person who is under the first person's care, hence the DSM-5 diagnosis of "Factitious Disorder Imposed on Another." One apparent purpose of the behavior is for the caretaker to indirectly assume the sick role; another is to be relieved of the caretaking role by having the child hospitalized. The most common case of factitious disorder by proxy involves a mother who deceives medical personnel into believing that her child is ill. The deception may involve a false medical history, contamination of laboratory samples, alteration of records, or induction of injury and illness in the child.

BC, a 1-month-old girl, was admitted for the evaluation of fever. Psychiatric consultation was requested due to inconsistencies in the mother's reporting of medical information despite her presentation as a knowledgeable and caring mother who worked as an emergency medical technician. BC's mother reported her own diagnosis of ovarian cancer when she was 3 months pregnant with BC. She reported undergoing a hysterectomy during her cesarean section, and that she had been getting radiation therapy at a local hospital since BC's birth. The pediatrician called the local hospital with the mother's permission and learned that she had a corpus luteum cyst removed at 3 months' gestation and mild hydronephrosis but no cancer or hysterectomy. BC's mother, when confronted with this, stated only that she might need a kidney transplant for the hydronephrosis.

On further exploration, it was discovered that the mother had brought her children to multiple emergency rooms, giving inaccurate histories that prompted excessive testing. At one visit, she told clinicians that her 2-year-old son had lupus and hypergammaglobulinemia, and at another visit, that he had asthma and seizures. She also pursued a minor cosmetic surgical procedure for him against his pediatrician's recommendation.

Clinicians suspected that BC's mother intentionally fabricated symptoms, such as by warming BC's thermometer, and that she did not actively induce symptoms in her children. She was faithful in keeping medical appointments, and her children appeared healthy and well cared for, despite her factitious behavior. The mother denied a psychiatric history but gave permission for clinicians to contact the local psychiatric hospital, which revealed her history of depression, anorexia, panic disorder, and a suicide attempt resulting in a psychiatric hospitalization. Subsequently, she received psychotherapy and psychopharmacotherapy, which she stopped a few months prior to this presentation. During BC's admission for fever, her mother agreed to resume psychiatric treatment. A social services referral was made, and the pediatrician decided to schedule regular follow-up visits for the children.

PATHOLOGY AND LABORATORY EXAMINATION

Psychological testing may reveal underlying pathology in individual patients. Features that are overrepresented in patients with factitious disorder include normal or above-average intelligence quotient, absence of a formal thought disorder, poor sense of identity, including confusion over sexual identity, poor sexual adjustment, poor frustration tolerance, strong dependence needs, and narcissism. An invalid test profile and elevations of all clinical scales on the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) indicate an attempt to appear more disturbed than is the case ("fake bad").

No laboratory or pathology tests are diagnostic of factitious disorders, although they may help to confirm the diagnosis by demonstrating deception. Certain tests (e.g., drug screening), however, may help confirm or rule out specific mental or medical disorders.

DIFFERENTIAL DIAGNOSIS

Any disorder in which physical signs and symptoms are prominent should be considered in the differential diagnosis, and the possibility of authentic or concomitant physical illness must always be explored. Additionally, a history of many surgeries in patients with factitious disorder may predispose such patients to complications or actual diseases, necessitating even further surgery. Factitious disorder is on a continuum between somatoform disorders and malingering, the goal being to assume the sick role. On the one hand, it is unconscious and nonvolitional, and on the other hand, it is conscious and willful (malingering).

Conversion Disorders

A factitious disorder is differentiated from conversion disorder by the voluntary production of factitious symptoms, the extreme course of multiple hospitalizations, and the seeming willingness of patients with a factitious disorder to undergo an extraordinary number of mutilating procedures. Patients with conversion disorder are not usually conversant with medical terminology and hospital routines, and their symptoms have a direct temporal relation or symbolic reference to specific emotional conflicts.

Hypochondriasis or illness anxiety disorder differs from factitious disorder in that the hypochondriacal patient does not voluntarily initiate the production of symptoms, and hypochondriasis typically has a later age of onset. As with conversion disorder, patients with hypochondriasis do not usually submit to potentially mutilating procedures.

Personality Disorders

Because of their pathological lying, lack of close relationships with others, hostile and manipulative manner, and associated substance abuse

and criminal history, patients with factitious disorder are often classified as having antisocial personality disorder. Antisocial persons, however, do not usually volunteer for invasive procedures or resort to a way of life marked by repeated or long-term hospitalization.

Because of attention seeking and an occasional flair for the dramatic, patients with factitious disorder may be classified as having histrionic personality disorder. But not all such patients have a dramatic flair; many are withdrawn and bland.

Consideration of the patient's chaotic lifestyle, history of disturbed interpersonal relationships, identity crisis, substance abuse, self-damaging acts, and manipulative tactics may lead to the diagnosis of borderline personality disorder. Persons with factitious disorder usually do not have the eccentricities of dress, thought, or communication that characterize schizotypal personality disorder patients.

Schizophrenia

The diagnosis of schizophrenia is often based on patients' admittedly bizarre lifestyles, but patients with factitious disorder do not usually meet the diagnostic criteria for schizophrenia unless they have the fixed delusion that they are actually ill and act on this belief by seeking hospitalization. Such a practice seems to be the exception; few patients with factitious disorder show evidence of a severe thought disorder or bizarre delusions.

Malingering

Factitious disorders must be distinguished from malingering. Malingerers have an obvious, recognizable environmental goal in producing signs and symptoms. They may seek hospitalization to secure financial compensation, evade the police, avoid work, or merely obtain free bed and board for the night, but they always have some apparent end for their behavior. Moreover, these patients can usually stop producing their signs and symptoms when they are no longer considered profitable or when the risk becomes too great.

Substance Abuse

Although patients with factitious disorders may have a complicating history of substance abuse, they should be considered not merely as substance abusers but as having coexisting diagnoses.

Ganser's Syndrome

Ganser's syndrome, a controversial condition most typically associated with prison inmates, is characterized by the use of approximate answers. Persons with the syndrome respond to simple questions with astonishingly incorrect answers. For example, when asked about the color of a blue car, the person answers "red" or answers "2 plus 2 equals 5." Ganser's syndrome may be a variant of malingering, in that the patients avoid punishment or responsibility for their actions. Ganser's syndrome can be classified in DSM-5 as a type of dissociative disorder and in *International Statistical Classification of Diseases and Related Health Problems*, 10th edition (ICD-10), it is classified under other dissociative or conversion disorders. In contrast, patients with factitious disorder with predominantly psychological signs and symptoms may *intentionally* give approximate answers.

COURSE AND PROGNOSIS

Factitious disorders typically begin in early adulthood, although they can appear during childhood or adolescence. The onset of the disorder or of discrete episodes of seeking treatment may follow real illness, loss, rejection, or abandonment. Usually, the patient or a close relative had a hospitalization in childhood or early adolescence for a genuine physical illness. Thereafter, a long pattern of successive hospitalizations begins insidiously and evolves. As the disorder progresses, the patient becomes knowledgeable about medicine and hospitals. The onset of the disorder in patients who had early hospitalizations for actual illness is earlier than generally reported.

Factitious disorders are incapacitating to the patient and often produce severe trauma or untoward reactions related to treatment. A course of repeated or long-term hospitalization is obviously incompatible with meaningful vocational work and sustained interpersonal relationships. The prognosis in most cases is poor. A few patients occasionally spend time in jail, usually for minor crimes, such as burglary, vagrancy, and disorderly conduct. Patients may also have a history of intermittent psychiatric hospitalization.

Although no adequate data are available about the ultimate outcome for the patients, a few of them probably die as a result of needless medication, instrumentation, or surgery. In view of the patients' often expert simulation and the risks that they take, some may die without the disorder being suspected. Possible features that indicate a favorable prognosis are (1) the presence of a depressive-masochistic personality; (2) functioning at a borderline, not a continuously psychotic, level; and (3) the attributes of an antisocial personality disorder with minimal symptoms.

TREATMENT

No specific psychiatric therapy has been effective in treating factitious disorders. It is a clinical paradox that patients with the disorders simulate serious illness and seek and submit to unnecessary treatment while they deny to themselves and others their true illness and thus avoid possible treatment for it. Ultimately, the patients elude meaningful therapy by abruptly leaving the hospital or failing to keep follow-up appointments.

Treatment, thus, is best focused on management rather than on cure. Guidelines for the treatment and management of factitious disorder are given in [Table 13.6-4](#). The three major goals in the treatment and management of factitious disorders are (1) to reduce the risk of morbidity and mortality, (2) to address the underlying emotional needs or psychiatric diagnosis underlying factitious illness behavior, and (3) to be mindful of legal and ethical issues. Perhaps the single most important factor in successful management is a physician's early recognition of the disorder. In this way, physicians can forestall a multitude of painful and potentially dangerous diagnostic procedures for these patients. Good liaison between psychiatrists and the medical or surgical staff is strongly advised. Although a few cases of individual psychotherapy have been reported in the literature, no consensus exists about the best approach. In general, working in concert with the patient's primary care physician is more effective than working with the patient in isolation.

Table 13.6-4
Guidelines for Management and Treatment of Factitious Disorder

Active pursuit of a prompt diagnosis can minimize the risk of morbidity and mortality.

Minimize harm. Avoid unnecessary tests and procedures, especially if invasive. Treat according to clinical judgment, keeping in mind that subjective complaints may be deceptive.

Regular interdisciplinary meetings to reduce conflict and splitting among staff. Manage staff countertransference.

Consider facilitating healing by using the double-bind technique or face-saving behavioral strategies, such as self-hypnosis or biofeedback.

Steer the patient toward psychiatric treatment in an empathic, nonconfrontational, face-saving manner. Avoid aggressive direct confrontation.

Treat underlying psychiatric disturbances, such as Axis I disorders and Axis II disorders. In psychotherapy, address coping strategies and emotional conflicts.

Appoint a primary care provider as a gatekeeper for all medical and psychiatric treatment.

Consider involving risk management professionals and bioethicists from an early point.

Consider appointing a guardian for medical and psychiatric decisions.

Consider prosecution for fraud, as a behavioral disincentive.

The personal reactions of physicians and staff members are of great significance in treating and establishing a working alliance with these patients, who invariably evoke feelings of futility, bewilderment, betrayal, hostility, and even contempt. In essence, staff members are forced to abandon a basic element of their relationship with patients—accepting the truthfulness of the patients' statements. One appropriate psychiatric intervention is to suggest to the staff ways of remaining aware that even though the patient's illness is factitious, the patient is ill.

Physicians should try not to feel resentment when patients humiliate their diagnostic prowess, and they should avoid any unmasking ceremony that sets up the patients as adversaries and precipitates their flight from the hospital. The staff should not perform unnecessary procedures or discharge patients abruptly, both of which are manifestations of anger.

Clinicians who find themselves involved with patients with factitious disorders may become angry at the patients for lying and deceiving them. Hence, therapists must be mindful of countertransference whenever they suspect factitious disorder. Often, the diagnosis is unclear because a definitive physical cause cannot be entirely ruled out. Although the use of confrontation is controversial, at some point in the treatment, patients must be made to face reality. Most patients simply leave treatment when their methods of gaining attention are identified and exposed. In some cases, clinicians should reframe the factitious disorder as a cry for help, so that patients do not view the clinicians' responses as punitive. A major role for psychiatrists working with patients with factitious disorder is to help other staff members in the hospital deal with their own sense of outrage at having been duped. Education about the disorder and some attempt to understand the patient's motivations may help staff members maintain their professional conduct in the face of extreme frustration.

In cases of factitious disorder by proxy, legal intervention has been obtained in several instances, particularly with children. The senselessness of the disorder and the denial of false action by parents are obstacles to successful court action and often make conclusive proof unobtainable. In such cases, the child welfare services should be notified, and arrangements made for ongoing monitoring of the children's health (see [Table 13.6-5](#) for interventions for pediatric factitious disorder by proxy).

 **Table 13.6-5**
Interventions for Pediatric Factitious Disorder by Proxy

A pediatrician should serve as "gatekeeper" for medical care utilization. All other physicians should coordinate care with the gatekeeper.

Child protective services should be informed whenever a child is harmed.

Family psychotherapy and/or individual psychotherapy should be instituted for the perpetrating parent and the child.

Health insurance companies, school officials, and other nonmedical sources should be asked to report possible medical use to the physician gatekeeper. Permission of a parent or of child protective services must first be obtained.

The possibility should be considered of admitting the child to an inpatient or partial hospital setting to facilitate diagnostic monitoring of symptoms and to institute a treatment plan.

The child may require placement in another family. The perpetrating parent may need to be removed from the child through criminal prosecution and incarceration.

(Table by Dora L. Wang, M.D., Seth Powsner, M.D., and Stuart J. Eisendrath, M.D.)

Pharmacotherapy of factitious disorders is of limited use. Major mental disorders such as schizophrenia will respond to antipsychotic medication; however, in all cases, medication should be administered carefully because of the potential for abuse. Selective serotonin reuptake inhibitors (SSRIs) may be useful in decreasing impulsive behavior when that is a major component in acting-out factitious behavior.

13.7 Pain Disorder

In the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), pain disorder warranted its own diagnostic category; but in the current fifth edition (DSM-5), it is diagnosed as a variant of somatic symptom disorder. Its importance is such, however, that it warrants a separate discussion in this textbook.

A pain disorder is characterized by the presence of, and focus on, pain in one or more body sites and is sufficiently severe to come to clinical attention. Psychological factors are necessary in the genesis, severity, or maintenance of the pain, which causes significant distress, impairment, or both. The physician does not have to judge the pain to be “inappropriate” or “in excess of what would be expected.” Rather, the phenomenological and diagnostic focus is on the importance of psychological factors and the degree of impairment caused by the pain. The disorder has been called somatoform pain disorder, psychogenic pain disorder, idiopathic pain disorder, and atypical pain disorder. Pain disorder is diagnosed as “Unspecified Somatic Symptom Disorder” in DSM-5 or it may be designated as a “specifier” under that heading.

EPIDEMIOLOGY

The prevalence of pain disorder appears to be common. Recent work indicates that the 6-month and lifetime prevalence is approximately 5 and 12 percent, respectively. It has been estimated that 10 to 15 percent of adults in the United States have some form of work disability because of back pain alone in any year. Approximately 3 percent of people in a general practice have persistent pain, with at least 1 day per month of activity restriction because of the pain.

Pain disorder can begin at any age. The gender ratio is unknown. Pain disorder is associated with other psychiatric disorders, especially affective and anxiety disorders. Chronic pain appears to be most frequently associated with depressive disorders, and acute pain appears to be more commonly associated with anxiety disorders. The associated psychiatric disorders may precede the pain disorder, may co-occur with it, or may result from it. Depressive disorders, alcohol dependence, and chronic pain may be more common in relatives of individuals with chronic pain disorder. Individuals whose pain is associated with severe depression and those whose pain is related to a terminal illness, such as cancer, are at increased risk for suicide. Differences may exist in how various ethnic and cultural groups respond to pain, but the usefulness of cultural factors for the clinician remains obscure to the treatment of individuals with pain disorder because of a lack of good data and because of high individual variability.

ETIOLOGY

Psychodynamic Factors

Patients who experience bodily aches and pains without identifiable and adequate physical causes may be symbolically expressing an intrapsychic conflict through the body. Patients suffering from alexithymia, who are unable to articulate their internal feeling states in words, express their feelings with their bodies. Other patients may unconsciously regard emotional pain as weak and somehow lacking legitimacy. By displacing the problem to the body, they may feel they have a legitimate claim to the fulfillment of their dependency needs. The symbolic meaning of body disturbances may also relate to atonement for perceived sin, to expiation of guilt, or to suppressed aggression. Many patients have intractable and unresponsive pain because they are convinced they deserve to suffer.

Pain can function as a method of obtaining love, a punishment for wrongdoing, and a way of expiating guilt and atoning for an innate sense of badness. Among the defense mechanisms used by patients with pain disorder are displacement, substitution, and repression. Identification plays a part when a patient takes on the role of an ambivalent love object who also has pain, such as a parent.

Behavioral Factors

Pain behaviors are reinforced when rewarded and are inhibited when ignored or punished. For example, moderate pain symptoms may become intense when followed by the solicitous and attentive behavior of others, by monetary gain, or by the successful avoidance of distasteful activities.

Interpersonal Factors

Intractable pain has been conceptualized as a means for manipulation and gaining advantage in interpersonal relationships, for example, to ensure the devotion of a family member or to stabilize a fragile marriage. Such secondary gain is most important to patients with pain disorder.

Biological Factors

The cerebral cortex can inhibit the firing of afferent pain fibers. Serotonin is probably the main neurotransmitter in the descending inhibitory pathways, and endorphins also play a role in the central nervous system modulation of pain. Endorphin deficiency seems to correlate with augmentation of incoming sensory stimuli. Some patients may have pain disorder, rather than another mental disorder, because of sensory and limbic structural or chemical abnormalities that predispose them to experience pain.

DIAGNOSIS AND CLINICAL FEATURES

Patients with pain disorder are not a uniform group, but a heterogeneous collection of persons with low back pain, headache, atypical facial pain, chronic pelvic pain, and other kinds of pain. A patient's pain may be posttraumatic, neuropathic, neurological, iatrogenic, or musculoskeletal; to meet a diagnosis of pain disorder, however, the disorder must have a psychological factor judged to be significantly involved in the pain symptoms and their ramifications.

Patients with pain disorder often have long histories of medical and surgical care. They visit many physicians, request many medications, and may be especially insistent in their desire for surgery. Indeed, they can be completely preoccupied with their pain and cite it as the source of all their misery. Such patients often deny any other sources of emotional dysphoria and insist that their lives are blissful except for their pain. Their clinical picture can be complicated by substance-related disorders, because these patients attempt to reduce the pain through the use of alcohol and other substances.

At least one study has correlated the number of pain symptoms to the likelihood and severity of symptoms of somatic symptom disorder, depressive disorder, and anxiety disorder. Major depressive disorder is present in about 25 to 50 percent of patients with pain disorder, and dysthymic disorder or depressive disorder symptoms are reported in 60 to 100 percent of the patients. Some investigators believe that chronic pain is almost always a variant of a depressive disorder, a masked or somatized form of depression. The most prominent depressive symptoms in patients with pain disorder are anergia, anhedonia, decreased libido, insomnia, and irritability; diurnal variation, weight loss, and psychomotor retardation appear to be less common.

A 54-year-old accountant sought out his family physician with complaints of severe back pain that came on suddenly while trying to lift a piece of heavy furniture at home. On examination he showed no focal neurological signs but was unable to straighten up into an upright position.

The patient was referred for magnetic resonance imaging (MRI), which revealed no structural abnormalities. He was advised to have several sessions with a physical therapist to treat what was diagnosed as “back strain,” but as the therapy progressed, his pain became more severe, and he complained of muscle tension in his neck in addition to his back and spent most of his days sitting in a chair or lying on a bedboard on his bed.

He was eventually referred to a psychiatrist and talked about the stress he was experiencing at work since an assistant that he relied on was fired because of his firm’s need to downsize. His work load had increased tremendously as a result. The formulation by the psychiatrist was that the patient was “somatizing” his anger, transforming the strong affect into pain that enabled him to escape from the stressful situation. A course of psychoeducation was begun in which these dynamics were explored. Equally important was his asserting himself at work, explaining that the load he was expected to carry was too much and that help was required. When this was accomplished, the patient’s back pain disappeared within a matter of days.

DIFFERENTIAL DIAGNOSIS

Purely physical pain can be difficult to distinguish from purely psychogenic pain, especially because the two are not mutually exclusive. Physical pain fluctuates in intensity and is highly sensitive to emotional, cognitive, attentional, and situational influences. Pain that does not vary and is insensitive to any of these factors is likely to be psychogenic. When pain does not wax and wane and is not even temporarily relieved by distraction or analgesics, clinicians can suspect an important psychogenic component.

Pain disorder must be distinguished from other somatic symptom disorders, although there may be overlap. Patients with hypochondriacal preoccupations may complain of pain, and aspects of the clinical presentation of hypochondriasis, such as bodily preoccupation and disease conviction, can also be present in patients with pain disorder. Patients with hypochondriasis tend to have many more symptoms than patients with pain disorder, and their symptoms tend to fluctuate more than those of patients with pain disorder. Conversion disorder is generally short-lived, whereas pain disorder is chronic. In addition, pain is, by definition, not a symptom in conversion disorder. Malingering patients consciously provide false reports, and their complaints are usually connected to clearly recognizable goals.

The differential diagnosis can be difficult because patients with pain disorder often receive disability compensation or a litigation award. Muscle contraction (tension) headaches, for example, have a pathophysiological mechanism to account for the pain and so are not diagnosed as pain disorder. Patients with pain disorder are not pretending to be in pain, however. As in all of these disorders, symptoms are not imaginary.

COURSE AND PROGNOSIS

The pain in pain disorder generally begins abruptly and increases in severity for a few weeks or months. The prognosis varies, although pain disorder can often be chronic, distressful, and completely disabling. Acute pain disorders have a more favorable prognosis than chronic pain disorders. A wide range of variability is seen in the onset and course of chronic pain disorder. In many cases, the pain has been present for many years by the time the individual comes to psychiatric care, owing to the reluctance of the patient and the physician’s tendency to see pain as a psychiatric disorder. People with pain disorder who resume participation in regularly scheduled activities, despite the pain, have a more favorable prognosis than people who allow the pain to become the determining factor in their lifestyle.

TREATMENT

Because it may not be possible to reduce the pain, the treatment approach must address rehabilitation. Clinicians should discuss the issue of psychological factors early in treatment and should frankly tell patients that such factors are important in the cause and consequences of both physical and psychogenic pain. Therapists should also explain how various brain circuits that are involved with emotions (e.g., the limbic system) can influence the sensory pain pathways. For example, persons who hit their head while happy at a party can seem to experience less pain than when they hit their head while angry and at work. Nevertheless, therapists must fully understand that the patient’s experiences of pain are real.

Pharmacotherapy

Analgesic medications do not generally benefit most patients with pain disorder. In addition, substance abuse and dependence are often major problems for such patients who receive long-term analgesic treatment. Sedatives and antianxiety agents are not especially beneficial and are also subject to abuse, misuse, and adverse effects.

Antidepressants, such as tricyclics and selective serotonin reuptake inhibitors (SSRIs), are the most effective pharmacological agents. Whether antidepressants reduce pain through their antidepressant action or exert an independent, direct analgesic effect (possibly by stimulating efferent inhibitory pain pathways) remains controversial. The success of SSRIs supports the hypothesis that serotonin is important in the pathophysiology of the disorder. Amphetamines, which have analgesic effects, may benefit some patients, especially when used as an adjunct to SSRIs, but dosages must be monitored carefully.

Psychotherapy

Some outcome data indicate that psychodynamic psychotherapy can benefit patients with pain disorder. The first step in psychotherapy is to develop a solid therapeutic alliance by empathizing with the patient’s suffering. Clinicians should not confront somatizing patients with comments such as “*This is all in your head.*” For the patient, the pain is real, and clinicians must acknowledge the reality of the pain, even as they understand that it is largely intrapsychic in origin. A useful entry point into the emotional aspects of the pain is to examine its interpersonal ramifications in the patient’s life. In marital therapy, for example, the psychotherapist may soon get to the source of the patient’s psychological pain and the function of the physical complaints in significant relationships. Cognitive therapy has been used to alter negative thoughts and to foster a positive attitude.

Other Therapies

Biofeedback can be helpful in the treatment of pain disorder, particularly with migraine pain, myofascial pain, and muscle tension states, such as tension headaches. Hypnosis, transcutaneous nerve stimulation, and dorsal column stimulation have also been used. Nerve blocks and surgical ablative procedures are effective for some patients with pain disorder; but these procedures must be repeated, because the pain returns after 6 to 18 months.

Pain Control Programs

Sometimes it may be necessary to remove patients from their usual settings and place them in a comprehensive inpatient or outpatient pain control program or clinic. Multidisciplinary pain units use many modalities, such as cognitive, behavior, and group therapies. They provide extensive physical conditioning through physical therapy and exercise and offer vocational evaluation and rehabilitation. Concurrent mental disorders are diagnosed and treated, and patients who are dependent on analgesics and hypnotics are detoxified. Inpatient multimodal treatment programs generally report encouraging results.

13.8 Consultation-Liaison Psychiatry

Consultation-liaison (C-L) psychiatry is the study, practice, and teaching of the relation between medical and psychiatric disorders. In C-L psychiatry, psychiatrists serve as consultants to medical colleagues (either another psychiatrist or, more commonly, a nonpsychiatric physician) or to other mental health professionals (psychologist, social worker, or psychiatric nurse). In addition, C-L psychiatrists consult regarding patients in medical or surgical settings and provide follow-up psychiatric treatment as needed. C-L psychiatry is associated with all the diagnostic, therapeutic, research, and teaching services that psychiatrists perform in the general hospital and serves as a bridge between psychiatry and other specialties.

In the medical wards of the hospital, C-L psychiatrists must play many roles: skillful and brief interviewer, good psychiatrist and psychotherapist, teacher, and knowledgeable physician who understands the medical aspects of the case. The C-L psychiatrist is part of the medical team who makes a unique contribution to the patient's total medical treatment. The scope of C-L psychiatry is outlined in [Table 13.8-1](#).

Table 13.8-1
Scope of Consultation-Liaison Psychiatry

1. Understand the impact of medical illness and the system in which it is treated and how this affects the presentation, experience, and impact of psychiatric and psychosocial morbidity.
2. Conduct a biopsychosociocultural assessment, create a formulation, and implement appropriate treatment in the context of the general hospital including effective communication with the rest of the treatment team.
3. Assess reactions to illness, and differentiate the presentation of depression and anxiety in the medical setting.
4. Understand the combined trajectories of illness and the developmental issues of the person with mental health problems and mental illness.
5. Ability to assess and treat "Somatic Symptom and Related Disorders."
6. Ability to assess and manage common Neurocognitive Disorders, with a particular emphasis on delirium.
7. Understand the particular needs of special populations with psychiatric and psychosocial morbidity in the medical settings, including the young, the old, the indigenous, and those with intellectual disabilities.
8. Assess and manage acute and emergency presentations of psychiatric morbidity in the general medical setting.

(From the Royal Australia and New Zealand College of Psychiatry, with permission.)

DIAGNOSIS

Knowledge of psychiatric diagnosis is essential to C-L psychiatrists. Both dementia and delirium frequently complicate medical illness, especially among hospital patients. Delirium occurs in 15 to 30 percent of hospitalized patients. Psychoses and other mental disorders often complicate the treatment of medical illness, and deviant illness behavior, such as suicide, is a common problem in patients who are organically ill. C-L psychiatrists must be aware of the many medical illnesses that can have psychiatric symptoms. Lifetime prevalence of mental illness in chronically physically ill patients is more than 40 percent, particularly substance abuse and mood and anxiety disorders. Interviews and serial clinical observations are the C-L psychiatrist's tools for diagnosis. The purposes of the diagnosis are to identify (1) mental disorders and psychological responses to physical illness, (2) patients' personality features, and (3) patients' characteristic coping techniques to recommend the most appropriate therapeutic intervention for patients' needs.

TREATMENT

The C-L psychiatrists' principal contribution to medical treatment is a comprehensive analysis of a patient's response to illness, psychological and social resources, coping style, and psychiatric illness, if any. This assessment is the basis of the patient treatment plan. In discussing the plan, C-L psychiatrists provide their patient assessment to nonpsychiatric health professionals. Psychiatrists' recommendations should be clear, concrete guidelines for action. A C-L psychiatrist may recommend a specific therapy, suggest areas for further medical inquiry, inform doctors and nurses of their roles in the patient's psychosocial care, recommend a transfer to a psychiatric facility for long-term psychiatric treatment, or suggest or undertake brief psychotherapy with the patient on the medical ward.

C-L psychiatrists must deal with a broad range of psychiatric disorders, the most common symptoms being anxiety, depression, and disorientation. Treatment problems account for 50 percent of the consultation requests made of psychiatrists.

Common C-L Problems

Suicide Attempt or Threat. Suicide rates are higher in persons with medical illness than in those without medical or surgical problems. High-risk factors for suicide are men over 45 years of age, no social support, alcohol dependence, previous suicide attempt, and incapacitating or catastrophic medical illness, especially if accompanied by severe pain. If suicide risk is present, the patient should be transferred to a psychiatric unit or started on 24-hour nursing care.

Depression. As mentioned, suicidal risk must be assessed in every depressed patient. Depression without suicidal ideation is not uncommon in hospitalized patients, and treatment with antidepressant medication can be started if necessary. A careful assessment of drug-drug interactions must be made before prescribing, which should be undertaken in collaboration with the patient's primary physician. Antidepressants should be used cautiously in cardiac patients because of conduction side effects and orthostatic hypotension.

Agitation. Agitation is often related to the presence of a cognitive disorder or associated with withdrawal from drugs (e.g., opioids, alcohol, sedative hypnotics). Antipsychotic medications (e.g., haloperidol [Haldol]) are very useful for excessive agitation. Physical restraints should be used with great caution and only as a last resort. The patient should be examined for command hallucinations or paranoid ideation to which he or she is responding to in an agitated manner. Toxic reactions to medications that cause agitation should always be ruled out.

Hallucinations. The most common cause of hallucinations is delirium tremens, which usually begin 3 to 4 days after hospitalization. Patients in intensive care units (ICU) who experience sensory isolation may respond with hallucinatory activity. Conditions such as brief psychotic disorder, schizophrenia, and neurocognitive disorders are associated with hallucinations, and they respond rapidly to antipsychotic medication. Formication, in which the patient believes that bugs are crawling over the skin, is often associated with cocaine use.

Sleep-Wake Disorders. A common cause of insomnia in hospitalized patients is pain, which when treated, solves the sleep problem. Early morning awakening is associated with depression, and difficulty falling asleep is associated with anxiety. Depending on the cause, antianxiety or antidepressant agents may be prescribed. Early substance withdrawal as a cause of insomnia should be considered in the differential diagnosis.

Confusion. Delirium is the most common cause of confusion or disorientation among hospitalized patients in general hospitals. The causes are myriad and relate to metabolic status, neurological findings, substance abuse, and mental illness, among many others. Small doses of antipsychotics may be used when major agitation occurs in conjunction with the confused state; however, sedatives, such as benzodiazepines, can worsen the condition and cause sundowner syndrome (ataxia, disorientation). If sensory deprivation is a contributing factor, the environment can be modified so that the patient has sensory cues (e.g., radio, clock, no curtains around the bed). [Table 13.8-2](#) lists the probable causes of confusional states that require urgent attention.

Table 13.8-2
Some Clues to Causes of Acute Confusional States Demanding Urgent Attention

Metabolic Disorders

1. Hypoglycemia: history of diabetes or alcoholism; reduced level of consciousness, shaky, sweaty, perhaps combative
2. Hyperglycemia: history of diabetes; complaints of increased thirst, urination, or flu-like symptoms
3. Hyponatremia: underlying illness like lung cancer, recent stroke, chronic pulmonary infections, heart failure, cirrhosis, diuretic use
4. Hypernatremia: dehydration from inadequate fluid intake or excessive fluid loss without replacement
5. Hypercalcemia: underlying disorder such as cancer metastatic to bone, sarcoidosis, lung and renal cell cancer, multiple myeloma, and/or prolonged immobilization
6. Hypoxia: inadequate oxygen supplied to the brain because of poor pulmonary or cardiac function or carbon monoxide poisoning
7. Hypercarbia: history of chronic lung disease characterized by carbon dioxide retention; may use oxygen at home
8. Hepatic encephalopathy: history of chronic liver disease or alcoholism; probably jaundiced; ascites
9. Uremia: history of kidney disease, enlarged prostate, recent inability to pass urine
10. Thiamine deficiency (Wernicke's encephalopathy): variable degrees of ophthalmoplegia, ataxia, and mental disturbance; history of nutritional deficiency secondary to alcoholism, particularly of thiamine; since remaining thiamine in the body is rapidly used when the patient is given intravenous glucose, any patient with alcoholism should immediately receive intramuscular thiamine before glucose infusion to prevent precipitating this encephalopathy; untreated, the disorder rapidly progresses to a permanent memory disorder (Korsakoff's syndrome) and, in some advanced cases, death
11. Hypothyroidism: history of progressive fatigue, constipation, sensitivity to cold, weight gain, coarsening of hair and skin, mental slowing; examination shows abnormally low temperature and enlarged heart and slow pulse; may be precipitated by the effects of lithium on thyroid function
12. Hyperthyroidism: patient may be either hyperactive or apathetic; history may reveal rapid weight loss, diarrhea, heat intolerance, and emotional instability; examination shows goiter, silky fine hair, warm moist skin, proptosis and wide-eyed stare, fine tremor, rapid or irregular pulse; in elderly patients muscle weakness and heart failure may be most apparent

Systemic Illness

1. Decreased cardiac output from various causes, such as congestive heart failure, arrhythmia, pulmonary embolus, and myocardial infarction; acute myocardial infarction presents with confusion as the major symptom in 13% of elderly patients; aged patients do not complain of typical pain; often they complain of indigestion; vital signs may be abnormal, and patient may look ill (ashen coloring, weak, nauseated, sweaty) and be confused
2. Pneumonia: recent history of a cold, becoming bedridden and aspirating; fever may not be apparent, but tachycardia or hypotension are evident on vital signs
3. Urinary tract infection: especially in patients with indwelling urinary catheters, prostatic hypertrophy, diabetes, neurogenic bladder
4. Anemia: especially with acute blood loss (injury, intestinal bleeding), chronic illness, occult gastrointestinal malignancy
5. Acute surgical emergencies: infarction of the bowel, appendicitis, and volvulus are common and often present only with confusion and no other complaints
6. Hypertension: sustained or rapid increase in blood pressure may cause encephalopathy; often has history of elevated blood pressure; may occur in patient on MAO inhibitor antidepressants who has eaten food containing tyramine
7. Vasculitides: e.g., systemic lupus erythematosus; confusion arises from cerebral involvement or treatment with steroids
8. Any febrile illness and infection can cause confusion in the aged

Central Nervous System Disorders

1. Subdural or epidural hematoma: may or may not have history of head trauma; fluctuating mental status often present; may have no focal neurological signs
2. Seizure: unwitnessed seizure may be suggested if patient was found on floor with evidence of incontinence or vomiting; history of seizure disorder or alcoholism
3. Stroke: history of transient ischemic attacks or strokes; may have no signs except confusion
4. Infection: meningitis (bacterial, fungal, or tuberculous), viral encephalitis
5. Tumor, primary or metastatic: with a growing mass, raised intracranial pressure may cause local compression of vital structures or herniation of the brain; in the elderly, brain atrophy allows for greater space inside the skull so that symptoms may not appear until the mass is quite large
6. Normal pressure hydrocephalus: presents with triad of gait disturbance, incontinence, dementia; surgery may be curative

Drugs and Medication

1. Almost all drugs are capable of causing confusion in the elderly; the most commonly implicated drugs include those with strong anticholinergic effects (antidepressants, antipsychotics, and antiparkinsonian drugs, and many over-the-counter preparations), sedative-hypnotics (barbiturates, benzodiazepines), cardiac medications (digoxin, propranolol, lidocaine, quinidine), antihypertensives, anticonvulsants, cimetidine, nonnarcotic and narcotic analgesics, and corticosteroids
2. Alcohol: intoxication and withdrawal syndromes occur as in young patients, but poor health in the elderly may put geriatric patients at greater risk
3. Drug abuse: far less common in elderly persons, but chronic intoxication with bromides, minor tranquilizers (especially meprobamate, barbiturates) occurs

(From SL Minden. Elderly psychiatric emergency patients. In: Bassuk EL, Birk AW, eds. *Emergency Psychiatry*. New York: Plenum; 1984:360, with permission.)

Noncompliance or Refusal to Consent to Procedure. Issues such as noncompliance and refusal to consent to a procedure can sometimes be traced to the relationship of the patient and his or her treating doctor, which should be explored. A negative transference toward the physician is a common cause of noncompliance. Patients who fear medication or who fear a procedure often respond well to education and reassurance. Patients whose refusal to give consent is related to impaired judgment can be declared incompetent, but only by a judge. Cognitive disorder is the main cause of impaired judgment in hospitalized patients.

No Organic Basis for Symptoms. The C-L psychiatrist is often called in when the physician cannot find evidence of medical or surgical disease to account for the patient's symptoms. In these instances, several psychiatric conditions must be considered, including conversion disorder, somatization disorder, factitious disorders, and malingering. Glove and stocking anesthesia with autonomic nervous system symptoms is seen in conversion disorder; multiple bodily complaints are present in somatization disorder; the wish to be in the hospital occurs in factitious disorder; and obvious secondary gain is observed in patients who are malingering (e.g., compensation cases).

C-L Psychiatry in Special Situations

Intensive Care Units. All ICUs deal with patients who experience anxiety, depression, and delirium. ICUs also impose extraordinarily high stress on staff and patients, which is related to the intensity of the problems. Patients and staff members alike frequently observe cardiac arrests, deaths, and medical disasters, which leave them all autonomically aroused and psychologically defensive. ICU nurses and their patients experience particularly high levels of anxiety and depression. As a result, nurse burnout and high turnover rates are common.

The problem of stress among ICU staff receives much attention, especially in the nursing literature. Much less attention is given to the house staff, especially those on the surgical services. All persons in ICUs must be able to deal directly with their feelings about their extraordinary experiences and difficult emotional and physical circumstances. Regular support groups in which persons can discuss their feelings are important to the ICU staff and the house staff. Such support groups protect staff members from the otherwise predictable psychiatric morbidity that some may experience and also protect their patients from the loss of concentration, decreased energy, and psychomotor-retarded communications that some staff members otherwise exhibit.

Hemodialysis Units. Hemodialysis units present a paradigm of complex modern medical treatment settings. Patients are coping with lifelong, debilitating, and limiting disease; they are totally dependent on a multiplex group of caretakers for access to a machine controlling their well-being. Dialysis is scheduled three times a week and takes 4 to 6 hours; thus, it disrupts patients' previous living routines.

In this context, patients first and foremost fight the disease. Invariably, however, they also must come to terms with a level of dependence on others probably not experienced since childhood. Predictably, patients entering dialysis struggle for their independence; regress to childhood states; show denial by acting out against doctor's orders (by breaking their diet or by missing sessions); show anger directed against staff members; bargain and plead; or become infantilized and obsequious; however, most often they are accepting and courageous.

The determinants of patients' responses to entering dialysis include personality styles and previous experiences with this or another chronic illness. Patients who have had time to react and adapt to their chronic renal failure face less new psychological work of adaptation than those with recent renal failure and machine dependence.

Although little has been written about social factors, the effects of culture in reaction to dialysis and the management of the dialysis unit are known to be important. Units are run with a firm hand, which is consistent in dealing with patients; clear contingencies are in place for behavioral failures; and adequate psychological support is available for staff members, which tend to produce the best results.

Complications of dialysis treatment can include psychiatric problems, such as depression, and suicide is not rare. Sexual problems can be neurogenic, psychogenic, or related to gonadal dysfunction and testicular atrophy. Dialysis dementia is a rare condition that evidences loss of memory, disorientation, dystonias, and seizures. The disorder occurs in patients who have been receiving dialysis treatment for many years. The cause is unknown.

The psychological treatment of dialysis patients falls into two areas. First, careful preparation before dialysis, including the work of adaptation to chronic illness, is important, especially in dealing with denial and unrealistic expectations. Predialysis, all patients should have a psychosocial evaluation. Second, once in a dialysis program, patients need periodic specific inquiries about adaptation that do not encourage dependence or the sick role. Staff members should be sensitive to the likelihood of depression and sexual problems. Group sessions function well for support, and patient self-help groups restore a useful social network, self-esteem, and self-mastery. When needed, tricyclic drugs or phenothiazines can be used for dialysis patients. Psychiatric care is most effective when brief and problem oriented.

The use of home dialysis units has improved attitudes toward treatment. Patients treated at home can integrate the treatment into their daily lives more easily, and they feel more autonomous and less dependent on others for their care than do those who are treated in the hospital.

Surgical Units. Some surgeons believe that patients who expect to die during surgery often will. This belief now seems less superstitious than it once did. Chase Patterson Kimball and others have studied the premonitory psychological adjustment of patients scheduled for surgery and have shown that those who show evident depression or anxiety and deny it have a higher risk for morbidity and mortality than those who, given similar depression or anxiety, can express it. Even better results occur in those with a positive attitude toward impending surgery. The factors that contribute to an improved outcome for surgery are informed consent and education so that patients know what they can expect to feel, where they will be (e.g., it is useful to show patients the recovery room), what loss of function to expect, what tubes and gadgets will be in place, and how to cope with the anticipated pain. If patients will not be able to talk or see after surgery, it is helpful to explain before surgery what they can do to compensate for these losses. If postoperative states such as confusion, delirium, and pain can be predicted, they should be discussed with patients in advance so they do not experience them as unwarranted or as signs of danger. Constructive family support members can help both before and after surgery.

Transplantation Issues. Transplantation programs have expanded over the past decade, and C-L psychiatrists play an important role in helping patients and their families deal with the many psychosocial issues involved: (1) which and when patients on a waiting list will receive organs, (2) anxiety about the procedure, (3) fear of death, (4) organ rejection, and (5) adaptation to life after successful transplantation. After transplant, patients require complex aftercare, and achieving compliance with medication may be difficult without supportive psychotherapy. This is particularly relevant to patients who have received liver transplants as a result of hepatitis C brought on by promiscuous sexual behavior and to drug addicts who use contaminated needles.

Group therapy with patients who have had similar transplantation procedures benefits members who can support one another and share information and feelings about particular stressors related to their disease. Groups may be conducted or supervised by the psychiatrist. Psychiatrists must be especially concerned about psychiatric complication. Within 1 year of transplant, almost 20 percent of patients experience a major depression or an adjustment disorder with depressed mood. In such cases, evaluation for suicidal ideation and risk is important. In addition to depression, another 10 percent of patients experience signs of posttraumatic stress disorder, with nightmares and anxiety attacks related to the procedure. Other issues concern whether or not the transplanted organ came from a cadaver or from a living donor who may or may not be related to the patient. Pretransplant consulting sessions with potential organ donors help them to deal with fears about surgery and concerns about who will receive their donated organ. Sometimes, both the recipient and donor may be counseled together, as in cases where one sibling is donating a kidney to another. Peer support groups with both donors and recipients have also been used to facilitate coping with transplantation issues.

PSYCHO-ONCOLOGY

Psycho-oncology seeks to study both the impact of cancer on psychological functioning and the role that psychological and behavioral variables may play in cancer risk and survival. A hallmark of psycho-oncology research has been intervention studies that attempt to influence the course of illness in patients with cancer. A landmark study by David Spiegel found that women with metastatic breast cancer who received weekly group psychotherapy survived an average of 18 months longer than control patients randomly assigned to routine care. In another study, patients with malignant melanoma who received structured group intervention exhibited a statistically significant lower recurrence of cancer and a lower mortality rate than patients who did not receive such therapy. Patients with malignant melanoma who received the group intervention also exhibited significantly more large granular lymphocytes and natural killer (NK) cells as well as indications of increased NK cell activity, suggesting an increased immune response. Another study used a group behavioral intervention (relaxation, guided imagery, and biofeedback training) for patients with breast cancer, who demonstrated higher NK cell activity and lymphocyte mitogen responses than the controls.

Because new treatment protocols, in many cases, have transformed cancer from an incurable to frequently chronic and often curable disease, the psychiatric aspects of cancer—the reactions to both the diagnosis and the treatment—are increasingly important. At least half of the persons who contract cancer in the United States each year are alive 5 years later. Currently, an estimated 3 million cancer survivors have no evidence of the disease.

About half of all cancer patients have mental disorders. The largest groups are those with adjustment disorder (68 percent), and major depressive disorder (13 percent) and delirium (8 percent) are the next most common diagnoses. Most of these disorders are thought to be reactive to the knowledge of having cancer.

When persons learn that they have cancer, their psychological reactions include fear of death, disfigurement, and disability; fear of abandonment and loss of independence; fear of disruption in relationships, role functioning, and financial standings; and denial, anxiety, anger, and guilt. Although suicidal thoughts and wishes are frequent in persons with cancer, the actual incidence of suicide is only slightly higher than that in the general population.

Psychiatrists should make a careful assessment of psychiatric and medical issues in every patient. Special attention should be given to family factors, in particular, preexisting intrafamily conflicts, family abandonment, and family exhaustion.

Chronic Fatigue Syndrome and Fibromyalgia

CHRONIC FATIGUE SYNDROME

Chronic fatigue syndrome (CFS) (referred to as *myalgic encephalomyelitis* in the United Kingdom and Canada) is characterized by 6 months or more of severe, debilitating fatigue, often accompanied by myalgia, headaches, pharyngitis, low-grade fever, cognitive complaints, gastrointestinal symptoms, and tender lymph nodes. The search continues for an infectious cause of chronic fatigue because of the high percentage of patients who report abrupt onset after severe flu-like illness.

The syndrome of chronic, debilitating fatigue has been an important clinical syndrome for psychiatry and neurology since the post-Civil War era in the 19th century. At the time the condition was known as neurasthenia or neurocirculatory asthenia. The disorder decreased in frequency during the mid-20th century but reappeared in the United States in the mid-1980s. In 1988, the US Centers for Disease Control and Prevention (CDC) defined specific diagnostic criteria for CFS. The disorder is classified in the tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) as an ill-defined condition of unknown etiology under the heading "Malaise and Fatigue" and is subdivided into asthenia and unspecified disability.

Epidemiology

The exact incidence and prevalence of CFS are unknown, but the incidence ranges from 0.007 percent to 2.8 percent in the general adult population. The illness is observed primarily in young adults (ages 20 to 40). CFS also occurs in children and adolescents but at a lower rate. Women are at least twice as likely as men to be affected.

In the United States, studies show that about 25 percent of the general adult population experience fatigue lasting 2 weeks or longer. When the fatigue persists beyond 6 months, it is defined as chronic fatigue. The symptoms of chronic fatigue often coexist with other illnesses, such as fibromyalgia, irritable bowel syndrome, and temporomandibular joint disorder.

Etiology

The cause of the disorder is unknown. The diagnosis can be made only after all other medical and psychiatric causes of chronic fatiguing illness have been excluded. Scientific studies have validated no pathognomonic signs or diagnostic tests for this condition.

Investigators have tried to implicate the Epstein-Barr virus (EBV) as the etiological agent in CFS. EBV infection, however, is associated with specific antibodies and atypical lymphocytosis, which are absent in CFS. Results of tests for other viral agents, such as enteroviruses, herpesvirus, and retroviruses, have been negative. Some investigators have found nonspecific markers of immune abnormalities in patients with CFS; for example, reduced proliferation responses of peripheral blood lymphocytes, but these responses are similar to those detected in some patients with major depression.

Several reports have shown a disruption in the hypothalamic-pituitary-axis (HPA) in patients with CFS, with mild hypocortisolism. Because of this, exogenous cortisol has been used to reduce fatigue but with equivocal results. Cytokines such as interferon (IFN)- α and interleukin (IL)-6 are under investigation as possible etiologic factors. Elevated levels have been found in the brains of some patients with CFS.

Some magnetic resonance imaging (MRI) studies have found a decrease in volumetric regional gray and white matter in patients with CFS.

CFS may be familial. In one study, the correlation within twin pairs for monozygotic twins was more than 2.5 times greater than the correlation for dizygotic twins. Further studies are needed, however.

Diagnosis and Clinical Features

Because CFS has no pathognomonic features, diagnosis is difficult. Physicians should attempt to delineate as many signs and symptoms as possible to facilitate the process. Although chronic fatigue is the most common complaint, most patients have many other symptoms ([Table 14-1](#)). As a patient's history unfolds, clinicians are likely to think of a variety of disease states that fall within the range of neurological, metabolic, or psychiatric disorders to account for the patient's distress. In most cases, however, no picture of any disorder clearly emerges from history taking alone.

Table 14-1
Signs and Symptoms Reported by Patients with Chronic Fatigue Syndrome

Fatigue or exhaustion	Double vision
Headache	Sensitivity to bright lights
Malaise	Numbness and/or tingling in extremities
Short-term memory loss	Fainting spells
Muscle pain	Light-headedness
Difficulty concentrating	Dizziness
Joint pain	Clumsiness
Depression	Insomnia
Abdominal pain	Fever or sensation of fever
Lymph node pain	Chills
Sore throat	Night sweats
Lack of restful sleep	Weight gain
Muscle weakness	Allergies
Bitter or metallic taste	Chemical sensitivities
Balance disturbance	Palpitations
Diarrhea	Shortness of breath
Constipation	Flushing rash of the face and cheeks
Bloating	Swelling of the extremities or eyelids
Panic attacks	Burning on urination
Eye pain	Sexual dysfunction
Scratchiness in eyes	Hair loss
Blurring of vision	

The physical examination is also an unreliable source of diagnostic certainty. In addition to chronic fatigue, for example, patients may complain of feeling warm or having chills with normal body temperature, and others may complain of lymph node tenderness in the absence of node enlargement. These and other equivocal findings neither confirm nor rule out the disorder.

The CDC diagnostic criteria for CFS, which are listed in [Table 14-2](#), include fatigue for at least 6 months, impaired memory or concentration, sore throat, tender or enlarged lymph nodes, muscle pain, arthralgias, headache, sleep disturbance, and postexertional malaise. Fatigue, the most obvious symptom, is characterized by severe mental and physical exhaustion, sufficient to cause a 50 percent reduction in patients' activities. The onset is usually gradual, but some patients have an acute onset that resembles a flu-like illness.

 **Table 14-2**
Centers for Disease Control and Prevention Criteria for Chronic Fatigue Syndrome

- A. Severe unexplained fatigue for over 6 months that is:
 - (1) Of a new or definite onset
 - (2) Not due to continuing exertion
 - (3) Not resolved by rest
 - (4) Functionally impairing
- B. The presence of four or more of the following new symptoms:
 - (1) Impaired memory or concentration
 - (2) Sore throat
 - (3) Tender lymph nodes
 - (4) Muscle pain
 - (5) Pain in several joints
 - (6) New pattern of headaches
 - (7) Unrefreshing sleep
 - (8) Postexertional malaise lasting more than 24 hours

In some cases, a noticeable correlation exists between CFS and neurally mediated hypotension, an autonomic nervous system dysfunction. It has been suggested that patients presenting with CFS symptoms undergo a tilt-table test to delineate symptoms attributable to hypotension so that they may be placed on appropriate pharmacotherapy.

A 55-year-old woman is referred to a neuromuscular disease specialist by her primary care physician for assessment and treatment of chronic fatigue. The symptoms have lasted for about 2 years and have worsened. Her primary complaint is a debilitating fatigue, which she calls "weakness." She also has painful sensations and aching in her muscles and joints, which is exacerbating whenever she "pushes" herself to be more active. Thorough internal medicine and rheumatological evaluations have yielded no definite findings except a persistently low-grade elevation of the sedimentation rate, at about 35 mm. She is taking prednisone, 20 mg per day, and she wishes to continue this medication, but her rheumatologist recommends against it. This caused conflict with her physician, and he refused to see her any longer or to prescribe the prednisone. Her primary care physician wanted to refer her to a psychiatrist, but she refused.

The patient had a refined manner, dressed tastefully, and spoke articulately. She was mildly obese and moved slowly, even laboriously, as she entered the consultation room. She opened the interview and controlled the early stages of the interaction by explaining that she needs to have the prednisone, or she will just "die." Before she began the daily prednisone dosing about a year previously, she explained, she was almost immobile; sitting at home in a large chair, requiring constant care from her husband, who was a prominent attorney in town. "It almost ruined his practice," she explained. "He couldn't work. He had to come home to look after me several times each day."

As she spoke during the opening stages of the interview, the theme developed into that of psychosomatics.

"Don't say this is all in my head," she said forcefully. "Because it is not," she says. "It is true that I had some...difficulties when I was young," she continued. "But that has nothing to do with what is happening now." She paused and looked squarely at the consultant. "Look at me!" she said. "Do I look depressed to you? Do I look anxious? Do I look like a psychiatry patient?" The consultant had to admit that she did not show clear and present psychiatric signs and symptoms.

Judging by the patient's clinical history, it was clear that the patient has been relatively healthy, except for the neuropsychiatric symptoms of fatigue. In addition to the prednisone, she took a selective serotonin reuptake inhibitor (SSRI) medication at a modest dose

and a sleep medication each night. She also took an angiotensin-converting enzyme (ACE) inhibitor for hypertension.

The patient showed no overt red flags to suggest unusual stressors or markers for psychopathology. Although she did not have a career outside the home, she was usually active in the community as a volunteer or a member of various boards. Her marriage to the attorney was her second marriage and they had been married 20 years.

Her fatigue symptoms developed insidiously over the past 2 to 3 years and became so profound that she ceased all community activities and sat at home. Even with the prednisone, which the patient stated had “done miracles,” the patient had not returned to her premorbid functioning level in terms of leaving her house to continue her work as a volunteer or community board member. (Adapted from Randolph B. Schiffer, M.D., and James W. Albers, M.D., Ph.D.)

Differential Diagnosis

Chronic fatigue must be differentiated from endocrine disorders (e.g., hypothyroidism), neurological disorders (e.g., multiple sclerosis [MS]), infectious disorders (e.g., acquired immune deficiency syndrome [AIDS], infectious mononucleosis), and psychiatric disorders (e.g., depressive disorders). The evaluation process is complex, and a diagnostic scheme is listed in [Table 14-3](#).

 **Table 14-3**
Approach to the Assessment of Persistent Fatigue

History

- ▶ Record the medical and psychosocial circumstances at onset of symptoms.
- ▶ Assess previous physical and psychological health.
- ▶ Seek clues to underlying medical disorder (e.g., fevers, weight loss, dyspnea).
- ▶ Assess the impact of the symptoms on the patient's lifestyle.

Characteristic symptoms of chronic fatigue syndrome (CFS) include fatigue, myalgia, arthralgia, impaired memory and concentration, and unrefreshing sleep.

Physical Examination

- ▶ Seek abnormalities to suggest an underlying medical disorder:
 - ▶ Hypothyroidism
 - ▶ Chronic hepatitis
 - ▶ Chronic anemia
 - ▶ Neuromuscular disease
 - ▶ Sleep apnea syndrome
 - ▶ Occult malignancy, etc.

The physical examination in patients with CFS characteristically shows no abnormalities.

Mental State Examination

- ▶ Past or family history of psychiatric disorder, notably depression, anxiety
 - ▶ Past history of frequent episodes of medically unexplained symptoms
 - ▶ Past history of alcohol or substance abuse
 - ▶ Current symptoms: depression, anxiety, self-destructive thoughts, and use of over-the-counter medications
 - ▶ Current signs of psychomotor retardation
 - ▶ Evaluate psychosocial support system
- CFS patients have depressive symptoms, but not guilt, suicidal ideation, or observable psychomotor slowing.*

Laboratory Investigation

- ▶ Screening tests:
 - ▶ Urinalysis
 - ▶ Blood count and differential
 - ▶ Erythrocyte sedimentation rate
 - ▶ Renal function tests
 - ▶ Additional investigations as clinically indicated (e.g., sleep study)

The diagnosis of CFS is primarily one of exclusion of alternative conditions.

- ▶ Liver function tests
- ▶ Calcium, phosphate
- ▶ Random blood glucose
- ▶ Thyroid function tests (including thyroid stimulating hormone level)

Chronic Fatigue Syndrome

- ▶ *Unexplained, persistent, or relapsing chronic fatigue lasting 6 or more consecutive months that is of new or definite onset; is not the result of ongoing exertion; is not substantially relieved by rest; and results in substantial reduction in previous levels of occupational, educational, social, or personal activities; and*

Four more of the following symptoms occurring concurrently: (1) impairment of short-term memory or concentration; (2) sore throat; (3) tender cervical or axillary lymph nodes; (4) muscle pain, or multijoint pain; (5) headaches; (6) unrefreshing sleep; and (7) postexertional malaise.

(From Hickie JB, Lloyd AR, Wakefield D. Chronic fatigue syndrome: Current perspectives on evaluation and management. *Med J Aust.* 1995;163:315, with permission.)

Up to 80 percent of patients with CFS meet the diagnostic criteria for major depression. The correlation is so high that many psychiatrists believe that all cases of this syndrome are depressive disorders, yet patients with CFS rarely report feelings of guilt, suicidal ideation, or anhedonia and show little or no weight loss. Also, usually, no family history of depression or other genetic loading for psychiatric disorder is found and few, if any, stressful events have occurred in patients' lives that might precipitate or account for a depressive illness. In addition, although some patients respond to antidepressant medication, many eventually become refractory to all psychopharmacological agents. Regardless of diagnostic labeling, however, depressive comorbidity requires treatment with either antidepressants, cognitive-behavioral therapy, or a combination of both.

Course and Prognosis

Spontaneous recovery is rare in patients with CFS, but improvement does occur. At present, most reports on the course and prognosis are based on small samples. In one study, 63 percent of patients with the syndrome, followed for up to 4 years, reported improvement. Patients with the best prognosis have had no previous or concurrent psychiatric illness, are able to maintain social contacts, and continue to work, even at reduced levels.

Treatment

Treatment of CFS is mainly supportive. Physicians must first establish rapport and not dismiss patients' complaints as being without foundation. The complaints are not imaginary. A careful medical examination is necessary, and a psychiatric evaluation is indicated, both of which are geared to rule out other causes for the symptoms.

No effective medical treatment is known. Antiviral agents and corticosteroids are not useful, although a few patients have shown a

lessening of fatigue with the antiviral drug amantadine (Symmetrel). Symptomatic treatment (e.g., analgesics for arthralgias and muscular pain) is the usual approach, but nonsteroidal anti-inflammatory drugs (NSAIDs) are not effective. Patients must be encouraged to continue their daily activities and to resist their fatigue as much as possible. A reduced workload is far better than absence from work. Several studies have reported a positive effect from graded exercise therapy (GET).

Psychiatric treatment is desirable, especially when depression is present. In many cases, symptoms improve markedly when patients are in psychotherapy. Cognitive-behavioral therapy is especially useful. Therapy is geared toward helping patients overcome and correct mistaken beliefs, such as fear that any activity causing fatigue worsens the disorder. Pharmacological agents, especially antidepressants with nonsedating qualities, such as bupropion (Wellbutrin), may be helpful. Nefazodone (Serzone) was reported to decrease pain and improve sleep and memory in some patients. Analeptics (e.g., amphetamine or methylphenidate [Ritalin]) may help reduce fatigue. Table 14-4 contains recommendations for a general approach to pharmacotherapy.

 **Table 14-4**
Recommendations for a Logical Pharmacotherapy of Chronic Fatigue

- ▶ Establish a collaborative patient–physician treatment framework.
- ▶ Avoid premature diagnostic closure.
- ▶ Determine what self-administered, over-the-counter medications the patient is already taking and assess closely for interaction with the proposed medication.
- ▶ Discuss the role of medication and identify clear treatment goals:
 - Psychiatric syndromes
 - Domains of symptomatic distress (e.g., musculoskeletal pain, poor sleep quality, fatigue, subjective cognitive changes, and mood or anxiety symptoms)
- ▶ Choice of agent should be based on:
 - The predicted side-effect profile
 - The patient's preference
 - Medical contraindications to the use of a particular medication
- ▶ Begin therapy at the lowest possible dose, and increase the dose gradually; observe and discuss side effects during treatment, clarifying issues of significant medical concern.
- ▶ Attempt thorough trial to known optimal target dose of drug or until maximum clinical effect is evident.
- ▶ Ongoing discussion of the patient's specific response pattern should occur, clarifying the patient's expectations about the treatment.
- ▶ Do not continue treatment indefinitely without evidence of clear clinical response; if necessary, discontinue treatment and reassess during medication-free state.
- ▶ Avoid polypharmacy; assess treatment response to one agent at a time.
- ▶ Frame pharmacotherapy with respect to other aspects of the treatment plan; use medication as setting a context for a multidimensional treatment framework.

(From Demitrack MA. Psychopharmacological principles in the treatment of chronic fatigue syndrome. In: Demitrack MA, Abbey SE, eds. *Chronic Fatigue Syndrome*. New York: Guilford; 1996:281, with permission.)

Self-help groups have helped patients with CFS. They derive benefit from the group dynamic of instilling hope, offering identification, sharing experiences, and imparting information. The cohesion of members in such groups also raises self-esteem, which is usually impaired in these patients, who often feel that their physicians are not taking them seriously. For this reason, many persons with the syndrome rely on vitamins, minerals, and miscellaneous herbal products or treatment methods that fall under the rubric of alternative medicine. Neither these nor other unidentified general tonics have been peer reviewed in the medical literature, and they are of little or no benefit.

FIBROMYALGIA

Fibromyalgia is characterized by pain and stiffness of the soft tissues, such as muscles, ligaments, and tendons. Local areas of tenderness are referred to as “trigger points.” The cervical and thoracic areas are affected most often, but the pain may be located in the arms, shoulders, low back, or legs.

Comorbidity

There is a significant overlap and comorbidity between patients with fibromyalgia and other psychiatric disorders, such as depression, panic and anxiety, and posttraumatic stress disorder (PTSD). Fibromyalgia is often present in CFS and depressive disorders. The onset of the psychiatric comorbidity most often occurs over a year before the onset of fibromyalgia.

There is also significant comorbidity between patients with fibromyalgia and rheumatologic disorders, such as rheumatoid arthritis, systemic lupus, and others. The symptomatology of fibromyalgia does not correlate well with disease activity of associated medical diseases, however, when such diseases are present.

Epidemiology

Fibromyalgia most commonly affects women (3 percent) more than men (1 percent), particularly those of working age. In fact, the diagnosis of fibromyalgia is associated with work disability at rates approaching 50 percent in primary care settings. There are about 5 million Americans age 18 or older with the disorder.

Etiology

The etiology of fibromyalgia remains unclear. However, it is often precipitated by stress that causes localized arterial spasms that interfere with perfusion of oxygen in the affected areas.

Diagnosis and Clinical Features

The diagnosis of fibromyalgia is made after excluding rheumatic disease or hypothyroidism. According to the 2010 American College of Rheumatology criteria, patients must have widespread pain for at least 3 months at predefined tender points upon palpation. The symptoms of fibromyalgia are almost always broader than pain alone and include complaints of fatigue, muscular weakness, sleep disturbance, and impairment of certain cognitive domains such as concentration (Table 14-5).

Table 14-5
American College of Rheumatology Fibromyalgia Diagnostic Criteria

A patient satisfies diagnostic criteria for fibromyalgia if the following 3 conditions are met:

1. Widespread pain index (WPI) ≥ 7 and symptom severity (SS) scale score ≥ 5 or WPI 3–6 and SS scale score ≥ 9 .
2. Symptoms have been present at a similar level for at least 3 months.
3. The patient does not have a disorder that would otherwise explain the pain.

Ascertainment

1. WPI: note the number areas in which the patient has had pain over the last week. In how many areas has the patient had pain?
Score will be between 0 and 19.

Shoulder girdle, left	Hip (buttock, trochanter), left	Jaw, left	Upper back
Shoulder girdle, right	Hip (buttock, trochanter), right	Jaw, right	Lower back
Upper arm, left	Upper leg, left	Chest	Neck
Upper arm, right	Upper leg, right	Abdomen	
Lower arm, left	Lower leg, left		
Lower arm, right	Lower leg, right		

2. SS scale score:

Fatigue

Waking unrefreshed

Cognitive symptoms

For each of the 3 symptoms above, indicate the level of severity over the past week using the following scale:

0 = no problem

1 = few symptoms

2 = moderate, considerable problems, often present and/or at a moderate level

3 = severe: pervasive, continuous, life-disturbing problems

Considering somatic symptoms in general, indicate whether the patient has*:

0 = no symptoms

1 = few symptoms

2 = a moderate number of symptoms

3 = a great deal of symptoms

The SS scale score is the sum of the severity of the 3 symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12.

*Somatic symptoms that might be considered: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in the ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

(From Wolfe F, Clauw DJ, Fitzcharles MA, Goldenberg DL, Katz RS, Mease P, Russell AS, Russell IJ, Winfield JB, Yunus MB. The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity. *Arthritis Care Res.* 2010;62(5):607, with permission.)

Treatment

Varieties of psychotropic drugs are commonly prescribed for fibromyalgia, especially antidepressants. Pregabalin (Lyrica), an antiepileptic agent, has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of pain associated with fibromyalgia. A typical dosing for pregabalin is 150 mg three times a day. A wide spectrum of other analgesics, including aspirin and acetaminophen, is prescribed for such patients. Some patients may respond to NSAIDs. Patients with more severe cases may respond to injections of an anesthetic (e.g., procaine) into the affected area; steroid injections are usually not warranted. The SSRI and serotonin-norepinephrine reuptake inhibitor (SNRI) antidepressant duloxetine (Cymbalta) has been reported to be effective in treating patients with this disorder. Experience suggests, however, that benefits from such therapies are neither long lasting nor associated with return to employment.

Nonpharmacologic treatment plans have generally included GET regimens and rehabilitation programs, with modest symptomatic benefits. Massage of trigger points may also be of use. Psychotherapy is of help to enable patients to gain insight into the nature of the disorder and also to help them identify and deal with psychosocial stressors.

15.1 Anorexia Nervosa

The term *anorexia nervosa* is derived from the Greek term for “loss of appetite” and a Latin word implying nervous origin. Anorexia nervosa is a syndrome characterized by three essential criteria. The first is a self-induced starvation to a significant degree—a *behavior*. The second is a relentless drive for thinness or a morbid fear of fatness—a *psychopathology*. The third criterion is the presence of medical signs and symptoms resulting from starvation—a *physiological symptomatology*. Anorexia nervosa is often, but not always, associated with disturbances of body image, the perception that one is distressingly large despite obvious medical starvation. The distortion of body image is disturbing when present, but not pathognomic, invariable, or required for diagnosis. Two subtypes of anorexia nervosa exist: restricting and binge/purge. The theme in all anorexia nervosa subtypes is the highly disproportionate emphasis placed on thinness as a vital source, sometimes the only source, of self-esteem, with weight, and to a lesser degree, shape, becoming the overriding and consuming daylong preoccupation of thoughts, mood, and behaviors.

Approximately half of anorexic persons will lose weight by drastically reducing their total food intake. The other half of these patients will not only diet but will also regularly engage in binge eating followed by purging behaviors. Some patients routinely purge after eating small amounts of food. Anorexia nervosa is much more prevalent in females than in males and usually has its onset in adolescence. Hypotheses of an underlying psychological disturbance in young women with the disorder include conflicts surrounding the transition from girlhood to womanhood. Psychological issues related to feelings of helplessness and difficulty establishing autonomy have also been suggested as contributing to the development of the disorder. Bulimic symptoms can occur as a separate disorder (bulimia nervosa, which is discussed in Section 15.2) or as part of anorexia nervosa. Persons with either disorder are excessively preoccupied with weight, food, and body shape. The outcome of anorexia nervosa varies from spontaneous recovery to a waxing and waning course to death.

EPIDEMIOLOGY

Anorexia nervosa has been reported more frequently over the past several decades, with increasing reports of the disorder in prepubertal girls and in boys. The most common ages of onset of anorexia nervosa are the midteens, but up to 5 percent of anorectic patients have the onset of the disorder in their early 20s. The most common age of onset is between 14 and 18 years. Anorexia nervosa is estimated to occur in about 0.5 to 1 percent of adolescent girls. It occurs 10 to 20 times more often in females than in males. The prevalence of young women with some symptoms of anorexia nervosa who do not meet the diagnostic criteria is estimated to be close to 5 percent. Although the disorder was initially reported most often among the upper classes, recent epidemiological surveys do not show that distribution. It seems to be most frequent in developed countries, and it may be seen with greatest frequency among young women in professions that require thinness, such as modeling and ballet.

COMORBIDITY

Table 15.1-1 lists comorbid psychiatric conditions associated with anorexia nervosa. Overall, anorexia nervosa is associated with depression in 65 percent of cases, social phobia in 35 percent of cases, and obsessive-compulsive disorder in 25 percent of cases.

Table 15.1-1
Comorbid Psychiatric Conditions Associated with Anorexia Nervosa

Diagnosis	Restricting-Type Anorexia Nervosa (%)	Binge Eating and Purging Type Anorexia Nervosa (%)
Any affective disorder	57	100
Intermittent depressive disorder	29	44
Major depression	57	66
Minor depression	0	11
Mania/hypomania	0	33
Any anxiety disorder	57	67
Phobic disorder	43	11
Panic disorder	29	22
Generalized anxiety disorder	14	11
Obsessive-compulsive disorder	14	56
Any substance abuse/dependence	14	33
Drug	14	22
Alcohol	0	33
Schizophrenia	0	0
Any codiagnoses	71	100
3 or more codiagnoses	71	100
Female	100	89
Single	71	89
Age ($x \pm SD$)	23.6 \pm 10.8	25.0 \pm 6.4
No. of codiagnoses ($x \pm SD$)	2.3 \pm 2.5	3.8 \pm 1.4

SD, standard deviation.

ETIOLOGY

Biological, social, and psychological factors are implicated in the causes of anorexia nervosa. Some evidence points to higher concordance rates in monozygotic twins than in dizygotic twins. Sisters of patients with anorexia nervosa are likely to be afflicted, but this association may reflect social influences more than genetic factors. Major mood disorders are more common in family members than in the general population. Neurochemically, diminished norepinephrine turnover and activity are suggested by reduced 3-methoxy-4-hydroxyphenylglycol (MHPG) levels in the urine and the cerebrospinal fluid (CSF) of some patients with anorexia nervosa. An inverse relation is seen between MHPG and depression in these patients; an increase in MHPG is associated with a decrease in depression.

Biological Factors

Endogenous opioids may contribute to the denial of hunger in patients with anorexia nervosa. Preliminary studies show dramatic weight gains in some patients who are given opiate antagonists. Starvation results in many biochemical changes, some of which are also present in depression, such as hypercortisolemia and nonsuppression by dexamethasone. Thyroid function is suppressed as well. These abnormalities are corrected by realimentation. Starvation may produce amenorrhea, which reflects lowered hormonal levels (luteinizing, follicle-stimulating, and gonadotropin-releasing hormones). Some patients with anorexia nervosa, however, may become amenorrheic before significant weight loss. Several computed tomographic (CT) studies reveal enlarged CSF spaces (enlarged sulci and ventricles) in anorectic patients during starvation, a finding that is reversed by weight gain. In one positron emission tomographic (PET) scan study, caudate nucleus metabolism was higher in the anorectic state than after realimentation.

Some authors have proposed a hypothalamic-pituitary axis (neuroendocrine) dysfunction. Some studies have shown evidence for dysfunction in serotonin, dopamine, and norepinephrine, three neurotransmitters involved in regulating eating behavior in the paraventricular nucleus of the hypothalamus. Other humoral factors that may be involved include corticotropin-releasing factor (CRF), neuropeptide Y, gonadotropin-releasing hormone, and thyroid-stimulating hormone. Table 15.1-2 lists the neuroendocrine changes associated with anorexia nervosa.

Table 15.1-2
Neuroendocrine Changes in Anorexia Nervosa and Experimental Starvation

Hormone	Anorexia Nervosa	Weight Loss
Corticotropin-releasing hormone (CRH)	Increased	Increased
Plasma cortisol levels	Mildly increased	Mildly increased
Diurnal cortisol difference	Blunted	Blunted
Luteinizing hormone (LH)	Decreased, prepubertal pattern	Decreased
Follicle-stimulating hormone (FSH)	Decreased, prepubertal pattern	Decreased
Growth hormone (GH)	Impaired regulation Increased basal levels and limited response to pharmacological probes	Same
Somatomedin C	Decreased	Decreased
Thyroxine (T ₄)	Normal or slightly decreased	Normal or slightly decreased
Triiodothyronine (T ₃)	Mildly decreased	Mildly decreased
Reverse T ₃	Mildly increased	Mildly increased
Thyrotropin-stimulating hormone (TSH)	Normal	Normal
TSH response to thyrotropin-releasing hormone (TRH)	Delayed or blunted	Delayed or blunted
Insulin	Delayed release	–
C-peptide	Decreased	–
Vasopressin	Secretion uncoupled from osmotic challenge	–
Serotonin	Increased function with weight restoration	–
Norepinephrine	Reduced turnover	Reduced turnover
Dopamine	Blunted response to pharmacological probes	–

Social Factors

Patients with anorexia nervosa find support for their practices in society's emphasis on thinness and exercise. No family constellations are specific to anorexia nervosa, but some evidence indicates that these patients have close, but troubled, relationships with their parents. Families of children who present with eating disorders, especially binge eating or purging subtypes, may exhibit high levels of hostility, chaos, and isolation and low levels of nurturance and empathy. An adolescent with a severe eating disorder may tend to draw attention away from strained marital relationships.

Vocational and avocational interests interact with other vulnerability factors to increase the probability of developing eating disorders. In young women, participation in strict ballet schools increases the probability of developing anorexia nervosa at least sevenfold. In high school boys, wrestling is associated with a prevalence of full or partial eating-disorder syndromes during wrestling season of approximately 17 percent, with a minority developing an eating disorder and not improving spontaneously at the end of training. Although these athletic activities probably select for perfectionistic and persevering youth in the first place, pressures regarding weight and shape generated in these social milieus reinforce the likelihood that these predisposing factors will be channeled toward eating disorders.

A gay orientation in men is a proved predisposing factor, not because of sexual orientation or sexual behavior per se, but because norms for slimness, albeit muscular slimness, are very strong in the gay community, only slightly lower than for heterosexual women. In contrast, a lesbian orientation may be slightly protective, because lesbian communities may be more tolerant of higher weights and a more normative natural distribution of body shapes than their heterosexual female counterparts.

Psychological and Psychodynamic Factors

Anorexia nervosa appears to be a reaction to the demand that adolescents behave more independently and increase their social and sexual functioning. Patients with the disorder substitute their preoccupations, which are similar to obsessions, with eating and weight gain for other, normal adolescent pursuits. These patients typically lack a sense of autonomy and selfhood. Many experience their bodies as somehow under the control of their parents, so that self-starvation may be an effort to gain validation as a unique and special person. Only through acts of extraordinary self-discipline can an anorectic patient develop a sense of autonomy and selfhood.

Psychoanalytic clinicians who treat patients with anorexia nervosa generally agree that these young patients have been unable to separate psychologically from their mothers. The body may be perceived as though it were inhabited by the introject of an intrusive and unempathic mother. Starvation may unconsciously mean arresting the growth of this intrusive internal object and thereby destroying it. Often, a projective identification process is involved in the interactions between the patient and the patient's family. Many anorectic patients feel that oral desires are greedy and unacceptable; therefore, these desires are projectively disavowed. Other theories have focused on fantasies of oral impregnation. Parents respond to the refusal to eat by becoming frantic about whether the patient is actually eating. The patient can then view the parents as the ones who have unacceptable desires and can projectively disavow them; that is, others may be voracious and ruled by desire but not the patient.

DIAGNOSIS AND CLINICAL FEATURES

The onset of anorexia nervosa usually occurs between the ages of 10 and 30 years. It is present when (1) an individual voluntarily reduces and maintains an unhealthy degree of weight loss or fails to gain weight proportional to growth; (2) an individual experiences an intense fear of becoming fat, has a relentless drive for thinness despite obvious medical starvation, or both; (3) an individual experiences significant starvation-related medical symptomatology, often, but not exclusively, abnormal reproductive hormone functioning, but also hypothermia, bradycardia, orthostasis, and severely reduced body fat stores; and (4) the behaviors and psychopathology are present for at least 3 months. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) diagnostic criteria for anorexia nervosa are given in Table 15.1-3.

 **Table 15.1-3**
DSM-5 Diagnostic Criteria for Anorexia Nervosa

- A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children or adolescents, less than that minimally expected.
- B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Coding note: The ICD-9-CM code for anorexia nervosa is 307.1, which is assigned regardless of the subtype. The ICD-10-CM code depends on the subtype (see below).

Specify whether:

(F50.01) Restricting type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.

(F50.02) Binge-eating/ purging type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Specify if:

In partial remission: After full criteria for anorexia nervosa were previously met, Criterion A (low body weight) has not been met for a sustained period, but either Criterion B (intense fear of gaining weight or becoming fat or behavior that interferes with weight gain) or Criterion C (disturbances in self-perception of weight and shape) is still met.

In full remission: After full criteria for anorexia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based, for adults, on current body mass index (BMI) (see below) or, for children and adolescents, on BMI percentile. The ranges below are derived from World Health Organization categories for thinness in adults; for children and adolescents, corresponding BMI percentiles should be used. The level of severity may be increased to reflect clinical symptoms, the degree of functional disability, and the need for supervision.

Mild: BMI ≥ 17 kg/m²

Moderate: BMI 16–16.99 kg/m²

Severe: BMI 15–15.99 kg/m²

Extreme: BMI < 15 kg/m²

An intense fear of gaining weight and becoming obese is present in all patients with the disorder and undoubtedly contributes to their lack of interest in, and even resistance to, therapy. Most aberrant behavior directed toward losing weight occurs in secret. Patients with anorexia nervosa usually refuse to eat with their families or in public places. They lose weight by drastically reducing their total food intake, with a disproportionate decrease in high-carbohydrate and fatty foods.

As mentioned, the term *anorexia* is a misnomer, because loss of appetite is usually rare until late in the disorder. Evidence that patients are constantly thinking about food is their passion for collecting recipes and for preparing elaborate meals for others. Some patients cannot continuously control their voluntary restriction of food intake and so have eating binges. These binges usually occur secretly and often at

night and are frequently followed by self-induced vomiting. Patients abuse laxatives and even diuretics to lose weight, and ritualistic exercising, extensive cycling, walking, jogging, and running are common activities.

Patients with the disorder exhibit peculiar behavior about food. They hide food all over the house and frequently carry large quantities of candies in their pockets and purses. While eating meals, they try to dispose of food in their napkins or hide it in their pockets. They cut their meat into very small pieces and spend a great deal of time rearranging the pieces on their plates. If the patients are confronted with their peculiar behavior, they often deny that their behavior is unusual or flatly refuse to discuss it.

Obsessive-compulsive behavior, depression, and anxiety are other psychiatric symptoms of anorexia nervosa most frequently noted clinically. Patients tend to be rigid and perfectionist, and somatic complaints, especially epigastric discomfort, are usual. Compulsive stealing, usually of candies and laxatives but occasionally of clothes and other items, may occur.

Poor sexual adjustment is frequently described in patients with the disorder. Many adolescent patients with anorexia nervosa have delayed psychosocial sexual development; in adults, a markedly decreased interest in sex often accompanies onset of the disorder. A minority of anorexic patients has a premorbid history of promiscuity, substance abuse, or both but during the disorder show a decreased interest in sex.

Patients usually come to medical attention when their weight loss becomes apparent. As the weight loss grows profound, physical signs such as hypothermia (as low as 35°C), dependent edema, bradycardia, hypotension, and lanugo (the appearance of neonatal-like hair) appear, and patients show a variety of metabolic changes (Fig. 15.1-1). Some female patients with anorexia nervosa come to medical attention because of amenorrhea, which often appears before their weight loss is noticeable. Some patients induce vomiting or abuse purgatives and diuretics; such behavior causes concern about hypokalemic alkalosis. Impaired water diuresis may be noted.

FIGURE 15.1-1
A patient with anorexia nervosa. (Courtesy of Katherine Halmi, M.D.)

Electrocardiographic (ECG) changes, such as T wave flattening or inversion, ST segment depression, and lengthening of the QT interval, have been noted in the emaciated stage of anorexia nervosa. ECG changes may also result from potassium loss, which can lead to death. Gastric dilation is a rare complication of anorexia nervosa. In some patients, aortography has shown a superior mesenteric artery syndrome. Other medical complications of eating disorders are listed in Table 15.1-4.

Table 15.1-4
Medical Complications of Eating Disorders

Disorder and System Affected	Consequence
Anorexia Nervosa	
Vital signs	Bradycardia, hypotension with marked orthostatic changes, hypothermia, poikilothermia
General	Muscle atrophy, loss of body fat
Central nervous system	Generalized brain atrophy with enlarged ventricles, decreased cortical mass, seizures, abnormal electroencephalogram
Cardiovascular	Peripheral (starvation) edema, decreased cardiac diameter, narrowed left ventricular wall, decreased response to exercise demand, superior mesenteric artery syndrome
Renal	Prerenal azotemia
Hematologic	Anemia of starvation, leukopenia, hypocellular bone marrow
Gastrointestinal	Delayed gastric emptying, gastric dilatation, decreased intestinal lipase and lactase
Metabolic	Hypercholesterolemia, nonsymptomatic hypoglycemia, elevated liver enzymes, decreased bone mineral density
Endocrine	Low luteinizing hormone, low follicle-stimulating hormone, low estrogen or testosterone, low/normal thyroxine, low triiodothyronine, increased reverse triiodothyronine, elevated cortisol, elevated growth hormone, partial diabetes insipidus, increased prolactin
Bulimia Nervosa and Binge Eating and Purging Type Anorexia Nervosa	
Metabolic	Hypokalemic alkalosis or acidosis, hyponatremia, dehydration
Renal	Prerenal azotemia, acute and chronic renal failure
Cardiovascular	Arrhythmias, myocardial toxicity from emetine (ipecac)
Dental	Lingual surface enamel loss, multiple caries
Gastrointestinal	Swollen parotid glands, elevated serum amylase levels, gastric distention, irritable bowel syndrome, melanosis coli from laxative abuse
Musculoskeletal	Cramps, tetany

SUBTYPES

Anorexia nervosa has been divided into two clinical subtypes: the food-restricting category and the purging category. In the food-restricting

category, present in approximately 50 percent of cases, food intake is highly restricted (usually with attempts to consume fewer than 300 to 500 calories per day and no fat grams), and the patient may be relentlessly and compulsively overactive, with overuse athletic injuries. In the purging subtype, patients alternate attempts at rigorous dieting with intermittent binge or purge episodes. Purging represents a secondary compensation for the unwanted calories, most often accomplished by self-induced vomiting, frequently by laxative abuse, less frequently by diuretics, and occasionally with emetics. Sometimes, repetitive purging occurs without prior binge eating, after ingesting only relatively few calories. Both types may be socially isolated and have depressive disorder symptoms and diminished sexual interest. Overexercising and perfectionistic traits are also common in both types.

A new diagnostic category in DSM-5 is binge eating disorder (see Section 15.3) characterized by episodic bouts of the intake of excessive amounts of food but without purging or similar compensatory behavior.

Those who practice binge eating and purging share many features with persons who have bulimia nervosa without anorexia nervosa. Those who binge eat and purge tend to have families in which some members are obese, and they themselves have histories of heavier body weights before the disorder than do persons with the restricting type. Binge eating–purging persons are likely to be associated with substance abuse, impulse control disorders, and personality disorders. Persons with restricting anorexia nervosa often have obsessive-compulsive traits with respect to food and other matters. Some persons with anorexia nervosa may purge but not binge.

Persons with anorexia nervosa have high rates of comorbid major depressive disorders; major depressive disorder or dysthymic disorder has been reported in up to 50 percent of patients with anorexia nervosa. The suicide rate is higher in persons with the binge eating–purging type of anorexia nervosa than in those with the restricting type.

Patients with anorexia nervosa are often secretive, deny their symptoms, and resist treatment. In almost all cases, relatives or intimate acquaintances must confirm a patient's history. The mental status examination usually shows a patient who is alert and knowledgeable on the subject of nutrition and who is preoccupied with food and weight.

A patient must have a thorough general physical and neurological examination. If the patient is vomiting, a hypokalemic alkalosis may be present. Because most patients are dehydrated, serum electrolyte levels must be determined initially and periodically. Hospitalization may be necessary to deal with medical complications.

A young woman who weighed 10 percent above the average weight but was otherwise healthy, functioning well, and working hard as a university student joined a track team, started training for hours a day, more than her teammates, began to perceive herself as fat and thought that her performance would be enhanced if she lost weight. She started to diet and reduced her weight to 87 percent of the “ideal weight” for her age according to standard tables. At her point of maximum weight loss, her performance actually declined, and she pushed herself even harder in her training regimen. She started to feel apathetic and morbidly afraid of becoming fat. Her food intake became restricted and she stopped eating anything containing fat. Her menstrual periods became skimpy and infrequent but did not cease. (Courtesy of Arnold E. Andersen, M.D., and Joel Yager, M.D.)

PATHOLOGY AND LABORATORY EXAMINATION

A complete blood count often reveals leukopenia with a relative lymphocytosis in emaciated patients with anorexia nervosa. If binge eating and purging are present, serum electrolyte determination reveals hypokalemic alkalosis. Fasting serum glucose concentrations are often low during the emaciated phase, and serum salivary amylase concentrations are often elevated if the patient is vomiting. The ECG may show ST segment and T-wave changes, which are usually secondary to electrolyte disturbances; emaciated patients have hypotension and bradycardia. Young girls may have a high serum cholesterol level. All these values revert to normal with nutritional rehabilitation and cessation of purging behaviors. Endocrine changes that may occur, such as amenorrhea, mild hypothyroidism, and hypersecretion of corticotrophin-releasing hormone, are caused by the underweight condition and revert to normal with weight gain.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anorexia nervosa is complicated by patients' denial of the symptoms, the secrecy surrounding their bizarre eating rituals, and their resistance to seeking treatment. Thus, it may be difficult to identify the mechanism of weight loss and the patient's associated ruminative thoughts about distortions of body image.

Clinicians must ascertain that a patient does not have a medical illness that can account for the weight loss (e.g., a brain tumor or cancer). Weight loss, peculiar eating behaviors, and vomiting can occur in several mental disorders. Depressive disorders and anorexia nervosa have several features in common, such as depressed feelings, crying spells, sleep disturbance, obsessive ruminations, and occasional suicidal thoughts. The two disorders, however, have several distinguishing features. Generally, a patient with a depressive disorder has decreased appetite, whereas a patient with anorexia nervosa claims to have normal appetite and to feel hungry; only in the severe stages of anorexia nervosa do patients actually have decreased appetite. In contrast to depressive agitation, the hyperactivity seen in anorexia nervosa is planned and ritualistic. The preoccupation with recipes, the caloric content of foods, and the preparation of gourmet feasts is typical of patients with anorexia nervosa but is absent in patients with a depressive disorder. In depressive disorders, patients have no intense fear of obesity or disturbance of body image.

Weight fluctuations, vomiting, and peculiar food handling may occur in somatization disorder. On rare occasions, a patient fulfills the diagnostic criteria for both somatization disorder and anorexia nervosa; in such a case, both diagnoses should be made. Generally, the weight loss in somatization disorder is not as severe as that in anorexia nervosa, nor does a patient with somatization disorder express a morbid fear of becoming overweight, as is common in those with anorexia nervosa. Amenorrhea for 3 months or longer is unusual in somatization disorder.

In patients with schizophrenia, delusions about food are seldom concerned with caloric content. More likely, they believe the food to be poisoned. Patients with schizophrenia are rarely preoccupied with a fear of becoming obese and do not have the hyperactivity that is seen in patients with anorexia nervosa. Patients with schizophrenia have bizarre eating habits but not the entire syndrome of anorexia nervosa.

Anorexia nervosa must be differentiated from bulimia nervosa, a disorder in which episodic binge eating, followed by depressive moods, self-deprecating thoughts, and self-induced vomiting occur while patients maintain their weight within a normal range. Patients with bulimia nervosa seldom lose 15 percent of their weight, but the two conditions frequently coexist.

Rare conditions of unknown etiology are seen in which hyperactivity of the vagus nerve causes changes in eating patterns that are associated with weight loss, sometimes of severe degree. In such cases bradycardia, hypotension, and other parasympathomimetic signs and symptoms are seen. Because the vagus nerve relates to the enteric nervous system, eating may be associated with gastric distress such as nausea or bloating. Patients do not generally lose their appetite. Treatment is symptomatic and anticholinergic drugs can reverse hypotension and bradycardia, which may be life-threatening.

COURSE AND PROGNOSIS

The course of anorexia nervosa varies greatly—spontaneous recovery without treatment, recovery after a variety of treatments, a fluctuating course of weight gains followed by relapses, and a gradually deteriorating course resulting in death caused by complications of starvation. One study reviewing subtypes of anorectic patients found that restricting-type anorectic patients seemed less likely to recover than those of

the binge eating-purging type. The short-term response of patients to almost all hospital treatment programs is good. Those who have regained sufficient weight, however, often continue their preoccupation with food and body weight, have poor social relationships, and exhibit depression. In general, the prognosis is not good. Studies have shown a range of mortality rates from 5 to 18 percent.

Indicators of a favorable outcome are admission of hunger, lessening of denial and immaturity, and improved self-esteem. Such factors as childhood neuroticism, parental conflict, bulimia nervosa, vomiting, laxative abuse, and various behavioral manifestations (e.g., obsessive-compulsive, hysterical, depressive, psychosomatic, neurotic, and denial symptoms) have been related to poor outcome in some studies, but not in others.

Ten-year outcome studies in the United States have shown that about one fourth of patients recover completely and another one half are markedly improved and functioning fairly well. The other one fourth includes an overall 7 percent mortality rate and those who are functioning poorly with a chronic underweight condition. Swedish and English studies over a 20- and 30-year period show a mortality rate of 18 percent. About half of patients with anorexia nervosa eventually will have the symptoms of bulimia, usually within the first year after the onset of anorexia nervosa.

TREATMENT

In view of the complicated psychological and medical implications of anorexia nervosa, a comprehensive treatment plan, including hospitalization when necessary and both individual and family therapy, is recommended. Behavioral, interpersonal, and cognitive approaches are used and, in many cases, medication may be indicated.

Hospitalization

The first consideration in the treatment of anorexia nervosa is to restore patients' nutritional state; dehydration, starvation, and electrolyte imbalances can seriously compromise health and, in some cases, lead to death. The decision to hospitalize a patient is based on the patient's medical condition and the amount of structure needed to ensure patient cooperation. In general, patients with anorexia nervosa who are 20 percent below the expected weight for their height are recommended for inpatient programs, and patients who are 30 percent below their expected weight require psychiatric hospitalization for 2 to 6 months.

Inpatient psychiatric programs for patients with anorexia nervosa generally use a combination of a behavioral management approach, individual psychotherapy, family education and therapy, and, in some cases, psychotropic medications. Successful treatment is promoted by the ability of staff members to maintain a firm yet supportive approach to patients, often through a combination of positive reinforcers (praise) and negative reinforcers (restriction of exercise). The program must have some flexibility for individualizing treatment to meet patients' needs and cognitive abilities. Patients must become willing participants for treatment to succeed in the long run.

Most patients are uninterested in psychiatric treatment and even resist it; they are brought to a doctor's office unwillingly by agonizing relatives or friends. The patients rarely accept the recommendation of hospitalization without arguing and criticizing the proposed program. Emphasizing the benefits, such as relief of insomnia and depressive signs and symptoms, may help persuade the patients to admit themselves willingly to the hospital. Relatives' support and confidence in the physicians and treatment team are essential when firm recommendations must be carried out. Patients' families should be warned that the patients will resist admission and, for the first several weeks of treatment, will make many dramatic pleas for their families' support to obtain release from the hospital program. Compulsory admission or commitment should be obtained only when the risk of death from the complications of malnutrition is likely. On rare occasions, patients prove that the doctor's statements about the probable failure of outpatient treatment are wrong. They may gain a specified amount of weight by the time of each outpatient visit, but such behavior is uncommon, and a period of inpatient care is usually necessary.

Hospital Management. The following considerations apply to the general management of patients with anorexia nervosa during a hospitalized treatment program. Patients should be weighed daily, early in the morning after emptying the bladder. The daily fluid intake and urine output should be recorded. If vomiting is occurring, hospital staff members must monitor serum electrolyte levels regularly and watch for the development of hypokalemia. Because food is often regurgitated after meals, the staff may be able to control vomiting by making the bathroom inaccessible for at least 2 hours after meals or by having an attendant in the bathroom to prevent the opportunity for vomiting. Constipation in these patients is relieved when they begin to eat normally. Stool softeners may occasionally be given, but never laxatives. If diarrhea occurs, it usually means that patients are surreptitiously taking laxatives. Because of the rare complication of stomach dilation and the possibility of circulatory overload when patients immediately start eating an enormous number of calories, the hospital staff should give patients about 500 calories over the amount required to maintain their present weight (usually 1,500 to 2,000 calories a day). It is wise to give these calories in six equal feedings throughout the day, so that patients need not eat a large amount of food at one sitting. Giving patients a liquid food supplement such as Sustagen may be advisable, because they may be less apprehensive about gaining weight slowly with the formula than by eating food. After patients are discharged from the hospital, clinicians usually find it necessary to continue outpatient supervision of the problems identified in the patients and their families.

Psychotherapy

Cognitive-Behavioral Therapy. Cognitive and behavioral therapy principles can be applied in both inpatient and outpatient settings and have been found effective for inducing weight gain. Monitoring is an essential component of cognitive-behavioral therapy. Patients are taught to monitor their food intake, their feelings and emotions, their bingeing and purging behaviors, and their problems in interpersonal relationships. Patients are taught cognitive restructuring to identify automatic thoughts and to challenge their core beliefs. Problem solving is a specific method whereby patients learn how to think through and devise strategies to cope with their food-related and interpersonal problems. Patients' vulnerability to rely on anorectic behavior as a means of coping can be addressed if they can learn to use these techniques effectively.

Dynamic Psychotherapy. Dynamic expressive-supportive psychotherapy is sometimes used in the treatment of patients with anorexia nervosa, but their resistance may make the process difficult and painstaking. Because patients view their symptoms as constituting the core of their specialness, therapists must avoid excessive investment in trying to change their eating behavior. The opening phase of the psychotherapy process must be geared toward building a therapeutic alliance. Patients may experience early interpretations as though someone else were telling them what they really feel and thereby minimizing and invalidating their own experiences. Therapists who empathize with patients' points of view and take an active interest in what their patients think and feel, however, convey to patients that their autonomy is respected. Above all, psychotherapists must be flexible, persistent, and durable in the face of patients' tendencies to defeat any efforts to help them.

Family Therapy. A family analysis should be done for all patients with anorexia nervosa who are living with their families, which is used as a basis for a clinical judgment on what type of family therapy or counseling is advisable. In some cases, family therapy is not possible; however, issues of family relationships can then be addressed in individual therapy. Sometimes, brief counseling sessions with immediate family members is the extent of family therapy required. In one controlled family therapy study in London, anorectic patients under the age of 18 benefited from family therapy, whereas patients over the age of 18 did worse in family therapy than with the control

therapy. No controlled studies have been reported on the combination of individual and family therapy; however, in actual practice, most clinicians provide individual therapy and some form of family counseling in managing patients with anorexia nervosa.

Pharmacotherapy

Pharmacological studies have not yet identified any medication that yields definitive improvement of the core symptoms of anorexia nervosa. Some reports support the use of cyproheptadine (Periactin), a drug with antihistaminic and antiserotonergic properties, for patients with the restricting type of anorexia nervosa. Amitriptyline (Elavil) has also been reported to have some benefit. Other medications that have been tried by patients with anorexia nervosa with variable results include clomipramine (Anafranil), pimozone (Orap), and chlorpromazine (Thorazine). Trials of fluoxetine (Prozac) have resulted in some reports of weight gain, and serotonergic agents may yield positive responses in some cases. In patients with anorexia nervosa and coexisting depressive disorders, the depressive condition should be treated. Concern exists about the use of tricyclic drugs in low-weight, depressed patients with anorexia nervosa, who may be vulnerable to hypotension, cardiac arrhythmia, and dehydration. Once an adequate nutritional status has been attained, the risk of serious adverse effects from the tricyclic drugs may decrease; in some patients, the depression improves with weight gain and normalized nutritional status.

15.2 Bulimia Nervosa

Bulimia nervosa is characterized by episodes of binge eating combined with inappropriate ways of stopping weight gain. Physical discomfort—for example, abdominal pain or nausea—terminates the binge eating, which is often followed by feelings of guilt, depression, or self-disgust. Unlike patients with anorexia nervosa, those with bulimia nervosa typically maintain a normal body weight.

The term *bulimia nervosa* derives from the terms for “ox-hunger” in Greek and “nervous involvement” in Latin. For some patients, bulimia nervosa may represent a failed attempt at anorexia nervosa, sharing the goal of becoming very thin, but occurring in an individual less able to sustain prolonged semistarvation or severe hunger as consistently as classic restricting anorexia nervosa patients. For others, eating binges represent “breakthrough eating” episodes of giving in to hunger pangs generated by efforts to restrict eating so as to maintain a socially desirable level of thinness. Still others use binge eating as a means to self-medicate during times of emotional distress. Regardless of the reason, eating binges provoke panic as individuals feel that their eating has been out of control. The unwanted binges lead to secondary attempts to avoid the feared weight gain by a variety of compensatory behaviors, such as purging or excessive exercise.

EPIDEMIOLOGY

Bulimia nervosa is more prevalent than anorexia nervosa. Estimates of bulimia nervosa range from 1 to 4 percent of young women. As with anorexia nervosa, bulimia nervosa is more common in women than in men, but its onset is often later in adolescence than that of anorexia nervosa. The onset may also occur in early adulthood. Approximately 20 percent of college women experience transient bulimic symptoms at some point during their college years. Although bulimia nervosa is often present in normal-weight young women, they sometimes have a history of obesity. In industrialized countries the prevalence is about 1 percent of the general population. In the United States, bulimia nervosa may be more prevalent among Hispanics and blacks than non-Hispanic whites.

ETIOLOGY

Biological Factors

Some investigators have attempted to associate cycles of bingeing and purging with various neurotransmitters. Because antidepressants often benefit patients with bulimia nervosa and because serotonin has been linked to satiety, serotonin and norepinephrine have been implicated. Because plasma endorphin levels are raised in some bulimia nervosa patients who vomit, the feeling of well-being after vomiting that some of these patients experience may be mediated by raised endorphin levels. Increased frequency of bulimia nervosa is found in first-degree relatives of persons with the disorder.

Recent research using functional magnetic resonance imaging (MRI) suggests that overeating in bulimia nervosa may result from an exaggerated perception of hunger signals related to sweet taste mediated by the right anterior insula area of the brain.

Social Factors

Patients with bulimia nervosa, as with those with anorexia nervosa, tend to be high achievers and to respond to societal pressures to be slender. As with anorexia nervosa patients, many patients with bulimia nervosa are depressed and have increased familial depression, but the families of patients with bulimia nervosa are generally less close and more conflictual than the families of those with anorexia nervosa. Patients with bulimia nervosa describe their parents as neglectful and rejecting.

Psychological Factors

Patients with bulimia nervosa, as with those with anorexia nervosa, have difficulties with adolescent demands, but patients with bulimia nervosa are more outgoing, angry, and impulsive than those with anorexia nervosa. Alcohol dependence, shoplifting, and emotional lability (including suicide attempts) are associated with bulimia nervosa. These patients generally experience their uncontrolled eating as more ego-dystonic than do patients with anorexia nervosa and so seek help more readily.

Patients with bulimia nervosa lack superego control and the ego strength of their counterparts with anorexia nervosa. Their difficulties in controlling their impulses are often manifested by substance dependence and self-destructive sexual relationships in addition to the binge eating and purging that characterize the disorder. Many patients with bulimia nervosa have histories of difficulties separating from caretakers, as manifested by the absence of transitional objects during their early childhood years. Some clinicians have observed that patients with bulimia nervosa use their own bodies as transitional objects. The struggle for separation from a maternal figure is played out in the ambivalence toward food; eating may represent a wish to fuse with the caretaker, and regurgitating may unconsciously express a wish for separation.

DIAGNOSIS AND CLINICAL FEATURES

Bulimia nervosa is present when (1) episodes of binge eating occurs relatively frequently (once a week or more) for at least 3 months; (2) compensatory behaviors are practiced after binge eating to prevent weight gain, primarily self-induced vomiting, laxative abuse, diuretics, enemas, abuse of emetics (80 percent of cases), and, less commonly, severe dieting and strenuous exercise (20 percent of cases); (3) weight is not severely lowered as in anorexia nervosa; and (4) the patient has a morbid fear of fatness, a relentless drive for thinness, or both and a disproportionate amount of self-evaluation that depends on body weight and shape. When making a diagnosis of bulimia nervosa, clinicians should explore the possibility that the patient has experienced a brief or prolonged prior bout of anorexia nervosa, which is present in approximately half of those with bulimia nervosa. Binging usually precedes vomiting by about 1 year. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) diagnostic criteria for bulimia nervosa are listed in [Table 15.2-1](#).

 **Table 15.2-1**
DSM-5 Diagnostic Criteria for Bulimia Nervosa

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour time period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
 2. A sense of lack of control over eating during episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify if:

In partial remission: After full criteria for bulimia nervosa were previously met, some, but not all, of the criteria have been met for a sustained period of time.

In full remission: After full criteria for bulimia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based on the frequency of inappropriate compensatory behaviors (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: An average of 1–3 episodes of inappropriate compensatory behaviors per week.

Moderate: An average of 4–7 episodes of inappropriate compensatory behaviors per week.

Severe: An average of 8–13 episodes of inappropriate compensatory behaviors per week.

Extreme: An average of 14 or more episodes of inappropriate compensatory behaviors per week.

Vomiting is common and is usually induced by sticking a finger down the throat, although some patients are able to vomit at will. Vomiting decreases the abdominal pain and the feeling of being bloated and allows patients to continue eating without fear of gaining weight. The acid content of vomitus can damage tooth enamel, a not uncommon finding in patients with the disorder. Depression, sometimes called *postbinge anguish*, often follows the episode. During binges, patients eat food that is sweet, high in calories, and generally soft or smooth textured, such as cakes and pastry. Some patients prefer bulky foods without regard to taste. The food is eaten secretly and rapidly and is sometimes not even chewed.

Annie is a 26-year-old Dutch woman. She works as a nurse in a city hospital and lives alone. Annie would wake up at night, go to her kitchen, and start eating whatever food she could lay her hands on. She stopped only after an hour or two when she could find no more food. The bouts of overeating went on for 5 years until she consulted her general practitioner, who referred her to outpatient psychiatric treatment for a depression related to the eating spells. Annie's spells of uncontrollable overeating were preceded by a feeling of severe tension and were followed by relaxation, although this was coupled with shame and despair. During the year before her referral, the frequency of the overeating spells had increased to two or three times a week. They usually appeared at night after just a few hours of sleep. After eating her way through whatever she could find, she would feel bloated but would not vomit. She tried to get rid of the food by taking large quantities of laxatives. Her weight was unstable, but she managed to keep it within normal limits simply by fasting between the overeating spells. Annie despised obesity but had never really been slim. Her bouts of overeating made her feel increasingly low-spirited and despairing. She had even considered committing suicide by taking an overdose of the sleeping tablets that her general practitioner had prescribed because of her interrupted sleep. Annie managed to do her job adequately and had taken only a few days of

sick leave.

Annie was brought up in a village, where her father was a schoolteacher. After secondary school she trained as a nurse and had various jobs on geriatric wards. Annie had always been very sensitive and fearful of criticism and had low self-esteem. She tried hard to live up to expectations and felt frustrated by minor criticisms. She had been in love more than once, but never dared to become engaged because she feared rejection and possibly also because she feared a sexual relationship. She had only a few close friends because she had difficulty engaging in close relationships. She often felt tense and diffident in company. She avoided going to meetings or parties because she feared being criticized or rejected.

On examination Annie appeared quiet and reticent. Her mood was mildly depressed, and she cried silently as she described her difficulties. No psychotic features were suspected. She was otherwise healthy and of average weight. She perceived her own weight to be slightly higher than the weight she would prefer. She said she was afraid of becoming obese. (Courtesy of *International Statistical Classification of Diseases and Related Health Problems*, 10th ed. Casebook)

Most patients with bulimia nervosa are within their normal weight range, but some may be underweight or overweight. These patients are concerned about their body image and their appearance, worried about how others see them, and concerned about their sexual attractiveness. Most are sexually active, compared with anorexia nervosa patients, who are not interested in sex. Pica and struggles during meals are sometimes revealed in the histories of patients with bulimia nervosa.

Bulimia nervosa occurs in persons with high rates of mood disorders and impulse control disorders. Bulimia nervosa is also reported to occur in those at risk for substance-related disorders and a variety of personality disorders. Patients with bulimia nervosa also have increased rates of anxiety disorders, bipolar I disorder, dissociative disorders, and histories of sexual abuse.

Subtypes

Evidence indicates that bulimic persons who purge differ from binge eaters who do not purge in that the latter tend to have less body-image disturbance and less anxiety concerning eating. Those with bulimia nervosa who do not purge tend to be obese. Distinct physiological differences also exist between patients with bulimia who purge and those who do not. Because of all these differences, the diagnosis of bulimia nervosa is sometimes subtyped into a purging type, for those who regularly engage in self-induced vomiting or the use of laxatives or diuretics, and a nonpurging type, for those who use strict dieting, fasting, or vigorous exercise but do not regularly engage in purging. Patients who purge may have a different course from that of patients who binge and then diet or exercise.

Patients with purging type may be at risk for certain medical complications such as hypokalemia from vomiting or laxative abuse and hypochloremic alkalosis. Those who vomit repeatedly are at risk for gastric and esophageal tears, although these complications are rare.

PATHOLOGY AND LABORATORY EXAMINATIONS

Bulimia nervosa can result in electrolyte abnormalities and various degrees of starvation, although it may not be as obvious as in low-weight patients with anorexia nervosa. Thus, even normal-weight patients with bulimia nervosa should have laboratory studies of electrolytes and metabolism. In general, thyroid function remains intact in bulimia nervosa, but patients may show nonsuppression on a dexamethasone-suppression test. Dehydration and electrolyte disturbances are likely to occur in patients with bulimia nervosa who purge regularly. These patients commonly exhibit hypomagnesemia and hyperamylasemia. Although not a core diagnostic feature, many patients with bulimia nervosa have menstrual disturbances. Hypotension and bradycardia occur in some patients.

DIFFERENTIAL DIAGNOSIS

The diagnosis of bulimia nervosa cannot be made if the binge-eating and purging behaviors occur exclusively during episodes of anorexia nervosa. In such cases, the diagnosis is anorexia nervosa, binge eating-purging type.

Clinicians must ascertain that patients have no neurological disease, such as epileptic-equivalent seizures, central nervous system tumors, Klüver-Bucy syndrome, or Kleine-Levin syndrome. The pathological features manifested by Klüver-Bucy syndrome are visual agnosia, compulsive licking and biting, examination of objects by the mouth, inability to ignore any stimulus, placidity, altered sexual behavior (hypersexuality), and altered dietary habits, especially hyperphagia. The syndrome is exceedingly rare and is unlikely to cause a problem in differential diagnosis. Kleine-Levin syndrome consists of periodic hypersomnia lasting for 2 to 3 weeks and hyperphagia. As in bulimia nervosa, the onset is usually during adolescence, but the syndrome is more common in men than in women.

Patients with bulimia nervosa who have concurrent seasonal affective disorder and patterns of atypical depression (with overeating and oversleeping in low-light months) may manifest seasonal worsening of both bulimia nervosa and depressive features. In these cases, binges are typically much more severe during winter months. Bright light therapy (10,000 lux for 30 minutes, in early morning, at 18 to 22 inches from the eyes) may be a useful component of comprehensive treatment of an eating disorder with seasonal affective disorder.

Some patients with bulimia nervosa—perhaps 15 percent—have multiple comorbid impulsive behaviors, including substance abuse, and lack of ability to control themselves in such diverse areas as money management (resulting in impulse buying and compulsive shopping) and sexual relationships (often resulting in brief, passionate attachments and promiscuity). They exhibit self-mutilation, chaotic emotions, and chaotic sleeping patterns. They often meet criteria for borderline personality disorder and other mixed personality disorders and, not infrequently, bipolar II disorder.

COURSE AND PROGNOSIS

Bulimia nervosa is characterized by higher rates of partial and full recovery compared with anorexia nervosa. As noted in the treatment section, those treated fare much better than those who are untreated. Patients who are untreated tend to remain chronic or may show small, but generally unimpressive, degrees of improvement with time. In a 10-year follow-up study of patients who had previously participated in treatment programs, the number of women who continued to meet the full criteria for bulimia nervosa declined as the duration of follow-up increased. Approximately 30 percent continued to engage in recurrent binge-eating or purging behaviors. A history of substance use problems and a longer duration of the disorder at presentation predicted worse outcome. Approximately 40 percent of women were fully recovered at follow-up. The mortality rate for bulimia nervosa has been estimated at 2 percent per decade according to DSM-5.

TREATMENT

Most patients with uncomplicated bulimia nervosa do not require hospitalization. In general, patients with bulimia nervosa are not as secretive about their symptoms as patients with anorexia nervosa. Therefore, outpatient treatment is usually not difficult, but psychotherapy is frequently stormy and may be prolonged. Some obese patients with bulimia nervosa who have had prolonged psychotherapy do surprisingly well. In some cases—when eating binges are out of control, outpatient treatment does not work, or a patient exhibits such additional psychiatric symptoms as suicidality and substance abuse—hospitalization may become necessary. In addition, electrolyte and metabolic disturbances resulting from severe purging may necessitate hospitalization.

Psychotherapy

Cognitive-Behavioral Therapy. Cognitive-behavioral therapy (CBT) should be considered the benchmark, first-line treatment for bulimia nervosa. The data supporting the efficacy of CBT are based on strict adherence to rigorously implemented, highly detailed, manual-guided treatments that include about 18 to 20 sessions over 5 to 6 months. CBT implements a number of cognitive and behavioral procedures to (1) interrupt the self-maintaining behavioral cycle of bingeing and dieting and (2) alter the individual's dysfunctional cognitions; beliefs about food, weight, body image; and overall self-concept.

Dynamic Psychotherapy. Psychodynamic treatment of patients with bulimia nervosa has been of limited success. Psychodynamic formulations revealed a tendency to concretize introjective and projective defense mechanisms. In a manner analogous to splitting, patients divide food into two categories: items that are nutritious and those that are unhealthy. Food that is designated nutritious may be ingested and retained because it unconsciously symbolizes good introjects. But junk food is unconsciously associated with bad introjects and, therefore, is expelled by vomiting, with the unconscious fantasy that all destructiveness, hate, and badness are being evacuated. Patients can temporarily feel good after vomiting because of the fantasized evacuation, but the associated feeling of "being all good" is short-lived because it is based on an unstable combination of splitting and projection.

Other Modalities. Controlled trials have shown that a variety of novel ways of administering and facilitating cognitive-behavioral therapy are effective for bulimia nervosa. Some have been incorporated in "stepped-care" programs and including Internet-based platforms, computer facilitated programs, email enhanced programs, and administration of cognitive-behavioral therapy via telemedicine to remote areas.

Pharmacotherapy

Antidepressant medications have been shown to be helpful in treating bulimia. This includes the selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine (Prozac). This may be based on elevating central 5-hydroxytryptamine levels. Antidepressant medications can reduce binge eating and purging independent of the presence of a mood disorder. Thus, antidepressants have been used successfully for particularly difficult binge-purge cycles that do not respond to psychotherapy alone. Imipramine (Tofranil), desipramine (Norpramin), trazodone (Desyrel), and monoamine oxidase inhibitors (MAOIs) have been helpful. In general, most of the antidepressants have been effective at dosages usually given in the treatment of depressive disorders. Dosages of fluoxetine that are effective in decreasing binge eating, however, may be higher (60 to 80 mg a day) than those used for depressive disorders. Medication is helpful in patients with comorbid depressive disorders and bulimia nervosa. Carbamazepine (Tegretol) and lithium (Eskalith) have not shown impressive results as treatments for binge eating, but they have been used in the treatment of patients with bulimia nervosa with comorbid mood disorders, such as bipolar I disorder. Evidence indicates that the use of antidepressants alone results in a 22 percent rate of abstinence from bingeing and purging; other studies show that CBT and medications are the most effective combination.

15.3 Binge Eating Disorder and Other Eating Disorders

BINGE EATING DISORDER

Individuals with binge eating disorder engage in recurrent binge eating during which they eat an abnormally large amount of food over a short time. Unlike bulimia nervosa, patients with binge eating disorder do not compensate in any way after a binge episode (e.g., laxative use). Binge episodes often occur in private, generally include foods of dense caloric content, and, during the binge, the person feels he or she cannot control his or her eating.

Epidemiology

Binge eating disorder is the most common eating disorder. It appears in approximately 25 percent of patients who seek medical care for obesity and in 50 to 75 percent of those with severe obesity (body mass index [BMI] greater than 40). It is more common in females (4 percent) than in males (2 percent).

Etiology

The cause of binge eating disorder is unknown. Impulsive and extroverted personality styles are linked to the disorder as are persons who place themselves on a very low calorie diet. Binge eating may also occur during periods of stress. It may be used to reduce anxiety or alleviate depressive moods.

Diagnosis and Clinical Features

To be diagnosed with binge eating disorder the binges must be characterized by four features: (1) eating more rapidly than normal and to the point of being uncomfortably full, (2) eating large amounts of food even when not hungry, (3) eating alone, and (4) feeling guilty or otherwise upset about the episode. Binges must occur at least once a week for at least 3 months. The guidelines from the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* are presented in [Table 15.3-1](#).

Table 15.3-1
DSM-5 Diagnostic Criteria for Binge Eating Disorder

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most people would eat in a similar period of time under similar circumstances.
 - 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. The binge-eating episodes are associated with
 - 1. Eating much more rapidly than normal.
 - 2. Eating until feeling uncomfortably full.
 - 3. Eating large amounts of food when not feeling physically hungry.
 - 4. Eating alone because of feeling embarrassed by how much one is eating.
 - 5. Feeling disgusted with oneself, depressed, or very guilty afterward.
- C. Marked distress regarding binge eating is present.
- D. The binge eating occurs, on average, at least once a week for 3 months.
- E. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

Specify if:

In partial remission: After full criteria for binge-eating disorder were previously met, binge eating occurs at an average frequency of less than one episode per week for a sustained period of time.

In full remission: After full criteria for binge-eating disorder were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based on the frequency of episodes of binge eating (see below).

The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: 1–3 binge eating episodes per week.

Moderate: 4–7 binge-eating episodes per week.

Severe: 8–13 binge-eating episodes per week.

Extreme: 14 or more binge-eating episodes per week.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Approximately half of individuals with binge eating disorder are obese. Additionally, obese individuals with binge eating disorder have an earlier onset of obesity than those without the disorder. Patients with binge eating disorder are also more likely to have an unstable weight history with frequent episodes of weight cycling (the gaining or losing of more than 10 kg). The disorder may be associated with insomnia, early menarche, neck or shoulder and lower back pain, chronic muscle pain, and metabolic disorders.

Differential Diagnosis

Binge eating disorder and bulimia nervosa share the same core feature of recurrent binge eating. Binge eating disorder is distinct from bulimia nervosa, however, in that binge eating disorder patients do not report recurrent compensatory behavior such as vomiting, laxative abuse, or excessive dieting. Binge eating disorder is distinct from anorexia nervosa in that patients do not exhibit an excessive drive for thinness and are of normal weight or are obese.

The prevalence of binge eating disorder is higher in overweight populations (3 percent) than in the general population (approximately 2 percent). However there are some distinctions. Obese patients with binge eating disorder have a greater caloric intake during bingeing and nonbinging episodes, greater eating disorder pathology (i.e., more emotional eating, chaotic eating habits), and higher rates of comorbid psychiatric disorders. Binge eating disorder is also more prevalent in families than obesity.

Course and Prognosis

Little is known about the course of binge eating disorder. Severe obesity is a long-term effect in over 3 percent of patients with the disorder. One prospective study of women in the community with binge eating disorder suggested that by 5 years of follow-up fewer than one fifth of the sample still had clinically significant eating disorder symptoms.

Treatment

Psychotherapy. Cognitive-behavioral therapy (CBT) is the most effective psychological treatment for binge eating disorder. CBT has been shown to lead to decreases in binge eating and associated problems (e.g., depression); however, studies have not shown marked weight

loss as a result of CBT, and CBT combined with psychopharmacological treatments such as selective serotonin reuptake inhibitors (SSRIs) show better results than CBT alone. Exercise has also shown a reduction in binge eating when combined with CBT. Interpersonal psychotherapy (IPT) has also shown to be effective in the treatment of binge eating disorder; however, therapy focuses more on the interpersonal problems that contribute to the disorder rather than disturbances in eating behavior.

Self-Help Groups. Self-help groups such as Overeaters Anonymous (OA) have proven to be helpful in patients with binge eating disorder. For the treatment of moderate obesity, organizations such as Weight Watchers can be extremely helpful and do not involve common fads or quick fixes.

Psychopharmacotherapy. Symptoms of binge eating may benefit from medication treatment with several SSRIs, desipramine (Norpramin), imipramine (Tofranil), topiramate (Topamax), and sibutramine (Meridia). SSRI medications that have demonstrated improvement in mood as well as binge eating include fluvoxamine (Luvox), citalopram (Celexa), and sertraline (Zoloft). Some studies showed that high-dose SSRI treatment (e.g., fluoxetine [Paxil] at 60 to 100 mg) often initially resulted in weight loss. However, the weight loss was ordinarily short lived, even when medication was continued, and weight always returned when medication was discontinued. Amphetamine and amphetamine-like drugs may help but are of little use over the long term.

Most, but not all, studies show that medication added to CBT is more effective than medication alone. For example, studies indicate that CBT did better than fluvoxamine or desipramine as a monotherapy for binge eating disorder; however, when CBT was used in combination with these agents, more improvement was seen in terms of weight loss compared with CBT alone.

OTHER SPECIFIED FEEDING OR EATING DISORDER

The diagnostic category of “other specified feeding or eating disorder” can be used for eating conditions that may cause significant distress but do not meet the full criteria for a classified eating disorder. Conditions included in this category include night eating syndrome, purging disorder, and subthreshold forms of anorexia nervosa, bulimia nervosa, and binge eating disorder.

Night Eating Syndrome

Night eating syndrome is characterized by the consumption of large amounts of food after the evening meal. Individuals generally have little appetite during the day and suffer from insomnia.

Epidemiology. Night eating syndrome occurs in approximately 2 percent of the general population; however, it has a higher prevalence among patients with insomnia, obesity (10 to 15 percent), eating disorders, and other psychiatric disorders. The disorder usually begins in early adulthood.

Etiology. Little is known about the cause of night eating disorder; however, the hormones melatonin, leptin, ghrelin, and cortisol have been studied in relation to the disorder. Night eating syndrome also appears to run in families; patients with night eating syndrome are five times more likely to have a first-degree relative with night eating syndrome.

Diagnosis and Clinical Features

The diagnosis of night eating disorder includes recurrent episodes of hyperphagia or night eating; the lack of desire for food in the morning; and insomnia. Symptoms must persist for at least 3 months and cannot be secondary to another medical or mental condition.

Patients with night eating syndrome usually consume a large portion of their daily calorie intake after the evening meal. They are also more likely to wake up during the night and to eat upon awakening. Nocturnal eating tends to occur during non-rapid eye movement (REM) sleep and is usually short in duration. Patients are also prone to low sleep efficiency. Patients believe that they can only sleep if they eat. Depressed mood is common among these patients, especially during the evening and night hours.

Differential Diagnosis. Night eating disorder is common among patients with other eating disorders, particularly bulimia nervosa and binge eating disorder. Although night eating can be found in bulimia nervosa and binge eating disorder, it is the characteristic sign of night eating disorder. Also, the amount of food consumed during eating episodes is usually lower in night eating disorder than in bulimia nervosa and binge eating disorder. Unlike other eating disorders, patients with night eating syndrome are not overly concerned about body image and weight. Patients with night eating disorder are also at higher risk for obesity and metabolic syndrome.

Sleep-related eating disorder is characterized by recurrent episodes of involuntary eating during the night. These episodes can lead to serious consequences such as the ingesting of nonedible foods or substances, dangerous behaviors while searching for or preparing food, and sleep-related injury. The eating episodes usually occur after the patient has gone to sleep and may occur while the patient is unconscious or asleep. Sleep-related eating disorder also has a high comorbidity with sleepwalking, restless leg syndrome, and obstructive sleep apnea, conditions that are rarely found among night eating syndrome patients. Episodes of sleep-related eating disorder have been reported after the use of certain medications, including zolpidem (Ambien), triazolam (Halcion), olanzapine (Zyprexa), and risperidone (Risperdal).

Course and Prognosis. The age of onset for night eating syndrome ranges from the late teens to late 20s and has a long-lasting course with periods of remission with treatment. Patients who experience poor sleep quality are more likely to develop diabetes, obesity, hypertension, and cardiovascular disease.

Treatment. Various studies have shown positive results in patients treated with SSRIs who showed improvement in nighttime awakenings, nocturnal eating, and postevening caloric intake. Weight loss and a reduction in nocturnal eating have been associated with an addition of topiramate to medication regimens.

In patients with comorbid major depression and night eating syndrome, bright light therapy has shown to decrease depressed mood. CBT has also been helpful.

Purging Disorder

Purging disorder is characterized by recurrent purging behavior after consuming a small amount of food in persons of normal weight who have a distorted view of their weight or body image. Purging behavior includes self-induced vomiting, laxative abuse, enemas, and diuretics. To make the diagnosis, the behavior must not be associated with anorexia nervosa. Purging disorder is differentiated from bulimia nervosa because purging behavior occurs after eating small quantities of food or drink and does not occur as a result of a binge episode. Purging episodes should occur at least once a week over a 3-month period before the diagnosis is made.

15.4 Obesity and the Metabolic Syndrome

Obesity is a chronic illness manifested by an excess of body fat. It is generally measured by the *body mass index* (BMI), but a more accurate method is to use body composition analysis also known as *biometric impedance analysis* (BIA). Excess body fat generally results from a greater amount of calories consumed than are burnt off. In healthy individuals, body fat—which is different from the BMI—varies by gender. It ranges from 10 to 13 percent of essential fat to 25 to 31 percent on average of body weight in healthy women. In men, it ranges from 2 to 5 percent of essential fat to 18 to 24 percent on average. The global epidemic of obesity has resulted in an alarming increase in associated morbidity and mortality. Although manifestation of obesity and its comorbid states are largely physical, it has overwhelming psychological ramifications. The diagnosis of obesity using the BMI is discussed below.

COMORBIDITY

Evidence shows a correlation between obesity and psychiatric disorders. In fact, among treatment-seeking obese patients, there is a higher prevalence of morbid psychiatric illness by 40 to 60 percent. Disorders associated with obesity include eating disorders (particularly binge eating disorder), substance use disorders, psychotic disorders (schizophrenia), mood disorders, anxiety disorders, personality disorders, attention-deficit/hyperactivity disorder (ADHD), and posttraumatic stress disorder (PTSD).

There are two eating disorders that can be associated with obesity: bulimia nervosa and binge eating disorder. Both of these disorders are distinct in their clinical characteristics and have some similarities. They both are associated with significant psychopathology and need to be addressed multimodally to ensure success. It is important to note that not all patients with bulimia nervosa are obese; they may be overweight or of normal weight. See Sections 15.2 and 15.3 for further discussions on bulimia nervosa and binge eating disorder, respectively.

EPIDEMIOLOGY

Obesity rates continue to grow at epidemic proportions in the United States and other industrialized nations, representing a serious public health threat to millions of people. In the United States, approximately 36 percent of adults are obese. The prevalence of obesity is highest in minority populations, particularly among non-Hispanic black women. More than one half of these individuals, 40 years of age or older, are obese and more than 80 percent are overweight. The prevalence of obesity in adolescents in the United States has also increased from about 15 percent in 2000 to about 35 percent in 2012, while the prevalence rates for overweight children ages 6 to 11 range from 14 to 25 percent; however, there has been a slight decrease in recent years.

Obesity also has economic effects. On an individual level, medical spending is approximately 42 percent higher for an obese person compared with that for a person of normal weight. On a national level, costs attributed to both overweight (BMI 25 to 29.9) and obesity (BMI greater than 30) account for 9.1 percent of US health care costs, and if the current trend continues, obesity will account for 16 percent of US health care costs by 2030.

ETIOLOGY

Persons with no medical etiology accumulate fat by eating more calories than are expended as energy; thus intake of energy exceeds its dissipation. To reduce body fat, fewer calories must be consumed or more calories must be burnt. An error of no more than 10 percent in either intake or output would lead to a 30-pound change in body weight in 1 year.

Satiety

Satiety is the feeling that results when hunger is satisfied. Persons stop eating at the end of a meal because they have replenished nutrients that had been depleted. Persons become hungry again when nutrients restored by earlier meals are once again depleted. It seems reasonable that a metabolic signal, derived from food that has been absorbed, is carried by the blood to the brain, where the signal activates receptor cells, probably in the hypothalamus, to produce satiety. Some studies have shown evidence for dysfunction in serotonin, dopamine, and norepinephrine involvement in regulating eating behavior through the hypothalamus. Other hormonal factors that may be involved include corticotrophin-releasing factor (CRF), neuropeptide Y, gonadotropin-releasing hormone, and thyroid-stimulating hormone. A newly found substance, obestatin, which is made in the stomach, is a hormone that in animal experiments produces satiety and may have potential use as a weight-loss agent in humans. Hunger results from a decrease in the strength of metabolic signals, secondary to the depletion of critical nutrients.

Cannabinoid receptors are related to appetite and are stimulated with cannabis (marijuana) use. A cannabinoid inverse antagonist has been developed that blocks appetite.

Satiety occurs soon after the beginning of a meal and before the total caloric content of the meal has been absorbed; therefore, satiety is only one regulatory mechanism controlling food intake. Appetite, defined as the desire for food, is also involved. A hungry person may eat to full satisfaction when food is available, but appetite can also induce a person to overeat past the point of satiety. Appetite may be increased by psychological factors such as thoughts or feelings, and an abnormal appetite may result in an abnormal increase in food intake. Eating is also affected by cannabinoid receptors, which, when stimulated, increase appetite. Marijuana acts on that receptor that accounts for the “munchies” associated with marijuana use. A drug called rimonabant (Acomplia) is an inverse agonist to the cannabidiol receptor, meaning that it blocks appetite. It was withdrawn from the market because of adverse effects; however, in theory, inverse cannabinoid receptor agonists may have clinical use.

The olfactory system may play a role in satiety. Experiments have shown that strong stimulation of the olfactory bulbs in the nose with food odors by use of an inhaler saturated with a particular smell produces satiety for that food. This may have implications for therapy of obesity.

Genetic Factors

The existence of numerous forms of inherited obesity in animals and the ease with which adiposity can be produced by selective breeding make it clear that genetic factors can play a role in obesity. These factors must also be presumed to be important in human obesity.

About 80 percent of patients who are obese have a family history of obesity. This fact can be accounted for not only by genetic factors but also in part by identification with fat parents and by learned oral methods for coping with anxiety. Nonetheless, studies show that identical twins raised apart can both be obese, an observation that suggests a hereditary role. To date, no specific genetic marker of obesity has been found. [Table 15.4-1](#) lists the genetic factors affecting body weight.

 **Table 15.4-1**
Genetic Factors Affecting Body Weight

	Genetic Factor Description
Leptin	Highly expressed in areas of the hypothalamus that control feeding behavior, hunger, body temperature, and energy expenditure. The mechanisms by which leptin suppresses feeding and exerts its effects on metabolism are largely unknown.
Neuropeptide Y	Synthesized in many areas of the brain; it is a potent stimulator of feeding. Leptin appears to suppress feeding in part by inhibiting expression of neuropeptide Y.
Ghrelin	An acylated, 28–amino acid peptide secreted primarily by the stomach. Ghrelin circulates in the blood and activates neuropeptide Y neurons in the hypothalamic arcuate nucleus, thereby stimulating food intake.
Melanocortin	Acts on certain hypothalamic neurons that inhibit feeding. Targeted disruptions of the melanocortin-4 receptor in mice are associated with development of obesity.
Carboxypeptidase E	The enzyme necessary for processing proinsulin and perhaps other hormones, such as neuropeptide Y. Mice with mutations in this gene gradually become obese as they age and develop hyperglycemia that can be suppressed by treatment with insulin.
Mitochondrial uncoupling proteins	First discovered in brown fat and subsequently identified in white fat and muscle cells. May play an important role in energy expenditure and body weight regulation.
Tubby protein	Highly expressed in the paraventricular nucleus of the hypothalamus and other regions of the brain. Mice with naturally occurring or engineered mutations in the tubby gene show adult onset of obesity, but the mechanisms involved are not known.

(Adapted from Comuzzie AG, Williams JT, Martin LJ, Blanger J. Searching for genes underlying normal variation in human adiposity. *J Mol Med*. 2001;79:57.)

Developmental Factors

Early in life, adipose tissue grows by increases in both cell number and cell size. Once the number of adipocytes has been established, it does not seem to be susceptible to change. Obesity that begins early in life is characterized by adipose tissue with an increased number of adipocytes of increased size. Obesity that begins in adult life, on the other hand, results solely from an increase in the size of the adipocytes. In both instances, weight reduction produces a decrease in cell size. The greater number and size of adipocytes in patients with juvenile-onset diabetes may be a factor in their widely recognized difficulties with weight reduction and the persistence of their obesity.

The distribution and amount of fat vary in individuals, and fat in different body areas has different characteristics. Fat cells around the waist, flanks, and abdomen (the so-called potbelly) are more active metabolically than those in the thighs and buttocks. The former pattern is more common in men and has a higher correlation with cardiovascular disease than does the latter pattern. Women, whose fat distribution is in the thighs and buttocks, may become obsessed with nostrums that are advertised to reduce fat in these areas (so-called cellulite, which is not a medical term), but no externally applied preparation to reduce this fat pattern exists. Men with abdominal fat may attempt to reduce their girth with machines that exercise the abdominal muscles, but exercise has no effect on loss of this type of fat. A hormone called leptin, which is made by fat cells, acts as a fat thermostat. When the blood level of leptin is low, more fat is consumed; when high, less fat is consumed. Further research is needed to determine whether this might lead to new ways of managing obesity.

Physical Activity Factors

The marked decrease in physical activity in affluent societies seems to be the major factor in the rise of obesity as a public health problem. Physical inactivity restricts energy expenditure and may contribute to increased food intake. Although food intake increases with increasing energy expenditure over a wide range of energy demands, intake does not decrease proportionately when physical activity falls below a certain minimum level.

Brain-Damage Factors

Destruction of the ventromedial hypothalamus can produce obesity in animals, but this is probably a very rare cause of obesity in humans. There is evidence that the central nervous system, particularly in the lateral and ventromedial hypothalamic areas, adjusts to food intake in response to changing energy requirements so as to maintain fat stores at a baseline

determined by a specific set point. This set point varies from one person to another and depends on height and body build.

Health Factors

In only a small number of cases is obesity the consequence of identifiable illness. Such cases include a variety of rare genetic disorders, such as Prader-Willi syndrome, as well as neuroendocrine abnormalities (Table 15.4-2). Hypothalamic obesity results from damage to the ventromedial region of the hypothalamus (VMH), which has been studied extensively in laboratory animals and is a known center of appetite and weight regulation. In humans, damage to the VMH may result from trauma, surgery, malignancy, or inflammatory disease.

Table 15.4-2
Illnesses that Can Explain Some Cases of Obesity

Genetic (dysmorphic) obesities
Autosomal recessive
X-linked
Chromosomal (e.g., Prader-Willi syndrome)
Neuroendocrine obesities
Hypothalamic syndromes
Cushing's syndrome
Hypothyroidism
Polycystic ovarian syndrome (Stein-Leventhal syndrome)
Pseudohypoparathyroidism
Hypogonadism
Growth hormone deficiency
Insulinoma and hyperinsulinism
Iatrogenic obesities
Drugs (psychiatric)
Hypothalamic surgery (neuroendocrine)

(Adapted from Bray GA. An approach to the classification and evaluation of obesity. In: Bjorntorp P, Brodoff BN, eds. *Obesity*. Philadelphia: Lippincott Williams & Wilkins; 1992.)

Some forms of depression, particularly seasonal affective disorder, are associated with weight gain. Most persons who live in seasonal climates report increases in appetite and weight during the fall and winter months, with decreases in the spring and summer. Depressed patients usually lose weight, but some will gain weight.

Other Clinical Factors

A variety of clinical disorders are associated with obesity. Cushing's disease is associated with a characteristic fat distribution and moon-like face (Fig. 15.4-1). Myxedema is associated with weight gain, although not invariably. Other neuroendocrine disorders include adiposogenital dystrophy (Fröhlich's syndrome), which is characterized by obesity and sexual and skeletal abnormalities.

FIGURE 15.4-1

Cushing's syndrome. Plethoric, "moon-faced" with "sun-fish" mouth. (From Douthwait AH, ed. *French's Index of Differential Diagnosis*. 7th ed. Baltimore: Williams & Wilkins; 1954:513, with permission.)

Psychotropic Drugs

Long-term use of steroid medications is associated with significant weight gain, as is the use of several psychotropic agents. Patients treated for major depression, psychotic disturbances, and bipolar disorder typically gain 3 to 10 kg, with even larger gains with chronic use. This can produce the so-called metabolic syndrome discussed below.

Psychological Factors

Although psychological factors are evidently crucial to the development of obesity, how such psychological factors result in obesity is not known. The food-regulating mechanism is susceptible to environmental influence, and cultural, family, and psychodynamic factors have all been shown to contribute to the development of obesity. Although many investigators have proposed that specific family histories, precipitating factors, personality structures, or unconscious conflicts cause obesity, overweight persons may suffer from every conceivable psychiatric disorder and come from a variety of disturbed backgrounds. Many obese patients are emotionally disturbed persons who, because of the availability of the overeating mechanism in their environments, have learned to use hyperphagia as a means of coping with psychological problems. Some patients may show signs of serious mental disorder when they attain normal weight because they no longer have that coping mechanism.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of obesity, if done in a sophisticated way, involves the assessment of body fat. As this is rarely practical, the use of height and weight to calculate BMI is recommended. Figure 15.4-2 presents a chart for determining BMI from height and weight.

Weight (lb)	Height (ft.in)																	
	4'10"	4'11"	5'0"	5'1"	5'2"	5'3"	5'4"	5'5"	5'6"	5'7"	5'8"	5'9"	5'10"	5'11"	6'0"	6'1"		6'2"
125	26	25	24	24	23	22	22	21	20	20	19	18	18	17	17	17	16	Underweight
130	27	26	25	25	24	23	22	22	21	20	20	19	19	18	18	17	17	
135	28	27	26	26	25	24	23	23	22	21	21	20	19	19	18	18	17	
140	29	28	27	27	26	25	24	23	23	22	21	21	20	20	19	19	18	
145	30	29	28	27	27	26	25	24	23	23	22	21	21	20	20	19	19	Normal Weight
150	31	30	29	28	27	27	26	25	24	24	23	22	22	21	20	20	19	
155	32	31	30	29	28	28	27	26	25	24	24	23	22	22	21	20	20	
160	33	32	31	30	29	28	28	27	26	25	24	24	23	22	22	21	21	
165	34	33	32	31	30	29	28	28	27	26	25	24	24	23	22	22	21	
170	35	34	33	32	31	30	29	28	28	27	26	25	24	24	23	22	22

275	58	56	54	52	50	49	47	46	44	43	42	41	40	38	37	36	35	

FIGURE 15.4-2

Body mass index (BMI) chart. To determine BMI, find the patient's weight on the left of the graph and their height on the top of the graph. Follow the two categories toward the middle of the graph until they intersect. This point represents the patient's BMI.

In most cases of obesity, it is not possible to identify the precise etiology, given the multitude of possible causes and their interactions. Instances of secondary obesity (described in Table 15.4-3) are rare but should not be overlooked.

Table 15.4-3
Psychiatric Medications and Changes in Body Weight

Tendency to Increase Appetite and Body Weight

Greatest	Intermediate	Least
Antidepressant Drugs		
Amitriptyline (Elavil)	Doxepin (Adapin, Sinequan) Imipramine (Tofranil) Mirtazapine (Remeron) Nortriptyline (Pamelor)	Amoxapine (Asendin) Desipramine (Norpramin) Trazodone (Desyrel) Tranylcypromine (Parnate) Fluoxetine (Prozac) ² Sertraline (Zoloft) ² Bupropion (Wellbutrin) ² Venlafaxine (Effexor) ²
Mood Stabilizers		
Lithium (Eskalith) Valproic acid (Depakene)	Carbamazepine (Tegretol)	Topiramate (Topamax)
Antipsychotic Drugs		
Chlorpromazine (Thorazine)	Haloperidol (Haldol)	Ziprasidone (Geodon) Aripiprazole (Abilify) Molindone (Moban) ²
Clozapine (Clozaril) Thioridazine (Mellaril) Mesoridazine (Serentil) Olanzapine (Zyprexa) Sertindole (Serdolect) Risperidone (Risperdal)	Trifluoperazine (Stelazine) Perphenazine (Trilafon) Thiothixene (Navane) Fluphenazine (Permitil, Prolixin)	

²May decrease appetite and facilitate weight loss.

(Adapted from Allison DB, Mentore JL, Heo M, Chandler LP, Capeller JC, Infante MC, Weiden PJ. Antipsychotic-induced weight gain: A comprehensive research synthesis. *Am J Psychiatry*. 1999;156:1686; and Bernstein JG. Management of psychotropic drug-induced obesity. In: Bjorntorp P, Brodoff BN, eds. *Obesity*. Philadelphia: Lippincott Williams & Wilkins; 1992.)

The habitual eating patterns of many obese persons often seem similar to patterns found in experimental obesity. Impaired satiety is a particularly important problem. Obese persons seem inordinately susceptible to food cues in their environment, to the palatability of foods, and to the inability to stop eating if food is available. Obese persons are usually susceptible to all kinds of external stimuli to eating, but they remain relatively unresponsive to the usual internal signals of hunger. Some are unable to distinguish between hunger and other kinds of dysphoria.

DIFFERENTIAL DIAGNOSIS

Other Syndromes

The night eating syndrome, in which persons eat excessively after they have had their evening meal, seems to be precipitated by stressful life circumstances and, once present, tends to recur daily until the stress is alleviated. Night eating may also occur as a result of using sedatives to sleep, which may produce sleepwalking and eating. This has been reported with the use of zolpidem (Ambien) in patients. (See [Section 15.3](#) for further discussion on night eating syndrome.)

Binge eating disorder is characterized by sudden, compulsive ingestion of very large amounts of food in a short time, usually with great subsequent agitation and self-condemnation. Binge eating also appears to represent a reaction to stress. In contrast to night eating syndrome, however, these bouts of overeating are not periodic, and they are far more often linked to specific precipitating circumstances. Pickwickian syndrome is said to exist when a person is 100 percent over desirable weight and has associated respiratory and cardiovascular pathology.

Body Dysmorphic Disorder (Dysmorphophobia)

Some obese persons feel that their bodies are grotesque and loathsome and that others view them with hostility and contempt. This feeling is closely associated with self-consciousness and impaired social functioning. Emotionally healthy obese persons have no body image disturbances, and only a minority of neurotic obese persons have such disturbances. The disorder is confined mainly to persons who have been obese since childhood; even among them, less than half suffer from it. (See [Section 10.2](#) for a complete discussion of body dysmorphic disorder.)

COURSE AND PROGNOSIS

Effects on Health

Obesity has adverse effects on health and is associated with a broad range of illnesses ([Table 15.4-4](#)). There is a strong correlation between obesity and cardiovascular disorders. Hypertension (blood pressure higher than 140/90 mm Hg) is three times higher for persons who are overweight, and hypercholesterolemia (blood cholesterol over 240 mg/dL) is twice as common. Studies show that blood pressure and cholesterol levels can be reduced by weight reduction. Diabetes, which has clear genetic determinations, can often be reversed with weight reduction, especially type 2 diabetes (mature-onset or noninsulin-dependent diabetes mellitus).

 **Table 15.4-4**
Health Disorders Thought to Be Caused or Exacerbated by Obesity

Heart

- Premature coronary heart disease
- Left ventricular hypertrophy
- Angina pectoris
- Sudden death (ventricular arrhythmia)
- Congestive heart failure

Vascular system

- Hypertension
- Cerebrovascular disorder (cerebral infarction or hemorrhage)
- Venous stasis (with lower-extremity edema, varicose veins)

Respiratory system

- Obstructive sleep apnea
- Pickwickian syndrome (alveolar hypoventilation)
- Secondary polycythemia
- Right ventricular hypertrophy (sometimes leading to failure)

Hepatobiliary system

- Cholelithiasis and cholecystitis
- Hepatic steatosis

Hormonal and metabolic functions

- Diabetes mellitus (insulin independent)
- Gout (hyperuricemia)
- Hyperlipidemias (hypertriglyceridemia and hypercholesterolemia)

Kidney

- Proteinuria and, in very severe obesity, nephrosis
- Renal vein thrombosis

Joints, muscles, and connective tissue

- Osteoarthritis of knees
- Bone spurs of the heel
- Osteoarthrosis of spine (in women)
- Aggravation of preexisting postural faults

Neoplasia

- In women: increased risk of cancer of endometrium, breast, cervix, ovary, gallbladder, and biliary passages
- In men: increased risk of cancer of colon, rectum, and prostate

(Reprinted from Vanitallie TB. Obesity: Adverse effects on health and longevity. *Am J Clin Nutr.* 1979;32:2723, with permission.)

According to the National Institutes of Health data, obese men, regardless of smoking habits, have a higher mortality from colon, rectal, and prostate cancer than men of normal weight. Obese women have a higher mortality from cancer of the gallbladder, biliary passages, breast (postmenopause), uterus (including cervix and endometrium), and ovaries than women of normal weight.

Longevity

Reliable studies indicate that the more overweight a person is, the higher is that person's risk for death. A person who reduces weight to acceptable levels has a mortality decline to normal rates. Weight reduction may be lifesaving for patients with extreme obesity, defined as weight that is twice the desirable weight. Such patients may have cardiorespiratory failure, especially when asleep (sleep apnea).

A number of studies have demonstrated that decreasing caloric intake by 30 percent or more in young or middle-aged laboratory animals prevents or retards age-related chronic diseases and significantly prolongs the maximal lifespan. The mechanisms through which this effect is mediated are not known, but they may include reductions in metabolic rate, oxidative stress, and inflammation; improved insulin sensitivity; and changes in neuroendocrine and sympathetic nervous system function. Whether long-term calorie restriction with adequate nutrition slows aging in humans is not yet known.

Prognosis

The prognosis for weight reduction is poor, and the course of obesity tends toward inexorable progression. Of patients who lose significant amounts of weight, 90 percent regain it eventually. The prognosis is particularly poor for those who become obese in childhood. Juvenile-onset obesity tends to be more severe, more resistant to treatment, and more likely to be associated with emotional disturbance than is adult obesity.

Discrimination Toward the Obese. Overweight and obese individuals are subject to significant prejudice and discrimination in the United States and other industrialized nations. In a culture in which beauty ideals are thin and highly unrealistic, overweight people are blamed for their condition and are the subject of teasing, bias, and discrimination (sometimes called "fatism"). Income and earning power are suppressed in overweight people, and untoward social conditions, such as absence of romantic relationships, are more common. Furthermore, obese individuals face limited access to health care and may receive biased diagnoses and treatment from medical and mental health providers.

TREATMENT

As mentioned above, many patients routinely treated for obesity may develop anxiety or depression. A high incidence of emotional disturbances has been reported among obese persons undergoing long-term, in-hospital treatment by fasting or severe calorie restriction. Obese persons with extensive psychopathology, those with a history of emotional disturbance during dieting, and those in the midst of a life crisis should attempt weight reduction cautiously and under careful supervision.

Diet

The basis of weight reduction is simple—establish a caloric deficit by bringing intake below output. The simplest way to reduce caloric intake is by means of a low-calorie diet. This strategy requires an adequate amount of protein intake with balanced carbohydrate and fat intake and should be done under medical supervision. The best long-term effects are achieved with a balanced diet that contains readily available foods. For most persons, the most satisfactory reducing diet consists of their usual foods in amounts determined with the aid of tables of food values, which are available in standard books on dieting. Such a diet gives the best chance of long-term maintenance of weight loss. Total unmodified fasts are used for short-term weight loss, but they have associated morbidity including orthostatic hypotension, sodium diuresis, and impaired nitrogen balance.

Ketogenic diets are high-protein, high-fat diets used to promote weight loss. They have high cholesterol content and produce ketosis, which is associated with nausea, hypotension, and lethargy. Many obese persons find it tempting to use a novel or even bizarre diet. Table 15.4-5 contains details and comparisons of various types of diets. Whatever effectiveness these diets may have in large part results from their monotony. When a dieter stops the diet and returns to the usual fare, the incentives to overeat are multiplied.

In general, the best method of weight loss is a balanced diet of 1,100 to 1,200 calories. Such a diet can be followed for long periods but should be supplemented with vitamins, particularly iron, folic acid, zinc, and vitamin B₆.

Table 15.4-5
Types of Diets

Type of Diet	Calorie Deficit	Weight Loss	Important Supplementary Measures	Content
Low Calorie Diet (LCD)	-500 to -1,000 cal/day	0.5-1 kg/wk	Diet record very important for success	Carbs 55% Protein 15% Fat <30%
Very Low Calorie Diet (VLCD)	800 cal/day	15-25% in 8-12 wks	Support and electrolyte monitoring	Protein 70-100 g/day full replacement of vitamin/mineral/electrolytes
Fasting	<200 cal/day	50% of weight loss is water weight	Dangerous and not done anymore	Liquids
Popular diets				
1. South Beach diet/New Diet Revolution/Zone diet	<30 g of carb/day	20 lbs in 6 months	Difficult to follow over a long period. Cardiac or renal effects need to be evaluated	High fat, low carb
2. Weight Watchers/Jenny Craig/Nutrisystem	Goal is to provide great range of food choice while maintaining a negative energy balance	1-2 lbs/week	Has been shown to reduce cholesterol and blood pressure	Mod fat, balanced nutrient reduction, 20-30% fat, 15-20% protein, 55-60% carbs
3. Ornish program/Pritikin program	Mostly vegetarian diet, no caffeine, no caloric restriction, just one type of food	—	Combines meditation, stress reduction, and smoking cessation	Very low fat, <10-19% cal from fat/20% protein, and 70% complex carbs like fruit and grain

Exercise

Increased physical activity is an important part of a weight-reduction regimen. Because caloric expenditure in most forms of physical activity is directly proportional to body weight, obese persons expend more calories than persons of normal weight with the same amount of activity. Furthermore, increased physical activity may actually decrease food intake by formerly sedentary persons. This combination of increased caloric expenditure and decreased food intake makes an increase in physical activity a highly desirable feature of any weight-reduction program. Exercise also helps maintain weight loss. It is essential in the treatment of the metabolic syndrome.

Lifestyle Change

A lifestyle change empowers the patient to set goals of weight management. Simple lifestyle modification strategies that patients should be encouraged to follow include:

Personal behavior during a meal:

- ▶ Eat slowly and savor each mouthful
- ▶ Chew each bite 30 times before swallowing
- ▶ Put the fork down between bites
- ▶ Delay eating for 2 to 3 minutes and converse
- ▶ Postpone a snack for 10 minutes
- ▶ Serve food on a smaller plate
- ▶ Divide portions in half so another portion may be permitted

Reduce eating cues:

- ▶ Eat only at one designated place
- ▶ Leave the table as soon as eating is done
- ▶ Do not combine eating with other activities (e.g., reading or watching television)
- ▶ Do not put bowls of food on the table
- ▶ Stock home with healthier food choices
- ▶ Shop for groceries from a list after a full meal
- ▶ Plan meals
- ▶ Keep a food diary to link eating with hunger and nonhunger episodes

- ▶ Substitute other activities for snacking

Pharmacotherapy

Various drugs, some more effective than others, are used to treat obesity. Table 15.4-6 lists the drugs currently available for this use. Drug treatment is effective because it suppresses appetite, but tolerance to this effect may develop after several weeks of use. An initial trial period of 4 weeks with a specific drug can be used; then, if the patient responds with weight loss, the drug can be continued to see whether tolerance develops. If a drug remains effective, it can be dispensed for a longer time until the desired weight is achieved.

Table 15.4-6
Common Drugs for the Treatment of Obesity

Generic Name	Trade Name(s)	Usual Dosage Range (mg/day)
Amphetamine and dextroamphetamine	Biphentine	12.5–20
Methamphetamine	Desoxyn	10–15
Benzphetamine	Didrex	75–150
Phendimetrazine	Bontril, Plegine, Prelu-2, X-Troazine	105
Phentermine hydrochloride	Adipex-P, Fastin, Oby-trim	18.75–37.5
Resin	Ionamin	15–30
Diethylpropion hydrochloride	Tenuate	75
Mazindol	Sanorex, Mazanor	3–9
Sibutramine	Meridia	10–15
Orlistat	Xenical	360
Lorcaserin	Belviq	10 twice a day
Phentermine-topiramate	Qsymia	3.75–15 phentermine 23–92 topiramate

Orlistat. One weight-loss medication approved by the Food and Drug Administration (FDA) for long-term use is orlistat (Xenical), which is a selective gastric and pancreatic lipase inhibitor that reduces the absorption of dietary fat (which is then excreted in stool). In clinical trials, orlistat (120 mg, three times a day), in combination with a low-calorie diet, induced losses of approximately 10 percent of initial weight in the first 6 months, which were generally well maintained for periods up to 24 months. Because of its peripheral mechanism of action, orlistat is generally free of the central nervous system effects (i.e., increased pulse, dry mouth, insomnia) that are associated with weight-loss medications. The principal adverse effects of orlistat are gastrointestinal; patients must consume 30 percent or fewer calories from fat to prevent adverse events that include oily stool, flatulence with discharge, and fecal urgency. A lower dosed over-the-counter formulation of orlistat (Alli) was approved by the FDA in 2007.

Sibutramine. Sibutramine (Meridia) is a β -phenylethylamine that inhibits the reuptake of serotonin and norepinephrine (and dopamine to a limited extent). It was approved by the FDA in 1997 for weight loss and the maintenance of weight loss (i.e., long-term use).

Lorcaserin. Lorcaserin (Belviq) has been approved by the FDA for the treatment of obesity in adults. Lorcaserin is a selective serotonin agonist that suppresses appetite and reduces food intake. One double-blind, placebo-controlled trial showed that obese patients lost about 4 percent more of their body weight in 1 year while on lorcaserin compared with controls. Additionally, weight loss was maintained in 70 percent of patients who took lorcaserin for 2 years. Another trial showed that obese patients who took lorcaserin 10 mg 1 to 2 times per day in conjunction with nutritional and exercise programs lost 6 percent of their body weight after 1 year. The recommended dosage is 10 mg twice a day. If the patient does not see a 5 percent reduction of their body weight within 12 weeks of treatment, lorcaserin treatment should be discontinued. Side effects of lorcaserin include headaches, dizziness, fatigue, nausea, dry mouth, and constipation. Rare but serious side effects include a chemical imbalance (serotonin syndrome), suicidal thoughts, psychiatric problems, and problems with memory or comprehension. Pregnant women should not take lorcaserin.

Phentermine-topiramate. Phentermine-topiramate (Qsymia) has been approved by the FDA for weight management treatment in conjunction with diet and exercise. It combines lower doses of immediate-release phentermine, a weight-loss drug prescribed for short-term use, and controlled-release topiramate, an anticonvulsant. Patients should start at the lowest dose (3.75 mg phentermine/23 mg topiramate extended release), then increase to the recommended dose (7.5 mg/46 mg). In some circumstances, patients may have their dose increased to the highest dose (15 mg/92 mg). In clinical trials, patients have shown an average weight loss ranging from 7 percent (lowest dose) to 9 percent (recommended dose) over those taking a placebo. Side effects include paraesthesia, dry mouth, altered taste, increased heart rate, possible birth defects, and psychiatric problems (depression, suicidal thoughts, impaired memory, and concentration). If the patients do not see a 3 percent reduction in their body weight after 12 weeks on the recommended dose, the dosage may be increased to the highest dose. If patients do not see a 5 percent reduction in their body weight after 12 weeks on the highest dose, treatment with Qsymia should be discontinued.

Surgery

Gastroplasty. Vertical banded gastroplasty (VBG) is a restrictive-only operation that involves creating a small gastric reservoir or pouch measuring 15 to 20 mL in volume, which then empties into the residual stomach through a calibrated or banded outlet. On average, patients lose 40 to 50 pounds of excess body weight over the first 1 to 2 years postoperatively. Vomiting, electrolyte imbalance, and obstruction may occur. A syndrome called *dumping*, which consists of palpitations, weakness, and sweating, may follow surgical procedures in some patients if they ingest large amounts of carbohydrates in a single meal. Due to such complications, VBG is now only performed in a few centers in the United States.

Gastric Bypass. Since the early 1990s, gastric bypass (Fig. 15.4-3) has greatly replaced VBG as the operation of choice. The procedure involves dividing the stomach into two pouches—a small upper pouch and a larger lower “remnant” pouch—and then rearranging the small intestine to connect to both. The expected weight loss averages 70 percent of excess body weight with the maximum weight loss occurring by 3 years postoperatively (Fig. 15.4-4). The main complications of gastric bypass surgery are primarily seen during the perioperative period. Mortality is less than 0.5 percent and is mainly due to pulmonary emboli or sepsis secondary to anastomotic leakage. Vitamin B₁₂ and iron deficiencies may present and may require oral supplementation. All patients need to take multivitamins postoperatively and need to be followed at regular intervals for nutritional assessment. About 10 to 15 percent of patients will either fail to achieve significant weight loss or regain a significant amount of their loss after 2 or 3 years. This is usually due to consumption of carbohydrates, such as potato chips

or other snack foods. Psychological treatment of abnormal eating behaviors is essential to prevent weight gain.

FIGURE 15.4-3

FIGURE 15.4-4

A. Preoperative photograph of a woman who lost 140 pounds after laparoscopic gastric bypass surgery with significant deflation and poor skin quality. B. Postoperative photograph after extended vertical thigh lift demonstrates tightening of the skin and dramatic improvement of the thigh appearance. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Gastric Banding. Laparoscopic adjustable gastric band was approved by the FDA in 2002 and is one of the least invasive operations for obesity because it does not involve cutting the stomach or the intestine. It involves placing a band around the upper part of the stomach, creating a smaller stomach above the band and a larger stomach below the band (Fig. 15.4-5). The smaller stomach allows the patient to feel fuller quicker, thus reducing the amount of food intake. Average weight loss is approximately 37 to 50 percent of excess body weight. Complications involve band movement, erosion, malfunction, and slippage (stomach herniating through the band). Improvements in the design of the band and newer placement techniques appear to be reducing complications.

FIGURE 15.4-5

Laparoscopic adjustable gastric band. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Other Methods. The surgical removal of fat (lipectomy) has no effect on weight loss in the long run nor does liposuction, which has value only for cosmetic reasons. Bariatric surgery is now recommended in individuals who have serious obesity-related health complications and a BMI of greater than 35 kg/m² (or a BMI greater than 40 kg/m² in the absence of major health complications). Before surgery, candidates should have tried to lose weight using the safer, more traditional options of diet, exercise, and weight loss medication.

Psychotherapy

The psychological problems of obese persons vary, and there is no particular personality type that is more prone to obesity. Some patients may respond to insight-oriented psychodynamic therapy with weight loss, but this treatment has not had much success. Uncovering the unconscious causes of overeating may not alter the behavior of persons who overeat in response to stress, although it may serve to augment other treatment methods. Years after successful psychotherapy many persons who overeat under stress continue to do so. Obese persons seem particularly vulnerable to overdependency on a therapist, and the inordinate regression that may occur during the uncovering psychotherapies should be carefully monitored.

Behavior modification has been the most successful of the therapeutic approaches for obesity and is considered the method of choice. Patients are taught to recognize external cues that are associated with eating and to keep diaries of foods consumed in particular circumstances, such as at the movies or while watching television, or during certain emotional states, such as anxiety or depression. Patients are also taught to develop new eating patterns, such as eating slowly, chewing food well, not reading while eating, and not eating between meals or when not seated. Operant conditioning therapies that use rewards such as praise or new clothes to reinforce weight loss have also been successful. Group therapy helps to maintain motivation, to promote identification among members who have lost weight, and to provide education about nutrition.

Comprehensive Approach

The National Heart, Lung, and Blood Institute formulated key recommendations for patients and the public regarding weight loss. These are listed in [Table 15.4-7](#).

Table 15.4-7
Key Recommendations for Healthy Weight

- ▶ Weight loss to lower elevated blood pressure in overweight and obese persons with high blood pressure.
- ▶ Weight loss to lower elevated levels of total cholesterol, low-density lipoprotein (LDL)-cholesterol, and triglycerides, and to raise low levels of high-density lipoprotein (HDL)-cholesterol in overweight and obese persons with dyslipidemia.
- ▶ Weight loss to lower elevated blood glucose levels in overweight and obese persons with type 2 diabetes.
- ▶ Use the body mass index (BMI) to classify overweight and obesity and to estimate relative risk of disease compared to normal weight.
- ▶ The waist circumference should be used to assess abdominal fat content.
- ▶ The initial goal of weight loss therapy should be to reduce body weight by about 10 percent from baseline. With success, and if warranted, further weight loss can be attempted.
- ▶ Weight loss should be about 1 to 2 pounds per week for a period of 6 months, with the subsequent strategy based on the amount of weight lost.
- ▶ Low calorie diets (LCD) for weight loss in overweight and obese persons. Reducing fat as part of an LCD is a practical way to reduce calories.
- ▶ Reducing dietary fat alone without reducing calories is not sufficient for weight loss. However, reducing dietary fat, along with reducing dietary carbohydrates, can help reduce calories.
- ▶ A diet that is individually planned to help create a deficit of 500 to 1,000 kcal/day should be an integral part of any program aimed at achieving a weight loss of 1 to 2 pounds per week.
- ▶ Physical activity should be part of a comprehensive weight loss therapy and weight control program because it (1) modestly contributes to weight loss in overweight and obese adults, (2) may decrease abdominal fat, (3) increases cardiorespiratory fitness, and (4) may help with maintenance of weight loss.
- ▶ Physical activity should be an integral part of weight loss therapy and weight maintenance. Initially, moderate levels of physical activity for 30 to 45 minutes, 3 to 5 days a week, should be encouraged. All adults should set a long-term goal to accumulate at least 30 minutes or more of moderate-intensity physical activity on most, and preferably all, days of the week.
- ▶ The combination of a reduced calorie diet and increased physical activity is recommended because it produces weight loss that may also result in decreases in abdominal fat and increases in cardiorespiratory fitness.
- ▶ Behavior therapy is a useful adjunct when incorporated into treatment for weight loss and weight maintenance.
- ▶ Weight loss and weight maintenance therapy should employ the combination of LCDs, increased physical activity, and behavior therapy.
- ▶ After successful weight loss, the likelihood of weight loss maintenance is enhanced by a program consisting of dietary therapy, physical activity, and behavior therapy, which should be continued indefinitely. Drug therapy can also be used. However, drug safety and efficacy beyond 1 year of total treatment have not been established.
- ▶ A weight maintenance program should be a priority after the initial 6 months of weight loss therapy.

(Formulated from the Obesity Education Institute, National Institute of Health.)

METABOLIC SYNDROME

The metabolic syndrome consists of a cluster of metabolic abnormalities associated with obesity and that contribute to an increased risk of cardiovascular disease and type 2 diabetes. The syndrome is diagnosed when a patient has three or more of the following five risk factors: (1) abdominal obesity, (2) high triglyceride level, (3) low HDL cholesterol level, (4) hypertension, and (5) an elevated fasting blood glucose level. [Table 15.4-8](#) lists the criteria as set forth by the World Health Organization (WHO). The syndrome is believed to occur in about 30 percent of the American population, but is also well known in other industrialized countries around the world.

 **Table 15.4-8**
World Health Organization Clinical Criteria for Metabolic Syndrome

Insulin resistance, identified by 1 of the following:

- ▶ Type 2 diabetes
- ▶ Impaired fasting glucose
- ▶ Impaired glucose tolerance
- ▶ Or for those with normal fasting glucose levels (<100 mg/dL), glucose uptake below the lowest quartile for background population under investigation under hyperinsulinemic, euglycemic conditions

Plus any 2 of the following:

- ▶ Antihypertensive medication and/or high blood pressure (≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic)
- ▶ Plasma triglycerides ≥ 150 mg/dL (≥ 1.7 mmol/L)
- ▶ BMI >30 kg/m² and/or waist:hip ratio >0.9 in men, >0.85 in women
- ▶ Urinary albumin excretion rate ≥ 20 μ g/min or albumin:creatinine ratio ≥ 30 mg/g

The cause of the syndrome is unknown, but obesity, insulin resistance, and a genetic vulnerability are involved. Treatment involves weight loss, exercise, and the use of statins and antihypertensives as needed to lower lipid levels and blood pressure, respectively. Because of the increased risk of mortality, it is important that the syndrome be recognized early and treated.

Second-generation (atypical) antipsychotic medications have been implicated as a cause of metabolic syndrome. In patients with schizophrenia, treatment with these medications can cause a rapid increase in body weight in the first few months of therapy, which may continue on for more than a year. In addition, insulin resistance leading to type 2 diabetes has been associated with an atherogenic lipid profile.

Clozapine (Clozaril) and olanzapine (Zyprexa) are the two drugs most implicated, but other atypical antipsychotics may also be involved.

Patients prescribed second-generation antipsychotic medications should be monitored periodically with hemoglobin A1c, fasting blood glucose levels at the beginning of treatment and during its course. Lipid profiles should also be obtained. [Table 15.4-9](#) lists screening procedures for patients taking these medications.

 **Table 15.4-9**
Screen Patients Before Prescribing Antipsychotics

- ▶ Personal history of obesity
- ▶ Family history of obesity
- ▶ Diabetes
- ▶ Dyslipidemias
- ▶ Hypertension
- ▶ Cardiovascular disease
- ▶ Body mass index
- ▶ Waist circumference at level of umbilicus
- ▶ Blood pressure
- ▶ Fasting plasma glucose
- ▶ Fasting lipid profile

(Data from American Diabetes Association; 2004.)

Psychological reactions to the metabolic syndrome depend on the signs and symptoms experienced by the patient. Those who suffer primarily from obesity must deal with self-esteem issues from being overweight as well as the stress of participating in weight loss programs. In many cases of obesity, eating is a way of satisfying deep-seated dependency needs. As weight is lost, some patients become depressed or anxious. Cases of psychosis have been reported in a few markedly obese patients during or after the process of losing a vast amount of weight. Other metabolic discrepancies, particularly variations in blood sugar, may be accompanied by irritability or other mood changes. Finally, fatigue is a common occurrence in patients with this syndrome. As the condition improves, especially if exercise is part of the regimen, fatigue eventually diminishes; but patients may be misdiagnosed as having a dysthymic disorder or chronic fatigue syndrome if metabolic causes of fatigue are not considered.

Normal Sleep and Sleep-Wake Disorders

16.1 Normal Sleep

Sleep is one of the most significant of human behaviors, occupying roughly one third of human life. It is a universal behavior that has been demonstrated in every animal species studied, from insects to mammals. Sleep is a process the brain requires for proper functioning. Prolonged sleep deprivation leads to severe physical and cognitive impairment and, eventually, death. Sleep may appear to be a passive process but in fact can be associated with a high degree of brain activation. There are several distinct types of sleep that differ both qualitatively and quantitatively. Each type of sleep has unique characteristics, functional importance, and regulatory mechanisms. Selectively depriving a person of one particular type of sleep produces compensatory rebound when the individual is allowed to sleep ad lib. Sleep is particularly relevant to psychiatry since sleep disturbances can occur in virtually all psychiatric illnesses and are frequently part of the diagnostic criteria for specific disorders.

The ancient Greeks ascribed the need for sleep to the god Hypnos (sleep) and his son Morpheus, also a creature of the night, who brought dreams in human forms. Dreams have played an important role in psychoanalysis. Freud believed dreams to be the “royal road to the unconscious.” They have figured prominently in art and literature from ancient times to the present.

ELECTROPHYSIOLOGY OF SLEEP

Sleep is made up of two physiological states: non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. In NREM sleep, which is composed of stages 1 through 4, most physiological functions are markedly lower than in wakefulness. REM sleep is a qualitatively different kind of sleep, characterized by a high level of brain activity and physiological activity levels similar to those in wakefulness. About 90 minutes after sleep onset, NREM yields to the first REM episode of the night. This REM latency of 90 minutes is a consistent finding in normal adults; shortening of REM latency frequently occurs with such disorders as narcolepsy and depressive disorders.

For clinical and research applications, sleep is typically scored in epochs of 30 seconds, with stages of sleep defined by the visual scoring of three parameters: electroencephalogram (EEG), electro-oculogram (EOG), and electromyogram (EMG) recorded beneath the chin. The EEG records the rapid conjugate eye movements that are the identifying feature of the sleep state (no or few rapid eye movements occur in NREM sleep); the EEG pattern consists of low-voltage, random, fast activity with sawtooth waves (Fig. 16.1-1); the EMG shows a marked reduction in muscle tone. The criteria defined by Allan Rechtschaffen and Anthony Kales in 1968 are accepted in clinical practice and for research around the world (Table 16.1-1).

FIGURE 16.1-1

Electroencephalogram patterns for stages of human sleep and wakefulness. REM, rapid eye movement. (From Butkov N. *Atlas of Clinical Polysomnography*. Medford, OR: Synapse Media; 1996, with permission.)

Table 16.1-1
Stages of Sleep—Electrophysiological Criteria

	Electroencephalogram	Electrooculogram	Electromyogram
Wakefulness	Low-voltage, mixed frequency activity; Alpha (8–13 cps) activity with eyes closed	Eye movements and eye blinks	High tonic activity and voluntary movements
Nonrapid eye movement sleep			
Stage I	Low-voltage, mixed frequency activity; Theta (3–7 cps) activity, vertex sharp waves	Slow eye movements	Tonic activity slightly decreased from wakefulness
Stage II	Low-voltage, mixed frequency background with sleep spindles (12–14 cps bursts) and K complexes (negative sharp wave followed by positive slow wave)	None	Low tonic activity
Stage III	High-amplitude ($\geq 75 \mu\text{V}$) slow waves (≤ 2 cps) occupying 20 to 50% of epoch	None	Low tonic activity
Stage IV	High-amplitude slow waves occupy $>50\%$ of epoch	None	Low tonic activity
REM sleep	Low-voltage, mixed frequency activity; Saw-tooth waves, theta activity, and slow alpha activity	REMs	Tonic atonia with phasic twitches

cps, cycles per second; REM, rapid eye movement.
 (Criteria from Rechtschaffen A, Kales A. *A Manual of Standardized Terminology, Techniques, and Scoring System for Sleep Stages of Human Subjects*. UCLA, Los Angeles: Brain Information Service/Brain Research Institute; 1968, with permission.)

In normal persons, NREM sleep is a peaceful state relative to waking. The pulse rate is typically slowed five to ten beats a minute below the level of restful waking and is very regular. Respiration is similarly affected, and blood pressure also tends to be low, with few minute-to-minute variations. The body musculature resting muscle potential is lower in REM sleep than in a waking state. Episodic, involuntary body movements are present in NREM sleep. There are few, if any, REMs and seldom do any penile erections occur in men. Blood flow through most tissues, including cerebral blood flow, is slightly reduced.

The deepest portions of NREM sleep—stages 3 and 4—are sometimes associated with unusual arousal characteristics. When persons are aroused 30 minutes to 1 hour after sleep onset—usually in slow-wave sleep—they are disoriented, and their thinking is disorganized. Brief arousals from slow-wave sleep are also associated with amnesia for events that occur during the arousal. The disorganization during arousal from stage 3 or stage 4 may result in specific problems, including enuresis, somnambulism, and stage 4 nightmares or night terrors.

Polygraphic measures during REM sleep show irregular patterns, sometimes close to aroused waking patterns. Otherwise, if researchers were unaware of the behavioral stage and happened to be recording a variety of physiological measures (aside from muscle tone) during REM periods, they undoubtedly would conclude that the person or animal they were studying was in an active waking state. Because of this observation, REM sleep has also been termed *paradoxical sleep*. Pulse, respiration, and blood pressure in humans are all high during REM sleep—much higher than during NREM sleep and often higher than during waking. Even more striking than the level or rate is the variability from minute to minute. Brain oxygen use increases during REM sleep. The ventilatory response to increased levels of carbon dioxide (CO_2) is depressed during REM sleep, so that no increase in tidal volume occurs as the partial pressure of carbon dioxide (Pco_2) increases. Thermoregulation is altered during REM sleep. In contrast to the homeothermic condition of temperature regulation during wakefulness or NREM sleep, a poikilothermic condition (a state in which animal temperature varies with the changes in the temperature of the surrounding medium) prevails during REM sleep. Poikilothermia, which is characteristic of reptiles, results in a failure to respond to changes in ambient temperature with shivering or sweating, whichever is appropriate to maintaining body temperature. Almost every REM period in men is accompanied by a partial or full penile erection. This finding is clinically significant in evaluating the cause of impotence; the nocturnal penile tumescence study is one of the most commonly requested sleep laboratory tests. Another physiological change that occurs during REM sleep is the near-total paralysis of the skeletal (postural) muscles. Because of this motor inhibition, body movement is absent during REM sleep. Probably the most distinctive feature of REM sleep is dreaming. Persons awakened during REM sleep frequently (60 to 90 percent of the time) report that they had been dreaming. Dreams during REM sleep are typically abstract and surreal. Dreaming does occur during NREM sleep, but it is typically lucid and purposeful.

The cyclical nature of sleep is regular and reliable; a REM period occurs about every 90 to 100 minutes during the night (Fig. 16.1-2). The first REM period tends to be the shortest, usually lasting less than 10 minutes; later REM periods may last 15 to 40 minutes each. Most REM periods occur in the last third of the night, whereas most stage 4 sleep occurs in the first third of the night.

FIGURE 16.1-2

Sleep pattern in a young, healthy subject. REM, rapid eye movement. (From Gillian JC, Seifritz E, Zoltoltoski RK, Salin-Pascual RJ. Basic science of sleep. In: Sadock BJ, Sadock VA, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 7th ed. Vol. 1. Philadelphia: Lippincott Williams & Wilkins; 2000:199, with permission.)

These sleep patterns change over a person's life span. In the neonatal period, REM sleep represents more than 50 percent of total sleep time, and the EEG pattern moves from the alert state directly to the REM state without going through stages 1 through 4. Newborns sleep about 16 hours a day, with brief periods of wakefulness. By 4 months of age, the pattern shifts so that the total percentage of REM sleep drops to less than 40 percent, and entry into sleep occurs with an initial period of NREM sleep. By young adulthood, the distribution of sleep stages is as follows:

- NREM (75 percent)
- Stage 1: 5 percent
- Stage 2: 45 percent
- Stage 3: 12 percent
- Stage 4: 13 percent
- REM (25 percent)

This distribution remains relatively constant into old age, although a reduction occurs in both slow-wave sleep and REM sleep in older persons.

SLEEP REGULATION

Most researchers think that there is not one simple sleep control center but a small number of interconnecting systems or centers that are located chiefly in the brainstem and that mutually activate and inhibit one another. Many studies also support the role of serotonin in sleep regulation. Prevention of serotonin synthesis or destruction of the dorsal raphe nucleus of the brainstem, which contains nearly all the brain's serotonergic cell bodies, reduces sleep for a considerable time. Synthesis and release of serotonin by serotonergic neurons are influenced by the availability of amino acid precursors of this neurotransmitter, such as L-tryptophan. Ingestion of large amounts of L-tryptophan (1 to 15 g) reduces sleep latency and nocturnal awakenings. Conversely, L-tryptophan deficiency is associated with less time spent in REM sleep. Norepinephrine-containing neurons with cell bodies located in the locus ceruleus play an important role in controlling normal sleep patterns. Drugs and manipulations that increase the firing of these noradrenergic neurons markedly reduce REM sleep (REM-off neurons) and increase wakefulness. In humans with implanted electrodes (for the control of spasticity), electrical stimulation of the locus ceruleus profoundly disrupts all sleep parameters.

Brain acetylcholine is also involved in sleep, particularly in the production of REM sleep. In animal studies, the injection of cholinergic-muscarinic agonists into pontine reticular formation neurons (REM-on neurons) results in a shift from wakefulness to REM sleep. Disturbances in central cholinergic activity are associated with the sleep changes observed in major depressive disorder. Compared with healthy persons and nondepressed psychiatric controls, patients who are depressed have marked disruptions of REM sleep patterns. These disruptions include shortened REM latency (60 minutes or less), an increased percentage of REM sleep, and a shift in REM distribution from the last half to the first half of the night. Administration of a muscarinic agonist, such as arecoline, to depressed patients during the first or second NREM period results in a rapid onset of REM sleep. Depression can be associated with an underlying supersensitivity to acetylcholine. Drugs that reduce REM sleep, such as antidepressants, produce beneficial effects in depression. Indeed, about half the patients with major depressive disorder experience temporary improvement when they are deprived of sleep or when sleep is restricted. Conversely, reserpine (Serpasil), one of the few drugs that increase REM sleep, also produces depression. Patients with dementia of the Alzheimer's type have sleep disturbances characterized by reduced REM and slow-wave sleep. The loss of cholinergic neurons in the basal forebrain has been implicated as the cause of these changes.

Melatonin secretion from the pineal gland is inhibited by bright light, so the lowest serum melatonin concentrations occur during the day. The suprachiasmatic nucleus of the hypothalamus may act as the anatomical site of a circadian pacemaker that regulates melatonin secretion and the entrainment of the brain to a 24-hour sleep-wake cycle. Evidence shows that dopamine has an alerting effect. Drugs that increase dopamine concentrations in the brain tend to produce arousal and wakefulness. In contrast, dopamine blockers, such as pimozide (Orap) and the phenothiazines, tend to increase sleep time. A hypothesized homeostatic drive to sleep, perhaps in the form of an endogenous substance—process S—may accumulate during wakefulness and act to induce sleep. Another compound—process C—may act as a regulator of body temperature and sleep duration.

FUNCTIONS OF SLEEP

The functions of sleep have been examined in a variety of ways. Most investigators conclude that sleep serves a restorative, homeostatic function and appears to be crucial for normal thermoregulation and energy conservation. As NREM sleep increases after exercise and starvation, this stage may be associated with satisfying metabolic needs.

Sleep Deprivation

Prolonged periods of sleep deprivation sometimes lead to ego disorganization, hallucinations, and delusions. Depriving persons of REM sleep by awakening them at the beginning of REM cycles increases the number of REM periods and the amount of REM sleep (rebound increase) when they are allowed to sleep without interruption. REM-deprived patients may exhibit irritability and lethargy. In studies with rats, sleep deprivation produces a syndrome that includes a debilitated appearance, skin lesions, increased food intake, weight loss, increased energy expenditure, decreased body temperature, and death. The neuroendocrine changes include increased plasma norepinephrine and decreased plasma thyroxine levels.

Sleep Requirements

Some persons are normally short sleepers who require fewer than 6 hours of sleep each night to function adequately. Long sleepers are those who sleep more than 9 hours each night to function adequately. Long sleepers have more REM periods and more rapid eye movements within each period (known as *REM density*) than short sleepers. These movements are sometimes considered a measure of the intensity of REM sleep and are related to the vividness of dreaming. Short sleepers are generally efficient, ambitious, socially adept, and content. Long sleepers tend to be mildly depressed, anxious, and socially withdrawn. Sleep needs increase with physical work, exercise, illness, pregnancy, general mental stress, and increased mental activity. REM periods increase after strong psychological stimuli, such as difficult learning situations and stress, and after the use of chemicals or drugs that decrease brain catecholamines.

Sleep-Wake Rhythm

Without external clues, the natural body clock follows a 25-hour cycle. The influence of external factors—such as the light-dark cycle, daily routines, meal periods, and other external synchronizers—entrain persons to the 24-hour clock. Sleep is also influenced by biological rhythms. Within a 24-hour period, adults sleep once, sometimes twice. This rhythm is not present at birth but develops over the first 2 years of life. Some women exhibit sleep pattern changes during the phases of the menstrual cycle. Naps taken at different times of the day differ greatly in their proportions of REM and NREM sleep. In a normal nighttime sleeper, a nap taken in the morning or at noon includes a great deal of REM sleep, whereas a nap taken in the afternoon or the early evening has much less REM sleep. A circadian cycle apparently affects the tendency to have REM sleep. Sleep patterns are not physiologically the same when persons sleep in the daytime or during the time when they are accustomed to being awake; the psychological and behavioral effects of sleep differ as well. In a world of industry and communications that often functions 24 hours a day, these interactions are becoming increasingly significant. Even in persons who work at night, interference with the various rhythms can produce problems. The best-known example is jet lag, in which, after flying east to west, persons try to convince their bodies to go to sleep at a time that is out of phase with some body cycles. Most persons adapt within a few days, but some require more time. Conditions in these persons' bodies apparently involve long-term cycle disruption and interference.

16.2 Sleep-Wake Disorders

Sleep is regulated by several basic mechanisms, and when these systems go awry, sleep disorders occur. Interest in sleep disorders was initially found among psychiatrists, psychologists, and neurologists. The past three decades have witnessed discoveries that make sleep medicine truly multidisciplinary. Research illustrating the medical consequences of sleep-disordered breathing attracted many pulmonary and internal medicine specialists to the field. Sleep-wake disorder–related endocrinology and circadian rhythm research has migrated from the laboratory bench to the bedside. Nonetheless, the seriousness of sleep disorders remains poorly recognized by the general public and the vast majority of clinical practitioners.

Sleep disorders are both dangerous and expensive to treat. Obstructive sleep apnea research verifies its contribution to hypertension, heart failure, and stroke. Investigations link many major industrial catastrophes to sleepiness. Sleepiness is a serious, potentially life-threatening condition that affects not only the sleepy individual but also his or her family, coworkers, and society in general. In fact, sleep-related motor vehicle accidents represent a major public safety concern, and some states have enacted criminal statutes to deter sleepy driving. Sleep disorders' direct cost per annum in the United States is estimated at \$16 billion, with indirect costs ranging upward to more than \$100 billion. [Table 16.2-1](#) lists the terms used in this section to diagnose and describe sleep disorders.

Table 16.2-1
Common Polysomnographic Measures

Sleep latency: Period of time from turning out the lights until the appearance of stage 2 sleep
Early morning awakening: Time of being continuously awake from the last stage of the sleep until the end of the sleep record (usually at 7 A.M.)
Sleep efficiency: Total sleep time or total time of the sleep record × 100
Apnea index: Number of apneas longer than 10 seconds per hour of sleep
Nocturnal myoclonus index: Number of periodic leg movements per hour
Rapid eye movement (REM) latency: Period of time from the onset of sleep until the first REM period of the night
Sleep-onset REM period: REM sleep within the first 10 minutes of sleep.

SLEEP DISORDER CLASSIFICATION

DSM-5

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) of the American Psychiatric Association (APA) lists ten disorders or disorder groups as sleep-wake disorders. The DSM-5 classifies sleep disorders on the basis of clinical diagnostic criteria and presumed etiology. The disorders described in DSM-5 are only a fraction of the known sleep disorders; they provide a framework for clinical assessment. The sleep-wake disorders' current classifications in accordance with the DSM-5 include the following:

1. Insomnia Disorder
2. Hypersomnolence Disorder
3. Narcolepsy
4. Breathing-Related Sleep Disorders:
 - a. Obstructive Sleep Apnea Hypopnea
 - b. Central Sleep Apnea
 - i. Idiopathic central sleep apnea
 - ii. Cheyne-Stokes breathing
 - iii. Central sleep apnea comorbid with opioid use
 - c. Sleep-Related Hypoventilation
5. Circadian Rhythm Sleep-Wake Disorders:
 - a. Delayed sleep phase type
 - b. Advanced sleep phase type
 - c. Irregular sleep-wake type
 - d. Non-24-hour sleep-wake type
 - e. Shift work type
 - f. Unspecified type
6. Parasomnias
7. Non-Rapid Eye Movement Sleep Arousal Disorders:
 - a. Sleepwalking type
 - b. Sleep terror type
8. Nightmare Disorder
9. Rapid Eye Movement Sleep Behavior Disorder
10. Restless Legs Syndrome
11. Substance/Medication-Induced Sleep Disorder

Other Classification Systems

ICSD-2. A different classification system of sleep-wake disorders is used by the American Sleep Disorders Association published in the

second edition of *International Classification of Sleep Disorders: Diagnostic and Coding Manual (ICSD-2)*. ICSD-2 provides a detailed and comprehensive classification system for sleep-wake disorders. Table 16.2-2 presents an outline of this classification.

Table 16.2-2

Outline of Sleep-Wake Disorders in the Second Edition of the International Classification of Sleep Disorders

- I. Insomnia
 - 1. Adjustment Insomnia
 - 2. Psychophysiological Insomnia
 - 3. Paradoxical Insomnia
 - 4. Idiopathic Insomnia
 - 5. Insomnia Due to Mental Disorder
 - 6. Inadequate Sleep Hygiene
 - 7. Behavioral Insomnia of Childhood
 - 8. Insomnia Due to Drug or Substance
 - 9. Insomnia Due to Medical Condition
 - 10. Insomnia Not Due to Substance or Known Physiological Condition, Unspecified (*Nonorganic Insomnia, NOS*)
 - 11. Physiological (*Organic*) Insomnia, Unspecified
- II. Sleep-Related Breathing Disorders
 - A. Central Sleep Apnea Syndromes
 - 1. Primary Central Sleep Apnea
 - 2. Central Sleep Apnea Due to Cheyne-Stokes Breathing Pattern
 - 3. Central Sleep Apnea Due to High-Altitude Periodic Breathing
 - 4. Central Sleep Apnea Due to Medical Condition Not Cheyne-Stokes
 - 5. Central Sleep Apnea Due to Drug or Substance
 - 6. Primary Sleep Apnea of Infancy
 - B. Obstructive Sleep Apnea Syndrome
 - 7. Obstructive Sleep Apnea, Adult
 - 8. Obstructive Sleep Apnea, Pediatric
 - C. Sleep-Related Hypoventilation/Hypoxemic Syndrome
 - 9. Sleep-Related Nonobstructive Alveolar Hypoventilation, Idiopathic
 - 10. Congenital Central Alveolar Hypoventilation Syndrome
 - D. Sleep-Related Hypoventilation/Hypoxemia Due to Medical Condition
 - 11. Sleep-Related Hypoventilation/Hypoxemia Due to Pulmonary Parenchymal or Vascular Pathology
 - 12. Sleep-Related Hypoventilation/Hypoxemia Due to Lower Airway Obstruction
 - 13. Sleep-Related Hypoventilation/Hypoxemia Due to Neuromuscular and Chest Wall Disorders
 - E. Other Sleep-Related Breathing Disorder
 - 14. Sleep Apnea/Sleep-Related Breathing Disorder, Unspecified
- III. Hypersomnia of Central Origin Not Due to a Circadian Rhythm Sleep Disorder, Sleep-Related Breathing Disorder, or Other Cause of Disturbed Nocturnal Sleep
 - 1. Narcolepsy with Cataplexy
 - 2. Narcolepsy without Cataplexy
 - 3. Narcolepsy Due to Medical Condition
 - 4. Narcolepsy, Unspecified
 - 5. Recurrent Hypersomnia
 - Kleine-Levin Syndrome
 - Menstrual-Related Hypersomnia
 - 6. Idiopathic Hypersomnia with Long Sleep Time
 - 7. Idiopathic Hypersomnia without Long Sleep Time
 - 8. Behaviorally Induced Insufficient Sleep Syndrome
 - 9. Hypersomnia Due to Medical Condition
 - 10. Hypersomnia Due to Drug or Substance
 - 11. Hypersomnia Not Due to Substance Use or Known Physiological Condition (*Nonorganic Hypersomnia, NOS*)
 - 12. Physiological (*Organic*) Hypersomnia, Unspecified (*Organic Hypersomnia, NOS*)
- IV. Circadian Rhythm Sleep Disorders
 - 1. Circadian Rhythm Sleep Disorder, Delayed-Sleep-Phase Type
 - 2. Circadian Rhythm Sleep Disorder, Advanced-Sleep-Phase Type
 - 3. Circadian Rhythm Sleep Disorder, Irregular Sleep-Wake Type
 - 4. Circadian Rhythm Sleep Disorder, Free-Running Type
 - 5. Circadian Rhythm Sleep Disorder, Jet Lag Type (*Jet Lag Disorder*)
 - 6. Circadian Rhythm Sleep Disorder, Shift Work Type (*Shift Work Disorder*)
 - 7. Circadian Rhythm Sleep Disorder Due to Medical Condition
 - 8. Other Circadian Rhythm Sleep Disorder
 - 9. Other Circadian Rhythm Sleep Disorder Due to Drug or Substance Use
- V. Parasomnias
 - A. Disorders of Arousal (from NREM Sleep)
 - 1. Confusional Arousals
 - 2. Sleepwalking
 - 3. Sleep Terrors
 - B. Parasomnias Usually Associated with REM Sleep
 - 4. REM Sleep Behavior Disorder (including Parasomnia Overlap Disorder and Status Dissociatus)
 - 5. Recurrent Isolated Sleep Paralysis
 - 6. Nightmare Disorder
 - C. Other Parasomnias
 - 7. Sleep-Related Dissociative Disorder
 - 8. Sleep Enuresis
 - 9. Sleep-Related Groaning (*Cathrenia*)
 - 10. Exploding Head Syndrome
 - 11. Sleep-Related Hallucinations
 - 12. Sleep-Related Eating Disorder
 - 13. Parasomnia, Unspecified
 - 14. Parasomnia Due to Drug or Substance
 - 15. Parasomnia Due to Medical Condition
- IV. Sleep-Related Movement Disorders
 - 1. Restless Legs Syndrome
 - 2. Periodic Limb Movement Disorder
 - 3. Sleep-Related Leg Cramps
 - 4. Sleep-Related Bruxism
 - 5. Sleep-Related Rhythmic Movement
 - 6. Sleep-Related Movement Disorder, Unspecified
 - 7. Sleep-Related Movement Disorder Due to Drug or Substance
 - 8. Sleep-Related Movement Disorder Due to Medical Condition
- VII. Isolated Symptoms, Apparently Normal Variants, and Unresolved Issues
 - 1. Long Sleeper
 - 2. Short Sleeper
 - 3. Snoring
 - 4. Sleep Talking
 - 5. Sleep Starts (*Hypnic Jerk*)
 - 6. Benign Sleep Myoclonus of Infancy
 - 7. Hypnagogic Foot Tremor and Alternating Leg Muscle Activation during Sleep
 - 8. Propriospinal Cyclones at Sleep Onset
 - 9. Excessive Fragmentary Myoclonus
- VIII. Other Sleep Disorders
 - 1. Other Physiological (*Organic*) Sleep Disorders
 - 2. Other Sleep Disorder Not Due to Substance or Known Physiological Conditions
 - 3. Environmental Sleep Disorder

NOS, not otherwise specified; NREM, non-rapid eye movement; REM, rapid eye movement.

ICD-10. The tenth revision of the *International Statistical Classification of Diseases and Related Health Problems (ICD-10)* of the World Health Organization (WHO) includes many (but not all) of the ICSD-2 diagnostic classifications. In addition, their organizational schemas differ from DSM-5 and often lump multiple nosological entities into a single diagnostic classification. The subject of sleep disorders covers only those of nonorganic type in ICD-10. These disorders are classified as dyssomnias, psychogenic conditions “in which the predominant disturbances...[are] in the amount, quality, or timing of sleep” because of emotional causes, and parasomnias, “abnormal episodic events occurring during sleep.” The dyssomnias include insomnia, hypersomnia, and disorder of the sleep-wake schedule. The parasomnias in childhood are related to development; those in adulthood are psychogenic and include sleepwalking, sleep terrors, and nightmares. Sleep disorders of organic origin, nonpsychogenic disorders such as narcolepsy and cataplexy, and sleep apnea and episodic movement disorders are discussed under other categories.

The ICD-10 notes that sleep disorders are often symptoms of other disorders, but even when they are not, the specific sleep disorder should be diagnosed along with as many other relevant diagnoses as necessary to describe the “psychopathology and/or pathophysiology involved in a given case.” Table 16.2-3 presents the ICD-10 criteria for nonorganic sleep disorders.

Table 16.2-3

ICD-10 Diagnostic Criteria for Nonorganic Sleep Disorders

Note: A more comprehensive classification of sleep disorders is available (*International Classification of Sleep Disorders*⁴), but it should be noted that this is organized differently from ICD-10.

For some research purposes, where particularly homogeneous groups of sleep disorders are required, four or more events occurring within a 1-year period may be considered as a criterion for use of categories sleepwalking (somnambulism), sleep terrors (night terrors), and nightmares.

Nonorganic Insomnia

- A. The individual complains of difficulty falling asleep, difficulty maintaining sleep, or nonrefreshing sleep.
- B. The sleep disturbance occurs at least 3 times a week for at least 1 month.
- C. The sleep disturbance results in marked personal distress or interference with personal functioning in daily living.
- D. There is no known causative organic factor, such as a neurological or other medical condition, psychoactive substance use disorder, or a medication.

Nonorganic Hypersomnia

- A. The individual complains of excessive daytime sleepiness or sleep attacks or of prolonged transition to the fully aroused state upon awakening (sleep drunkenness), which is not accounted for by an inadequate amount of sleep.
- B. This sleep disturbance occurs nearly every day for at least 1 month or recurrently for shorter periods of time and causes either marked distress or interference with personal functioning in daily living.
- C. There are no auxiliary symptoms of narcolepsy (cataplexy, sleep paralysis, hypnagogic hallucinations) and no clinical evidence for sleep apnea (nocturnal breath cessation, typical intermittent snoring sounds, etc.).
- D. There is no known causative organic factor, such as a neurological or other medical condition, psychoactive substance use disorder, or a medication.

Nonorganic Disorder of the Sleep-Wake Schedule

- A. The individual's sleep-wake pattern is out of synchrony with the desired sleep-wake schedule, as imposed by societal demands and shared by most people in the individual's environment.
- B. As a result of disturbance of the sleep-wake schedule, the individual experiences insomnia during the major sleep period or hypersomnia during the waking period, nearly every day for at least 1 month or recurrently for shorter periods of time.
- C. The unsatisfactory quantity, quality, and timing of sleep causes either marked personal distress or interference with personal functioning in daily living.
- D. There is no known causative organic factor such as a neurological or other medical condition, psychoactive substance use disorder, or a medication.

Sleepwalking (Somnambulism)

- A. The predominant symptom is repeated (two or more) episodes of rising from bed, usually during the first third of nocturnal sleep, and walking about for between several minutes and half an hour.
- B. During an episode, the individual has a blank, staring face, is relatively unresponsive to the efforts of others to influence the event or to communicate with him or her, and can be awakened only with considerable difficulty.
- C. Upon awakening (either from an episode or the next morning), the individual has amnesia for the episode.
- D. Within several minutes of awakening from the episode, there is no impairment of mental activity or behavior, although there may initially be a short period of some confusion and disorientation.
- E. There is no evidence of an organic mental disorder, such as dementia, or a physical disorder, such as epilepsy.

Sleep Terrors (Night Terrors)

- A. Repeated (two or more) episodes in which the individual gets up from sleep with a panicky scream and intense anxiety, body motility, and autonomic hyperactivity (such as tachycardia, heart pounding, rapid breathing, and sweating).
- B. The episodes occur mainly during the first third of sleep.
- C. The duration of the episode is less than 10 minutes.
- D. If others try to comfort the individual during the episode, there is a lack of response followed by disorientation and preservative movements.
- E. The individual has limited recall of the event.
- F. There is no known causative organic factor, such as neurological or other medical condition, psychoactive substance use disorder, or a medication.

Nightmares

- A. The individual wakes from nocturnal sleep or naps with detailed and vivid recall or intensely frightening dreams, usually involving threats to survival, security, or self-esteem. The awakening may occur during any part of the sleep period, but typically during the second half.
- B. Upon awakening from the frightening dreams, the individual rapidly becomes oriented and alert.
- C. The dream experience itself and the disturbance of sleep resulting from the awakenings associated with the episodes cause marked distress to the individual.
- D. There is no known causative organic factor, such as neurological or other medical condition, psychoactive substance use disorder, or a medication.

Other Nonorganic Sleep Disorders

Nonorganic Sleep Disorder, Unspecified

INSOMNIA DISORDER

Insomnia is defined as difficulty initiating or maintaining sleep. It is the most common sleep complaint and may be transient or persistent. Population surveys show a 1-year prevalence rate of 30 to 45 percent in adults.

DSM-5 defines insomnia disorder as dissatisfaction with sleep quantity or quality associated with one or more of the following symptoms: difficulty in initiating sleep, difficulty in maintaining sleep with frequent awakenings or problems returning to sleep, and early morning awakening with inability to return to sleep (Table 16.2-4).

Table 16.2-4
DSM-5 Diagnostic Criteria for Insomnia Disorder

- A. A predominant complaint of dissatisfaction with sleep quantity or quality, associated with one (or more) of the following symptoms:
1. Difficulty initiating sleep. (In children, this may manifest as difficulty initiating sleep without caregiver intervention.)
 2. Difficulty maintaining sleep, characterized by frequent awakenings or problems returning to sleep after awakenings. (In children, this may manifest as difficulty returning to sleep without caregiver intervention.)
 3. Early-morning awakening with inability to return to sleep.
- B. The sleep disturbance causes clinically significant distress or impairment in social, occupational, educational, academic, behavioral, or other important areas of functioning.
- C. The sleep difficulty occurs at least 3 nights per week.
- D. The sleep difficulty is present for at least 3 months.
- E. The sleep difficulty occurs despite adequate opportunity for sleep.
- F. The insomnia is not better explained by and does not occur exclusively during the course of another sleep-wake disorder (e.g., narcolepsy, a breathing-related sleep disorder, a circadian rhythm sleep-wake disorder, a parasomnia).
- G. The insomnia is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication).
- H. Coexisting mental disorders and medical conditions do not adequately explain the predominant complaint of insomnia.
- Specify if:
- With non-sleep disorder mental comorbidity, including substance use disorders
 - With other medical comorbidity
 - With other sleep disorder
- Coding note:** The code 780.52 (G47.00) applies to all three specifiers. Code also the relevant associated mental disorder, medical condition, or other sleep disorder immediately after the code for insomnia disorder in order to indicate the association.
- Specify if:
- Episodic:** Symptoms last at least 1 month but less than 3 months.
 - Persistent:** Symptoms last 3 months or longer.
 - Recurrent:** Two (or more) episodes within the space of 1 year.
- Note:** Acute and short-term insomnia (i.e., symptoms lasting less than 3 months but otherwise meeting all criteria with regard to frequency, intensity, distress, and/or impairment) should be coded as an other specified insomnia disorder.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

It is now recognized that insomnia can be an independent condition. In the past, practitioners were admonished to treat insomnia's cause rather than the symptoms. There was an implicit notion that by doing so, the sleep problems would improve. Clinical experience suggested otherwise. Consequently, current therapeutics favor providing relief and managing symptoms. In the past it was argued that if insomnia was related to depression, treating the insomnia would mask the depression and thereby interfere with antidepressant treatment regimens. This does not appear to happen.

Descriptively, insomnia can be categorized in terms of how it affects sleep (e.g., sleep-onset insomnia, sleep-maintenance insomnia, or early-morning awakening). Insomnia can also be classified according to its duration (e.g., transient, short term, and long term). According to the Gallup Survey, approximately one third of the US population has several serious bouts of insomnia yearly; however, in 9 percent of the general population, insomnia is a chronic condition. Individuals with chronic insomnia have more than twice as many motor vehicle accidents as the general population, but only 5 percent of those with chronic insomnia see a health care provider to seek help for sleeplessness. Nonetheless, 40 percent or more of those individuals with chronic insomnia self-medicate with over-the-counter drugs, alcohol, or both.

A brief period of insomnia is most often associated with anxiety, either as a sequela to an anxious experience or in anticipation of an anxiety-provoking experience (e.g., an examination or an impending job interview). In some persons, transient insomnia of this kind may be related to grief, loss, or almost any life change or stress. The condition is not likely to be serious, although a psychotic episode or a severe depression sometimes begins with acute insomnia. Specific treatment for the condition is usually not required. When treatment with hypnotic medication is indicated, both the physician and the patient should be clear that the treatment is of short duration and that some symptoms, including a brief recurrence of the insomnia, may be expected when the medication is discontinued.

Persistent insomnia is composed of a fairly common group of conditions in which the problem is difficulty falling asleep or remaining asleep. This insomnia involves two sometimes separable, but often intertwined, problems: somatized tension and anxiety and a conditioned associative response. Patients often have no clear complaint other than insomnia. They may not experience anxiety per se but discharge the anxiety through physiological channels; they may complain chiefly of apprehensive feelings or ruminative thoughts that appear to keep them from falling asleep. Sometimes (but not always) a patient describes the condition's exacerbation at times of stress at work or at home and its remission during vacations.

Sleep state misperception (also known as *subjective insomnia*) is characterized by a dissociation between the patient's experience of sleeping and the objective polygraphic measures of sleep. The ultimate cause of this dissociation is not yet understood, although it appears to be a specific case of a general phenomenon seen in many areas of medicine. Sleep state misperception is diagnosed when a patient complains of difficulty initiating or maintaining sleep and no objective evidence of sleep disruption is found. For example, a patient sleeping in the laboratory reports taking more than an hour to fall asleep, awakening more than 30 times, and sleeping less than 2 hours the entire night. By contrast, the polysomnogram shows sleep onset occurring within 15 minutes, few awakenings, a 90 percent sleep efficiency, and total sleep time exceeding 7 hours. Sleep state misperception can occur in individuals who are apparently free from psychopathology or it can represent a somatic delusion or hypochondriasis. Some patients with sleep state misperception have obsessional features concerning somatic functions. Short-term sleep state misperception can occur during periods of stress, and some clinicians believe it can result from latent or ineffectively treated anxiety or depressive disorders. Cognitive relabeling, diffusing the worry about being unable to sleep, or both can help. Interestingly, anxiolytics can profoundly reduce the perception of sleeplessness without markedly changing sleep physiologically.

Psychophysiological insomnia typically presents as a primary complaint of difficulty in going to sleep. A patient may describe this as having gone on for years and usually denies that it is associated with stressful periods in his or her life. Objects associated with sleep (e.g., the bed, the bedroom) likewise become conditioned stimuli that evoke insomnia. Thus, psychophysiological insomnia is sometimes called *conditioned insomnia*. Psychophysiological insomnia often occurs in combination with other causes of insomnia, including episodes of stress and anxiety disorders, delayed sleep phase syndrome, and hypnotic drug use and withdrawal. In contrast to the insomnia in patients with psychiatric disorders, daytime adaptation is generally good. Work and relationships are satisfying; however, extreme tiredness can exist. Other features include (1) excessive worry about not being able to sleep; (2) trying too hard to sleep; (3) rumination, inability to clear one's mind while trying to sleep; (4) increased muscle tension when attempting to sleep; (5) other somatic manifestations of anxiety; (6) being able to sleep better away from one's own bedroom; and (7) being able to fall asleep when not trying (e.g., watching television). The sleep complaint becomes fixed over time. Interestingly, many patients with psychophysiological insomnia sleep well in the laboratory.

Ms. W, a 41-year-old divorced white woman, presented with a 2.5-year complaint of sleeplessness. She had some difficulty falling asleep (30 to 45 minutes sleep onset latency) and awakened every hour or two after sleep onset. These awakenings could last 15 minutes to several hours, and she estimated approximately 4.5 hours of sleep on an average night. She rarely took daytime naps notwithstanding feeling tired and edgy. She described her sleep problem as follows: "It seems like I never get into a deep sleep. I have never been a heavy sleeper, but now the slightest noise wakes me up. Sometimes I have a hard time getting my mind to shut down." She viewed the bedroom as an unpleasant place of sleeplessness and stated, "I tried staying at a friend's house where it is quiet, but then I couldn't sleep because of the silence."

At times, Ms. W would be unsure whether she was asleep or awake. She had a history of clock watching (to time her wakefulness) but

stopped doing this when she realized it was contributing to the problem. Reportedly the insomnia is unrelated to seasonal changes, menstrual cycle, or time-zone translocation. Her basic sleep hygiene was good. Appetite and libido were unchanged. She denied mood disturbance, except that she was quite frustrated and concerned about sleeplessness and its effect on her work. Her work involved sitting at a microscope for 6 hours of a 9-hour working day and meticulously documenting her findings. Her final output had not suffered, but she now had to “double check” for accuracy.

She described herself as a worrier and a Type A personality. She did not know how to relax. For example, on vacation she continually worried about things that could go wrong. She could not even begin to unwind until she had arrived at the destination, checked in, and unpacked. Even then, she was unable to relax.

Medical history was unremarkable except for tonsillectomy (age 16 years), migraine headaches (current), and diet-controlled hypercholesterolemia. She took naproxen (Aleve) as needed for headache. She did not drink caffeinated beverages, smoke tobacco, or drink alcoholic beverages. She did not use recreational drugs.

The problem with insomnia began after relocation to a new city and place of employment. She attributed her insomnia to the noisy neighborhood in which she lived. She first sought treatment 18 months previously. Her family practice physician diagnosed depression and she was started on fluoxetine (Prozac), which made her “climb the walls.” Antihistamines were tried next with similar results. She was then switched to low-dose trazodone (Desyrel; for sleep) and developed nausea. After these medical interventions, she sought medical care elsewhere. Zolpidem (Ambien), 5 mg, was prescribed, but it made her feel drugged, and on discontinuation she had withdrawal effects. Another family practice physician diagnosed “nonspecific anxiety disorder” and began buspirone (BuSpar), an experience she described as “having an alien try to climb out of my skin.” Buspirone was discontinued. Paroxetine (Paxil) was tried for 8 weeks with no effect. Finally, a psychiatrist was consulted, who diagnosed adult attention-deficit disorder (without hyperactivity) and suggested treatment with methylphenidate (Ritalin). At this point, the patient was convinced that a stimulant would not help her insomnia and demanded referral to a sleep disorders center.

Ms. W’s symptoms fell into the broad category of insomnia, and the symptoms had begun after she had moved from one city to another. Environmental sleep disorder (noise) and adjustment sleep disorder (new job, city, and apartment) were likely initial diagnoses. However, a more chronic, endogenous problem had become operative. Ms. W was a “worrier” and meticulous, but she did not reach diagnostic criteria for personality or anxiety disorders. Dyssomnia associated with mood disorder should be considered in any patient with sleep maintenance problems and early-morning awakening insomnia. However, this patient did not have other significant signs of depression. Unfortunately, many patients are misdiagnosed with depression or “masked depression” on the sole basis of an insomnia complaint and unsuccessfully treated with antidepressant medication. Ms. W’s job demanded long hours with focused concentration. Her job performance had been superior for many years notwithstanding insomnia. Thus, a diagnosis of attention-deficit disorder was unlikely. Idiopathic insomnia implies a childhood complaint, which Ms. W denied.

The likely working diagnosis was psychophysiological insomnia (PPI). There may have been some sleep state misperception (she was sometimes unclear on whether she was awake or asleep), but this could not adequately account for the constellation of symptoms. An initial treatment plan should include further documentation of the sleep pattern using a sleep log. Behavioral treatments would likely benefit this patient. Medications with sedative effects are sometimes useful during the initial treatment of PPI. However, thus far in this patient they had done more harm than good. She would likely be a challenging patient to treat. (Courtesy of Max Hirshkowitz, Ph.D., Rhoda G. Seplowitz-Hafkin, M.D., and Amir Sharafkhaneh, M.D., Ph.D.)

Idiopathic insomnia typically starts early in life, sometimes at birth, and continues throughout life. As the name implies, its cause is unknown; suspected causes include neurochemical imbalance in brainstem reticular formation, impaired regulation of brainstem sleep generators (e.g., raphe nuclei, locus ceruleus), or basal forebrain dysfunction. Treatment is difficult, but improved sleep hygiene, relaxation therapy, and judicious use of hypnotic medicines are reportedly helpful.

Primary insomnia is diagnosed when the chief complaint is nonrestorative sleep or difficulty in initiating or maintaining sleep, and the complaint continues for at least a month (according to ICD-10, the disturbance must occur at least three times a week for a month). The term *primary* indicates that the insomnia is independent of any known physical or mental condition. Primary insomnia is often characterized both by difficulty falling asleep and by repeated awakening. Increased nighttime physiological or psychological arousal and negative conditioning for sleep are frequently evident. Patients with primary insomnia are generally preoccupied with getting enough sleep. The more they try to sleep, the greater the sense of frustration and distress and the more elusive sleep becomes.

Treating Insomnia

Pharmacological Treatment. Primary insomnia is commonly treated with benzodiazepines, zolpidem, eszopiclone (Lunesta), zaleplon (Sonata), and other hypnotics. Hypnotic drugs should be used with care. In general, sleep medications should not be prescribed for more than 2 weeks because tolerance and withdrawal may result. For many years, benzodiazepines were the most commonly prescribed sedative-hypnotic medications for treating insomnia. Benzodiazepine-receptor agonists represent the current standard for sedative-hypnotic medications used to treat insomnia. Long-acting sleep medications (e.g., flurazepam [Dalmane], quazepam [Doral]) are best for middle-of-the-night insomnia; short-acting drugs (e.g., zolpidem, triazolam [Halcion]) are useful for persons who have difficulty falling asleep. The melatonin-receptor agonist ramelteon (Rozerem) has also been approved for treating sleep-onset insomnia. Sedating antidepressants, such as trazodone, are also frequently prescribed as sleep aids.

A variety of over-the-counter (OTC) sleep aids are also available. Nonprescription formulas include sedating antihistamines, protein precursors, and other substances. L-Tryptophan was popular and readily available at health food stores until an outbreak of eosinophilia led to its being pulled off the shelves. Melatonin is a leader among self-administered food additives believed by some to alleviate sleeplessness. Melatonin is an endogenous hormone produced by the pineal gland, which is linked to the regulation of sleep. Administration of exogenous melatonin has yielded mixed results, however, in clinical research.

Prescription medicines are rigorously tested in clinical trials; therefore, they hold an advantage over the virtually untested OTCs. To attain U.S. Food and Drug Administration (FDA) approval as a hypnotic, a medication must be safe and effective. Most hypnotic medications are approved for short-term, not long-term, use. Exceptions include zolpidem modified release, eszopiclone, and ramelteon, all of which are approved for long-term therapy. When properly used, hypnotics can provide immediate and adequate relief from sleeplessness. Insomnia, however, usually returns on discontinuation of dosing.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) as a treatment modality uses a combination of behavioral and cognitive techniques to overcome dysfunctional sleep behaviors, misperceptions, and distorted, disruptive thoughts about sleep. Behavioral techniques include universal sleep hygiene, stimulus control therapy, sleep restriction therapy, relaxation therapies, and biofeedback.

Studies repeatedly show significant improvement in sleep symptoms, including number and duration of awakenings and sleep latency from CBT. Short-term benefits are similar to that of medication, but CBT tends to have lasting benefits even 36 months after treatment. With cessation of the medication, insomnia frequently returns and is sometimes accompanied by rebound insomnia. CBT has not been shown to produce any adverse effects. There are no established “best practice” guidelines for length or quantity of sessions.

CBT, however, is not without limitations. Most data do not compare the efficacy of the individual components of CBT. However, sleep

hygiene education alone produces an insignificant effect on sleep. In addition, there are no studies demonstrating evidence for improved efficacy with the combination of the aforementioned components or what cognitive therapy adds to the behavioral component. Intuitively, it would seem that the multicomponent approach addresses many of the variables contributing to insomnia.

The effects of CBT take longer to emerge than effects of medications. Usually when patients finally come for treatment of their insomnia, they are desperate. This makes it difficult to convince them to try a therapy that may take several weeks before it will provide relief. Furthermore, patients do not assume a passive role in this type of therapy; they must be active participants. Many individuals not only want a “quick fix,” but they also want to undergo a procedure or have something administered rather than be involved in the therapeutic process. For CBT to be effective, patients must commit to come to multiple sessions and also be open to the idea that modifying thoughts and behaviors about sleep can improve the symptoms of insomnia. The “quick fix” model is more familiar to primary care providers, whereas psychiatrists are used to the delayed response of antidepressants and other psychotropics. Therefore, psychiatrists may be more amenable to recommending CBT. Another barrier for physicians using CBT in clinical practice is that providing CBT for insomnia requires a greater time commitment than prescribing a sleep aid.

Although firmly focused on cognitive and behavioral issues, it helps to extend CBT just slightly into the psychodynamic sphere. For some patients with long-standing difficulty sleeping, being an insomniac becomes an important part of their identity. There may be primary or secondary gain to such identification. It is the negative emotional response (i.e., anger at the inability to control one’s sleep, feeling like a failure because one cannot sleep) to insomnia that contributes to its chronicity. In general, these individuals tend to internalize rather than express emotion, feel a heightened need for control, experience interpersonal difficulties, and have significant discontent with past events. For this subset of people, if the emotional response is not addressed, there is more likely to be a limited response to CBT or a relapse of insomnia over time. The clinician who is attuned to a patient’s tendency to view something as a failure rather than a challenge will be better able to intercept barriers to treatment.

Universal Sleep Hygiene. A common finding is that a patient’s lifestyle leads to sleep disturbance. This is usually phrased as *inadequate sleep hygiene*, referring to a problem in following generally accepted practices to aid sleep. These include, for instance, keeping regular hours of bedtime and arousal, avoiding excessive caffeine, not eating heavy meals before bedtime, and getting adequate exercise. Many behaviors can interfere with sleep and may do so by increasing nervous system arousal near bedtime or by altering circadian rhythms.

The focus of universal sleep hygiene is on modifiable environmental and lifestyle components that may interfere with sleep, as well as behaviors that may improve sleep. Treatment should focus on one to three problem areas at a time. Especially because some of these behaviors are difficult to change, only one or two items that are collaboratively chosen by the patient and clinician should be addressed. This gives the patient the best chance at a successful intervention. Overwhelming the patient with too many lifestyle changes or a complex regimen seldom succeeds. Some general “dos and don’ts” are instructive. Sleep-enhancing directives are enumerated in [Table 16.2-5](#). Often a few simple alterations in a patient’s habits or sleep environment can be effective. The clinician, however, needs to spend time reviewing both the patient’s routine and its irregularity. In some respects, the essence of insomnia is its variability. The day-to-day changes in behavior and the changing severity of sleeplessness can obscure the factors responsible for the problem. A carefully explained program of sleep hygiene, with follow-up, represents a fairly inexpensive but effective intervention. Furthermore, improving sleep habits can enhance sleep even when the major cause of insomnia is physical.

 **Table 16.2-5**
Dos and Don’ts for Good Sleep Hygiene

	DO	DON'T
Maintain regular hours of bedtime and arising	✓	
If you are hungry, have a light snack before bedtime	✓	
Maintain a regular exercise schedule	✓	
Give yourself approximately an hour to wind down before going to bed	✓	
If you are preoccupied or worried about something at bedtime, write it down and deal with it in the morning	✓	
Keep the bedroom cool	✓	
Keep the bedroom dark	✓	
Keep the bedroom quiet	✓	
Take naps		✓
Watch the clock so you know how bad your insomnia actually is		✓
Exercise right before going to bed in order wear yourself out		✓
Watch television in bed when you cannot sleep		✓
Eat a heavy meal before bedtime to help you sleep		✓
Drink coffee in the afternoon and evening		✓
If you cannot sleep, smoke a cigarette		✓
Use alcohol to help in going to sleep		✓
Read in bed when you cannot sleep		✓
Eat in bed		✓
Exercise in bed		✓
Talk on the phone in bed		✓

Stimulus Control Therapy. Stimulus control therapy is a deconditioning paradigm developed by Richard Bootzin and colleagues at the University of Arizona. This treatment aims to break the cycle of problems commonly associated with difficulty initiating sleep. By attempting to undo conditioning that undermines sleep, stimulus control therapy helps reduce both primary and reactive factors involved in insomnia. The rules attempt to enhance stimulus cues for sleeping and diminish associations with sleeplessness. The instructions are simple; however, they must be followed consistently. The *first* rule is, go to bed only when sleepy to maximize success. *Second*, use the bed only for sleeping. Do not watch television in bed, do not read, do not eat, and do not talk on the telephone while in bed. *Third*, do not lie in bed and become frustrated if unable to sleep. After a few minutes (do not watch the clock), get up, go to another room, and do something nonarousing until sleepiness returns. The goal is to associate the bed with rapid sleep onset. Rule three should be repeated as often as needed. The *fourth and final* instruction attempts to enhance the mechanisms underlying the circadian and sleep-wake cycles—that is, awaken at the same time every morning (regardless of bedtime, total sleep time, or day of week) and totally avoid napping. Stimulus control therapy does work; however, results might not be seen during the first few weeks or month. If continually practiced, the bouts of insomnia lessen in both frequency and severity.

Sleep Restriction Therapy. Sleep restriction therapy is a strategy designed to increase sleep efficiency by decreasing the amount of

time spent awake while lying in bed. Developed by Arthur Spielman, this therapy specifically targets those patients who lie awake in bed unable to sleep. Restricting time in bed can help to consolidate sleep. If the patient reports sleeping only 5 hours of a scheduled 8-hour time in bed, reduce the time in bed. It is advised, however, not to reduce bedtime to less than 4 hours per night and to warn the patient about the hazards of daytime sleepiness. Sleep at other times during the day must be avoided, except in the elderly, who may take a 30-minute nap. The clinician then monitors sleep efficiency (time asleep as a percentage of the time in bed). When sleep efficiency reaches 85 percent (averaged over five nights), time in bed is increased by 15 minutes. Sleep restriction therapy produces a gradual and steady decline in nocturnal wakefulness.

Relaxation Therapy and Biofeedback. The most important aspects of relaxation therapy are that it be performed properly. Self-hypnosis, progressive relaxation, guided imagery, and deep breathing exercises are all effective if they produce relaxation. The goal is to find the optimal technique for each patient, but not all patients need help in relaxing. *Progressive muscle relaxation* is especially useful for patients who experience muscle tension. The patients should purposefully tense (5 to 6 seconds) and then relax (20 to 30 seconds) muscle groups, beginning at the head and ending at the feet. The patient should appreciate the difference between tension and relaxation. *Guided imagery* has the patient visualize a pleasant, restful scene, engaging all of his or her senses. *Breathing exercises* are practiced for at least 20 minutes per day for 2 weeks. Once mastered, the technique should be used once at bedtime for 30 minutes. If it does not work, the patient should try again another night. It is important that the technique not become associated with failure to fall asleep.

The patient is instructed to perform *abdominal breathing* as follows. The patient must become comfortable with each step before moving on to the next:

First, in the supine position, the patient should breathe normally through his or her mouth or nose, whichever is more comfortable, and attend to his or her breathing pattern.

Second, while maintaining that rhythm, the patient should begin to breathe more with his or her abdomen and less with his or her chest.

Third, the patient should pause for a half second after each breath cycle (in and out) and evaluate the breath. How did it feel? Was it smooth? Eventually each breath will become uniform and smooth.

Fourth, the patient should find a place where he or she can best feel the air move in and out. Concentrate on that spot and on the air moving in and out.

Fifth, the patient should visualize intrusive thoughts as floating away; if there are too many thoughts, stop practicing and try again later.

Biofeedback provides stimulus cues for physiological markers of relaxation and can increase self-awareness. A machine is used to measure muscle tension in the forehead or finger temperature. Finger temperature rises when a person becomes more relaxed. Patients require careful and adequate training; simply giving them an instruction tape is not especially helpful. Techniques are ideally mastered during the day for several weeks before application to the sleep problem; this is best achieved outside of the bed. By the time the techniques are applied in bed, the skill should be automatic. Relaxation techniques readily lend themselves to being combined with sleep hygiene and stimulus control therapies. Sometimes, they make for good distractions from thinking about the inability to sleep. The ruminations fuel the insomnia, and if the ruminator can be distracted, then the person may sleep better.

Cognitive Training. This effective, validated treatment for a variety of psychiatric conditions, including major depression and generalized anxiety, has been adapted for use with insomnia. The cognitive aspect of insomnia treatment targets the negative emotional response to an appraisal of a sleep-related situation. The negative emotional response is thought to produce emotional arousal, which in turn contributes to or perpetuates insomnia. People who have maladaptive cognitions tend to exaggerate the negative consequences of insomnia: "There must be something really wrong with me if I can't fall asleep in 40 minutes." They also tend to have unrealistic expectations about their sleep requirements: "If I don't sleep 8 hours a night then my whole day will be ruined." The first step is to identify these cognitions, then challenge their validity, and finally substitute them with more adaptive cognitions.

DH was a 42-year-old man with a 5-year history of insomnia. He identified being fired from his job and the birth of a colicky baby as precipitating factors in his inability to sleep. However, even after he found a new position with better hours and pay and with the child sleeping through the night, DH continued to experience difficulty falling and staying asleep. Perpetuating factors included low back pain and a spouse with periodic limb movement disorder. He reported spending 8 to 9 hours in bed each night and sleeping only 4 to 5 hours intermittently. He watched 1 hour of television in bed before turning out the light for bedtime. He spent hours watching his minutes tick away. He did not awake feeling rested, and when his alarm went off he was frequently already awake and had thoughts such as, "I hardly slept at all last night. I should be able to get more sleep. There must be something wrong with me. Great, I'll be too tired to concentrate on anything today."

Examples of maladaptive thoughts: "I should be able to get more sleep." This is a faulty appraisal of sleeping ability and may relate to a need for control over sleep. This need for control interferes with having a more laissez-faire attitude about a few missed hours of rest. Such thoughts can also lead to feelings of frustration and anger. "Great, I'll be too tired to concentrate on anything today." This is a misattribution of daytime impairment due to poor sleep. DH was also magnifying the negative and discounting the positive with his black-and-white or all-or-nothing thinking. Could DH be too tired to concentrate on some things but not all things? Might his inability to concentrate be due to a myriad of other factors? "There must be something wrong with me [if I can't get enough sleep]." This is catastrophizing and emotional reasoning: Just because a person had a feeling does not mean that the thought or feeling is true. A strongly held belief that sleeplessness negatively affects physical and mental health can set off catastrophizing. (Courtesy of Max Hirshkowitz, Ph.D., Rhoda G. Sepulowitz-Hafkin, M.D., and Amir Sharafkhaneh, M.D., Ph.D.)

Paradoxical Intention. This is a cognitive technique with conflicting evidence regarding its efficacy. In clinical practice compliance is often a barrier, but it does work for a limited number of patients. The theory is that performance anxiety interferes with sleep onset. Thus, when the patient tries to stay awake for as long as possible rather than trying to fall asleep, performance anxiety will be reduced and sleep latency will improve.

HYPERMORNOLENCE DISORDER

Excessive sleepiness (hypersomnolence) is a serious, debilitating, potentially life-threatening noncommunicable condition. It affects not only the afflicted individual but also his or her family, coworkers, and the public at large. Sleepiness can be a consequence of (1) insufficient sleep, (2) basic neurologic dysfunction in brain systems regulating sleep, (3) disrupted sleep, or (4) the phase of an individual's circadian rhythm. A sleep history questionnaire is often helpful in diagnosing a patient's sleep disorder (Table 16.2-6). The sleep debt produced by insufficient sleep is cumulative. If one reduces sleep duration by 1 to 2 hours per night and continues this regimen for a week, sleepiness will reach pathological levels. When sleep debt is added to sleep disruption or a basic neurologic dysfunction in sleep mechanisms, there is increasing risk that an individual will lapse unexpectedly into sleep. Sleep onset in such circumstances characteristically occurs without warning. Sleepiness can be episodic and occur as irresistible sleep attacks, occur in the morning as sleep drunkenness, or be chronic. Fatigue,

tiredness, and sleepiness are terms that are used by most people synonymously; however, one can be tired but not sleepy, sleepy but not tired, or sleepy and tired. In this section, the term *sleepiness* will refer to drowsiness, a propensity to lapse into sleep, and when extreme, an inability to maintain wakefulness.

Table 16.2-6
Sleep History Questionnaire

Patient name _____
Date _____
Please check the appropriate box or give short answers for the following:

	Yes	No
1. Do you feel sleepy or have sleep attacks during the day?	<input type="checkbox"/>	<input type="checkbox"/>
2. Do you nap during the day?	<input type="checkbox"/>	<input type="checkbox"/>
3. Do you have trouble concentrating during the day?	<input type="checkbox"/>	<input type="checkbox"/>
4. Do you have trouble falling asleep when you first go to bed?	<input type="checkbox"/>	<input type="checkbox"/>
5. Do you awaken during the night?	<input type="checkbox"/>	<input type="checkbox"/>
6. Do you awaken more than once?	<input type="checkbox"/>	<input type="checkbox"/>
7. Do you awaken too early in the morning?	<input type="checkbox"/>	<input type="checkbox"/>
8. How long have you had trouble sleeping? What do you think precipitated the problem?		

9. How would you describe your usual night's sleep (hours of sleep, quality of sleep, etc.)?		

10. Does your schedule for sleep and rising on the weekend differ from what it is during the week?	<input type="checkbox"/>	<input type="checkbox"/>
11. Do others live at home who interrupt your sleep?	<input type="checkbox"/>	<input type="checkbox"/>
12. Are you regularly awakened at night by pain or the need to use the bathroom?	<input type="checkbox"/>	<input type="checkbox"/>
13. Does your job require shift changes or travel?	<input type="checkbox"/>	<input type="checkbox"/>
14. Do you drink caffeinated beverages (coffee, tea, or soft drinks)?	<input type="checkbox"/>	<input type="checkbox"/>
15. Apart from difficulty in sleeping, what, if any, other medical problems do you have?		

16. What sleep medications, prescription or nonprescription, do you take? (Please include the dosage, how often you take it, and for how many months or years you have taken it.)		

17. What other prescription and over-the-counter medications do you regularly use? (Again, please include the dosage, the frequency, and the duration.)		

18. Have you ever suffered from depression, anxiety, or similar problems?	<input type="checkbox"/>	<input type="checkbox"/>
19. Do you snore?	<input type="checkbox"/>	<input type="checkbox"/>
Questions for the Sleep Partner		
1. Does your sleep partner snore?	<input type="checkbox"/>	<input type="checkbox"/>
2. Does your sleep partner seem to stop breathing repeatedly during the night?	<input type="checkbox"/>	<input type="checkbox"/>
3. Does your sleep partner jerk his or her legs or kick you while he or she is sleeping?	<input type="checkbox"/>	<input type="checkbox"/>
4. Have you ever experienced trouble sleeping? Please explain.	<input type="checkbox"/>	<input type="checkbox"/>

Sleepiness adversely affects attention, concentration, memory, and higher-order cognitive processes. Serious results of sleepiness include failure at school, loss of employment, motor vehicle accidents, and industrial disasters. The transportation industry, including trucking, railroad, marine, and aviation, is particularly prone to sleep-related accidents. There are many sleep disorders associated with excessive daytime sleepiness; however, sleep-disordered breathing is by far the most common dyssomnia seen in sleep disorder centers.

Primary hypersomnia is diagnosed when no other cause can be found for excessive somnolence occurring for at least 1 month. Some persons are long sleepers who, as with short sleepers, show a normal variation. Their sleep, although long, is normal in architecture and physiology. Sleep efficiency and the sleep-wake schedule are normal. This pattern is without complaints about the quality of sleep, daytime sleepiness, or difficulties with the awake mood, motivation, and performance. Long sleep may be a lifetime pattern, and it appears to have a familial incidence. Many persons are variable sleepers and may become long sleepers at certain times in their lives.

Some persons have subjective complaints of feeling sleepy without objective findings. They do not have a tendency to fall asleep more often than is normal and do not have any objective signs. Clinicians should try to rule out clear-cut causes of excessive somnolence.

Types of Hypersomnia

Kleine-Levin Syndrome. Kleine-Levin syndrome is a relatively rare condition consisting of recurrent periods of prolonged sleep (from which patients may be aroused) with intervening periods of normal sleep and alert waking. During the hypersomniac episodes, wakeful periods are usually marked by withdrawal from social contacts and return to bed at the first opportunity. Kleine-Levin syndrome is the best-recognized recurrent hypersomnia though it is uncommon. It predominantly afflicts males in early adolescence; however, it can occur later in life and in females. With few exceptions, the first attack occurs between the ages of 10 and 21 years. Rare instances of onset in the fourth and fifth decades of life have been reported. In its classic form, the recurrent episodes are associated with extreme sleepiness (18-

hour to 20-hour sleep periods), voracious eating, hypersexuality, and disinhibition (e.g., aggression). Episodes typically last for a few days up to several weeks and appear once to ten times per year. A monosymptomatic hypersomnolent form can occur. The frequency of the human leukocyte antigen (HLA) is increased in patients with this syndrome.

Menstrual-Related Hypersomnia. In some women, recurrent episodes of hypersomnia are related to the menstrual cycle, experiencing intermittent episodes of marked hypersomnia at, or shortly before, the onset of their menses. The symptoms typically last for 1 week and resolve with menstruation. Nonspecific electroencephalogram (EEG) abnormalities similar to those associated with Kleine-Levin syndrome have been documented in several instances. Endocrine factors are probably involved, but no specific abnormalities in laboratory endocrine measures have been reported. Treatment with oral contraceptives is effective, and therefore the disorder is believed to be secondary to a hormone imbalance.

Idiopathic Hypersomnia. Idiopathic hypersomnia (IH) presents in several forms. It may be associated with very long sleep periods, after which the individual remains sleepy. IH can also occur without long sleep periods. IH is a disorder of excessive sleepiness in which patients do not have the ancillary symptoms associated with narcolepsy. Unlike narcolepsy, sleep is usually well preserved, and sleep efficiency remains high even in forms associated with very extended sleep schedules (12 hours or more). Furthermore, the patient readily falls asleep if given an opportunity to nap the following day. There is often elevated slow wave sleep; however, the EEG sleep pattern is essentially the same as that found in normal individuals who are sleep deprived. Unlike a sleep-deprived individual, the sleep pattern continues in this profile even after several nights of extended sleep. As the name indicates, the etiology of idiopathic hypersomnia is not known; however, a central nervous system cause is presumed. Three general categories have been developed. Subgroup 1 includes individuals who are HLA-Cw2 positive, have autonomic nervous system dysfunctions, and have other affected family members. Subgroup 2 includes status postviral infection patients (e.g., Guillain-Barré syndrome [ascending polyneuropathy], mononucleosis, and atypical viral pneumonia). Subgroup 3 idiopathic hypersomnia patients are nonfamilial and are not postviral (i.e., truly idiopathic).

Age of onset is characteristically between 15 and 30 years, and the hypersomnia becomes a lifelong problem. In addition to the prolonged, undisturbed, and unrefreshing nocturnal sleep, IH is associated with long nonrefreshing naps, difficulty awakening, sleep drunkenness, and automatic behaviors with amnesia. Other symptoms suggesting autonomic nervous system dysfunction are typical, including migraine-like headaches, fainting spells, syncope, orthostatic hypotension, and Raynaud-type phenomena with cold hands and feet.

Some patients with IH sleep less than 10 hours per night, have difficulty awakening, awake unrefreshed and even confused, and may take unintentional, unrefreshing daytime naps provoked by their daytime somnolence. Onset is typically before 25 years of age, and the course of the disorder is persistent and unremitting.

A 60-year-old accountant complained of excessive sleepiness and reported that he had to take about five half-hour naps throughout the day. He awakened feeling refreshed but unless he napped he could not function at work. He did not abuse substances and narcolepsy was ruled out; but on history he reported that both his father and paternal grandfather had the same sleep pattern. He was examined in a sleep laboratory and had a normal polysomnograph with 10 hours of uninterrupted sleep. A genetic predisposition for hypersomnolence was presumed to be the cause of his symptoms. He obtained some relief from small doses of amphetamine (2.5 mg) which he would use when he could not take his normal naps because of specific work obligations.

Behaviorally Induced Insufficient Sleep Syndrome. Insufficient sleep syndrome stems from an individual's disregard for the sleep-wake schedule. It is usually subclinical and occurs in a great proportion of the population. Medical help is generally not sought because the individual is aware of the cause of his or her sleepiness. Insufficient sleep, however, is an insidious killer and is related to many vehicular and industrial accidents. When an individual becomes progressively more and more sleep deprived, eventually payment for the sleep debt will be exacted. Excessive sleepiness associated with insufficient sleep can be unmasked by a heavy meal, low-dose alcohol ingestion, a warm room, and sedentary activity. Insufficient sleep syndrome is diagnosed when an individual does not schedule an adequate amount of time for sleep and as a result suffers from daytime sleepiness, fatigue, loss of concentration, memory impairment, irritability, and moodiness. Often the individual will fast and binge on sleep, nap, and extend the sleep period on weekends. Although caffeinated beverages are commonly self-administered, appropriate treatment involves increasing the duration and regularity of sleep. Recent studies indicate that metabolic disorders and insulin resistance may result from chronic insufficient sleep.

Hypersomnia Due to a Medical Condition. Medical conditions known to cause hypersomnia include head trauma, stroke, encephalitis, Parkinson's disease, inflammatory conditions, tumors, genetic diseases, and neurodegenerative diseases.

Hypersomnia Due to Drug or Substance Use. Sleepiness can be caused by use or abuse of sedative hypnotics, sedating antihistamines, sedating antidepressants, antiepileptics, neuroleptics, and opioid analgesics. Hypersomnia may also be provoked by withdrawal from traditional stimulants (cocaine, amphetamines), caffeine, or nicotine.

Treating Hypersomnia

Hypersomnia caused by insufficient sleep is treated by extending and regularizing the sleep period. If, however, the sleepiness arises from narcolepsy, medical conditions, or idiopathic hypersomnia, it is usually managed pharmacologically. There is no cure for these conditions, but symptoms are managed with either the wake-promoting substance modafinil (Provigil; first-line treatment) or traditional psychostimulants such as amphetamines and their derivatives (if modafinil fails). For narcolepsy (discussed below), rapid-eye-movement (REM) sleep-suppressing drugs (e.g., many antidepressants) are used to treat the cataplexy. This approach capitalizes on the anticholinergic REM sleep-suppressant properties of these drugs. Because cataplexy is presumably an intrusion of REM sleep phenomena into the awake state, the rationale is clear. Many reports indicate that imipramine (Tofranil) and protriptyline (Vivactil) are quite effective for reducing or eliminating cataplexy. Selective serotonin reuptake inhibitors (SSRIs) have gained popularity because they are associated with fewer side effects than the tricyclic antidepressants. More recently, sodium oxybate (Xyrem) has proven to be extremely effective for reducing cataplexy, even in cases in which the cataplexy was thought to be intractable. Studies also suggest that sodium oxybate helps to improve sleep and relieves some of the sleepiness associated with narcolepsy. Although drug therapies are the treatment of choice, the overall therapeutic approach should include scheduled naps, lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance (if stimulants are used), and careful monitoring of refills, general health, and cardiac status.

NARCOLEPSY

Narcolepsy is a condition characterized by excessive sleepiness, as well as auxiliary symptoms that represent the intrusion of aspects of REM sleep into the waking state (Table 16.2-7). The sleep attacks of narcolepsy represent episodes of irresistible sleepiness, leading to perhaps 10 to 20 minutes of sleep, after which the patient feels refreshed, at least briefly. They can occur at inappropriate times (e.g., while eating, talking, or driving and during sex). The REM sleep includes hypnagogic and hypnopompic hallucinations, cataplexy, and sleep paralysis. The appearance of REM sleep within 10 minutes of sleep onset (sleep-onset REM periods) is also considered evidence of narcolepsy. The

disorder can be dangerous because it can lead to automobile and industrial accidents.

Table 16.2-7
DSM-5 Diagnostic Criteria for Narcolepsy

- A. Recurrent periods of an irrepressible need to sleep, lapsing into sleep, or napping occurring within the same day. These must have been occurring at least three times per week over the past 3 months.
- B. The presence of at least one of the following:
1. Episodes of cataplexy, defined as either (a) or (b), occurring at least a few times per month:
 - a. In individuals with long-standing disease, brief (seconds to minutes) episodes of sudden bilateral loss of muscle tone with maintained consciousness that are precipitated by laughter or joking.
 - b. In children or in individuals within 6 months of onset, spontaneous grimaces or jaw-opening episodes with tongue thrusting or a global hypotonia, without any obvious emotional triggers.
 2. Hypocretin deficiency, as measured using cerebrospinal fluid (CSF) hypocretin-1 immunoreactivity values (less than or equal to one third of values obtained in healthy subjects tested using the same assay, or less than or equal to 110 pg/mL). Low CSF levels of hypocretin-1 must not be observed in the context of acute brain injury, inflammation, or infection.
 3. Nocturnal sleep polysomnography showing rapid eye movement (REM) sleep latency less than or equal to 15 minutes, or a multiple sleep latency test showing a mean sleep latency less than or equal to 8 minutes and two or more sleep-onset REM periods.
- Specify whether:
- 347.00 (G47.419) Narcolepsy without cataplexy but with hypocretin deficiency:** Criterion B requirements of low CSF hypocretin-1 levels and positive polysomnography/multiple sleep latency test are met, but no cataplexy is present (Criterion B1 not met).
- 347.01 (G47.411) Narcolepsy with cataplexy but without hypocretin deficiency:** In this rare subtype (less than 5 percent of narcolepsy cases), Criterion B requirements of cataplexy and positive polysomnography/multiple sleep latency test are met, but CSF hypocretin-1 levels are normal (Criterion B2 not met).
- 347.00 (G47.419) Autosomal dominant cerebellar ataxia, deafness, and narcolepsy:** This subtype is caused by exon 21 DNA (cytosine-5)-methyltransferase-1 mutations and is characterized by late-onset (age 30 to 40 years) narcolepsy (with low or intermediate CSF hypocretin-1 levels), deafness, cerebellar ataxia, and eventually dementia.
- 347.00 (G47.419) Autosomal dominant narcolepsy, obesity, and type 2 diabetes:** Narcolepsy, obesity, and type 2 diabetes with low CSF hypocretin-1 levels have been described in rare cases and are associated with a mutation in the myelin oligodendrocyte glycoprotein gene.
- 347.10 (G47.429) Narcolepsy secondary to another medical condition:** This subtype is for narcolepsy that develops secondary to medical conditions that cause infectious (e.g., Whipple's disease, sarcoidosis), traumatic, or tumoral destruction of hypocretin neurons.
- Coding note** (for ICD-9-CM code 347.10 only): Code first the underlying medical condition (e.g., 040.2 Whipple's disease; 347.10 narcolepsy secondary to Whipple's disease).
- Specify current severity:
- Mild:** Infrequent cataplexy (less than once per week), need for naps only once or twice per day, and less disturbed nocturnal sleep.
- Moderate:** Cataplexy once daily or every few days, disturbed nocturnal sleep, and need for multiple naps daily.
- Severe:** Drug-resistant cataplexy with multiple attacks daily, nearly constant sleepiness, and disturbed nocturnal sleep (i.e., movements, insomnia, and vivid dreaming).

Narcolepsy is not as rare as was once thought. It is estimated to occur in 0.02 to 0.16 percent of adults and shows some familial incidence. Narcolepsy is neither a type of epilepsy nor a psychogenic disturbance. It is an abnormality of the sleep mechanisms—specifically, REM-inhibiting mechanisms—and it has been studied in dogs, sheep, and humans. Narcolepsy can occur at any age, but it most frequently begins in adolescence or young adulthood, generally before the age of 30. The disorder either progresses slowly or reaches a plateau that is maintained throughout life.

The most common symptom is sleep attacks: Patients cannot avoid falling asleep. Often associated with the problem (close to 50 percent of long-standing cases) is cataplexy, a sudden loss of muscle tone, such as jaw drop, head drop, weakness of the knees, or paralysis of all skeletal muscles with collapse. Patients often remain awake during brief cataplectic episodes; the long episodes usually merge with sleep and show the electroencephalographic signs of REM sleep.

Other symptoms include hypnagogic or hypnopompic hallucinations, which are vivid perceptual experiences, either auditory or visual, occurring at sleep onset or on awakening. Patients are often momentarily frightened, but within 1 or 2 minutes they return to an entirely normal frame of mind and are aware that nothing was actually there.

Another uncommon symptom is sleep paralysis, most often occurring on awakening in the morning; during the episode, patients are apparently awake and conscious but unable to move a muscle. If the symptom persists for more than a few seconds, as it often does in narcolepsy, it can become extremely uncomfortable. (Isolated brief episodes of sleep paralysis occur in many nonnarcoleptic persons.) Patients with narcolepsy report falling asleep quickly at night but often experience broken sleep.

When the diagnosis is not clinically clear, a nighttime polysomnographic recording reveals a characteristic sleep-onset REM period (Fig. 16.2-1). A test of daytime multiple sleep latency (several recorded naps at 2-hour intervals) shows rapid sleep onset and usually one or more sleep-onset REM periods. A type of human leukocyte antigen, HLA-DR2, is found in 90 to 100 percent of patients with narcolepsy and only 10 to 35 percent of unaffected persons. One recent study showed that patients with narcolepsy are deficient in the neurotransmitter hypocretin, which stimulates appetite and alertness. Another study found that the number of hypocretin neurons (Hrct cells) in narcoleptics is 85 to 95 percent lower than in nonnarcoleptic brains.

FIGURE 16.2-1
Polygraphic tracing comparing normal sleep onset with that of a patient with narcolepsy. Each panel illustrates approximately 30 seconds of polysomnographic recording beginning with relaxed wakefulness. **A:** Normal sleep progression, showing a reduction of electroencephalogram (EEG) alpha activity and the development of slow rolling eye movements. **B:** The normally expected abatement of EEG alpha activity associated with increased theta activity and the appearance of a few slow eye movements. However, within 25 seconds (far right) a swift loss of muscle tone occurs, accompanied by rapid eye movements. This appearance of sleep-onset REM sleep (SOREM) characterizes narcolepsy and is part of the diagnostic criteria. EMG, electromyogram; EOG, electro-oculogram. (Courtesy of Constance A. Moore, M.D., Robert W. Williams, M.D., and Max Hirshkowitz, Ph.D.)

Narcolepsy is the prototypical example of sleepiness produced by a basic central nervous system dysfunction of sleep mechanisms. The etiology stems from a genetically triggered

hypocretin dysfunction and deficit. It has become apparent that the hypocretin system plays a critical role in narcolepsy. In a canine model of narcolepsy, mutations of hypocretin receptor-2 were identified that result in malfunctioning of this receptor. In human narcolepsy with HLA-DQB1*0602-positive individuals, levels of hypocretin receptor-1 are undetectable in cerebrospinal fluid (CSF). A strong association between narcolepsy and specific HLA suggests an autoimmune process that damages hypocretin-containing cells in the central nervous system (CNS).

The classic form of narcolepsy (*narcolepsy with cataplexy*) is characterized by a tetrad of symptoms: (1) excessive daytime sleepiness, (2) cataplexy, (3) sleep paralysis, and (4) hypnagogic hallucinations. Patients with narcolepsy often have an abnormal sleep architecture in which REM sleep occurs soon after sleep onset both at night and during daytime naps (Fig. 16.2-2). This, in connection with the symptom tetrad, makes narcolepsy appear to be a REM sleep intrusion syndrome presumably resultant from dysfunction of REM sleep generator gating mechanisms. The features of the tetrad match REM sleep characteristics. The sleep paralysis is similar to the muscle atonia that occurs during REM sleep. The hypnagogic hallucinations are vivid “dreams” that occur while the patient is still conscious or partially conscious. However, not all patients have the full constellation of symptoms. Narcolepsy is estimated to afflict 10 to 60 individuals per 10,000. Symptoms commonly appear in the second decade of life. Strong emotions usually act as the “trigger” for cataplexy. Common emotional triggers include laughter and anger. The severity of cataplexy ranges widely from transient weakness in the knees to total paralysis while the patient is fully conscious. Episodes may last from several seconds to minutes. Usually, the patient is unable to speak and may fall to the floor. Nocturnal sleep is often fragmented, and there can be considerable sleep disturbance. Patients may experience depression in relation to the narcolepsy, especially when it is not treated. Social isolation, difficulty with academics and employment, and fear of driving contribute to a sense of loss experienced by patients with narcolepsy.

FIGURE 16.2-2

Treating Narcolepsy

No cure exists for narcolepsy, but symptom management is possible. A regimen of forced naps at a regular time of day occasionally helps patients with narcolepsy and, in some cases, the regimen alone, without medication, can almost cure the condition. When medication is required, stimulants are most commonly used.

Modafinil, an α_1 -adrenergic receptor agonist, has been approved by the FDA to reduce the number of sleep attacks and to improve psychomotor performance in narcolepsy. This observation suggests the involvement of noradrenergic mechanisms in the disorder. Modafinil lacks some of the adverse effects of traditional psychostimulants. Nonetheless, the clinician must monitor its use and be sensitive to the patient developing a tolerance.

Sleep specialists often prescribe tricyclic drugs or SSRIs to reduce cataplexy. This approach capitalizes on the REM sleep-suppressant properties of these drugs. Because cataplexy is presumably an intrusion of REM sleep phenomena into the awake state, the rationale is clear. Many reports indicate that imipramine, modafinil, and fluoxetine are effective in reducing or eliminating cataplexy. Although drug therapy is the treatment of choice, the overall therapeutic approach should include scheduled naps, lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance, and careful monitoring of drug refills, general health, and cardiac status.

BREATHING-RELATED SLEEP DISORDERS

Sleep-disordered breathing includes conditions ranging from upper airway resistance syndrome to severe obstructive sleep apnea. Sleep-related breathing impairments such as apnea (absence of airflow) and hypopnea (reduction in airflow) are most often caused by airway obstruction; however, sometimes respiratory reduction results from central (brainstem) changes in ventilatory control, metabolic factors, or heart failure. Each sleep-disordered breathing event can be classified as central, obstructive, or mixed. Central apnea refers to decreased or absent respiratory effort. In DSM-5, three disorders are included under the category of breathing-related sleep disorders: obstructive sleep apnea hypopnea, central sleep apnea, and sleep-related hypoventilation.

Obstructive Sleep Apnea Hypopnea

Obstructive sleep apnea hypopnea, also referred to as obstructive sleep apnea (OSA), is characterized by repetitive collapse or partial collapse of the upper airway during sleep. As a person falls asleep, airway resistance increases. In some individuals this leads to increased respiratory effort or airway occlusion. These periods of functional obstruction of the upper airway result in decreases in arterial oxygen saturation and a transient arousal, after which respiration (at least briefly) resumes normally. An episode of sleep *apnea* is defined as a cessation of breathing for 10 seconds or more during sleep. During an obstructive apnea episode, respiratory effort continues but airflow ceases due to loss of airway patency. A reduction in breathing for at least 10 seconds is termed *hypopnea*. Partial obstructions (hypopnea) can lead to arousals and sleep fragmentation. The consequent reduction in ventilation can decrease oxyhemoglobin concentrations. Predisposing factors for OSA include being male, reaching middle age, being obese, and having micrognathia, retrognathia, nasopharyngeal abnormalities, hypothyroidism, and acromegaly.

A review of more than 4 million records from the Veterans Health Administration (VHA) found a 2.91 percent prevalence of sleep apnea in that population. Comorbid diagnoses included hypertension (60.1 percent), obesity (30.5 percent), diabetes mellitus (32.9 percent), and cardiovascular disease, including angina and myocardial infarction (27.6 percent), heart failure (13.5 percent), and stroke, including transient ischemic attacks (5.7 percent). Psychiatric comorbidity in the sleep apnea group was significantly higher ($P < 0.0001$) than in the non-sleep apnea group for the diagnoses of mood disorders, anxiety and posttraumatic stress disorder, psychosis, and dementia. There are several theories about the reasons for this association. Psychiatric disorders may be a consequence of sleep apnea (and disturbed sleep and hypoxia). Conversely, psychiatric disorders may predispose people to developing sleep disturbances such as sleep apnea.

Diagnosis. Clinical features associated with OSA hypopnea include excessive sleepiness, snoring, obesity, restless sleep, nocturnal awakenings with choking or gasping for breath, morning dry mouth, morning headaches, and heavy nocturnal sweating. Patients may also have hypertension, erectile failure in men, depression, heart failure, nocturia, polycythemia, and memory impairment as a result of obstructive sleep apnea hypopnea. Obstructive apnea and hypopnea episodes can occur in any state of sleep but are more typical during REM sleep, non-rapid-eye-movement (NREM) stage 1, and NREM stage 2 sleep.

On the polysomnogram, episodes of OSA in adults are characterized by multiple periods of at least 10 seconds in duration in which nasal and oral airflow ceases completely (an apnea) or partially (a hypopnea), while the abdominal and chest expansion leads indicate continuing efforts of the diaphragm and accessory muscles of respiration to move air through the obstruction (see Fig. 16.2-2). The arterial oxygen saturation drops and often a bradycardia is seen that may be accompanied by other arrhythmias, such as premature ventricular contractions. At the end, an arousal reflex takes place, seen as a waking signal and possibly as a motor artifact on the EEG channels. At this moment, sometimes called the *breakthrough*, the patient can be observed making brief restless movements in bed.

According to the American Academy of Sleep Medicine scoring manual, polysomnographic recordings are scored for events according to the following rules: Airway obstruction producing complete cessations of breathing for 10 or more seconds is scored as apnea. Partial obstructions with consequent drops in oxygen saturation are designated as hypopnea (4 percent or more required according to Medicare rules), and partial obstructions without significant oxygen saturation but terminated by an arousal are scored as respiratory effort-related arousal (RERA) episodes. The number of apnea episodes per hour of sleep is termed the *apnea index* (AI), the number of apnea plus hypopnea episodes per hour is called the *apnea plus hypopnea index* (AHI), and the number of apnea plus hypopnea plus RERA episodes is designated the *respiratory disturbance index* (RDI).

Treatment. A number of treatments are available for obstructive sleep apnea hypopnea, including weight loss, surgical intervention, positive airway pressure, and oral appliances. Weight loss is known to help many patients. However, because losing weight and keeping it off is difficult and unreliably achieved, the prudent clinician should recommend weight loss but also rely on other therapies.

Aggressive surgical treatments evolved soon after OSA's pathophysiological and potentially life-threatening consequences were recognized. The earliest surgical intervention was designed to create a patent airway; thus, in the late 1970s tracheostomies were performed on individuals with severe apnea. There is little doubt that tracheostomy succeeds in creating an airway. Although no longer the preferred treatment, it remains a standard against which newer, more refined therapies are judged. Second-generation surgical approaches attempt to correct airway obstructions and malformations. Early studies of uvulopalatopharyngoplasty (UPPP) suggested that modification of the soft palate effectively relieved most sleep apnea. Later follow-up results were less impressive. Approximately 30 to 50 percent of patients with sleep apnea benefit from UPPP. These patients are likely those with oropharyngeal obstruction; thus, careful attention to selection criteria presumably improves outcome. However, if obstruction occurs in the posterior airway space (PAS), maxillomandibular surgery may be appropriate. In retrognathic patients or in patients with cephalometrics revealing compromised PAS, moving the jaw forward can achieve impressive normalization of breathing during sleep.

Positive airway pressure (PAP) is the preferred treatment for sleep-disordered breathing (Fig. 16.2-3). The PAP apparatus consists of a fan-driven blower, a nasal or oronasal mask, and tubing connecting the two. The airflow through the mask provides a positive pressure that offsets oropharyngeal collapse produced by inspiratory negative thoracic pressure. In this manner it acts as a pneumatic splint, thereby maintaining the airway. When the pressure is properly titrated, even the most severe sleep apnea can be alleviated. Results are usually dramatic. PAP devices come in several varieties. The most common are systems that provide a single set continuous positive airway pressure (CPAP). For individuals who find it difficult to exhale against a continuous pressure, bilevel positive airway pressure (BPAP) may provide a solution. BPAP devices have different inspiratory and expiratory pressure settings. More recently, systems that sense the patient's changes in airway resistance and automatically adjust the positive airway pressure (APAP) have been gaining popularity. Such APAP systems should theoretically be able to adapt to changes in pressure requirements produced by sleep deprivation, medications, weight change, sleep stage, illness, and aging. Finally, timed bilevel and servoventilation systems have also been developed but fall into the category of noninvasive positive pressure ventilation (NIPPV) systems, which are more appropriate for treating other pulmonary diseases and breathing problems in neuromuscular diseases. The tremendous efficacy and remarkable safety of PAP therapies has made them the standard of care for patients who can tolerate sleeping with the machine. The major therapeutic challenge is utilization. Patient education and systematic follow-up are crucial. When problems with the mask, the pressure, nasal stuffiness, and other barriers to routine, nightly use arise, they must be remedied quickly to ensure therapeutic adherence. When used properly, the success of PAP therapy has rendered surgical intervention a secondary option, resorted to mainly after PAP failure, rejection, or nonadherence.

FIGURE 16.2-3

Sleep stage histogram illustrating the immediate, dramatic improvement in sleep architecture produced by treating obstructive sleep apnea with continuous positive airway pressure (CPAP) therapy. **A:** Illustrates the abnormal sleep pattern on a night when the patient had more than 200 episodes of obstructive sleep apnea. Sleep is disturbed by frequent awakenings while rapid eye movement (REM) and slow wave (stages 3 and 4) sleep are nearly absent. **B:** Data from the same patient being treated with CPAP on the next night. Normalization of sleep continuity with a massive rebound in REM and slow wave sleep is evident. (Courtesy of Constance A. Moore, M.D., Robert L. Williams, M.D., and Max Hirshkowitz, Ph.D.)

Oral appliances represent another therapeutic option that is gaining popularity. A variety of oral appliances have also been developed to treat snoring, and they appear to be beneficial for mild to moderate OSA cases. The general approach is to manipulate the position of the mandible, lift the palate, or retain the tongue. Randomized trials indicate that some oral appliances improve airway patency sufficiently to treat patients with sleep apnea. However, in patients with severe OSA, improvement does not always reach satisfactory levels; therefore, follow-up evaluations are needed.

In some patients, sleep-disordered breathing occurs only in the supine position. In such situations, preventing patients from sleeping on their backs may produce beneficial results. Tennis balls sewn onto or placed into pockets on the back of the nightshirt or foam wedges may accomplish this goal. Although such interventions are found to be useful in clinical practice, large-scale systematic clinical trials of this approach have not been performed.

Finally, drug therapies have been tried for OSA but without success. Medroxyprogesterone acetate (Provera) was originally thought to be helpful but is seldom used now. Similarly, tricyclic antidepressants sometimes decrease apnea severity by reducing REM sleep, the stage of sleep in which obstructive apnea is usually more frequent. Theophylline was reported to reduce apnea, but further study is needed. There were also animal studies suggesting that mirtazapine (Remeron) and similar serotonin presynaptic-affecting compounds improved breathing; however, studies in humans were disappointing. The only drug therapy approved for use in patients with OSA is the wake-promoting substance modafinil. Modafinil, however, does nothing to treat the pathophysiology of airway occlusion, but rather is used as an adjunct for treating the residual sleepiness that persists in about 8 to 12 percent of patients who are otherwise well treated with and adequately use PAP therapy.

Central Sleep Apnea

Central sleep apnea (CSA), which tends to occur in the elderly, results from periodic failure of CNS mechanisms that stimulate breathing. CSA is defined as the absence of breathing due to lack of respiratory effort. It is a disorder of ventilatory control in which repeated episodes of apneas and hypopneas occur in a periodic or intermittent pattern during sleep caused by variability in respiratory effort. The original teaching was that OSA results in a complaint of excessive sleepiness, whereas CSA is manifest as insomnia, but later case series have emphasized that either symptom may appear in either disorder. The polysomnographic features of CSA are similar to those of OSA, except that, during the periods of apnea, a cessation of respiratory effort is seen in the abdominal and chest expansion leads. DSM-5 specifies three subtypes of CSA: idiopathic CSA, Cheyne-Stokes breathing pattern, and CSA comorbid with opioid use. However, there are several different etiologies that can result in diminished effort to breathe, including the three subtypes above, as well as high altitude, brainstem lesions, specific medical conditions, specific drugs or substances, and congenital abnormalities.

Idiopathic CSA. There is an idiopathic form of CSA. Patients typically have low normal arterial carbon dioxide tension (PaCO_2) while awake and have a high ventilatory response to CO_2 . They present with daytime sleepiness, insomnia, or awakening with shortness of breath. Respiratory cessations during sleep occur independent of ventilatory effort. Polysomnography reveals five or more central apneas per hour of sleep.

Cheyne-Stokes Breathing. Cheyne-Stokes breathing is a unique breathing pattern consisting of prolonged hyperpneas during which tidal volume gradually waxes and wanes in a crescendo-decrescendo fashion. The hyperpneas alternate with apnea and hypopnea episodes that are associated with reduced ventilatory effort. This pattern is most common in older men with congestive heart failure or stroke. As with primary CSA, the patient presents with daytime sleepiness, insomnia, and awakening short of breath. Polysomnography reveals ten or more central apnea and hypopnea episodes per hour of sleep.

CSA Comorbid with Opioid Use. This is a third subtype of CSA in DSM-5, specified if opioid use disorder is present. There is an association with chronic use of long-acting opioid medications and impairment of neuromuscular respiratory control leading to CSA.

CSA Due to High Altitude. Central apnea at sleep onset is universal at elevations above 7,600 m but can occur at 5,000 m (especially with a rapid ascent). This subtype is no longer included in DSM-5 but may still have clinical significance. Periods of central apnea alternate with periods of hyperpnea in a 12-second to 34-second cycle. This is an extension of normal respiratory control at sleep onset where medullary pH receptors raise their set-point and require lower pH to respond. At high altitudes, hyperventilation causes a hypocapnic alkalosis that reduces ventilation during sleep. Sleep architecture may suffer, with increased duration in stages 1 and 2 and less slow wave sleep. REM sleep may not be affected. This condition can be treated with acetazolamide, which lowers serum pH and increases the respiratory drive. Acetazolamide side effects include metabolic acidosis, electrolyte imbalance, anaphylaxis, Stevens-Johnson syndrome, toxic epidermal necrolysis, and agranulocytosis. Common reactions include but are not limited to fatigue, anorexia, taste changes, polyuria, diarrhea, melena, tinnitus, and photosensitivity.

CSA Due to Medical Condition that Is Not Cheyne-Stokes. This form of CSA is usually caused by a brainstem lesion associated with a wide range of variable etiologies. Cardiac and renal disorders can also cause central apnea. Diagnostic criteria requires polysomnographically verified rate of ten or more central apneas and hypopneas per hour of sleep with a crescendo-decrescendo breathing pattern accompanied by arousals and fragmented sleep.

CSA Due to Drug or Substance Use. Central apnea episodes can be provoked by a variety of drugs or drug combinations, most notably long-acting opiates. However, other substances or medications have also been associated with alterations in neuromuscular control leading to CSA. Diagnostic criteria are a central apnea index (number of episodes per hour) of 5 or more and the patient taking a drug(s) for at least 2 months.

Primary Sleep Apnea of Infancy. This form of CSA involves prolonged apneas or hypopneas with concomitant hypoxemia, bradycardia, or both. This condition afflicts preterm neonates, presumably because their brainstems are not fully developed. The condition may be exacerbated by other medical problems that further compromise the infant's physiological and developmental status.

Sleep-Related Hypoventilation

Idiopathic Hypoventilation. Patients with idiopathic hypoventilation have normal lungs and a decrease in alveolar ventilation resulting in sleep-related arterial oxygen desaturation likely due to blunted chemoresponsiveness. They do not have lung disease, obesity, kyphoscoliosis, or other structural conditions that might cause hypoventilation. Polysomnography shows episodes of shallow breathing longer than 10 seconds in duration associated with arterial oxygen desaturation and frequent arousals from sleep associated with the breathing disturbances or bradycardia. Patients often complain of excessive daytime sleepiness, frequent arousals during sleep, or insomnia.

Congenital Central Alveolar Hypoventilation. Sometimes called Ondine's curse, congenital central alveolar hypoventilation parasomnia cannot be explained by primary pulmonary disease or ventilatory muscle weakness. The sleep-related hypoventilation results from a failure in automatic control of breathing. Although present at birth, congenital central hypoventilation syndrome may initially be unrecognized. In severe forms, treatment requires continual ventilatory support.

Comorbid Sleep-Related Hypoventilation. Comorbid sleep-related hypoventilation occurs when hypoventilation is a consequence of a medical condition, for example, pulmonary parenchymal or vascular pathology, lower airway obstruction, or

neuromuscular or chest wall disorders.

SLEEP-RELATED HYPOVENTILATION DUE TO PULMONARY PARENCHYMAL OR VASCULAR PATHOLOGY. Parenchymal lung disease or vascular disease is the primary cause of the hypoxemia. These diseases include interstitial lung diseases, idiopathic and secondary forms of pulmonary hypertension, cystic fibrosis (which affects lung parenchyma and lower airway), and hemoglobinopathies such as sickle cell anemia. Nocturnal hypoxemia can lead to pulmonary artery hypertension, cor pulmonale, and neurocognitive dysfunction. Sleep studies reveal sustained oxyhemoglobin desaturation during sleep occurring in the absence of detectable apnea or hypopnea episodes.

SLEEP-RELATED HYPOVENTILATION DUE TO LOWER AIRWAY OBSTRUCTION. This is diagnosed by a forced expiratory volume in 1 second (FEV1)/forced vital capacity (FVC) ratio that is less than 70 percent of predicted value on pulmonary function tests (PFTs). Chronic obstructive pulmonary disease (COPD) including emphysema and chronic bronchitis, α -1-antitrypsin deficiency, bronchiectasis, and cystic fibrosis form the majority of disorders that cause this sleep disturbance. Nocturnal hypoxemia can potentially lead to pulmonary artery hypertension and cor pulmonale. Sustained hypoxemia can also cause brain damage. Sleep studies reveal sustained oxyhemoglobin desaturation during sleep occurring in the absence of detectable apnea or hypopnea episodes.

SLEEP-RELATED HYPOVENTILATION DUE TO NEUROMUSCULAR AND CHEST WALL DISORDERS. Myasthenia gravis and amyotrophic lateral sclerosis (ALS) occurring together with OSA can exacerbate the hypoxemia produced by the neuromuscular and chest wall disorders.

CIRCADIAN RHYTHM SLEEP DISORDERS

Circadian rhythm sleep disorders include a wide range of conditions involving a misalignment between desired and actual sleep periods. This collection of sleep disorders shares the same basic underlying etiology—a desynchrony between an individual's internal circadian biological clock and the desired or conventional sleep-wake cycle. The circadian (*circa plus dias*, “approximately 1 day”) pacemaker is located in the suprachiasmatic nucleus (SCN). SCN firing oscillates with an almost sinusoidal pattern, the period of which is 24 hours, and the output correlates with the daily fluctuations in core body temperature. SCN firing patterns persists even in *cereau isolé* preparations (an animal with its mesencephalon transected). Mismatched circadian clock and desired schedules can arise from improper phase relationships between the two, travel across time zones, or dysfunctions in the basic biological rhythm.

Under normal circumstances the internal circadian pacemaker is reset each day by bright light, social cues, stimulants, and activity. In cases in which these factors fail to re-entrain the circadian rhythm, the circadian sleep disorders occur. DSM-5 lists six types of circadian rhythm sleep disorders: delayed sleep phase type, advanced sleep phase type, irregular sleep-wake type, non-24-hour sleep-wake type, shift work type, and unspecified type. Jet lag type and “due to a medical condition” are not included in DSM-5 but are included in other classification systems such as ICSD-2.

Delayed Sleep Phase Type

The delayed sleep phase circadian disorder occurs when the biological clock runs slower than 24 hours or is shifted later than the desired schedule. This produces a phase delay in the sleepiness-alertness cycle. Individuals with delayed sleep phase are more alert in the evening and early nighttime, stay up later, and are more tired in the morning. These individuals are commonly referred to as *night owls*.

Advanced Sleep Phase Type

Advanced sleep phase occurs when the circadian rhythm cycle is shifted earlier. Therefore, the sleepiness cycle is advanced with respect to clock time. Individuals with advanced sleep phase are drowsy in the evening, want to retire to bed earlier, awaken earlier, and are more alert in the early morning. Individuals with this pattern of advanced sleep phase are sometimes called *early birds* or *larks*.

Irregular Sleep-Wake Type

The irregular sleep-wake pattern occurs when the circadian sleep-wake rhythm is absent or pathologically diminished. The sleep-wake pattern is temporally disorganized, and the timing of sleep and wakefulness is unpredictable. Individuals with this condition have a normal amount of sleep during a 24-hour period; however, it is fragmented into three or more episodes that occur irregularly. There are symptoms of insomnia at night and excessive sleepiness during the day. Long daytime naps and inappropriate nocturnal wakefulness occur. Except in unusual circumstances, activities of daily life are significantly impaired. A history of reclusion or isolation may be associated with this disorder because decreased exposure to external stimuli can contribute to symptoms. Irregular sleep-wake type is typically associated with neurodegenerative disorders, such as Alzheimer's disease and some neurodevelopmental disorders in children.

Non-24-Hour Sleep-Wake Type (Free Running)

When the circadian sleep-wake pacemaker has a cycle length greater or less than 24 hours and is not reset each morning, a person may develop this type of circadian rhythm disorder, such as in blind or visually impaired persons. Under normal circumstances, resynchronization of the circadian rhythm occurs daily in response to the light-dark cycle. Problems occur incrementally when internal and environmental clocks become more and more out of phase. If the circadian clock's period is longer than 24 hours and does not reset each day, the patient experiences progressively worsening sleep-onset insomnia and daytime sleepiness. Sleep problems peak when circadian and environmental clocks are 12 hours out of phase and then begin to lessen, emulating progressively resolving advanced sleep phase. Eventually the clocks correlate, and the sleep-wake cycle is normal for a few days, after which the insomnia-hypersomnia cycle begins again. For this reason, non-24-hour sleep-wake disorder has been called *periodic insomnia* and *periodic excessive sleepiness*. Traumatic brain injury (TBI) has been associated with non-24-hour sleep-wake type. Blindness is a known risk factor. In both sighted and blind individuals, sequential measurement of phase markers such as melatonin may help in determining circadian phase. Both phototherapy and melatonin are being tried as treatments for this disorder.

Shift Work Type

Many service industries require 24-hour operation (e.g., transportation, health care). Similarly, as Western cultures became more capital intensive, mining and manufacturing became around-the-clock enterprises. The number of individuals doing shift work has been increasing steadily for decades. Shift workers commonly suffer from insomnia, excessive sleepiness, or both. Some individuals require only a short time to adjust to a shift change, whereas others have great difficulty. Frequent shift rotation adds to the problem. Furthermore, to meet social demands, shift workers often adopt a nonshifted sleep-wake schedule on weekends and holidays. Even those individuals who try to stay shifted usually retain an unshifted circadian rhythm. The result can be severe insomnia when attempting to sleep and excessive sleepiness when attempting to remain awake. The result is profound sleep deprivation as circadian rhythm continues to be poorly entrained to the sleep-wake schedule. The natural low point in the normal sleep-wake rhythm occurs at approximately 3:00 to 5:00 A.M. Of interest, this is precisely the time frame during which transportation and industrial accidents commonly occur as a direct consequence of sleepiness. Though unclear, DSM-5 seems to indicate that individuals experiencing jet lag are included under this subtype, noting that, despite different etiologies, individuals who travel across many time zones frequently may experience effects similar to those of shift work disorder.

Jet Lag Type

Removed from DSM-5, jet lag is still recognized as a circadian rhythm sleep disorder by the ICSD-2. With the advent of high-speed air travel, an induced desynchrony between circadian and environmental clocks became possible. Thus, the term *jet lag* came into use. When an individual rapidly travels across many time zones, either a circadian phase

advance or a phase delay is induced, depending on the direction of travel. Typically, translocation of one or two time zones will not produce a sustained problem; however, overseas travel can be marked by great difficulty in adjusting one's sleep-wake routine. Individuals who frequently travel for business can find themselves quite impaired at the time they need to make important decisions. Furthermore, "night owls" will experience greater difficulty adjusting to eastward travel because resynchronization requires phase advance. Similarly, "larks" theoretically will have more difficulty with westward travel. The number of time zones crossed is a critical factor. Normally, healthy individuals can easily adapt to one to two time zone changes per day; therefore, natural adjustment to an 8-hour translocation may take 4 or more days.

Due to Medical Condition

During illnesses that keep patients bedridden, during hospitalizations, and in some forms of dementia, individuals often sleep ad lib. The resulting chaotic sleep-wake pattern adversely affects the circadian rhythm. The breakdown in the sleep-wake cycle may be further exacerbated by medication with sedative properties. Sleep in patients in the intensive care unit is disturbed by noise, light, and the therapeutic and monitoring procedures being performed. The resulting disorganized sleep-wake pattern can produce a significant sleep disorder. In addition, abuse of recreational street drugs (e.g., methamphetamine and 3,4-methylenedioxymethamphetamine ["ecstasy"]) is associated with individuals remaining awake overnight or continuously for several days at a time. These episodes of prolonged wakefulness ultimately produce periods of profound hypersomnia (commonly called *crashing*).

Treatment of Circadian Rhythm Sleep Disorders

Chronotherapy is one technique used to reset the biological clock. It involves progressively phase delaying a person until the circadian oscillator is synchronized with the desired sleep-wake schedule. When individuals are deprived of environmental time cues and told to sleep when they feel sleepy, the typical "day" lasts 25 to 26 hours. This suggests that young and middle-aged adults have a propensity to phase delay. Thus, phase delaying each night by 2 to 3 hours is thought to be easier than phase advancing because it capitalizes on a natural tendency. Halting the phase delay at the appropriate moment and maintaining the desired synchrony can be a challenge. The patient also has to cope with an odd sleep-wake schedule for the better part of a week during therapy (which can interfere with school or work). For these reasons, the development of light therapy has in the past few years superseded chronotherapy.

Light or Photo- Therapy. Sleep disorders' research indicates that exposing an individual to bright lights (greater than 10,000 lux) can alter the endogenous biological rhythm. With precise timing of bright light exposure, the biological clock can be stopped and reset. Exposure to light modifies the set-point of the biological clock. Using core body temperature as a physiological marker, one can use bright lights to produce phase delay when presented before the temperature nadir. By contrast, light exposure after the temperature nadir evokes phase advance. The closer one presents light to the point of inflection (temperature nadir), the more robust is the response in altering the cycle. Thus, early-morning bright-light therapy can be used to phase advance individuals with delayed sleep phase syndrome. Similarly, exposure to bright light in the evening can help patients with advanced sleep phase syndrome. More recently, it was discovered that the blue part of the light spectrum is the crucial ingredient in phase setting and shifting. Light therapy is being applied to reset the circadian rhythm of shift workers, astronauts, and individuals experiencing jet lag.

Melatonin. Experimental use of melatonin to treat circadian rhythm disorders in the blind, e.g. non-24-hour sleep-wake disorder (see above), has proven successful. Researchers posit that melatonin secretion acts as the biological substrate for the internal circadian oscillator. Under normal circumstances, melatonin levels begin to rise at dusk and remain elevated until dawn. Bright light suppresses the release of melatonin. Melatonin, in a sense, is the signal of darkness in the brain. As such, it can be used clinically to manage sighted patients with disturbed sleep-wake cycles. Melatonin is available over the counter. A prescription form of melatonin (Circadin) is available in Europe, and a synthetic melatonin agonist (ramelteon [Rozerem]) is available in the United States. Ramelteon is FDA approved for treating patients with sleep-onset insomnia but is used off label for the entire spectrum of circadian rhythm sleep disorders. Of interest, the only medication approved for shift work sleep disorder is the wake-promoting compound modafinil. Modafinil is approved for treating sleepiness occurring during night shift work.

PARASOMNIAS

Parasomnias are sometimes referred to as disorders of partial arousal. In general, the parasomnias are a diverse collection of sleep disorders characterized by physiological or behavioral phenomena that occur during or are potentiated by sleep. One conceptual framework posits many parasomnias as overlaps or intrusions of one basic sleep-wake state into another. Wakefulness, NREM sleep, and REM sleep can be characterized as three basic states that differ in their neurological organization. During wakefulness, both the body and brain are active. In NREM sleep, both the body and brain are much less active. REM sleep, however, pairs an atonic body with an active brain (capable of creating elaborate dream fantasies). Regional cerebral blood flow, magnetic resonance imaging (MRI), and other imaging studies confirm increased brain activation during REM sleep. It certainly appears that in some parasomnias there are state boundary violations. For example, sleepwalking and sleep terrors involve momentary or partial wakeful behaviors suddenly occurring in NREM (slow wave) sleep. Similarly, isolated sleep paralysis is the persistence of REM sleep atonia into the wakefulness transition, whereas REM sleep behavior disorder is the failure of the mechanism, creating paralytic atonia such that individuals literally act out their dreams.

The frequency of significant parasomnias is variable, and the clinical significance often has more to do with the medical consequences or the evoked level of distress than with how often the abnormal events occur. For example, biannual REM sleep behavior disorder, in which the patient is seriously injured while enacting a dream, is more clinically urgent than weekly bruxism. Similarly, monthly recurrent nightmares that provoke severe insomnia and fear of sleeping can be more distressing than night terrors of the same frequency (at least to the patient). The irregularities of occurrence of most parasomnias make them difficult to document in the sleep laboratory. Sleep studies, however, are often conducted to make a differential diagnosis and rule out that the unusual behavior is secondary to seizure, sleep-disordered breathing, or another sleep disorder.

NREM Sleep Arousal Disorders

Sleepwalking. See Table 16.2-8 for DSM-5 diagnostic criteria for NREM sleep arousal disorders. Sleepwalking in its classic form, as the name implies, is a condition in which an individual arises from bed and ambulates without fully awakening. It is sometimes called somnambulism, and individuals can engage in a variety of complex behaviors while unconscious. Sleepwalking usually occurs during slow wave sleep and lies in the middle of a parasomnia continuum that ranges from "confused arousal" to "sleep terror." Sleepwalks characteristically begin toward the end of the first or second slow wave sleep episodes. Sleep deprivation and interruption of slow wave sleep appear to exacerbate, or even provoke, sleepwalking in susceptible individuals. Sleepwalking episodes may range from sitting up and attempting to walk to conducting an involved sequence of semipurposive actions. The sleepwalker often can successfully interact with the environment (e.g., avoiding tripping over objects). However, the sleepwalker may interact with the environment inappropriately, which sometimes results in injury (e.g., stepping out of an upstairs window or walking into the roadway). There are cases in which sleepwalkers have committed acts of violence. An individual who is sleepwalking is difficult to awaken. Once awake, the sleepwalker will usually appear confused. It is best to gently attempt to lead sleepwalkers back to bed rather than to attempt to awaken them by grabbing, shaking, or shouting. In their confused state, sleepwalkers may think they are being attacked and may react violently to defend themselves. Sleepwalking in adults is rare, has a familial pattern, and may occur as a primary parasomnia or secondary to another sleep disorder (e.g.,

sleep apnea). By contrast, sleepwalking is very common in children and has peak prevalence between ages 4 and 8 years. After adolescence, it usually disappears spontaneously. Nightly to weekly sleepwalking episodes associated with physical injury to the patient and others are considered severe. There are “specialized” forms of sleepwalking, most notably sleep-related eating behavior and sexsomnia.

Table 16.2-8
DSM-5 Diagnostic Criteria for Non-Rapid Eye Movement Sleep Arousal Disorders

- A. Recurrent episodes of incomplete awakening from sleep, usually occurring during the first third of the major sleep episode, accompanied by either one of the following:
1. **Sleepwalking:** Repeated episodes of rising from bed during sleep and walking about. While sleepwalking, the individual has a blank, staring face; is relatively unresponsive to the efforts of others to communicate with him or her; and can be awakened only with great difficulty.
 2. **Sleep terrors:** Recurrent episodes of abrupt terror arousals from sleep, usually beginning with a panicky scream. There is intense fear and signs of autonomic arousal, such as mydriasis, tachycardia, rapid breathing, and sweating, during each episode. There is relative unresponsiveness to efforts of others to comfort the individual during the episodes.
- B. No or little (e.g., only a single visual scene) dream imagery is recalled.
- C. Amnesia for the episodes is present.
- D. The episodes cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication).
- F. Coexisting mental and medical disorders do not explain the episodes of sleepwalking or sleep terrors.
- Coding note:** For ICD-9-CM, code **307.46** for all subtypes. For ICD-10-CM, code is based on subtype.
- Specify whether:
- 307.46 (F51.3) Sleepwalking type**
- Specify if:
- With sleep-related eating**
- With sleep-related sexual behavior (sexsomnia)**
- 307.46 (F51.4) Sleep terror type**

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

SLEEP-RELATED EATING. This occurs when an individual experiences episodes of ingesting food during sleep with varying degrees of amnesia. Individuals may find evidence of these episodes the next morning with little to no memory of their eating.

SEXSOMNIA. Sleep-related sexual behavior, or sexsomnia, is when a person engages in sexual activities (e.g., masturbation, fondling, sexual intercourse) during sleep without conscious awareness.

Sleep Terrors. Sleep terror disorder is an arousal in the first third of the night during deep NREM (stages 3 and 4) sleep. It is characterized by a sudden arousal with intense fearfulness. They usually begin with a piercing scream or cry and are accompanied by behavioral manifestations of intense anxiety bordering on panic. Autonomic and behavioral correlates of fright typically mark the experience. In a typical case of night terrors, no signs of temporal lobe epilepsy or other seizure disorders are seen, either clinically or on EEG recordings (Fig. 16.2-4). An individual experiencing a sleep terror usually sits up in bed, is unresponsive to stimuli, and, if awakened, is confused or disoriented. Vocalizations may occur, but they usually are incoherent. Notwithstanding the intensity of these events, amnesia for the episodes usually occurs. Like sleepwalking, these episodes usually arise from slow wave sleep. Fever and CNS depressant withdrawal potentiate sleep terror episodes. Unlike nightmares, in which an elaborate dream sequence unfolds, sleep terrors may be devoid of images or contain only fragments of very brief but frighteningly vivid but sometimes static images. It is sometimes called *pavor nocturnus*, incubus, or night terror, and a familial pattern has been reported. As with other slow wave sleep parasomnias, sleep deprivation can provoke or exacerbate sleep terrors. Psychopathology is seldom associated with sleep terrors in children; however, a history of traumatic experience or frank psychiatric problems is often comorbid in adults with this disorder. Severity ranges from less than once per month to almost nightly occurrence (with injury to the patient or others).

FIGURE 16.2-4

Polysomnogram of a sleep terror. **A:** Approximately 14 seconds of tracing occurring immediately before the sleep terror. Prominent electroencephalogram (EEG) slow wave activity and other characteristics of stage 4 sleep are seen. **B:** The awakening, accompanied by tachycardia and movement. EEG activity is ambiguous, and the patient eventually disconnected his electrodes as he thrashed about in bed (visible at the far right). Although the patient was screaming and greatly agitated, there was no report of dreaming. In the morning, there was little recollection of anything having occurred during the night. AT, anterior tibialis; EKG, electrocardiogram; EMG, electromyogram; EOG, electro-oculogram; RC MVMNT, rib cage movement. (Courtesy of Constance A. Moore, M.D., Robert L. Williams, M.D., and Max Hirshkowitz, Ph.D.)

Parasomnias Usually Associated with REM Sleep

REM Sleep Behavior Disorder (Including Parasomnia Overlap Disorder and Status Dissociatus). REM behavior disorder (RBD) involves a failure of the patient to have atonia (sleep paralysis) during the REM stage sleep. The result is that the patient literally enacts his or her dreams. Under normal circumstances, the dreamer is immobilized by REM-related hypopolarization of alpha and gamma motor neurons. Without this paralysis or with intermittent atonia, punching, kicking, leaping, and running from bed during attempted dream enactment occur. The activity has been correlated with dream imagery, and, unlike during sleepwalking, the individual seems unaware of the actual environment but rather is acting on the dream sensorium. Thus, a sleepwalker may calmly go to a bedroom window, open it, and step out. By contrast, a person with REM sleep behavior disorder would more likely dive through the window thinking it is a dream-visualized lake. Patients and bed partners frequently sustain injury, which is sometimes serious (e.g., lacerations, fractures). A wide variety of drugs and comorbid conditions can precipitate or worsen RBD. In animals, presumed RBD can be produced with bilateral peri-locus coeruleus lesions. In humans, there is a suggestion that RBD may result from diffuse hemispheric lesions, bilateral thalamic abnormalities, or brainstem lesions. Clonazepam (Klonopin) has been used successfully to treat RBD.

Recurrent Isolated Sleep Paralysis. Sleep paralysis is, as the name implies, an inability to make voluntary movements during sleep. It becomes a parasomnia when it occurs at sleep onset or on awakening, a time when the individual is partially conscious and aware of the surroundings. This inability to move can be extremely distressing, especially when it is coupled with the feeling that there is an intruder in the house or when hypnagogic hallucinations are occurring. Sleep paralysis is one of the tetrad of symptoms associated with narcolepsy; however, it is known to occur (with or without hypnagogia) in individuals that have neither cataplexy nor excessive daytime sleepiness. Although it is sometimes frightening, sleep paralysis is a feature of normal REM sleep briefly intruding into wakefulness. The paralysis may last from 1 to several minutes. It is interesting that the occurrence of sleep paralysis with hypnagogia may account for a variety of experiences in which the sleeper is confronted or attacked by some sort of “creature.” The common description is that a “presence” was felt to be near, the individual was paralyzed, and the creature talks, attacks, or sits on the sleeper’s chest and then vanishes. Whether it is called an incubus, “Old Hag,” a vampire, ghost oppression (*kanashibari* in Japanese), witch riding, or an alien encounter, elements common to sleep paralysis are seen. Irregular sleep, sleep deprivation, psychological stress, and shift work are thought to increase the likelihood of sleep paralysis occurring. Occasional sleep paralysis occurs in 7 to 8 percent of young adults. Estimates of at least one experience of sleep paralysis during the lifetime range from 25 to 50 percent. Improved sleep hygiene and assurance of sufficient sleep are first-line therapies. Sometimes, if the individual voluntarily makes very rapid eye movements or is touched by another person, the episode will terminate.

Nightmare Disorder. Nightmares are frightening or terrifying dreams. Sometimes called *dream anxiety attacks*, they produce sympathetic activation and ultimately awaken the dreamer. Nightmares occur in REM sleep and usually evolve from a long, complicated dream that becomes increasingly frightening. The person having been aroused to wakefulness, he or she typically remembers the dream (in contrast to sleep terrors). Some nightmares are recurrent, and reportedly when they occur in association with posttraumatic stress disorder they may be recollections of actual events. Common in children ages 3 to 6 years (prevalence estimates range from 10 to 50 percent), nightmares are rare in adults (1 percent or less). Frequent and distressing nightmares are sometimes responsible for insomnia because the individual is afraid to sleep. In Freudian terms, the nightmare is an example of the failure of the dream process that defuses the emotional content of the dream by disguising it symbolically, thus preserving sleep. Most patients afflicted with nightmares are free from psychiatric conditions. Nonetheless, individuals at risk for nightmares include those with schizotypal, borderline, and schizoid personality disorders, as well as those with schizophrenia. Having thin boundaries makes these individuals more vulnerable; furthermore, they may be at risk for schizophrenia. Traumatic events are known to induce nightmares, sometimes immediately, but at other times delayed. The nightmares can persist for many years. Several medications are known to sometimes provoke nightmares, including L-DOPA and β -adrenergic blockers, as does withdrawal from REM suppressant medications. Finally, drug or alcohol abuse is associated with nightmares.

Frequently occurring nightmares often produce a “fear of sleeping” type of insomnia. In turn, the insomnia may provoke sleep deprivation, which is known to exacerbate nightmares. In this manner, a vicious cycle is created. Treatment using behavioral techniques can be helpful. Universal sleep hygiene, stimulus control therapy, lucid dream therapy, and cognitive therapy reportedly improve sleep and reduce nightmares. In patients with nightmares related to posttraumatic stress disorder, nefazodone (an atypical antidepressant) reportedly provides therapeutic benefit. Benzodiazepines may also be helpful; however, systematic controlled trials are lacking.

Evidence for the use of prazosin (Minipress), a central nervous system α -1-receptor antagonist, in the treatment of posttraumatic stress disorder-related nightmares is growing. Prazosin significantly increased total sleep time and REM sleep time and significantly reduced trauma-related nightmares and distressed awakenings.

Other Parasomnias

Sleep Enuresis. Sleep enuresis is a disorder in which the individual urinates during sleep while in bed. *Bed-wetting*, as it is commonly called, has primary and secondary forms. In children, primary sleep enuresis is the continuance of bed-wetting since infancy. Secondary enuresis refers to relapse after toilet training was complete and there was a period during which the child remained dry. Usually, after toilet training bed-wetting spontaneously resolves before age 6 years. Prevalence progressively declines from 30 percent at age 4 years, to 10 percent at age 6 years, to 5 percent at age 10 years, and to 3 percent at age 12 years.

Parental primary enuresis increases the likelihood that the children will also have enuresis. A single recessive gene is suspected. Secondary enuresis in children may occur with the birth of a sibling and represent a “cry for attention.” Secondary enuresis can also be associated with nocturnal seizures, sleep deprivation, and urological anomalies. In adults, sleep enuresis is sometimes seen in patients with sleep-disordered breathing. In most cases, embarrassment, shame, and guilt are the most serious consequences. Nonetheless, if sleep enuresis is not addressed, it may leave psychosocial scars. A variety of medications have been used to treat sleep enuresis, including imipramine, oxybutynin chloride, and synthetic vasopressin. Behavioral treatments, including bladder training, using conditioning devices (bell and pad), and fluid restriction, have reportedly had good success when properly administered. Other treatments include psychotherapy, motivational strategies, and hypnotherapy.

Sleep-Related Groaning (Catathrenia). This disorder is a chronic condition characterized by prolonged, frequently loud groans during sleep. The groaning can occur in any sleep stage. The parasomnia may begin during childhood but often remains occult until the child has to share a room. Catathrenia is not related to any psychiatric or physiologic abnormalities. There is no known treatment, and it reportedly does not improve with CPAP therapy. Polysomnography with respiratory-sound monitoring reveals sounds during exhalation and respiratory dysrhythmia.

Sleep-Related Hallucinations. Sleep-related hallucinations are typically visual images occurring at sleep onset (hypnagogic) or on awakening (hypnopompic) from sleep. Sometimes difficult to differentiate from dreams, they are common in patients with narcolepsy. Complex hallucinations are rare and usually happen with abrupt awakening and without remembrance dreaming. Images tend to be vivid and immobile and persists for several minutes (usually disappearing when a light is turned on). The images can be frightening.

Sleep-Related Eating Disorder. This syndrome involves an inability to get back to sleep after awakening unless the individual has

something to eat or drink. After eating or drinking, return to sleep is normal. Nocturnal eating (drinking) syndrome predominantly affects infants and children; however, adult cases have been reported. It is believed that the problem is mainly associated with breastfeeding or bottle feeding. An infant will drink 4 to 8 oz or more at each awakening. Wetting is also excessive. Infants should be able to sleep through the night without feeding after age 6 months; however, in afflicted individuals, this does not happen. The syndrome invariably leads to the caregiver becoming sleep deprived. In adults, nocturnal eating can be conditioned to awakening. Eating may become obsessive, and several small meals may be eaten during the course of a night. The individual may be unaware of the activity, and weight gain can become a problem.

Parasomnia Due to Drug or Substance Use and Parasomnia Due to Medical Conditions. Many drugs and substances can trigger parasomnias, particularly those agents that lighten sleep; however, alcohol is notorious for producing sleepwalking (even in individuals who have taken sleeping pills). RBD can be provoked or worsened by biperiden (Akineton), tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), caffeine, venlafaxine (Effexor), selegiline (Eldepryl), and serotonin agonists. RBD may also occur during withdrawal from alcohol, meprobamate (Meprospan), pentazocine (Talwin), and nitrazepam (Nitrazadon). Medications known to provoke nightmares include L-DOPA and β -blockers. Nightmares can also be caused by drug-induced REM sleep rebound (e.g., withdrawal from REM-suppressing drugs such as methamphetamine) and alcohol abuse or withdrawal.

Seizure disorder should always be on the top of a differential diagnosis list for most parasomnias. In fact, the American Academy of Sleep Medicine practice guidelines concerning the indications for polysomnography include using sleep testing to rule out seizures when diagnosing sleep terror, sleepwalking, RBD, nightmares, and other parasomnias. Sleep-related breathing disorders are also known to trigger sleepwalking, enuresis, sleep terror, confusional arousal, and nightmares. RBD is associated with a variety of neurological conditions, including Parkinson's disease, dementia, progressive supranuclear palsy, Shy-Drager syndrome (a movement disorder with autonomic arousal symptoms), narcolepsy, and others.

Ms. R, a 20-year-old white woman, was referred with symptoms of talking, mumbling, and crying out during sleep. At least twice per week she screamed in her sleep. She was bothered with excessive sleepiness and falling asleep inappropriately, such as during a conversation. When inactive, she was tired and sleepy, even after a full 8-hour night of sleep. However, she had energy when motivated and led a vigorous life. Once, she awakened outside of her apartment and her roommate had to let her back in because she had locked herself out. She did not recall the sleepwalking episode or other nocturnal wanderings but sometimes remembered yelling. From the history, crying seemed to occur in light sleep, but she rarely recalled any sleep-related thoughts or dreams. However, there was a history of occasional nightmares and bruxism. The patient used an oral appliance to protect her teeth. Leg kicking and mild snoring without gasping or choking were noted. The patient also complained of leg kicking during sleep. Her sleep-wake schedule was irregular, and she averaged between 5 and 7 hours of sleep per night. She occasionally awakened with a headache in the morning.

Previous health history included a hospitalization for febrile convulsions during infancy, ophthalmologic surgery for strabismus during childhood, and tonsillectomy as a teenager. Her health was otherwise excellent. The patient did not smoke tobacco or drink alcohol.

By history, Ms. R had one or more of the parasomnias. Sleep talking alone does not require a sleep study, but this patient had nocturnal wanderings. Polysomnography with clinical EEG are indicated to rule out unrecognized nocturnal seizure disorder or other organic factors inducing sleepwalking. Sleepwalking is common and not necessarily considered abnormal in young children; however, in the adult it is rare and merits careful evaluation. Ms. R's excessive daytime sleepiness was likely due to insufficient sleep (5 to 7 hours per night) and possibly parasomnia-related disruption. Of interest, many parasomnias are exacerbated by sleep deprivation, as is nocturnal seizure disorder.

Sleep studies were performed using comprehensive, attended, laboratory polysomnography. Prior to the overnight study, a clinical EEG was performed. The clinical EEG study did not reveal any significant abnormal EEG activity during baseline, photic stimulation, or hyperventilation. An extended EEG montage was used during the sleep study. Overall sleep quality was within the normal range. Sleep efficiency was 96 percent, and latency to sleep was 1 minute. REM sleep percentage was elevated (31 percent), and latency to REM sleep was less than normal (57 minutes). Slow wave sleep was normal in percentage, but EEG delta activity was of very high amplitude. The overall macroarchitectural sleep pattern suggested rebound from sleep deprivation.

By contrast, sleep microarchitecture contained many abnormal features. There were high-amplitude paroxysmal EEG bursts. Excessively prolonged sleep spindles were noted, and rhythmic K complexes were observed (Fig. 16.2-5). There was one arousal out of slow wave sleep, with rhythmic EEG discharges alternating with sharp waves. Sharps and spikes occurred several times; however, the focus was difficult to localize (possibly right temporal lobe). There were frequent body movements and full body jerks, most of which occurred during NREM sleep. There were episodes of moaning during slow wave sleep and laughing during stage 2 sleep that was followed by high-amplitude theta bursts and REM sleep. There were frequent movements and arousals from REM sleep but no REM-related spikes or sharp waves. Seizure-like EEG activity was noted during the night and occurred predominantly during slow wave sleep. However, the patient did not attempt to sleepwalk. Sharp wave-and-spike activity increased during the final 45 minutes of the sleep study.

FIGURE 16.2-5

Tracings comparing normal sleep spindle activity during stage 2 sleep (A) with that of a patient chronically using a benzodiazepine (B). This patient had been treated with benzodiazepines for more than a decade and was currently taking an extremely high dose before being seen at the sleep disorders center. Sleep was grossly abnormal. The most obvious aberration was the tremendous increase in the frequency, magnitude, and duration of electroencephalogram (EEG) spindle activity (see panel B). In addition, slow wave sleep was absent, stage 2 was grossly elevated, and spindles even intruded into rapid eye movement sleep. EOG, electro-oculogram. Note: This sample is not from the patient described in the case. (Courtesy of Max Hirshkowitz, Ph.D., Rhoda G. Seplowitz-Hafkin, M.D., and Amir Sharafkhaneh, M.D., Ph.D.)

The patient did not have any sleep-related breathing impairment, and oxygen saturation nadir was 90 percent. She had no periodic limb movements during sleep, and polygraphic features associated with restless legs syndrome were absent. (Courtesy of Max Hirshkowitz, Ph.D., Rhoda G. Seplowitz-Hafkin, M.D., and Amir Sharafkhaneh, M.D., Ph.D.)

SLEEP-RELATED MOVEMENT DISORDERS

Restless Legs Syndrome

Restless legs syndrome (RLS) (also known as *Ekbom syndrome*) is an uncomfortable, subjective sensation of the limbs, usually the legs, sometimes described as a “creepy crawly” feeling, and the irresistible urge to move the legs when at rest or while trying to fall asleep. Patients often report the sensation of ants walking on the skin and crawling feelings in their legs. It tends to be worse at night and moving the legs or walking helps to alleviate the discomfort (Fig. 16.2-6). Thus, as the individual is lying in bed and relaxing, he or she is disturbed by these sensations. Then he or she moves the legs and again tries to fall asleep. This cycle sometimes continues for hours and results in profound insomnia. A National Institutes of Health workshop established criteria for the diagnosis of RLS. Uremia, neuropathies, and iron and folic acid deficiency anemias can produce secondary RLS. RLS is also reported in association with fibromyalgia, rheumatoid arthritis, diabetes, thyroid diseases, and COPD. Detailed history and physical examination are important parts of the RLS workup. In addition, the ferritin level should be checked in every patient with symptoms consistent with RLS. Pharmacologically, the dopaminergic agonists pramipexole (Mirapex) and ropinirole (Requip) are FDA approved and represent the treatments of choice. Other agents used to treat RLS include dopamine precursors (e.g., levodopa), benzodiazepines, opiates, and antiepileptic drugs (e.g., gabapentin [Neurontin]). Nonpharmacological treatments include avoiding alcohol use close to bedtime, massaging the affected parts of the legs, taking hot baths, applying hot or cold to the affected areas, and engaging in moderate exercise.

FIGURE 16.2-6

Restless legs syndrome. This patient presented with complaints of uncomfortable, crawling sensations in the legs when trying to fall asleep. Patients commonly report an urge to move the leg to dispel the sensation. This figure shows a bilateral pattern of leg electromyogram (EMG) activity; however, the discharge is more pronounced in the left anterior tibialis (*EMG-AT-L*) than the right (*EMG-AT-R*). This pattern continued for more than an hour as the patient attempted to fall asleep; note that the sharp activity in central and occipital encephalogram (EEG) (*C3-A2* and *O1-A2*, respectively) and electro-oculogram (EOG) is an electrocardiographic (ECG) artifact and not an EEG abnormality. (Courtesy of Constance A. Moore, M.D., Robert L. Williams, M.D., and Max Hirshkowitz, Ph.D.)

Periodic Limb Movement Disorder

Periodic limb movement disorder (PLMD), previously called *nocturnal myoclonus*, involves brief, stereotypic, repetitive, nonepileptiform movements of the limbs, usually the legs. It occurs primarily in NREM sleep and involves an extension of the big toe. A partial flexion of the ankle, knee, and hip may also occur. These movements range from 0.5 to 5 seconds in duration and occur every 20 to 40 seconds. The leg movements are frequently associated with brief arousals from sleep and as a result can (but do not always) disturb sleep architecture. The prevalence of PLMD increases with aging and can occur in association with folate deficiency, renal disease, anemia, and the use of antidepressants. Pharmacotherapy for PLMD associated with RLS is the same as for RLS. Clinical trials of pharmacotherapy for other forms of PLMD are lacking. However, benzodiazepines, especially clonazepam, and opiates improve sleep in patients with PLMD.

Sleep-Related Leg Cramps

Nocturnal leg cramps are much like leg cramps that occur during wakefulness. They usually affect the calf and are painful muscle contractions. The pain awakens the sleeper and thereby disrupts sleep. Metabolic disorders, mineral deficiencies, electrolytic imbalances, diabetes, and pregnancy are known precipitators. The reason that some individuals have repeated leg cramps during sleep and not during the day is not known.

Sleep-Related Bruxism

Sleep-related bruxism is diagnosed when an individual grinds or clenches the teeth during sleep. Formerly classified as a parasomnia, sleep bruxism can produce abnormal wear on the teeth, damage teeth, provoke tooth and jaw pain, or make loud unpleasant sounds that disturb the bed partner. Sometimes atypical facial pain and headache also result. More than 85 percent of the population may brux at one time or another; however, it is clinically significant in only about 5 percent. Teeth grinding occurs in any sleep stage but appears to be most common at transition to sleep, in stage 2 sleep, and during REM sleep. Some evidence indicates that teeth grinding during REM sleep is more commonly associated with dental wear or damage. Sleep bruxism does not appear to be exacerbated by dental malocclusion. It worsens during periods of stress. Researchers studying sleep bruxism have found that many patients seem to have less frequent teeth grinding when sleeping in the laboratory; therefore, repeated study may be needed to document the disorder. By contrast, bruxism frequently appears on polysomnographic recordings made for other purposes (Fig. 16.2-7). Sleep bruxism may occur secondary to sleep-related breathing disorders, the use of psychostimulants (e.g., amphetamine, cocaine), alcohol ingestion, and treatment with SSRIs. Differential diagnosis should rule out nocturnal seizures. Sleep bruxism can occur infrequently (monthly), regularly (weekly), or frequently (nightly). Severity is judged on the basis of sleep disruption, consequent pain, and dental damage. The usual treatment involves having the patient wear an oral appliance to protect the teeth during sleep. There are two basic types of appliances: the soft one (mouth guard) is typical used in the short term, whereas the hard acrylic one (bite splint) is used longer term and requires regular follow-up. Relaxation, biofeedback, hypnosis, physical therapy, and stress management are also used to treat sleep bruxism. A variety of drug therapies have been tried (benzodiazepines, muscle relaxants, dopaminergic agonists, and propranolol [Inderal]), but outcome data are not available.

FIGURE 16.2-7

Sleep-related bruxism. Approximately 25 seconds of tracing obtained from a patient during an episode of bruxism. Bruxism can occur during any stage of sleep or wakefulness. The interference pattern of electroencephalogram (EEG), electro-oculogram (EOG), and electromyogram (EMG) channels is typical and reflects the rhythmic jaw movement and grinding of the teeth. This patient had many such episodes, some of which caused awakening. Readily observable tooth damage and jaw pain were noted. AT-L, left anterior tibialis; AT-R, right anterior tibialis; EKG, electrocardiogram; INTRC, intercostal. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009.)

Sleep-Related Rhythmic Movement Disorder

This sleep disorder is marked by repetitive, rhythmic movements usually involving the head and neck. Usually occurring at the transition from wakefulness to sleep, this movement disorder may also continue during light sleep. Formerly classified as a parasomnia, sleep-related rhythmic movement disorder has many names, including *jactatio capitis nocturna*, head banging, head rolling, body rocking, and *rhythmie du sommeil*. A majority of infants body rock. Some clinicians believe that body rocking develops from the soothing effect of vestibular stimulation. If the rhythmic movement persists into childhood and involves head banging, the risk of injury increases. The male to female ratio is 4 to 1. Severity ranges from less than one episode weekly to nightly episodes producing injury.

Sleep-Related Movement Disorder Due to Drug or Substance Use and Sleep-Related Movement Disorder Due to Medical Condition

A variety of drugs, substances, and comorbid conditions can produce or exacerbate sleep-related movement disorders. Stimulants can produce rhythmic movement disorders and bruxism. Antidepressants (including most tricyclics and SSRIs), antiemetics, lithium (Eskalith), calcium-channel blockers, antihistamines, and neuroleptics can provoke restless legs symptoms and periodic limb movement disorder. Neurologic diseases that are associated with daytime movement disorders can also be associated with sleep-related movement disorders. Stress, anxiety, and sleep deprivation may contribute to bruxism.

ISOLATED SYMPTOMS, APPARENTLY NORMAL VARIANTS, AND UNRESOLVED ISSUES

Long Sleeper

Some individuals are sleepy when they have what most people consider a normal amount of sleep; however, when given the chance to sleep 10 to 12 hours, they are refreshed. These people are classified as long sleepers. This pattern of requiring more than the average amount of sleep is usually present since childhood. Polysomnography may help to differentiate a long sleeper from someone with idiopathic hypersomnia. There may be associated autonomic nervous system dysfunction or polysomnographic evidence of elevated slow wave sleep percentage in patients with idiopathic hypersomnia.

Short Sleeper

People who fall under the category of short sleeper require less than 5 hours of sleep per 24-hour period in order to maintain normal daytime functioning and mood. This appears to run in families, but the specific genes are unknown.

Snoring

Primary snoring consists of loud snoring in the absence of recurrent apnea or hypopnea episodes. The sound may disturb the bed partner to the extent that the persons sleep in

separate rooms. To be classified as primary snoring, the individual must not be suffering from excessive sleepiness. Snoring may become louder when the individual sleeps supine or during REM sleep. A variety of oral appliances have been developed to decrease snoring (see “Treatment” under “Breathing-Related Sleep Disorders”).

Sleep Talking

As the name implies, sleep talking in its classic form involves unconscious speech during sleep. It is seldom recognized in an individual unless it annoys the bed partner. It can be induced by fever, stress, or conversing with the sleeper. Somniloquy may accompany sleep terror, sleepwalking, confusional arousals, OSA, and REM sleep behavior disorder.

Sleep Starts (Hypnic Jerk)

Sleep starts are sudden, brief muscle contractions that occur at the transition between wakefulness and sleep in 60 to 70 percent of adults. The contractions commonly involve the legs; however, sometimes there is movement in the arms and head. This “hypnic jerk,” as it is sometimes called, is usually benign. The sleep start, however, can interfere with the ability to fall asleep and may be accompanied by sensations of falling, a hallucinated flash of light, or a loud crackling sound. In severe cases the sleep start produces profound sleep-onset insomnia.

Benign Sleep Myoclonus of Infancy

Previously called benign neonatal sleep myoclonus, this disorder is characterized by asynchronous jerking of limbs and trunk during quiet sleep in neonates. This benign, apparently rare parasomnia usually begins within the first week of life and may last a few days or several months. No treatment is recommended.

Hypnagogic Foot Tremor and Alternating Leg Muscle Activation during Sleep

Hypnagogic foot tremor (HFT) occurs at sleep onset or during stages 1 and 2 of sleep. It consists in a rhythmic movement of the toes or feet for seconds to minutes. Alternating leg muscle activation (ALMA) consists of brief activation of the anterior tibialis in one leg and then the other.

Propriospinal Myoclonus at Sleep Onset

This is a spinal cord-mediated movement disorder that is sometimes associated with spinal cord lesions. Movements appear during times of wakeful relaxation and then may interfere with sleep onset. They start in the abdominal and truncal muscles and then progress to the neck and proximal muscles of the limbs. Treatment with clonazepam or anticonvulsants may be effective.

Excessive Fragmentary Myoclonus

These small movements or muscle fasciculations of the fingers, toes, or corners of the mouth are involuntary and can occur during wakefulness or sleep. Although no visible movement is present, the patient is typically aware of the twitching. In patients with apnea, twitching may worsen during periods of hypoxemia.

OTHER SLEEP DISORDERS

Other Physiological (Organic) Sleep Disorders

This category is for sleep disorders that do not fit into any other ICSD-2 classification. The disorders in this category are suspected to have a medical or physiological etiology even if the etiology is not known at the time of diagnosis.

Other Sleep Disorder Not Due to Substance Use or Known Physiological Conditions

This category is for sleep disorders that do not fit into any other ICSD-2 classification and are believed to be due to psychiatric or behavioral factors.

Environmental Sleep Disorder

This is a sleep disorder secondary to environmental factors that contribute to insomnia or daytime somnolence (from insomnia or poor sleep). Noise, heat, cold, light, bed partner noise, bed partner activity, or perceived danger can induce an environmental sleep disorder. The insomnia or hypersomnia are directly caused by the disturbing environmental factor. An example of an environmental factor is having a neighbor who plays music loudly every night. Onset, course, and termination of the problem are correlated with the introduction, presence, and removal of the specific factor or factors. Thus, treatment involves identifying and removing the environmental irritant.

TOOLS IN SLEEP MEDICINE

Clinical Interview

A careful and thorough clinical interview is one of the most informative parts of a patient workup for sleep disorders. The habitual bedtime and arising times for both weekdays and weekends, the frequency, duration, and refreshingness of naps, and overall level of sleepiness are good places to begin. Specific sleep problems relating to difficulty initiating and maintaining sleep are important, including whether there is rumination at bedtime, fear of not being able to sleep, or excessive worry when attempting to sleep. Leg movement, leg sensations, leg cramps, teeth grinding, dream enactments (with or without injury), and other movements should be queried. Morning headaches, morning dry mouth, nocturnal reflux, hyperhidrosis, nocturia, enuresis, nocturnal tongue biting, nightmares, sleep terrors, and other sleep-related problems should be reviewed. Asking about the presence of family pets and whether they sleep in the bedroom (or bed) can be important in some cases.

Polysomnography

Polysomnography is the continuous, attended, comprehensive recording of the biophysiological changes that occur during sleep. Each 30-second segment of the recording is considered an “epoch.” A polysomnogram is typically recorded at night and lasts between 6 and 8 hours. Brain wave activity, eye movements, submental electromyography activity, nasal-oral airflow, respiratory effort, oxyhemoglobin saturation, heart rhythm, and leg movements during sleep are measured. Body position is usually noted, and snoring sounds may be recorded. Brain wave activity, eye movements, and submental electromyogram are important for identifying sleep stages. Muscle tension and movements subside with deeper sleep and can also be useful in the diagnosis of periodic limb movement disorder and restless legs syndrome. Nasal airflow, respiratory effort, and oxyhemoglobin saturation are instrumental in diagnosing sleep apnea and other sleep-related breathing disorders.

Indications for polysomnography include (1) diagnosis of sleep-related breathing disorders, (2) positive airway pressure titration and assessment of treatment efficacy, and (3) evaluation of sleep-related behaviors that are violent or may potentially harm the patient or bed partner. Polysomnography can also be used to diagnose atypical parasomnias, sleep-related problems secondary to neuromuscular disorders, periodic limb movement disorder, and arousals secondary to seizure disorder. In addition, patients with excessive daytime sleepiness or

those who wake up gasping or choking should be referred for polysomnography. A sleep study is not needed to diagnose RLS.

Referrals for polysomnography should be considered in cases in which sleeplessness has been present for 6 months or more for a minimum of four nights a week. It should also be considered when insomnia has not responded to pharmacological or behavioral therapy, sleep-promoting medications are contraindicated, or a medical or psychiatric cause has been excluded. Referral should also be made if the treatment of an underlying medical or psychiatric comorbidity has failed to resolve the insomnia.

Polysomnography is also recommended to assess sleep quality and quantity on the night just prior to a multiple sleep latency test being conducted to diagnose narcolepsy.

Multiple Sleep Latency Test

The multiple sleep latency test (MSLT) is indicated for diagnosing narcolepsy. Beginning 2 hours after morning awakening, 20-minute nap opportunities are provided during which the patient is instructed to let himself or herself fall asleep and not resist falling asleep. Electroencephalographic, electro-oculographic, and submental electromyography activity is recorded to determine sleep stage. The latency to sleep is used to assess the level of sleepiness, and the appearance of REM sleep on two or more nap opportunities confirms narcolepsy, especially when other ancillary symptoms are present (e.g., cataplexy, sleep paralysis, hypnagogia, and excessive sleepiness). If the patient falls asleep on a given nap opportunity, the nap is terminated 15 minutes after initial sleep onset. If the patient does not fall asleep, the session is terminated after 20 minutes of recording. Five nap opportunities are provided at 2-hour intervals across the day.

Maintenance of Wakefulness Test

Similar procedurally to the MSLT, the maintenance of wakefulness test (MWT) provides 40-minute test sessions at 2-hour intervals across the day, but the patient is instructed to try to remain awake. This technique is used to assess treatment outcomes and is sometimes required as part of “fit for duty” testing. Patients sit in a comfortable chair or on the bed with a bolster pillow in a darkened room while recordings are made. The first epoch of stage 2, 3, or 4 sleep or REM or three consecutive epochs of stage 1 mark unequivocal sleep onset. Falling asleep on MWT indicates some level of sleepiness. Fifty-nine percent of volunteers (presumably normal) remain awake for the entire 40 minutes across all four trials (using unequivocal sleep criteria). Any sleep latency of less than 8 minutes is abnormal. Sleep latency ranging from 8 to 40 minutes is of unknown significance. The mean sleep latency (first sleep epoch) is 30.4 ± 11.2 minutes, and the upper 95 percent confidence interval is 40 minutes.

Actigraphy

An actigraph is a device that measures and records movement. It is usually worn on the wrist (like a watch) and can be used as a rough measure of the sleep-wake cycle. Depending on the model and the settings, it can make continuous recordings for days or weeks. It can be especially useful for assessing insomnia, circadian rhythm disorders, movement disorders, and an assortment of rare events.

Home Sleep Testing

Recently approved by Medicare, home sleep testing involves recording a limited number of cardiopulmonary parameters to assess patients for sleep-related breathing disorders. Home sleep testing is much less expensive than polysomnography. Usually, airflow, respiratory effort, heart rhythm, snoring sounds, and oximetry are recorded. A number of devices are commercially available that are capable of detecting sleep apnea in patients with moderate to severe pathophysiology. Negative studies are problematic because home sleep testing is less sensitive than full laboratory polysomnography. Patients with negative tests notwithstanding obvious symptoms or comorbidity should be scheduled for laboratory sleep study. In addition, home sleep testing does not check for the full spectrum of sleep disorders; therefore, residual symptoms after a breathing disorder is diagnosed in this manner need careful follow-up.

Human Sexuality and Sexual Dysfunctions

▲ 17.1 Normal Sexuality

Sexuality has always been an area of interest to the medical community. In the classical era, Hippocrates cited the clitoris as the site of female sexual arousal, the first physician historically recorded to have made that assessment. In the middle ages, Islamic physicians recommended coitus interruptus as a form of birth control. At the end of the Renaissance and the beginning of the Reformation, a linen sheath was devised as a condom, not for purposes of birth control, but as protection against syphilis. During the Victorian era, sexologists such as Havelock Ellis (Fig. 17.1-1) and Richard von Krafft-Ebing (Fig. 17.1-2) presented diverging perspectives on sexual behavior. During that same period, Sigmund Freud developed his innovative theories on libido, childhood sexuality, and the effects of the sexual impulse on human behavior. In the modern era, the research of Alfred Kinsey, the work of William Masters and Virginia Johnson, and the development of drugs that prevent contraception, aid erection, and replace hormones that decrease with menopause and aging contributed to the development of an era of sexual liberality. Sex has also been a consistent focus of curiosity and interest to humankind in general. Depictions of sexual behavior have existed from the time of prehistoric cave drawings through Leonardo da Vinci's anatomical illustrations of intercourse to current pornographic sites on the Internet.

FIGURE 17.1-1

FIGURE 17.1-2
Richard von Krafft-Ebing. (Courtesy of NYU School of Medicine.)

Sexuality is determined by anatomy, physiology, the culture in which a person lives, relationships with others, and developmental experiences throughout the life cycle. It includes the perception of being male or female and private thoughts and fantasies as well as behavior. To the average person, sexual attraction to another person and the passion and love that follow are deeply associated with feelings of intimate happiness.

Normal sexual behavior brings pleasure to oneself and one's partner and involves stimulation of the primary sex organs including coitus; it is devoid of inappropriate feelings of guilt or anxiety and is not compulsive. Societal understanding of what defines normal sexual behavior is inconstant and varies from era to era, reflecting the cultural mores of the time.

TERMS

Sexuality and total personality are so entwined that to speak of sexuality as a separate entity is virtually impossible. The term *psychosexual*, therefore, is used to describe personality development and functioning as these are affected by sexuality. The term *psychosexual* applies to more than sexual feelings and behavior, and it is not synonymous with *libido* in the broad Freudian sense.

Freud's generalization that all pleasurable impulses and activities are originally sexual has given laypersons a somewhat distorted view of sexual concepts and has presented psychiatrists with a confused picture of motivation. For example, some oral activities are directed toward obtaining food, and others are directed toward achieving sexual gratification. Both activities are pleasure seeking and use the same organ, but they are not, as Freud contended, both necessarily sexual. Labeling of all pleasure-seeking behaviors as sexual makes it impossible to specify precise motivations. Persons may also use sexual activities for gratification of nonsexual needs, such as dependency, aggression, power, and status. Although sexual and nonsexual impulses can jointly motivate behavior, the analysis of behavior depends on understanding the underlying individual motivations and their interactions.

CHILDHOOD SEXUALITY

Before Freud described the effects of childhood experiences on personalities of adults, the universality of sexual activity and sexual learning in children was unrecognized. Most sexual learning experiences in childhood occur without the parents' knowledge, but awareness of a child's sex does influence parental behavior. Male infants, for instance, tend to be handled more vigorously and female infants tend to be cuddled more. Fathers spend more time with their infant sons than with their daughters, and they also tend to be more aware of their sons' adolescent concerns than of their daughters' anxieties. Boys are more likely than girls to be physically disciplined. A child's sex affects parental tolerance for aggression and reinforcement or extinction of activity and of intellectual, aesthetic, and athletic interests.

Observation of children reveals that genital play in infants is part of normal development. According to Harry Harlow, interaction with mothers and peers is necessary for the development of effective adult sexual behavior in monkeys, a finding that has relevance to the normal socialization of children. During a critical period in development, infants are especially susceptible to certain stimuli; later, they may be immune to these stimuli. The detailed relation of critical periods to psychosexual development has yet to be established; Freud's stages of psychosexual development—oral, anal, phallic, latent, and genital—presumably provide a broad framework.

PSYCHOSEXUAL FACTORS

Sexuality depends on four interrelated psychosexual factors: sexual identity, gender identity, sexual orientation, and sexual behavior. These factors affect personality, growth, development, and functioning. Sexuality is something more than physical sex, coital or noncoital, and something less than all behaviors directed toward attaining pleasure.

Sexual Identity and Gender Identity

Sexual identity is the pattern of a person's biological sexual characteristics: chromosomes, external genitalia, internal genitalia, hormonal composition, gonads, and secondary sex characteristics. In normal development, these characteristics form a cohesive pattern that leaves a person in no doubt about his or her sex. Gender identity is a person's sense of maleness or femaleness. Sexual identity and gender identity are interactive. Genetic influences and hormones affect behavior, and the environment affects hormonal production and gene expression (Table 17.1-1).

 **Table 17.1-1**
Classification of Intersexual Disorders^a

Syndrome	Description
Virilizing adrenal hyperplasia (adrenogenital syndrome)	Results from excess androgens in fetus with XX genotype; most common female intersex disorder; associated with enlarged clitoris, fused labia, hirsutism in adolescence
Turner's syndrome	Results from absence of second female sex chromosome (XO); associated with web neck, dwarfism, cubitus valgus; no sex hormones produced; infertile
Klinefelter's syndrome	Genotype is XXY; male habitus present with small penis and rudimentary testes because of low androgen production; weak libido; usually assigned as male
Androgen insensitivity syndrome (testicular-feminizing syndrome)	Congenital X-linked recessive disorder that results in inability of tissues to respond to androgens; external genitals look female and cryptorchid testes present; in extreme form patient has breasts, normal external genitals, short blind vagina, and absence of pubic and axillary hair
Enzymatic defects in XY genotype (e.g., 5- α -reductase deficiency, 17-hydroxy-steroid deficiency)	Congenital interruption in production of testosterone that produces ambiguous genitals and female habitus
Hermaphroditism	True hermaphrodite is rare and characterized by both testes and ovaries in same person (may be 46 XX or 46 XY)
Pseudohermaphroditism	Usually the result of endocrine or enzymatic defect (e.g., adrenal hyperplasia) in persons with normal chromosomes; female pseudohermaphrodites have masculine-looking genitals but are XX; male pseudohermaphrodites have rudimentary testes and external genitals and are XY

^aIntersexual disorders include a variety of syndromes that produce persons with gross anatomical or physiological aspects of the opposite sex.

Sexual Identity. Modern embryological studies have shown that all mammalian embryos, whether genetically male (XY genotype) or genetically female (XX genotype), are anatomically female during the early stages of fetal life. Differentiation of the male from the female results from the action of fetal androgens; the action begins about the sixth week of embryonic life and is completed by the end of the third month (Fig. 17.1-3). Recent research has focused on the possible roles of key genes in fetal sexual development. A testis develops as a result of SRY and SOX9 action, and an ovary develops in the absence of such action. DAX1 plays a part in the fetal development of both sexes and WNT4 action is needed for the development of the mullerian ducts in the female fetus. Other studies have explained the effects of fetal hormones on the masculinization or feminization of the brain. In animals, prenatal hormonal stimulation of the brain is necessary for male and female reproductive and copulatory behavior. The fetus is also vulnerable to exogenously administered androgens during that period. For instance, if a pregnant woman receives sufficient exogenous androgens, her female fetus that possesses ovaries can develop external genitalia resembling those of a male fetus (Fig. 17.1-4).

FIGURE 17.1-3

Differentiation of male and female external genitalia from indifferent primordia. Male differentiation occurs only in the presence of androgenic stimulation during the first 12 weeks of fetal life.

(Redrawn from van Wyk and Grumbach, 1968; from Brobeck JR, ed. *Best & Taylor's Physiological Basis of Medical Practice*. 9th ed. Baltimore: Williams & Wilkins; 1973, with permission.)

FIGURE 17.1-4

Twins born to a mother who received testosterone during pregnancy. Note the enlarged clitoris in each child. (Courtesy of Robert B. Greenblatt, M.D., and Virginia McNamarra, M.D.)

In the past, newborns with ambiguous genitalia were assigned their sexual identity at birth. The theory underlying this action was that parents and child would feel less confusion, and that the child would accept the assigned sex and more easily develop a stable sense of being male or female. Although this worked for some children, others developed a gender identity at odds with their assigned sex. For example, an infant designated female at birth could feel itself to be male throughout childhood, and more emphatically at puberty. In some cases, this conflict led to depression and even suicide. Current practice usually allows the child to develop with the ambiguity, which permits a sense of gender identity to evolve as the child grows. The gender identity is then more congruent with the child's emotional sense of maleness or femaleness. Ideally, the family receives support from a medical team composed of a pediatrician, an endocrinologist, and a psychiatrist throughout this developmental process.

Gender Identity. In infants with an unambiguous sexual identity, almost everyone has a firm conviction that "I am male" or "I am female" by 2 to 3 years of age. Yet, even if maleness and femaleness develop normally, persons must still develop a sense of masculinity or femininity.

Gender identity, according to Robert Stoller, "connotes psychological aspects of behavior related to masculinity and femininity." Stoller considers gender social and sex biological: "Most often the two are relatively congruent, that is, males tend to be manly and females womanly." But sex and gender can develop in conflicting or even opposite ways. Gender identity results from an almost infinite series of cues derived from experiences with family members, teachers, friends, and coworkers, and from cultural phenomena. Physical characteristics derived from a person's biological sex—such as physique, body shape, and physical dimensions—interrelate with an intricate system of stimuli, including rewards and punishment and parental gender labels, to establish gender identity.

Thus, formation of gender identity arises from parental and cultural attitudes, the infant's external genitalia, and a genetic influence, which is physiologically active by the sixth week of fetal life. Although family, cultural, and biological influences may complicate establishment of a sense of masculinity or femininity, persons usually develop a relatively secure sense of identification with their biological sex—a stable gender identity.

GENDER ROLE. Related to, and in part derived from, gender identity is gender role behavior. John Money and Anke Ehrhardt described gender role behavior as all those things that a person says or does to disclose himself or herself as having the status of boy or man, girl or woman, respectively. A gender role is not established at birth but is built up cumulatively through (1) experiences encountered and transacted through casual and unplanned learning, (2) explicit instruction and inculcation, and (3) spontaneously putting two and two

together to make sometimes four and sometimes five. The usual outcome is a congruence of gender identity and gender role. Although biological attributes are significant, the major factor in achieving the role appropriate to a person's sex is learning.

Research on sex differences in children's behavior reveals more psychological similarities than differences. Girls, however, are found to be less susceptible to tantrums after the age of 18 months than are boys, and boys generally are more physically and verbally aggressive than are girls from age 2 onward. Little girls and little boys are similarly active, but boys are more easily stimulated to sudden bursts of activity when they are in groups. Some researchers speculate that, although aggression is a learned behavior, male hormones may have sensitized boys' neural organizations to absorb these lessons more easily than do girls.

Persons' gender roles can seem to be opposed to their gender identities. Persons may identify with their own sex and yet adopt the dress, hairstyle, or other characteristics of the opposite sex. Or, they may identify with the opposite sex and yet for expediency adopt many behavioral characteristics of their own sex. A further discussion of gender issues appears in [Chapter 18](#).

Sexual Orientation

Sexual orientation describes the object of a person's sexual impulses: heterosexual (opposite sex), homosexual (same sex), or bisexual (both sexes). A group of people have defined themselves as "asexual" and assert this as a positive identity. Some researchers believe this lack of attraction to any object is a manifestation of a desire disorder. Other people wish not to define their sexual orientation at all and avoid labels. Still others describe themselves as polysexual or pansexual.

Sexual Behavior

The Central Nervous System and Sexual Behavior

THE BRAIN

Cortex. The cortex is involved both in controlling sexual impulses and in processing sexual stimuli that may lead to sexual activity. In studies of young men, some areas of the brain have been found to be more active during sexual stimulation than others. These include the orbitofrontal cortex, which is involved in emotions; the left anterior cingulate cortex, which is involved in hormone control and sexual arousal; and the right caudate nucleus, whose activity is a factor in whether sexual activity follows arousal.

Limbic System. In all mammals, the limbic system is directly involved with elements of sexual functioning. Chemical or electrical stimulation of the lower part of the septum and the contiguous preoptic area, the fimbria of the hippocampus, the mammillary bodies, and the anterior thalamic nuclei have all elicited penile erections.

Studies of the brain in women have revealed that those areas activated by emotions of fear or anxiety are notably quiescent when the woman experiences an orgasm.

Brainstem. Brainstem sites exert inhibitory and excitatory control over spinal sexual reflexes. The nucleus paragigantocellularis projects directly to pelvic efferent neurons in the lumbosacral spinal cord, apparently causing them to secrete serotonin, which is known to inhibit orgasms. The lumbosacral cord also receives projections from other serotonergic nuclei in the brainstem.

Brain Neurotransmitters. Many neurotransmitters, including dopamine, epinephrine, norepinephrine, and serotonin, are produced in the brain and affect sexual function. For example, an increase in dopamine is presumed to increase libido. Serotonin, produced in the upper pons and midbrain, exerts an inhibitory effect on sexual function. Oxytocin is released with orgasm and is believed to reinforce pleasurable activities.

SPINAL CORD. Sexual arousal and climax are ultimately organized at the spinal level. Sensory stimuli related to sexual function are conveyed via afferents from the pudendal, pelvic, and hypogastric nerves. Several separate experiments suggest that sexual reflexes are mediated by spinal neurons in the central gray region of the lumbosacral segments.

Physiological Responses. Sexual response is a true psychophysiological experience. Arousal is triggered by both psychological and physical stimuli; levels of tension are experienced both physiologically and emotionally; and, with orgasm, normally a subjective perception of a peak of physical reaction and release occurs along with a feeling of well-being. Psychosexual development, psychological attitudes toward sexuality, and attitudes toward one's sexual partner are directly involved with, and affect, the physiology of human sexual response.

Normally, men and women experience a sequence of physiological responses to sexual stimulation. In the first detailed description of these responses, Masters and Johnson observed that the physiological process involves increasing levels of vasocongestion and myotonia (tumesence) and the subsequent release of the vascular activity and muscle tone as a result of orgasm (detumesence). [Tables 17.1-2](#) and [17.1-3](#) describe the physiologic male and female sexual response cycles. It is important to remember that the sequence of responses can overlap and fluctuate. A sexual fantasy or the desire to have sex frequently precedes the physiological responses of excitement, orgasm and resolution, particularly in the male. In addition, a person's subjective experiences are as important to sexual satisfaction as the objective physiologic response. [Figures 17.1-5](#) and [17.1-6](#) illustrate several possible patterns in the phases of the male sexual response and female sexual response, respectively.

FIGURE 17.1-6

FIGURE 17.1-6

Female sexual response. An individual woman may experience any of these three patterns (A, B, or C) during a particular sexual experience. (From Walker JI, ed. *Essentials of Clinical Psychiatry*, Philadelphia: JB Lippincott; 1985:276. with permission.)

FIGURE 17.1-5

Male sexual response. An individual man may experience any of these three patterns (A, B, or C) during a particular sexual experience. (From Walker JI, ed. *Essentials of Clinical Psychiatry*. Philadelphia: JB Lippincott; 1985:276, with permission.)

Table 17.1-2
Male Sexual Response Cycle^a

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
	Lasts several minutes to several hours; heightened excitement before orgasm, 30 seconds to 3 minutes	3 to 15 seconds	10 to 15 minutes; if no orgasm, ½ to 1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck and can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Penis	Erection in 10 to 30 seconds caused by vasocongestion of erectile bodies of corpus cavernosa of shaft; loss of erection may occur with introduction of asexual stimulus, loud noise; with heightened excitement, size of glands and diameter of penile shaft increase further	Ejaculation; emission phase marked by three to four 0.8-second contractions of vas, seminal vesicles, prostate; ejaculation proper marked by 0.8-second contractions of urethra and ejaculatory spurt of 12 to 20 inches at age 18, decreasing with age to seepage at 70	Erection: partial involution in 5 to 10 seconds with variable refractory period; full detumescence in 5 to 30 minutes
Scrotum and testes	Tightening and lifting of scrotal sac and elevation of testes; with heightened excitement, 50% increase in size of testes over unstimulated state and flattening against perineum, signaling impending ejaculation	No change	Decrease to baseline size because of loss of vasocongestion; testicular and scrotal descent within 5 to 30 minutes after orgasm; involution may take several hours if no orgasmic release takes place
Cowper's glands	2 to 3 drops of mucoid fluid that contain viable sperm are secreted during heightened excitement	No change	No change
Other	Breasts: inconsistent nipple erection with heightened excitement before orgasm Myotonia: semispastic contractions of facial, abdominal, and intercostal muscles Tachycardia: up to 175 beats a minute Blood pressure: rise in systolic 20 to 80 mm; in diastolic 10 to 40 mm Respiration: increased	Loss of voluntary muscular control Rectum: rhythmical contractions of sphincter Heart rate: up to 180 beats a minute Blood pressure: up to 40 to 100 mm systolic; 20 to 50 mm diastolic Respiration: up to 40 respirations a minute	Return to baseline state in 5 to 10 minutes A refractory period follows orgasm, during which time the male cannot be rearoused to erection and is unresponsive to stimulation. The length of the refractory period is age and situation dependent

^aA desire phase consisting of sex fantasies and desire to have sex precedes excitement phase. (Table by Virginia Sadock, M.D.)

Table 17.1-3
Female Sexual Response Cycle^a

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
	Lasts several minutes to several hours; heightened excitement before orgasm, 30 seconds to 3 minutes	3 to 15 seconds	10 to 15 minutes; if no orgasm, 1/2 to 1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck; can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Breasts	Nipple erection in two thirds of women, venous congestion and areolar enlargement; size increases to one fourth over normal	Breasts may become tremulous	Return to normal in about 30 minutes
Clitoris	Enlargement in diameter of glands and shaft; just before orgasm, shaft retracts into prepuce	No change	Shaft returns to normal position in 5 to 10 seconds; detumescence in 5 to 30 minutes; if no orgasm, detumescence takes several hours
Labia majora	Nullipara: elevate and flatten against perineum Multipara: congestion and edema	No change	Nullipara: decrease to normal size in 1 to 2 minutes Multipara: decrease to normal size in 10 to 15 minutes
Labia minora	Size increased two to three times over normal; change to pink, red, deep red before orgasm	Contractions of proximal labia minora	Return to normal within 5 minutes
Vagina	Color change to dark purple; vaginal transudate appears 10 to 30 seconds after arousal; elongation and ballooning of vagina; lower third of vagina constricts before orgasm	3 to 15 contractions of lower third of vagina at intervals of 0.8 second	Ejaculate forms seminal pool in upper two thirds of vagina; congestion disappears in seconds or, if no orgasm, in 20 to 30 minutes
Uterus	Ascends into false pelvis; labor-like contractions begin in heightened excitement just before orgasm	Contractions throughout orgasm	Contractions cease, and uterus descends to normal position
Other	Myotonia A few drops of mucoid secretion from Bartholin's glands during heightened excitement Cervix swells slightly and is passively elevated with uterus	Loss of voluntary muscular control Rectum: rhythmical contractions of sphincter Hyperventilation and tachycardia	Return to baseline status in seconds to minutes Cervix color and size return to normal, and cervix descends into seminal pool

^aA desire phase consisting of sex fantasies and desire to have sex may precede or overlap with the excitement phase.
(Table by Virginia Sadock, M.D.)

HORMONES AND SEXUAL BEHAVIOR

In general, substances that increase dopamine levels in the brain increase desire, whereas substances that augment serotonin decrease desire. Testosterone increases libido in both men and women, although estrogen is a key factor in the lubrication involved in female arousal and may increase sensitivity in the woman to stimulation. Recent studies indicate that estrogen is also a factor in the male sexual response and that a decrease in estrogen in the middle-aged male results in greater fat accumulation just as it does in women. Progesterone mildly depresses desire in men and women as do excessive prolactin and cortisol. Oxytocin is involved in pleasurable sensations during sex and is found in higher levels in men and women following orgasm.

GENDER DIFFERENCES IN DESIRE AND EROTIC STIMULI

Sexual impulses and desire exist in men and women. In measuring desire by the frequency of spontaneous sexual thoughts, interest in participating in sexual activity, and alertness to sexual cues, males generally possess a higher baseline level of desire than do women, which may be biologically determined. Motivations for having sex, other than desire, exist in both men and women, but seem to be more varied and prevalent in women. In women they may include a wish to reinforce the pair bond, the need for a feeling of closeness, a way of preventing the man from straying, or a desire to please the partner.

Although explicit sexual fantasies are common to both sexes, the external stimuli for the fantasies frequently differ for men and women. Many men respond sexually to visual stimuli of nude or barely dressed women. Women report responding sexually to romantic stories such as a demonstrative hero whose passion for the heroine impels him toward a lifetime commitment to her. A complicating factor is that a woman's subjective sense of arousal is not always congruent with her physiological state of arousal. Specifically, her sense of excitement may reflect a readiness to be aroused rather than physiological lubrication. Conversely, she may experience signs of arousal, including vaginal lubrication, without being aware of them. This situation rarely occurs in men.

MASTURBATION

Masturbation is usually a normal precursor of object-related sexual behavior. No other form of sexual activity has been more frequently discussed, more roundly condemned, and more universally practiced than masturbation. Research by Kinsey into the prevalence of masturbation indicated that nearly all men and three fourths of all women masturbate sometime during their lives.

Longitudinal studies of development show that sexual self-stimulation is common in infancy and childhood. Just as infants learn to explore the functions of their fingers and mouths, they learn to do the same with their genitalia. At about 15 to 19 months of age, both sexes begin genital self-stimulation. Pleasurable sensations result from any gentle touch to the genital region. Those sensations, coupled with the ordinary desire for exploration of the body, produce a normal interest in masturbatory pleasure at that time. Children also develop an increased interest in the genitalia of others—parents, children, and even animals. As youngsters acquire playmates, the curiosity about their own and others' genitalia motivates episodes of exhibitionism or genital exploration. Such experiences, unless blocked by guilty fear, contribute to continued pleasure from sexual stimulation.

With the approach of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity intensifies, and masturbation increases. Adolescents are physically capable of coitus and orgasm, but are usually inhibited by social restraints. The dual and often conflicting pressures of establishing their sexual identities and controlling their sexual impulses produce a strong physiological sexual tension in teenagers that demands release, and masturbation is a normal way to reduce sexual tensions. In general, males learn to masturbate to orgasm earlier than females and masturbate more frequently. An important emotional difference between the adolescent and the youngster of earlier years is the presence of coital fantasies during masturbation in the adolescent. These fantasies are an important adjunct to the development of sexual identity; in the comparative safety of the imagination, the adolescent learns to perform the adult sex role. This autoerotic activity is usually maintained into the young adult years, when it is normally replaced by coitus.

Couples in a sexual relationship do not abandon masturbation entirely. When coitus is unsatisfactory or is unavailable because of illness or the absence of the partner, self-stimulation often serves an adaptive purpose, combining sensual pleasure and tension release.

Kinsey reported that when women masturbate, most prefer clitoral stimulation. Masters and Johnson stated that women prefer the shaft of the clitoris to the glans because the glans is hypersensitive to intense stimulation. Most men masturbate by vigorously stroking the penile

shaft and glans.

Several studies found that in men, orgasm from masturbation raised the serum prostate-specific antigen (PSA) significantly. Male patients scheduled for PSA tests should be advised not to masturbate (or have coitus) for at least 7 days prior to the examination.

Moral taboos against masturbation have generated myths that masturbation causes mental illness or decreased sexual potency. No scientific evidence supports such claims. Masturbation is a psychopathological symptom only when it becomes a compulsion beyond a person's willful control. Then, it is a symptom of emotional disturbance, not because it is sexual but because it is compulsive. Masturbation is probably a universal aspect of psychosexual development and, in most cases, it is adaptive.

COITUS

The first coitus is a rite of passage for both men and women. In the United States the overwhelming majority of people have experienced coitus by young adulthood, by their early 20s. In a study of persons ages 18 to 59, over 95 percent had included coitus in their last sexual interaction.

The young man experiencing intercourse for the first time is vulnerable in his pride and self-esteem. Cultural myths still perpetuate the idea that he should be able to have an erection with no, or little, stimulation, and that he should have an easy mastery over the situation, even though it is an act that he has never before experienced. Cultural pressure on the woman with her first coitus reflects remaining cultural ambivalence about her loss of virginity, despite the current era of sexual liberality. This is demonstrated in the statistic that only 50 percent of young women use contraception during their first coitus, and of that 50 percent, an even smaller number use it consistently thereafter. Young women with a history of masturbation are more likely to approach intercourse with positive anticipation and confidence.

In the last decade, coitus has also been part of the sexual repertoire of elderly adults, due to the development of sildenafil type drugs, which facilitate erections in men, and hormonally enhanced creams or hormonal pills, which counteract vaginal atrophy in postmenopausal women. Prior to the development of these drugs, many elderly adults enjoyed gratifying sex play, exclusive of coitus.

HOMOSEXUALITY

In 1973 homosexuality was eliminated as a diagnostic category by the American Psychiatric Association, and in 1980, it was removed from the Diagnostic and Statistical Manual of Mental Disorders (DSM). The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) states: "Sexual orientation alone is not to be regarded as a disorder." This change reflects a change in the understanding of homosexuality, which is now considered to occur with some regularity as a variant of human sexuality, not as a pathological disorder. As David Hawkins wrote, "The presence of homosexuality does not appear to be a matter of choice; the expression of it is a matter of choice."

Definition

The term *homosexuality* often describes a person's overt behavior, sexual orientation, and sense of personal or social identity. Many persons prefer to identify sexual orientation by using terms such as *lesbians* and *gay men*, rather than *homosexual*, which may imply pathology and etiology based on its origin as a medical term, and refer to sexual behavior with terms such as *same sex* and *male-female*. Hawkins wrote that the terms *gay* and *lesbian* refer to a combination of self-perceived identity and social identity; they reflect a person's sense of belonging to a social group that is similarly labeled. Homophobia is a negative attitude toward, or fear of, homosexuality or homosexuals. Heterosexism is the belief that a heterosexual relationship is preferable to all others; it implies discrimination against those practicing other forms of sexuality.

Prevalence

Recent research reports rates of homosexuality in 2 to 4 percent of the population. A 1994 survey by the US Bureau of the Census concluded that the male prevalence rate for homosexuality is 2 to 3 percent. A 1989 University of Chicago study showed that less than 1 percent of both sexes are exclusively homosexual. The Alan Guttmacher Institute found in 1993 that 1 percent of men reported exclusively same-sex activity in the previous year and that 2 percent reported a lifetime history of homosexual experiences.

Some lesbians and gay men, particularly the latter, report being aware of same-sex romantic attractions before puberty. According to Kinsey's data, about half of all prepubertal boys have had some genital experience with a male partner. These experiences are often exploratory, particularly when shared with a peer, not an adult, and typically lack a strong affective component. Most gay men recall the onset of romantic and erotic attractions to same-sex partners during early adolescence. For women, the onset of romantic feelings toward same-sex partners may also be in preadolescence, but the clear recognition of a same-sex partner preference typically occurs in middle to late adolescence or in young adulthood. More lesbians than gay men appear to have engaged in heterosexual experiences. In one study, 56 percent of lesbians had experienced heterosexual intercourse before their first genital homosexual experience, compared with 19 percent of gay men who had sampled heterosexual intercourse first. Nearly 40 percent of the lesbians had had heterosexual intercourse during the year preceding the survey.

Theoretical Issues

Psychological Factors. The determinants of homosexual behavior are enigmatic. Freud viewed homosexuality as an arrest of psychosexual development and mentioned castration fears and fears of maternal engulfment in the preoedipal phase of psychosexual development. According to psychodynamic theory, early life situations that can result in male homosexual behavior include a strong fixation on the mother; lack of effective fathering; inhibition of masculine development by the parents; fixation at, or regression to, the narcissistic stage of development; and losses when competing with brothers and sisters. Freud's views on the causes of female homosexuality included a lack of resolution of penis envy in association with unresolved oedipal conflicts.

Freud did not consider homosexuality a mental illness. In "Three Essays on the Theory of Sexuality," he wrote that homosexuality "is found in persons who exhibit no other serious deviations from normal whose efficiency is unimpaired and who are indeed distinguished by especially high intellectual development and ethical culture." In "Letter to an American Mother," Freud wrote, "Homosexuality is assuredly no advantage, but it is nothing to be ashamed of, no vice, no degradation, it cannot be classified as an illness; we consider it to be a variation of the sexual functions produced by a certain arrest of sexual development."

New Concepts of Psychoanalytic Factors. Some psychoanalysts have advanced new psychodynamic formulations that contrast with classic psychoanalytic theory. According to Richard Isay, gay men have described same-sex fantasies that occurred when they were 3 to 5 years of age, at about the same age that heterosexuals have male-female fantasies. Isay wrote that same-sex erotic fantasies in gay men center on the father or the father surrogate.

The child's perception of, and exposure to, these erotic feelings may account for such "atypical" behavior as greater secretiveness than other boys, self-isolation, and excessive emotionality. Some "feminine" traits may also be caused by identification with the mother or a mother surrogate. Such characteristics usually develop as a way of attracting the

father's love and attention in a manner similar to the way the heterosexual boy may pattern himself after his father to gain his mother's attention.

The psychodynamics of homosexuality in women may be similar. The little girl does not give up her original fixation on the mother as a love object and continues to seek it in adulthood.

Biological Factors. Recent studies indicate that genetic and biological components may contribute to sexual orientation. Gay men reportedly exhibit lower levels of circulatory androgens than do heterosexual men. Prenatal hormones appear to play a role in the organization of the central nervous system: The effective presence of androgens in prenatal life is purported to contribute to a sexual orientation toward females, and a deficiency of prenatal androgens (or tissue insensitivity to them) may lead to a sexual orientation toward males. Preadolescent girls exposed to large amounts of androgens before birth are uncharacteristically aggressive, and boys exposed to excessive female hormones in utero are less athletic, less assertive, and less aggressive than other boys. Women with hyperadrenocorticalism are lesbian and bisexual in greater proportion than women in the general population.

Genetic studies have shown a higher incidence of homosexual concordance among monozygotic twins than among dizygotic twins; these results suggest a genetic predisposition, but chromosome studies have been unable to differentiate homosexuals from heterosexuals. Gay men show a familial distribution; they have more brothers who are gay than do heterosexual men. One study found that 33 of 40 pairs of gay brothers shared a genetic marker on the bottom half of the X chromosome. Another study found that a group of cells in the hypothalamus was smaller in women and in gay men than in heterosexual men. Neither of these studies has been replicated.

Sexual Behavior Patterns. The behavioral features of gay men and lesbian women are as varied as those of heterosexuals. Gay men and lesbians engage in the same sexual practices as heterosexuals, with the obvious differences imposed by anatomy.

Many ongoing relationship patterns occur among gay men and lesbians. Some same-sex pairs live in a common household in either a monogamous or a primary relationship for decades; other gay men and lesbians typically have only fleeting sexual contacts. Although many gay men form stable relationships, male–male relationships appear to be less stable and more fleeting than female–female relationships. Gay-male couples are subjected to civil and social discrimination and do not have the legal social support system of marriage or the biological capacity for childbearing that bonds some otherwise incompatible heterosexual couples. Lesbian couples appear to experience less social stigmatization and to have more enduring monogamous or primary relationships. However, opinion polls have found changes in American attitudes toward homosexuality, indicating a greater acceptance of homosexuals than in the past. This acceptance is reflected in laws in several states extending civil privileges routinely accorded to heterosexual spouses to homosexual partners, such as hospital visiting privileges or the ability to adopt children. As of 2014, eighteen states legalized marriage between homosexuals. A greater number of states recognize as legal a marriage performed in those eighteen states even if homosexual marriage is not legal in the partners' state of residence.

Psychopathology. The range of psychopathology that may be found among distressed lesbians and gay men parallels that found among heterosexuals; some studies have reported a high suicide rate, however. Distress resulting only from conflict between gay men or lesbians and the societal value structure is not classifiable as a disorder. If the distress is sufficiently severe to warrant a diagnosis, adjustment disorder or a depressive disorder should be considered. Some gay men and lesbians with major depressive disorder may experience guilt and self-hatred that become directed toward their sexual orientation; then the desire for sexual reorientation is only a symptom of the depressive disorder.

Coming Out. According to Rochelle Klinger and Robert Cabaj, coming out is a “process by which an individual acknowledges his or her sexual orientation in the face of societal stigma and with successful resolution accepts himself or herself.” The authors wrote:

Successful coming out involves the individual accepting his or her sexual orientation and integrating it into all spheres (e.g., social, vocational, and familial). Another milestone that individuals and couples must eventually confront is the degree of disclosure of sexual orientation to the external world. Some degree of disclosure is probably necessary for successful coming out.

Difficulty negotiating coming out and disclosure is a common cause of relationship difficulties. For each person, problems resolving the coming out process can contribute to poor self-esteem caused by internalized homophobia and lead to deleterious effects on the person's ability to function in the relationship. Conflict can also arise within a relationship when partners disagree on the degree of disclosure.

LOVE AND INTIMACY

Freud postulated that psychological health could be determined by a person's ability to function well in two spheres, work and love. A person able to give and receive love with a minimum of fear and conflict has the capacity to develop genuinely intimate relationships with others. A desire to maintain closeness to the love object typifies being in love. Mature love is marked by the intimacy that is a special attribute of the relationship between two persons. When involved in an intimate relationship, the person actively strives for the growth and happiness of the loved person. Sex frequently acts as a catalyst in forming and maintaining intimate relationships. The quality of intimacy in a mature sexual relationship is what Rollo May called “active receiving,” in which a person, while loving, permits himself or herself to be loved. May describes the value of sexual love as an expansion of self-awareness, the experience of tenderness, an increase of self-affirmation and pride, and sometimes, at the moment of orgasm, loss of feeling of separateness. In that setting, sex and love are reciprocally enhancing and healthily fused.

Some persons experience conflicts that prevent them from fusing tender and passionate impulses. This can inhibit the expression of sexuality in a relationship, interfere with feelings of closeness to another person, and diminish a person's sense of adequacy and self-esteem. When these problems are severe, they may prevent the formation of, or commitment to, an intimate relationship.

SEX AND THE LAW

Medicine and the law both assess the impact of sexuality on the individual and society and determine what is healthy or legal behavior. Appropriateness or legality of sexual behavior, however, is not always viewed the same way by professionals in both disciplines. The issues at the interface of sexual science and the law often are emotionally charged and reflect cultural divisions about acceptable sexual mores. They include abortion, pornography, prostitution, sex education, the treatment of sex offenders, and the right to sexual privacy, among other issues. Laws regarding these issues (e.g., criminalization of oral or anal sex by consenting adults, or the need for parental permission by minors who are requesting an abortion) vary from state to state.

TAKING A SEX HISTORY

A sex history provides important information about patients, regardless of the presence of a sexual disorder or whether that is the patient's chief complaint. The information can be obtained gradually, through open-ended questions. The outline in [Table 17.1-4](#) provides a guide to the topics to be covered and a structure that can be used when time is limited.

Table 17.1-4
Taking a Sex History

- I. Identifying data
 - A. Age
 - B. Sex
 - C. Occupation
 - D. Relationship status—single, married, number of times previously married, separated, divorced, cohabiting, serious involvement, casual dating (difficulty forming or keeping relationships should be assessed throughout the interview)
 - E. Sexual orientation—heterosexual, homosexual, or bisexual (this may also be ascertained later in the interview)
- II. Current functioning
 - A. Unsatisfactory to highly satisfactory
 - B. If unsatisfactory, why?
 - C. Feeling about partner satisfaction
 - D. Dysfunctions?—e.g., lack of desire, erectile disorder, inhibited female interest/arousal, anorgasmia, premature ejaculation, retarded ejaculation, pain associated with intercourse (dysfunction discussed below)
 1. Onset—lifelong or acquired
 - a. If acquired, when?
 - b. Did onset coincide with drug use (medications or illegal recreational drugs), life stresses (e.g., loss of job, birth of child), interpersonal difficulties
 2. Generalized—occurs in most situations or with most partners
 3. Situational
 - a. Only with current partner
 - b. In any committed relationship
 - c. Only with masturbation
 - d. In socially proscribed circumstance (e.g., affair)
 - e. In definable circumstance (e.g., very late at night, in parental home, when partner initiated sex play)
 - E. Frequency—partnered sex (coital and noncoital sex play)
 - F. Desire/libido—how often are sexual feelings, thoughts, fantasies, dreams, experienced? (per day, week, etc.)
 - G. Description of typical sexual interaction
 1. Manner of initiation or invitation (e.g., verbal or physical? Does same person always initiate?)
 2. Presence, type, and extent of foreplay (e.g., kissing, caressing, manual or oral genital stimulation)
 3. Coitus? positions used?
 4. Verbalization during sex? if so, what kind?
 5. Afterplay? (whether sex act is completed or disrupted by dysfunction); typical activities (e.g., holding, talking, return to daily activities, sleeping)
 6. Feeling after sex: relaxed, tense, angry, loving
 - H. Sexual compulsivity?—intrusion of sexual thoughts or participation in sexual activities to a degree that interferes with relationships or work, requires deception and may endanger the patient
- III. Past sexual history
 - A. Childhood sexuality
 1. Parental attitudes about sex—degree of openness of reserve (assess unusual prudery or seductiveness)
 2. Parents' attitudes about nudity and modesty
 3. Learning about sex
 - a. From parents? (initiated by child's questions or parent volunteering information? which parent? what was child's age?) subjects covered (e.g., pregnancy, birth, intercourse, menstruation, nocturnal emission, masturbation)
 - b. From books, magazines, or friends at school or through religious group?
 - c. Significant misinformation
 - d. Feeling about information
 4. Viewing or hearing primal scene—reaction?
 5. Viewing sex play or intercourse of person other than parent
 6. Viewing sex between pets or other animals
 - B. Childhood sex activities
 1. Genital self-stimulation before adolescence; age? reaction if apprehended?
 2. Awareness of self as boy or girl; bathroom sensual activities? (regarding urine, feces, odor, enemas)
 3. Sexual play or exploration with another child (playing doctor)—type of activity (e.g., looking, manual touching, genital touching); reactions or consequences if apprehended (by whom?)
- IV. Adolescence
 - A. Age of onset of puberty—development of secondary sex characteristics, age of menarche for girl, wet dreams or first ejaculation for boy (preparation for and reaction to)
 - B. Sense of self as feminine or masculine—body image, acceptance by peers (opposite sex and same sex), sense of sexual desirability, onset of coital fantasies
 - C. Sex activities
 1. Masturbation—age begun; ever punished or prohibited? method used, accompanying fantasies, frequency (questions about masturbation and fantasies are among the most sensitive for patients to answer)
 2. Homosexual activities—ongoing or rare and experimental episodes, approached by others? If homosexual, has there been any heterosexual experimentation?
 3. Dating—casual or steady, description of first crush, infatuation, or first love.
 4. Experiences of kissing, necking, petting ("making out" or "fooling around"), age begun, frequency, number of partners, circumstances, type(s) of activity
 5. Orgasm—when first experienced? (may not be experienced during adolescence), with masturbation, during sleep, or with partner? with intercourse or other sex play? frequency?
 6. First coitus—age, circumstances, partner, reactions (may not be experienced during adolescence); contraception and/or safe sex precautions used
 - V. Adult sexual activities (may be experienced by some adolescents)
 - A. Premarital sex
 1. Types of sex play experiences—frequency of sexual interactions, types and number of partners
 2. Contraception and/or safe sex precautions used
 3. First coitus (if not experienced in adolescence) age, circumstances, partner
 4. Cohabitation—age begun, duration, description of partner, sexual fidelity, types of sexual activity, frequency, satisfaction, number of cohabiting relationships, reasons for breakup(s)
 5. Engagement—age, activity during engagement period with fiancé(e), with others; length of engagement
 - B. Marriage (if multiple marriages have occurred, explore sexual activity, reasons for marriage, and reasons for divorce in each marriage)
 1. Types and frequency of sexual interaction—describe typical sexual interaction (see above), satisfaction with sex life? view of partner's feeling
 2. First sexual experience with spouse—when? what were the circumstances? was it satisfying? disappointing?
 3. Honeymoon—setting, duration, pleasant or unpleasant, sexually active, frequency? problems? compatibility?
 4. Effect of pregnancies and children on marital sex
 5. Extramarital sex—number of incidents, partner; emotional attachment to extramarital partners? feelings about extramarital sex
 6. Postmarital masturbation—frequency? effect on marital sex?
 7. Extramarital sex by partner—effect on interviewee
 8. Ménage à trois or multiple sex (swinging)
 9. Areas of conflict in marriage (e.g., parenting, finances, division of responsibilities, priorities)
 - VI. Sex after widowhood, separation, divorce—celibacy, orgasms in sleep, masturbation, noncoital sex play, intercourse (number of and relationship to partners), other
 - VII. Special issues
 - A. History of rape, incest, sexual or physical abuse
 - B. Spousal abuse (current)
 - C. Chronic illness (physical or psychiatric)
 - D. History or presence of sexually transmitted diseases
 - E. Fertility problems
 - F. Abortions, miscarriages, or unwanted or illegitimate pregnancies
 - G. Gender identity conflict—(e.g., transsexualism, wearing clothes of opposite sex)
 - H. Paraphilias—(e.g., fetishes, voyeurism, sadomasochism)

▲ 17.2 Sexual Dysfunctions

The essential features of sexual dysfunctions are an inability to respond to sexual stimulation, or the experience of pain during the sexual act. Dysfunction can be defined by disturbance in the subjective sense of pleasure or desire usually associated with sex, or by the objective performance. According to the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems (ICD-10)*, sexual dysfunction refers to a person's inability "to participate in a sexual relationship as he or she would wish."

In the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5)*, the sexual dysfunctions include male hypoactive sexual desire disorder, female sexual interest/arousal disorder, erectile disorder, female orgasmic disorder, delayed ejaculation, premature (early) ejaculation, genito-pelvic pain/penetration disorder, substance/medication induced sexual dysfunction, other specified sexual dysfunction, and unspecified sexual dysfunction. Sexual dysfunctions are diagnosed only when they are a major part of the clinical picture. If more than one dysfunction exists, they should all be diagnosed. Sexual dysfunctions can be lifelong or acquired, generalized or situational, and result from psychological factors, physiological factors, combined factors, and numerous stressors including prohibitive cultural mores, health and partner issues, and relationship conflicts. If the dysfunction is attributable entirely to a general medical condition, substance use, or adverse effects of medication, then sexual dysfunction due to a general medical condition or substance-induced sexual dysfunction is diagnosed. In DSM-5, specification of the severity of the dysfunction is indicated by noting whether the patient's distress is mild, moderate, or severe.

Sexual dysfunctions are frequently associated with other mental disorders, such as depressive disorders, anxiety disorders, personality disorders, and schizophrenia. In many instances, a sexual dysfunction may be diagnosed in conjunction with another psychiatric disorder. If the dysfunction is largely attributable to an underlying psychiatric disorder, only the underlying disorder should be diagnosed. Sexual dysfunctions are usually self-perpetuating, with the patients increasingly subjected to ongoing performance anxiety and a concomitant inability to experience pleasure. In relationships, the sexually functional partner often reacts with distress or anger due to feelings of deprivation or a sense that he or she is an insufficiently attractive or adequate sexual partner. In such cases, the clinician must consider whether the sexual problem preceded or arose from relationship difficulties and weigh whether a diagnosis of sexual dysfunction relevant to relationship issues is more appropriate.

DESIRE, INTEREST, AND AROUSAL DISORDERS

Male Hypoactive Sexual Desire Disorder

This dysfunction is characterized by a deficiency or absence of sexual fantasies and desire for sexual activity for a minimum duration of approximately 6 months (Table 17.2-1). Men for whom this is a lifelong condition have never experienced many spontaneous erotic/sexual thoughts. Minimal spontaneous sexual thinking or minimal desire for sex ahead of sexual experiences is not considered a diagnosable disorder in women, particularly if desire is triggered during the sexual encounter. The reported prevalence of low desire is greatest at the younger and older ends of the age spectrum, with only 2 percent of men ages 16 to 44 affected by this disorder. A reported 6 percent of men ages 18 to 24, and 40 percent of men ages 66 to 74, have problems with sexual desire. Some men may confuse decreased desire with decreased activity. Their erotic thoughts and fantasies are undiminished, but they no longer act on them due to health issues, unavailability of a partner, or another sexual dysfunction such as erectile disorder.

 **Table 17.2-1**
DSM-5 Diagnostic Criteria for Male Hypoactive Sexual Desire Disorder

- A. Persistently or recurrently deficient (or absent) sexual/erotic thoughts or fantasies and desire for sexual activity. The judgment of deficiency is made by the clinician, taking into account factors that affect sexual functioning, such as age and general and sociocultural contexts of the individual's life.
 - B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
 - C. The symptoms in Criterion A cause clinically significant distress in the individual.
 - D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.
- Specify whether:
- Lifelong:** The disturbance has been present since the individual became sexually active.
 - Acquired:** The disturbance began after a period of relatively normal sexual function.
- Specify whether:
- Generalized:** Not limited to certain types of stimulation, situations, or partners.
 - Situational:** Only occurs with certain types of stimulation, situations, or partners.
- Specify current severity:
- Mild:** Evidence of mild distress over the symptoms in Criterion A.
 - Moderate:** Evidence of moderate distress over the symptoms in Criterion A.
 - Severe:** Evidence of severe or extreme distress over the symptoms in Criterion A.

A variety of causative factors are associated with low sexual desire. Patients with desire problems often use inhibition of desire defensively, to protect against unconscious fears about sex. Sigmund Freud conceptualized low sexual desire as the result of inhibition during the phallic psychosexual phase of development and of unresolved oedipal conflicts. Some men, fixated at the phallic state of development, are fearful of the vagina and believe that they will be castrated if they approach it. Freud called this concept *vagina dentata*; he theorized that men avoid contact with the vagina when they unconsciously believe that the vagina has teeth. Lack of desire can also result from chronic stress, anxiety, or depression.

Abstinence from sex for a prolonged period sometimes results in suppression of sexual impulses. Loss of desire may also be an expression of hostility to a partner or the sign of a deteriorating relationship. The presence of desire depends on several factors: biological drive, adequate self-esteem, the ability to accept oneself as a sexual person, the availability of an appropriate partner, and a good relationship in nonsexual areas with a partner. Damage to, or absence of, any of these factors can diminish desire.

In making the diagnosis, clinicians must evaluate a patient's age, general health, any medication regimen, and life stresses. The clinician must attempt to establish a baseline of sexual interest before the disorder began. The need for sexual contact and satisfaction varies among persons and over time in any given person. The diagnosis should not be made unless the lack of desire is a source of distress to a patient.

Female Sexual Interest/Arousal Disorder

The combination of interest (or desire) and arousal into one dysfunction category reflects the recognition that women do not necessarily move stepwise from desire to arousal, but often experience desire synchronously with, or even following, beginning feelings of arousal. This is particularly true for women in long-term relationships. As a corollary, women experiencing sexual dysfunction may experience either/or both inability to feel interest or arousal, and they may often have difficulty achieving orgasm or experience pain in addition. Some may experience dysfunction across the entire range of sexual response/pleasure. Complaints in this dysfunction category present variously as a decrease or paucity of erotic feelings, thoughts, or fantasies; a decreased impulse to initiate sex; a decreased or absent receptivity to partner overtures; or an inability to respond to partner stimulation (Table 17.2-2).

Table 17.2-2
DSM-5 Diagnostic Criteria for Female Sexual Interest/Arousal Disorder

- A. Lack of, or significantly reduced, sexual interest/arousal, as manifested by at least three of the following:
1. Absent/reduced interest in sexual activity.
 2. Absent/reduced sexual/erotic thoughts or fantasies.
 3. No/reduced initiation of sexual activity, and typically unresponsive to a partner's attempts to initiate.
 4. Absent/reduced sexual excitement/pleasure during sexual activity in almost all or all (approximately 75%–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts).
 5. Absent/reduced sexual interest/arousal in response to any internal or external sexual/erotic cues (e.g., written, verbal, visual).
 6. Absent/reduced genital or nongenital sensations during sexual activity in almost all or all (approximately 75%–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts).
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress (e.g., partner violence) or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.
- Specify whether:
- Lifelong:** The disturbance has been present since the individual became sexually active.
- Acquired:** The disturbance began after a period of relatively normal sexual function.
- Specify whether:
- Generalized:** Not limited to certain types of stimulation, situations, or partners.
- Situational:** Only occurs with certain types of stimulation, situations, or partners.
- Specify current severity:
- Mild:** Evidence of mild distress over the symptoms in Criterion A.
- Moderate:** Evidence of moderate distress over the symptoms in Criterion A.
- Severe:** Evidence of severe or extreme distress over the symptoms in Criterion A.

A complicating factor in this diagnosis is that a subjective sense of arousal is often poorly correlated with genital lubrication in both normal and dysfunctional women. Therefore, complaints of lack of pleasure are sufficient for this diagnosis even when vaginal lubrication and congestion are present. A woman complaining of lack of arousal may lubricate vaginally, but may not experience a subjective sense of excitement. Some studies using functional magnetic resonance imaging (fMRI) have revealed a low correlation between brain activation in areas controlling genital response and simultaneous ratings of subjective arousal. Physiological studies of sexual dysfunctions indicate that a hormonal pattern may contribute to responsiveness in women who have arousal dysfunction. William Masters and Virginia Johnson found that women are particularly desirous of sex before the onset of the menses. Other women report feeling the greatest sexual excitement immediately after the menses or at the time of ovulation. Alterations in testosterone, estrogen, prolactin, and thyroxin levels have been implicated in female sexual arousal disorder. In addition, medications with antihistaminic or anticholinergic properties cause a decrease in vaginal lubrication.

Factors such as life stresses, aging, menopause, adequate sexual stimulation, general health, and medication regimen must be evaluated before making this diagnosis. Relationship problems are particularly relevant to acquired interest/arousal disorder. In one study of couples with markedly decreased sexual interaction, the most prevalent etiology was marital discord.

Male Erectile Disorder

Male erectile disorder was historically called *impotence*. The term was dropped for a more medical designation, but also because it was considered derogatory and had negative connotations for the man with the problem. However, it describes with accuracy the feelings of powerlessness, helplessness, and resultant low self-esteem men with this dysfunction frequently suffer (Table 17.2-3). A man with lifelong male erectile disorder has never been able to obtain an erection sufficient for insertion. In acquired male erectile disorder, a man has successfully achieved penetration at some time in his sexual life but is later unable to do so. In situational male erectile disorder, a man is able to have coitus in certain circumstances but not in others; for example, he may function effectively with a prostitute but be unable to have an erection when with his partner.

Table 17.2-3
DSM-5 Diagnostic Criteria for Male Erectile Disorder

- A. At least one of the three following symptoms must be experienced on almost all or all (approximately 75%–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
1. Marked difficulty in obtaining an erection during sexual activity.
 2. Marked difficulty in maintaining an erection until the completion of sexual activity.
 3. Marked decrease in erectile rigidity.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

Specify whether:

Lifelong: The disturbance has been present since the individual became sexually active.

Acquired: The disturbance began after a period of relatively normal sexual function.

Specify whether:

Generalized: Not limited to certain types of stimulation, situations, or partners.

Situational: Only occurs with certain types of stimulation, situations, or partners.

Specify current severity:

Mild: Evidence of mild distress over the symptoms in Criterion A.

Moderate: Evidence of moderate distress over the symptoms in Criterion A.

Severe: Evidence of severe or extreme distress over the symptoms in Criterion A.

Acquired male erectile disorder has been reported in 10 to 20 percent of all men. Freud declared it common among his patients. Erectile disorder is the chief complaint of more than 50 percent of all men treated for sexual disorders. Lifelong male erectile disorder is rare; it occurs in about 1 percent of men younger than age 35. The incidence of erectile disorder increases with age. It has been reported variously as 2 to 8 percent of the young adult population. Alfred Kinsey reported that 75 percent of all men were impotent at age 80. There is a reported incidence of 40 to 50 percent in men between ages of 60 and 70. All men older than 40, Masters and Johnson claimed, have a fear of impotence, which the researchers believed reflected the masculine fear of loss of virility with advancing age. Male erectile disorder, however, is not universal in aging men; having an available sex partner is related to continuing potency, as is a history of consistent sexual activity and the absence of vascular, neurologic, or endocrine disease. Twenty percent of men fear erectile dysfunction prior to their first coitus; the reported incidence of actual erectile dysfunction during first coitus is 8 percent. As Stephen Levine has stated, the first sexual encounter “is a horse race between excitement and anxiety.”

Male erectile disorder can be organic or psychological, or a combination of both, but in young and middle-aged men the cause is usually psychological. A good history is of primary importance in determining the cause of the dysfunction. If a man reports having spontaneous erections at times when he does not plan to have intercourse, having morning erections, or having good erections with masturbation or with partners other than his usual one, the organic causes of his erectile disorder can be considered negligible, and costly diagnostic procedures can be avoided. Male erectile disorder caused by a general medical condition or a pharmacological substance is discussed later in this section.

Freud ascribed one type of erectile disorder to an inability to reconcile feelings of affection toward a woman with feelings of desire for her. Men with such conflicting feelings can function only with women whom they see as degraded (Madonna–Putana complex). Other factors that have been cited as contributing to impotence include a punitive superego, an inability to trust, and feelings of inadequacy or a sense of being undesirable as a partner. A man may be unable to express a sexual impulse because of fear, anxiety, anger, or moral prohibition. In an ongoing relationship, the disorder may reflect difficulties between the partners, particularly when a man cannot communicate his needs or his anger in a direct and constructive way. In addition, episodes of erectile disorder are reinforcing, with the man becoming increasingly anxious before each sexual encounter.

Mr. Y came for therapy after his wife complained about their lack of sexual interaction. The patient avoided sex because of his frequent erectile dysfunction and the painful feelings of inadequacy he suffered after his “failures.” He presented as an articulate, gentle, and self-blaming man.

He was faithful to his wife but masturbated frequently. His fantasies involved explicit sadistic components, including hanging and biting women. The contrast between his angry, aggressive fantasies and his loving, considerate behavior toward his wife symbolized his conflicts about his sexuality, his masculinity, and his mixed feelings about women. He was diagnosed with erectile disorder, situational type.

ORGASM DISORDERS

Female Orgasmic Disorder

Female orgasmic disorder, sometimes called *inhibited female orgasm* or *anorgasmia*, is defined as the recurrent or persistent inhibition of female orgasm, as manifested by the recurrent delay in, or absence of orgasm after a normal sexual excitement phase that a clinician judges to be adequate in focus, intensity, and duration—in short, a woman’s inability to achieve orgasm by masturbation or coitus (Table 17.2-4). Women who can achieve orgasm by one of these methods are not necessarily categorized as anorgasmic, although some sexual inhibition may be postulated. The complaint is reported by the woman, herself. However, some anorgasmic women are not distressed by the lack of climax and derive pleasure from sexual activity. In the latter instance, a woman may present with this complaint because her partner is troubled by her lack of orgasm.

Table 17.2-4
DSM-5 Diagnostic Criteria for Female Orgasmic Disorder

- A. Presence of either of the following symptoms and experienced on almost all or all (approximately 75%–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
1. Marked delay in, marked infrequency of, or absence of orgasm.
 2. Markedly reduced intensity of orgasmic sensations.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress (e.g., partner violence) or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.
- Specify whether:
- Lifelong:** The disturbance has been present since the individual became sexually active.
- Acquired:** The disturbance began after a period of relatively normal sexual function.
- Specify whether:
- Generalized:** Not limited to certain types of stimulation, situations, or partners.
- Situational:** Only occurs with certain types of stimulation, situations, or partners.
- Specify if:
- Never experienced an orgasm under any situation.**
- Specify current severity:
- Mild:** Evidence of mild distress over the symptoms in Criterion A.
- Moderate:** Evidence of moderate distress over the symptoms in Criterion A.
- Severe:** Evidence of severe or extreme distress over the symptoms in Criterion A.

Research on the physiology of the female sexual response has shown that orgasms caused by clitoral stimulation and those caused by vaginal stimulation are physiologically identical. Freud's theory that women must give up clitoral sensitivity for vaginal sensitivity to achieve sexual maturity is now considered misleading, but some women report that they gain a special sense of satisfaction from an orgasm precipitated by coitus. Some researchers attribute this satisfaction to the psychological feeling of closeness engendered by the act of coitus, but others maintain that the coital orgasm is a physiologically different experience. Many women achieve orgasm during coitus by a combination of manual clitoral stimulation and penile vaginal stimulation.

A woman with lifelong female orgasmic disorder has never experienced orgasm by any kind of stimulation. A woman with acquired orgasmic disorder has previously experienced at least one orgasm, regardless of the circumstances or means of stimulation, whether by masturbation or while dreaming during sleep. Studies have shown that women achieve orgasm more consistently with masturbation than with partnered sex. Kinsey found that 5 percent of married women older than age 35 years had never achieved orgasm by any means. The incidence of never having experienced orgasm is reported as 10 percent among all women. The incidence of orgasm increases with age. According to Kinsey, the first orgasm occurs during adolescence in about 50 percent of women as a result of masturbation or genital caressing with a partner; the rest usually experience orgasm as they get older. Lifelong female orgasmic disorder is more common among unmarried women than married women. Increased orgasmic potential in women older than 35 years of age has been explained on the basis of less psychological inhibition, greater sexual experience, or both.

Acquired female orgasmic disorder is a common complaint in clinical populations. One clinical treatment facility reported having about four times as many nonorgasmic women in its practice as female patients with all other sexual disorders. In another study, 46 percent of women complained of difficulty reaching orgasm. Inhibition of arousal and orgasmic problems often occur together. The overall prevalence of female orgasmic disorder from all causes is estimated to be 30 percent. A recent twin study suggests that orgasmic dysfunction in some females has a genetic basis and cannot be attributed solely to psychological differences. That study demonstrated an estimated heritability for difficulty reaching orgasm with intercourse of 34 percent and an estimated heritability in women who could not climax with masturbation of 45 percent.

Numerous psychological factors are associated with female orgasmic disorder. They include fears of impregnation, rejection by a sex partner, and damage to the vagina; hostility toward men; poor body image; and feelings of guilt about sexual impulses. Some women equate orgasm with loss of control or with aggressive, destructive, or violent impulses; their fear of these impulses may be expressed through inhibition of arousal or orgasm. Cultural expectations and social restrictions on women are also relevant. Many women have grown up to believe that sexual pleasure is not a natural entitlement for so-called decent women. Nonorgasmic women may be otherwise symptom free or may experience frustration in a variety of ways; they may have such pelvic complaints as lower abdominal pain, itching, and vaginal discharge, as well as increased tension, irritability, and fatigue.

Delayed Ejaculation

In male delayed ejaculation, sometimes called *retarded ejaculation*, a man achieves ejaculation during coitus with great difficulty, if at all (Table 17.2-5). The problem is rarely present with masturbation, but appears as a problem during partnered sex. A man with lifelong delayed ejaculation has never been able to ejaculate during partnered sexual activity. The problem is usually most pronounced during coital activity. The disorder is diagnosed as acquired if it develops after previously normal functioning. Some researchers think that orgasm and ejaculation should be differentiated, especially in the case of men who ejaculate but complain of a decreased or absent subjective sense of pleasure during the orgasmic experience (orgasmic anhedonia).

Table 17.2-5
DSM-5 Diagnostic Criteria for Delayed Ejaculation

- A. Either of the following symptoms must be experienced on almost all or all occasions (approximately 75%–100%) of partnered sexual activity (in identified situational contexts or, if generalized, in all contexts), and without the individual desiring delay:
1. Marked delay in ejaculation.
 2. Marked infrequency or absence of ejaculation.
- B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

Specify whether:

Lifelong: The disturbance has been present since the individual became sexually active.

Acquired: The disturbance began after a period of relatively normal sexual function.

Specify whether:

Generalized: Not limited to certain types of stimulation, situations, or partners.

Situational: Only occurs with certain types of stimulation, situations, or partners.

Specify current severity:

Mild: Evidence of mild distress over the symptoms in Criterion A.

Moderate: Evidence of moderate distress over the symptoms in Criterion A.

Severe: Evidence of severe or extreme distress over the symptoms in Criterion A.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.

The incidence of male orgasmic disorder is much lower than the incidence of premature ejaculation or erectile disorder. Masters and Johnson reported an incidence of delayed ejaculation of only 3.8 percent in one group of 447 men with sexual dysfunctions. A general prevalence of 5 percent has been reported. However, an increase in the presentation of this disorder in sex therapy programs has been seen in the last decade. This has been attributed to the increasing use of antidepressants, which can have a side effect of delayed ejaculation, as well as a high use of Internet pornography sites. These sites offer a level of stimulation involving such variety of people and acts that they may inure the man to the stimulation of more typical partnered activity. Recent studies of adolescent males who use these sites frequently, prior to live sexual interaction, have reported that these teens do not develop neuronal synapses that will enable them to respond to usual partnered interactions with sufficient pleasure to allow them to achieve climax.

Lifelong delayed ejaculation indicates severe psychopathology. A man may come from a rigid, puritanical background; he may perceive sex as sinful and the genitals as dirty; and he may have conscious or unconscious incest wishes and guilt. He usually has difficulty with closeness in areas beyond those of sexual relations. In a few cases, the condition is aggravated by an attention-deficit/hyperactivity disorder. A man's distractibility prevents sufficient arousal for climax to occur.

In an ongoing relationship, acquired male delayed ejaculation disorder frequently reflects interpersonal difficulties. The disorder may be a man's way of coping with real or fantasized changes in a relationship, such as plans for pregnancy about which the man is ambivalent, the loss of sexual attraction to the partner, or demands by the partner for greater commitment as expressed by sexual performance. In some men, the inability to ejaculate reflects unexpressed hostility toward a woman. The problem is more common among men with obsessive-compulsive disorder (OCD) than among others.

A couple presented with the man as the identified patient; he was unable to ejaculate with intercourse. He had always had difficulty reaching climax, except in rare circumstances. He ejaculated once when he was with two women at the same time and once when he was experimenting with cocaine. He currently was not using any substances except for a moderate use of alcohol. This patient was committed to his marriage, although he had extramarital sexual experiences. He did not ejaculate with coitus in those situations either, although he could climax with oral sex. He stated he was more interested in "the conquest" than in the sex itself. He could climax with masturbation, although he rarely masturbated himself, but went to massage parlors. He had issues with anger at women and considered his wife to be excessively critical.

He had difficulty doing any of the exercises that required him to pleasure his wife. His difficulty giving also made it hard for him to enjoy mutual pleasuring. It was easier for him to be the recipient of stimulation. Because of this patient's problems with impulsiveness, narcissism, and dependency, it was necessary to combine introspective psychotherapy with a regimen of behavioral exercises.

The patient was diagnosed with delayed ejaculation, lifelong type.

Premature (Early) Ejaculation

In premature ejaculation, men persistently or recurrently achieve orgasm and ejaculation before they wish to. The diagnosis is made when a man regularly ejaculates before or within approximately 1 minute after penetration. DSM-5 refers only to "vaginal penetration" in its diagnostic criteria, even though it is entirely possible for the disorder to occur in men who are homosexual and do not engage in vaginal penetration. DSM-5 defines the disorder as mild if ejaculation occurs within approximately 30 seconds to 1 minute of vaginal penetration, moderate if ejaculation occurs within approximately 15 to 30 seconds of vaginal penetration, and severe when ejaculation occurs at the start of sexual activity or within approximately 15 seconds of vaginal penetration. A difficulty with these specifiers involves time distortions, which patients make in both overestimating and underestimating time from penetration to climax. Clinicians need to consider factors that affect the duration of the excitement phase of the sexual response, such as age, the novelty of the sex partner, and the frequency of coitus (Table 17.2-6). As with the other sexual dysfunctions, premature ejaculation is not diagnosed when it is caused exclusively by organic factors or when it is symptomatic of another clinical psychiatric syndrome.

 **Table 17.2-6**
DSM-5 Diagnostic Criteria for Premature (Early) Ejaculation

- A. A persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within approximately 1 minute following vaginal penetration and before the individual wishes it.
- Note:** Although the diagnosis of premature (early) ejaculation may be applied to individuals engaged in nonvaginal sexual activities, specific duration criteria have not been established for these activities.
- B. The symptom in Criterion A must have been present for at least 6 months and must be experienced on almost all or all (approximately 75%–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts).
- C. The symptoms in Criterion A cause clinically significant distress in the individual.
- D. The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.
- Specify whether:
- Lifelong:** The disturbance has been present since the individual became sexually active.
- Acquired:** The disturbance began after a period of relatively normal sexual function.
- Specify whether:
- Generalized:** Not limited to certain types of stimulation, situations, or partners.
- Situational:** Only occurs with certain types of stimulation, situations, or partners.
- Specify current severity:
- Mild:** Ejaculation occurring within approximately 30 seconds to 1 minute of vaginal penetration.
- Moderate:** Ejaculation occurring within approximately 15–30 seconds of vaginal penetration.
- Severe:** Ejaculation occurring prior to sexual activity, at the start of sexual activity, or within approximately 15 seconds of vaginal penetration.

Premature ejaculation is more commonly reported among college-educated men than among men with less education. The complaint is thought to be related to their concern for partner satisfaction, but the true cause of this increased frequency has not been determined. Premature ejaculation is the chief complaint of about 35 to 40 percent of men treated for sexual disorders. In DSM-5, the writers state that the disorder, with its newly defined time parameter, would now be an accurate diagnosis for only 1 to 3 percent of men. Some researchers divide men who experience premature ejaculation into two groups: those who are physiologically predisposed to climax quickly because of shorter nerve latency time and those with a psychogenic or behaviorally conditioned cause. Difficulty in ejaculatory control can be associated with anxiety regarding the sex act, with unconscious fears about the vagina, or with negative cultural conditioning. Men whose early sexual contacts occurred largely with prostitutes who demanded that the sex act proceed quickly or whose sexual contacts took place in situations in which discovery would be embarrassing (e.g., in a shared dormitory room or in the parental home) might have been conditioned to achieve orgasm rapidly. With young, inexperienced men, who have the problem, it may resolve in time. In ongoing relationships, the partner has a great influence on a premature ejaculator, and a stressful marriage exacerbates the disorder. The developmental background and the psychodynamics found in premature ejaculation and in erectile disorder are similar.

SEXUAL PAIN DISORDERS

Genito-Pelvic Pain/Penetration Disorder

In DSM-5, this disorder refers to one or more of the following complaints, of which any two or more may occur together: difficulty having intercourse; genito-pelvic pain; fear of pain or penetration; and tension of the pelvic floor muscles. Previously, these pain disorders were diagnosed as *dyspareunia* or *vaginismus*. These former diagnoses could coexist or one could lead to the other and could understandably lead to fear of pain with sex. Thus, it is reasonable to gather these diagnoses into one diagnostic category. For the purposes of clinical discussion, however, the distinct categories of dyspareunia and vaginismus remain clinically useful.

Dyspareunia. Dyspareunia is recurrent or persistent genital pain occurring before, during, or after intercourse. Dyspareunia is related to, and often coincides with, vaginismus. Repeated episodes of vaginismus can lead to dyspareunia and vice versa; in either case, somatic causes must be ruled out. A pain disorder should not be diagnosed when an organic basis for pain is found or when it is caused by a lack of lubrication. DSM-5 cites that 15 percent of women in North America report recurrent pain during intercourse.

In most cases, dynamic factors are considered causative. Chronic pelvic pain is a common complaint in women with a history of rape or childhood sexual abuse. Painful coitus can result from tension and anxiety about the sex act that cause women to involuntarily contract their pelvic floor muscles. The pain is real and makes intercourse unpleasant or unbearable. Anticipation of further pain may cause women to avoid coitus altogether. If a partner proceeds with intercourse regardless of a woman's state of readiness, the condition is aggravated. There is an increase in reported dyspareunia postmenopausally due to hormonally induced physiological changes in the vagina; however, specific complaints of difficulty having intercourse occur more often in premenopausal women. There is some increase in dyspareunia in the immediate postpartum population, but it is usually temporary. Dyspareunia may present as any of the four complaints listed under genito-pelvic pain/penetration disorder and should be diagnosed as genito-pelvic pain/penetration disorder.

Vaginismus. Defined as a constriction of the outer third of the vagina due to involuntary pelvic floor muscle tightening or spasm, vaginismus interferes with penile insertion and intercourse. This response may occur during a gynecological examination when involuntary vaginal constriction prevents the introduction of the speculum into the vagina. The diagnosis is not made when the dysfunction is caused exclusively by organic factors or when it is symptomatic of another mental disorder.

Vaginismus may be complete, that is no penetration of the vagina is possible, whether by the penis, fingers, a speculum during gynecologic exam, or even if the woman tries to use the smallest size tampon. Many women who discover this complaint when they become sexually active have avoided the use of tampons previously. In a less severe form of vaginismus, pelvic floor muscle tightening due to pain or fear of pain makes penetration difficult, but not impossible. Penetration may be achieved with the smallest size speculum or little fingers. In mild cases, the muscles relax after the initial difficulty with penetration and the woman can continue with sexual play, sometimes even with coitus.

Miss B was a 27-year-old single woman who presented for therapy because of an inability to have intercourse. She described episodes with a recent boyfriend in which he had tried vaginal penetration but had been unable to enter. The boyfriend did not have erectile dysfunction. Miss B experienced desire and was able to achieve orgasm through manual or oral stimulation. For almost a year, she and her boyfriend had sex play without intercourse. However, he complained increasingly about his frustration at the lack of coitus, which he had enjoyed in previous relationships. Miss B had a conscious fear of penetration and dreaded going to the gynecologist, although she was able to use tampons when she menstruated. She was diagnosed with genito-pelvic pain/penetration disorder, lifelong type.

Vaginismus is less prevalent than female orgasmic disorder. It most often afflicts highly educated women and those in high socioeconomic groups. Women with vaginismus may consciously wish to have coitus, but unconsciously wish to keep a penis from entering their bodies. A sexual trauma, such as rape, may cause vaginismus. Anticipation of pain at the first coital experience may cause vaginismus. Clinicians have noted that a strict religious upbringing in which sex is associated with sin is frequent in these patients. Other women have problems in dyadic relationships; if women feel emotionally abused by their partners, they may protest in this nonverbal fashion. Some women who have experienced significant pain in childhood due to surgical or dental interventions become guarded about any breach of body integrity and develop vaginismus. Vaginismus may present as any of the four complaints under genito-pelvic pain/penetration disorder and should be diagnosed as genito-pelvic pain/penetration disorder.

SEXUAL DYSFUNCTION DUE TO A GENERAL MEDICAL CONDITION

Male Erectile Disorder Due to a General Medical Condition

The incidence of psychological, as opposed to organic, male erectile disorder has been the focus of many studies. Statistics indicate that 20 to 50 percent of men with erectile disorder have an organic basis for the disorder. A physiologic etiology is more likely in men older than 50 and the most likely cause in men older than age 60. The organic causes of male erectile disorder are listed in Table 17.2-7. Side effects of medication can impair male sexual functioning in a variety of ways (Table 17.2-8). Castration (removal of the testes) does not always lead to sexual dysfunction, because erection may still occur. A reflex arc, fired when the inner thigh is stimulated, passes through the sacral cord erectile center to account for the phenomenon.

Table 17.2-7
Diseases and Other Medical Conditions Implicated in Male Erectile Disorder

Infectious and parasitic diseases	Neurological disorders
Elephantiasis	Multiple sclerosis
Mumps	Transverse myelitis
Cardiovascular disease ^a	Parkinson's disease
Atherosclerotic disease	Temporal lobe epilepsy
Aortic aneurysm	Traumatic and neoplastic spinal cord diseases ^a
Leriche's syndrome	Central nervous system tumor
Cardiac failure	Amyotrophic lateral sclerosis
Renal and urological disorders	Peripheral neuropathy
Peyronie's disease	General paresis
Chronic renal failure	Tabes dorsalis
Hydrocele and varicocele	Pharmacological factors
Hepatic disorders	Alcohol and other dependence-inducing substances (heroin,
Cirrhosis (usually associated with alcohol dependence)	methadone, morphine, cocaine, amphetamines, and
Pulmonary disorders	barbiturates)
Respiratory failure	Prescribed drugs (psychotropic drugs, antihypertensive drugs,
Genetics	estrogens, and antiandrogens)
Klinefelter's syndrome	Poisoning
Congenital penile vascular and structural abnormalities	Lead (plumbism)
Nutritional disorders	Herbicides
Malnutrition	Surgical procedures ^a
Vitamin deficiencies	Perineal prostatectomy
Obesity	Abdominal-perineal colon resection
Endocrine disorders ^a	Sympathectomy (frequently interferes with ejaculation)
Diabetes mellitus	Aortoiliac surgery
Dysfunction of the pituitary-adrenal-testis axis	Radical cystectomy
Acromegaly	Retroperitoneal lymphadenectomy
Addison's disease	Miscellaneous
Chromophobe adenoma	Radiation therapy
Adrenal neoplasia	Pelvic fracture
Myxedema	Any severe systemic disease or debilitating condition
Hyperthyroidism	

^aIn the United States an estimated 2 million men are impotent because they have diabetes mellitus; an additional 300,000 are impotent because of other endocrine diseases; 1.5 million are impotent as a result of vascular disease; 180,000 because of multiple sclerosis; 400,000 because of traumas and fractures leading to pelvic fractures or spinal cord injuries; and another 650,000 are impotent as a result of radical surgery, including prostatectomies, colostomies, and cystectomies.

Propranolol (Inderal)	+	-

^aThe incidence of male erectile disorder associated with the use of tricyclic drugs is low.

^bTrazodone has been causative in some cases of priapism.

^cImpairment of sexual function is not a common complication of the use of antipsychotics. Priapism has occasionally occurred in association with the use of antipsychotics.

^dBenzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by those drugs enhances sexual function.

^eAll SSRIs can produce sexual dysfunction, more commonly, in men.

A number of procedures, benign and invasive, are used to help differentiate organically caused erectile disorder from functional erectile disorder. The procedures include monitoring nocturnal penile tumescence (erections that occur during sleep), normally associated with rapid eye movement; monitoring tumescence with a strain gauge; measuring blood pressure in the penis with a penile plethysmograph or an ultrasound (Doppler) flowmeter, both of which assess blood flow in the internal pudendal artery; and measuring pudendal nerve latency time. Other diagnostic tests that delineate organic bases for impotence include glucose tolerance tests, plasma hormone assays, liver and thyroid function tests, prolactin and follicle-stimulating hormone (FHS) determinations, and cystometric examinations. Invasive diagnostic studies include penile arteriography, infusion cavernosonography, and radioactive xenon penography. Invasive procedures require expert interpretation and are used only for patients who are candidates for vascular reconstructive procedures.

Dyspareunia Due to a General Medical Condition

An estimated 30 percent of all surgical procedures on the female genital area result in temporary dyspareunia. In addition, 30 to 40 percent of women with the complaint who are seen in sex therapy clinics have pelvic pathology. Organic abnormalities leading to dyspareunia and vaginismus include irritated or infected hymenal remnants, episiotomy scars, Bartholin's gland infection, various forms of vaginitis and cervicitis, endometriosis, and adenomyosis. Postcoital pain has been reported by women with myomata, endometriosis, and adenomyosis, and is attributed to the uterine contractions during orgasm. Postmenopausal women may have dyspareunia resulting from thinning of the vaginal mucosa and reduced lubrication.

Two conditions not readily apparent on physical examination that produce dyspareunia are vulvar vestibulitis and interstitial cystitis. The former may present with chronic vulvar pain and the latter produces pain most intensely following orgasm. Dyspareunia can also occur in men, but it is uncommon and is usually associated with an organic condition, such as Peyronie's disease, which consists of sclerotic plaques on the penis that cause penile curvature.

Male Hypoactive Sexual Desire Disorder and Female Interest/Arousal Disorder Due to a General Medical Condition

Sexual desire commonly decreases after major illness or surgery, particularly when the body image is affected after such procedures as mastectomy, ileostomy, hysterectomy, and prostatectomy. Illnesses that deplete a person's energy, chronic conditions that require physical and psychological adaptation, and serious illnesses that can cause a person to become depressed can all markedly lessen sexual desire.

In some cases, biochemical correlates are associated with hypoactive sexual desire disorder (Table 17.2-9). A recent study found markedly lower levels of serum testosterone in men complaining of low desire than in normal controls in a sleep-laboratory situation. Drugs that depress the central nervous system (CNS) or decrease testosterone production can decrease desire.

Table 17.2-9
Neurophysiology of Sexual Dysfunction

	DA	5-HT	NE	ACh	Clinical Correlation
Erection	↑	°	α, β ↓ ↑	M	Antipsychotics may lead to erectile dysfunction (DA block); DA agonists may lead to enhanced erection and libido; priapism with trazodone (α ₁ block); β-blockers may lead to impotence
Ejaculation and orgasm		± ↓	α ₁ ↑	M	α-Blockers (tricyclic drugs, MAOIs, thioridazine) may lead to impaired ejaculation; 5-HT agents may inhibit orgasm

↑, facilitates; ↓, inhibits or decreases; ±, some; ACh, acetylcholine; DA, dopamine; 5-HT, serotonin; M, modulates; NE, norepinephrine; °, minimal.

Other Male Sexual Dysfunction Due to a General Medical Condition

Delayed ejaculation can have physiological causes and can occur after surgery on the genitourinary tract, such as prostatectomy. It may also be associated with Parkinson's disease and other neurological disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drug guanethidine monosulfate (Ismelin), methyl dopa (Aldomet), the phenothiazines, the tricyclic drugs, and the selective serotonin reuptake inhibitors (SSRIs), among others, have been implicated in retarded ejaculation. In addition, delayed ejaculation must be differentiated from retrograde ejaculation, in which ejaculation occurs but the seminal fluid passes backward into the bladder. Retrograde ejaculation always has an organic cause. It can develop after genitourinary surgery and it is also associated with medications that have anticholinergic adverse effects, such as the phenothiazines.

Other Female Sexual Dysfunction Due to a General Medical Condition

Some medical conditions—specifically, endocrine diseases such as hypothyroidism, diabetes mellitus, and primary hyperprolactinemia—can affect a woman's ability to have orgasms. Several drugs also affect some women's capacity to have orgasms (Table 17.2-10) Antihypertensive medications, CNS stimulants, tricyclic drugs, SSRIs, and, frequently, monoamine oxidase inhibitors (MAOIs) have interfered with female orgasmic capacity. One study of women taking MAOIs, however, found that after 16 to 18 weeks of pharmacotherapy, the adverse effect of the medication disappeared and the women were able to re-experience orgasms, although they continued taking an undiminished dose of the drug.

Table 17.2-10
Some Antipsychotic Drugs Implemented in Inhibited Female Orgasm^a

Tricyclic antidepressants
Imipramine (Tofranil)
Clomipramine (Anafranil)
Nortriptyline (Aventyl)
Monoamine oxidase inhibitors
Tranylcypromine (Parnate)
Phenelzine (Nardil)
Isocarboxazid (Marplan)
Dopamine receptor antagonists
Thioridazine (Mellaril)
Trifluoperazine (Stelazine)
Selective serotonin reuptake inhibitors
Fluoxetine (Prozac)
Paroxetine (Paxil)
Sertraline (Zoloft)
Fluvoxamine (Luvox)
Citalopram (Celexa)

^aThe interrelation between female sexual dysfunction and pharmacological agents has been less extensively evaluated than male reactions. Oral contraceptives are reported to decrease libido in some women, and some drugs with anticholinergic side effects may impair arousal as well as orgasm. Prolonged use of oral contraceptives may also cause physiologic menopausal-like changes resulting in genito-pelvic pain/penetration disorder. Benzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by those drugs enhances sexual function. Both increase and decrease in libido have been reported with psychoactive agents. It is difficult to separate those effects from the underlying condition or from improvement of the condition. Sexual dysfunction associated with the use of a drug disappears when use of the drug is discontinued.

Substance/Medication-Induced Sexual Dysfunction

The diagnosis of substance-induced sexual dysfunction is used when evidence of substance intoxication or withdrawal is apparent from the history, physical examination, or laboratory findings. The disturbance in sexual function must be predominant in the clinical picture. Distressing sexual dysfunction occurs soon after significant substance intoxication or withdrawal, or after exposure to a medication or a change in medication use. Specified substances include alcohol, amphetamines or related substances, cocaine, opioids, sedatives, hypnotics, or anxiolytics, and other or unknown substances.

Abused recreational substances affect sexual function in various ways. In small doses, many substances enhance sexual performance by decreasing inhibition or anxiety or by causing a temporary elevation of mood. With continued use, however, erectile engorgement and orgasmic and ejaculatory capacities become impaired. The abuse of sedatives, anxiolytics, hypnotics, and particularly opiates and opioids nearly always depresses desire. Alcohol may foster the initiation of sexual activity by removing inhibition, but it also impairs performance. Cocaine and amphetamines produce the following similar effects: Although no direct evidence indicates that sexual drive is enhanced, users initially have feelings of increased energy and may become sexually active; ultimately, dysfunction occurs. Men usually go through two stages: an experience of prolonged erection without ejaculation, and then a gradual loss of erectile capability.

Patients recovering from substance dependency may need therapy to regain sexual function, partly because of psychological readjustment to a nondependent state. Many substance abusers have always had difficulty with intimate interactions. Others who spent their crucial developmental years under the influence of a substance have missed the experiences that would have enabled them to learn social and sexual skills.

Pharmacological Agents Implicated in Sexual Dysfunction

Almost every pharmacological agent, particularly those used in psychiatry, has been associated with an effect on sexuality. In men, these effects include decreased sex drive, erectile failure, decreased volume of ejaculate, and delayed or retrograde ejaculation. In women,

decreased sex drive, decreased vaginal lubrication, inhibited or delayed orgasm, and decreased or absent vaginal contractions may occur. Drugs may also enhance the sexual responses and increase the sex drive, but this is less common than adverse effects. The effects of psychoactive drugs are detailed later in this section.

Antipsychotic Drugs. Most antipsychotic drugs are dopamine receptor antagonists that also block adrenergic and cholinergic receptors, thus accounting for the adverse sexual effects (Table 17.2-11). Chlorpromazine (Thorazine) and trifluoperazine (Stelazine) are potent anticholinergics, and they impair erection and ejaculation. With some drugs, the seminal fluid backs up into the bladder rather than being propelled through the penile urethra. Patients still have a pleasurable sensation, but the orgasm is dry. When urinating after orgasm, the urine may be milky white because it contains the ejaculate. The condition is startling but harmless. Paradoxically, some rare cases of priapism have been reported with antipsychotics.

Table 17.2-11
Diagnostic Issues with Sex and Some Antipsychotic Drugs

Differential diagnosis of drug-induced sexual dysfunction	Problem after drug therapy started or drug overdose Problem not situation or partner specific Not a lifelong or recurrent problem No obvious nonpharmacological precipitant Dissipates with drug discontinuation
Antipsychotic drugs and ejaculatory problems	Perphenazine Chlorpromazine Trifluoperazine Haloperidol Mesoridazine Chlorprothixene
Antipsychotic drugs and priapism	Perphenazine Mesoridazine Chlorpromazine Thioridazine Fluphenazine Molindone Risperidone Clozapine

(Table by R. T. Seagraves, M.D.)

Antidepressant Drugs. The tricyclic and tetracyclic antidepressants have anticholinergic effects that interfere with erection and delay ejaculation. Because the anticholinergic effects vary among the cyclic antidepressants, those with the fewest effects (e.g., desipramine [Norpramin]) produce the fewest sexual adverse effects. The effects of the tricyclics and tetracyclics have not been documented sufficiently in women; however, few women seem to complain of any effects.

Some men report increased sensitivity of the glans that is pleasurable and that does not interfere with erection, although it delays ejaculation. In some cases, however, the tricyclic causes painful ejaculation, perhaps as the result of interference with seminal propulsion caused by interference with, in turn, urethral, prostatic, vas, and epididymal smooth muscle contractions. Clomipramine (Anafranil) has been reported to increase sex drive in some persons. Selegiline (Deprenyl), a selective MAO type B (MAO_B) inhibitor, and bupropion (Wellbutrin) have also been reported to increase sex drive, possibly by dopaminergic activity and increased production of norepinephrine.

Venlafaxine (Effexor) and the SSRIs most often have adverse effects because of the rise in serotonin levels. A lowering of the sex drive and difficulty reaching orgasm occur in both sexes. Reversal of those negative effects has been achieved with cyproheptadine (Periactin), an antihistamine with antiserotonergic effects, and with methylphenidate (Ritalin), which has adrenergic effects. Trazodone (Desyrel) is associated with the rare occurrence of priapism, the symptom of prolonged erection in the absence of sexual stimuli. That symptom appears to result from the α_2 -adrenergic antagonism of trazodone.

The MAOIs affect biogenic amines broadly. Accordingly, they produce impaired erection, delayed or retrograde ejaculation, vaginal dryness, and inhibited orgasm. Tranylcypromine (Parnate) has a paradoxical sexually stimulating effect in some persons, possibly as a result of its amphetamine-like properties.

Mr. W presented with the complaint of inability to achieve orgasm. His problem dated from the time, 18 months previously, when he had been placed on fluoxetine (Prozac). Before that time, he had been able to achieve orgasm through masturbation and through coitus with his wife.

Mr. W tried several other SSRIs, as well as venlafaxine, but the side effect of delayed ejaculation persisted. None of the usual antidotes to SSRI-induced anorgasmia proved effective, and the patient then was tried on antidepressants of other categories. Mr. W was able to respond to bupropion and clonazepam (Klonopin). This combination treated his depression and anxiety, and his delayed ejaculation resolved.

He was diagnosed with pharmacologically induced delayed ejaculation.

GENERAL EFFECTS. Because depression is associated with a decreased libido, varying levels of sexual dysfunction and anhedonia are part of the disease process. Some patients report improved sexual functioning as their depression improves as a result of antidepressant medication. The phenomenon makes the evaluation of sexual side effects difficult; also, the side effects may disappear with time, perhaps because a biogenic amine homeostatic mechanism comes into play.

Lithium. Lithium (Eskalith) regulates mood and, in the manic state, may reduce hypersexuality, possibly by a dopamine antagonist activity. In some patients, impaired erection has been reported.

Sympathomimetics. Psychostimulants, which are sometimes used in the treatment of depression, include amphetamines, methylphenidate, and pemoline (Cylert), which raise the plasma levels of norepinephrine and dopamine. Libido is increased; however, with prolonged use, men may experience a loss of desire and erections.

α -Adrenergic and β -Adrenergic Receptor Antagonists. α -Adrenergic and β -adrenergic receptor antagonists are used in the treatment of hypertension, angina, and certain cardiac arrhythmias. They diminish tonic sympathetic nerve outflow from vasomotor centers in the brain. As a result, they can cause impotence, decrease the volume of ejaculate, and produce retrograde ejaculation. Changes in libido have been reported in both sexes.

Suggestions have been made to use the side effects of drugs therapeutically. Thus, a drug that delays or interferes with ejaculation (e.g., fluoxetine) might be used to treat premature ejaculation.

Anticholinergics. The anticholinergics block cholinergic receptors and include such drugs as amantadine (Symmetrel) and benztrapine (Cogentin). They produce dryness of the mucous membranes (including those of the vagina) and erectile disorder. However, amantadine may reverse SSRI-induced orgasmic dysfunction through its dopaminergic effect.

Antihistamines. Drugs such as diphenhydramine (Benadryl) have anticholinergic activity and are mildly hypnotic. They may inhibit sexual function as a result. Cyproheptadine, although an antihistamine, also has potent activity as a serotonin antagonist. It is used to block the serotonergic sexual adverse effects produced by SSRIs, such as delayed orgasm.

Antianxiety Agents. The major class of anxiolytics is the benzodiazepines (e.g., diazepam [Valium]). They act on the γ -aminobutyric acid (GABA) receptors, which are believed to be involved in cognition, memory, and motor control. Because benzodiazepines decrease plasma epinephrine concentrations, they diminish anxiety, and as a result they improve sexual function in persons inhibited by anxiety.

Alcohol. Alcohol suppresses CNS activity generally and can produce erectile disorders in men as a result. Alcohol has a direct gonadal effect that decreases testosterone levels in men; paradoxically, it can produce a slight rise in testosterone levels in women. The latter finding may account for women who report increased libido after drinking small amounts of alcohol. The long-term use of alcohol reduces the ability of the liver to metabolize estrogenic compounds. In men, that produces signs of feminization (such as gynecomastia as a result of testicular atrophy).

Opioids. Opioids, such as heroin, have adverse sexual effects, such as erectile failure and decreased libido. The alteration of consciousness may enhance the sexual experience in occasional users.

Hallucinogens. The hallucinogens include lysergic acid diethylamide (LSD), phencyclidine (PCP), psilocybin (from some mushrooms), and mescaline (from peyote cactus). In addition to inducing hallucinations, the drugs cause loss of contact with reality and an expanding and heightening of consciousness. Some users report that the sexual experience is similarly enhanced, but others experience anxiety, delirium, or psychosis, which clearly interfere with sexual function.

Cannabis. The altered state of consciousness produced by cannabis may enhance sexual pleasure for some persons. Its prolonged use depresses testosterone levels.

Barbiturates and Similarly Acting Drugs. Barbiturates and similarly acting sedative-hypnotic drugs may enhance sexual responsiveness in persons who are sexually unresponsive as a result of anxiety. They have no direct effect on the sex organs; however, they do produce an alteration in consciousness that some persons find pleasurable. These drugs are subject to abuse, and use can be fatal when combined with alcohol or other CNS depressants.

Methaqualone (Quaalude) acquired a reputation as a sexual enhancer, which had no biological basis in fact. It is no longer marketed in the United States.

TREATMENT

Before 1970, the most common treatment of sexual dysfunctions was individual psychotherapy. Classic psychodynamic theory holds that sexual inadequacy has its roots in early developmental conflicts, and the sexual disorder is treated as part of a pervasive emotional disturbance. Treatment focuses on the exploration of unconscious conflicts, motivation, fantasy, and various interpersonal difficulties. One of the assumptions of therapy is that removal of the conflicts allows the sexual impulse to become structurally acceptable to the ego, and thereby the patient finds appropriate means of satisfaction in the environment. The symptoms of sexual dysfunctions, however, frequently become secondarily autonomous and continue to persist, even when other problems evolving from the patients' pathology have been resolved. The addition of behavioral techniques is often necessary to cure the sexual problem.

Dual-Sex Therapy

The theoretical basis of dual-sex therapy is the concept of the marital unit or dyad as the object of therapy; the approach represented the major advance in the diagnosis and treatment of sexual disorders in the 20th century. The methodology was originated and developed by Masters and Johnson. In dual-sex therapy, treatment is based on a concept that the couple must be treated when a dysfunctional person is in a relationship. Because both are involved in a sexually distressing situation, both must participate in the therapy program. The sexual problem often reflects other areas of disharmony or misunderstanding in the relationship so that the entire relationship is treated, with emphasis on the sexual functioning of the partners.

The keystone of the program is the roundtable session in which a male and female therapy team clarifies, discusses, and works through problems with the couple. The four-way sessions require active participation by the patients. Therapists and patients discuss the psychological and physiological aspects of sexual functioning, and therapists have an educative attitude. Therapists suggest specific sexual activities for the couple to follow in the privacy of their home. The aim of the therapy is to establish or reestablish communication within the partner unit. Sex is emphasized as a natural function that flourishes in the appropriate domestic climate, and improved communication is encouraged toward that end. In a variation of this therapy that has proved effective, one therapist may treat the couple. Treatment is short term and is behaviorally oriented. The therapists attempt to reflect the situation as they see it, rather than interpret underlying dynamics. An undistorted picture of the relationship presented by the therapists often corrects the myopic, narrow view held by each partner. This new perspective can interrupt the couple's destructive pattern of relating and can encourage improved, more effective communication. Specific exercises are prescribed for the couple to treat their particular problems. Sexual inadequacy often involves lack of information, misinformation, and performance fear. Therefore, the couple is specifically prohibited from any sexual play other than that prescribed by the therapists. Beginning exercises usually focus on heightening sensory awareness to touch, sight, sound, and smell. Initially, intercourse is interdicted, and the couple learn to give and receive bodily pleasure without the pressure of performance or penetration. At the same time, they learn how to communicate nonverbally in a mutually satisfactory way, and they learn that sexual foreplay is an enjoyable alternative to intercourse and orgasm.

During the sensate focus exercises, the couple receives much reinforcement to reduce anxiety. They are urged to use fantasies to distract them from obsessive concerns about performance (spectatoring). The needs of both the dysfunctional partner and the nondysfunctional partner are considered. If either partner becomes sexually excited by the exercises, the other is encouraged to bring him or her to orgasm by manual or oral means. Open communication between the partners is urged, and the expression of mutual needs is encouraged. Resistances, such as claims of fatigue or not enough time to complete the exercises, are common and must be dealt with by the therapists. Issues of body image, fear of being touched, and difficulty touching oneself arise frequently. Genital stimulation is eventually added to general body stimulation. The couple is instructed sequentially to try various positions for intercourse, without necessarily completing the act, and to use varieties of stimulating techniques before they are instructed to proceed with intercourse.

Psychotherapy sessions follow each new exercise period, and problems and satisfactions, both sexual and in other areas of the couple's lives, are discussed. Specific instructions and the introduction of new exercises geared to the individual couple's progress are reviewed in each session. Gradually, the couple gains confidence and learns to communicate, verbally and sexually. Dual-sex therapy is most effective when the sexual dysfunction exists apart from other psychopathology.

Specific Techniques and Exercises

Various techniques are used to treat the various sexual dysfunctions. In cases of vaginismus, a woman is advised to dilate her vaginal opening with her fingers or with size-graduated dilators. Dilators are also used to treat cases of dyspareunia. Sometimes, treatment is coordinated with specially trained physiotherapists who work with the patients to help them relax their perineal muscles.

In cases of premature ejaculation, an exercise known as the squeeze technique is used to raise the threshold of penile excitability. In this exercise, the man or the woman stimulates the erect penis until the earliest sensations of impending ejaculation are felt. At this point, the woman forcefully squeezes the coronal ridge of the glans, the erection is diminished, and ejaculation is inhibited. The exercise program eventually raises the threshold of the sensation of ejaculatory inevitability and allows the man to focus on sensations of arousal without anxiety and develop confidence in his sexual performance. A variant of the exercise is the stop-start technique developed by James H. Semans, in which the woman stops all stimulation of the penis when the man first senses an impending ejaculation. No squeeze is used. Research has shown that the presence or absence of circumcision has no bearing on a man's ejaculatory control; the glans is equally sensitive in the two states. Sex therapy has been most successful in the treatment of premature ejaculation.

A man with a sexual desire disorder or male erectile disorder is sometimes told to masturbate to prove that full erection and ejaculation are possible. Delayed ejaculation is managed initially by extravaginal ejaculation and then by gradual vaginal entry after stimulation to a point near ejaculation. Most importantly, the early exercises forbid ejaculation to remove the pressure to climax and allow the man to immerse himself in sexual pleasuring.

In cases of lifelong female orgasmic disorder, the woman is directed to masturbate, sometimes using a vibrator. The shaft of the clitoris is the masturbatory site most preferred by women, and orgasm depends on adequate clitoral stimulation. An area on the anterior wall of the vagina has been identified in some women as a site of sexual excitation, known as the *G-spot*; but reports of an ejaculatory phenomenon at orgasm in women following the stimulation of the G-spot have not been satisfactorily verified.

Hypnotherapy

Hypnotherapists focus specifically on the anxiety-producing situation—that is, the sexual interaction that results in dysfunction. The successful use of hypnosis enables patients to gain control over the symptom that has been lowering self-esteem and disrupting psychological homeostasis. The patient's cooperation is first obtained and encouraged during a series of nonhypnotic sessions with the therapist. Those discussions permit the development of a secure doctor-patient relationship, a sense of physical and psychological comfort on the part of the patient, and the establishment of mutually desired treatment goals. During this time, the therapist assesses the patient's capacity for the trance experience. The nonhypnotic sessions also permit the clinician to take a psychiatric history and perform a mental status examination before beginning hypnotherapy. The focus of treatment is on symptom removal and attitude alteration. The patient is instructed in developing alternative means of dealing with the anxiety-provoking situation, the sexual encounter.

In addition, patients are taught relaxation techniques to use on themselves before sexual relations. With these methods to alleviate anxiety, the physiological responses to sexual stimulation can more readily result in pleasurable excitation and discharge. Psychological impediments to vaginal lubrication, erection, and orgasms are removed, and normal sexual functioning ensues. Hypnosis may be added to a basic individual psychotherapy program to accelerate the effects of psychotherapeutic intervention.

Behavior Therapy

Behavioral approaches were initially designed for the treatment of phobias but are now used to treat other problems as well. Behavior therapists assume that sexual dysfunction is learned maladaptive behavior, which causes patients to be fearful of sexual interaction. Using traditional techniques, therapists set up a hierarchy of anxiety-provoking situations, ranging from least threatening (e.g., the thought of kissing) to most threatening (e.g., the thought of penile penetration). The behavior therapist enables the patient to master the anxiety through a standard program of systematic desensitization, which is designed to inhibit the learned anxious response by encouraging behaviors antithetical to anxiety. The patient first deals with the least anxiety-producing situation in fantasy and progresses by steps to the most anxiety-producing situation. Medication, hypnosis, and special training in deep muscle relaxation are sometimes used to help with the initial mastery of anxiety.

Assertiveness training is helpful in teaching patients to express sexual needs openly and without fear. Exercises in assertiveness are given in conjunction with sex therapy; patients are encouraged to make sexual requests and to refuse to comply with requests perceived as unreasonable. Sexual exercises may be prescribed for patients to perform at home, and a hierarchy may be established, starting with those activities that have proved most pleasurable and successful in the past.

One treatment variation involves the participation of the patient's sexual partner in the desensitization program. The partner, rather than the therapist, presents items of increasing stimulation value to the patient. A cooperative partner is necessary to help the patient carry gains made during treatment sessions to sexual activity at home.

Mindfulness

Mindfulness is a cognitive technique that has been helpful in the treatment of sexual dysfunction. The patient is directed to focus on the moment and maintain an awareness of sensations—visual, tactile, auditory, and olfactory—that he or she experiences in the moment. The aim is to distract the patient from spectating (watching him or herself) and center the person on the sensations that lead to arousal and/or orgasm. Hopefully, this shift in focus allows patients to become immersed in the pleasure of the experience and remove themselves from self-judgment and performance anxiety.

Group Therapy

Group therapy has been used to examine both intrapsychic and interpersonal problems in patients with sexual disorders. A therapy group provides a strong support system for a patient who feels ashamed, anxious, or guilty about a particular sexual problem. It is a useful forum in which to counteract sexual myths, correct misconceptions, and provide accurate information about sexual anatomy, physiology, and varieties of behavior.

Groups for the treatment of sexual disorders can be organized in several ways. Members may all share the same problem, such as premature ejaculation; members may all be of the same sex with different sexual problems; or groups may be composed of both men and women who are experiencing a variety of sexual problems. Group therapy can be an adjunct to other forms of therapy or the prime mode of treatment. Groups organized to treat a particular dysfunction are usually behavioral in approach.

Groups composed of married couples with sexual dysfunctions have also been effective. A group provides the opportunity to gather accurate information, offers consensual validation of individual preferences, and enhances self-esteem and self-acceptance. Techniques, such as role playing and psychodrama, may be used in treatment. Such groups are not indicated for couples when one partner is uncooperative, when a patient has a severe depressive disorder or psychosis, when a patient finds explicit sexual audiovisual material

repugnant, or when a patient fears or dislikes groups.

Analytically Oriented Sex Therapy

One of the most effective treatment modalities is the use of sex therapy integrated with psychodynamic and psychoanalytically oriented psychotherapy. The sex therapy is conducted over a longer period than usual, which allows learning or relearning of sexual satisfaction under the realities of patients' day-to-day lives. The addition of psychodynamic conceptualizations to behavioral techniques used to treat sexual dysfunctions allows the treatment of patients with sexual disorders associated with other psychopathology.

The material and dynamics that emerge in patients in analytically oriented sex therapy are the same as those in psychoanalytic therapy, such as dreams, fear of punishment, aggressive feelings, difficulty trusting a partner, fear of intimacy, oedipal feelings, and fear of genital mutilation. The combined approach of analytically oriented sex therapy is used by the general psychiatrist who carefully judges the optimal timing of sex therapy and the ability of patients to tolerate the directive approach that focuses on their sexual difficulties.

Biological Treatments

Biological treatments, including pharmacotherapy, surgery, and mechanical devices, are used to treat specific cases of sexual disorder. Most of the recent advances involve male sexual dysfunction. Current studies are under way to test biological treatment of sexual dysfunction in women.

Pharmacotherapy. The major new medications to treat sexual dysfunction are sildenafil (Viagra) and its congeners (Table 17.2-12); oral phentolamine (Vasomax); alprostadil (Caverject), and injectable medications; papaverine, prostaglandin E1, phentolamine, or some combination of these (Edex); and a transurethral alprostadil (MUSE), all used to treat erectile disorder.

Table 17.2-12
Pharmacokinetics of the PDE-5 Inhibitors

1. Out-of-control behavior
2. Severe adverse consequences (medical, legal, interpersonal) due to sexual behavior
3. Persistent pursuit of self-destructive or high-risk sexual behavior
4. Repeated attempts to limit or stop sexual behavior
5. Sexual obsession and fantasy as a primary coping mechanism
6. The need for increasing amounts of sexual activity
7. Severe mood changes related to sexual activity (e.g., depression, euphoria)
8. Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experience
9. Interference of sexual behavior in social, occupational, or recreational activities

(Data from Carnes P. *Don't Call It Love*. New York: Bantam Books; 1991.)

Sildenafil is a nitric oxide enhancer that facilitates the inflow of blood to the penis necessary for an erection. The drug takes effect about 1 hour after ingestion, and its effect can last up to 4 hours. Sildenafil is not effective in the absence of sexual stimulation. The most common adverse events associated with its use are headaches, flushing, and dyspepsia. The use of sildenafil is contraindicated for persons taking organic nitrates. The concomitant action of the two drugs can result in large, sudden, and sometimes fatal drops in systemic blood pressure. Sildenafil is not effective in all cases of erectile dysfunction. It fails to produce an erection that is sufficiently rigid for penetration in about 50 percent of men who have had radical prostate surgery or in those with long-standing insulin-dependent diabetes. It is also ineffective in certain cases of nerve damage.

A small number of patients developed nonarteritic ischemic optic neuropathy (NAION) soon after use of sildenafil. Six patients had vision loss within 24 hours after use of the agent. Both eyes were affected in one individual. All affected individuals had preexisting hypertension, diabetes, elevated cholesterol, or hyperlipidemia. Although very rare, sildenafil may provoke NAION in individuals with an arteriosclerotic risk profile. Very rare cases of hearing loss have also been reported.

Sildenafil use in women results in vaginal lubrication, but not in increased desire. Anecdotal reports, however, describe individual women who have experienced intensified excitement with sildenafil.

Oral phentolamine and apomorphine are not US Food and Drug Administration (FDA) approved at present, but have proved effective as potency enhancers in men with minimal erectile dysfunction. Phentolamine reduces sympathetic tone and relaxes corporeal smooth muscle. Adverse events include hypotension, tachycardia, and dizziness. Apomorphine effects are mediated by the autonomic nervous system and result in vasodilation that facilitates the inflow of blood to the penis. Adverse events include nausea and sweating.

In contrast to the oral medications, injectable and transurethral forms of alprostadil act locally on the penis and can produce erections in the absence of sexual stimulation. Alprostadil contains a naturally occurring form of prostaglandin E, a vasodilating agent. Alprostadil may be administered by direct injection into the corpora cavernosa or by intraurethral insertion of a pellet through a canula. The firm erection produced within 2 to 3 minutes after administration of the drug may last as long as 1 hour. Infrequent and reversible adverse effects of injections include penile bruising and changes in liver function test results. Possible hazardous sequelae exist, including priapism and sclerosis of the small veins of the penis. Users of transurethral alprostadil sometimes complain of burning sensations in the penis.

Two small trials found different topical agents effective in alleviating erectile dysfunction. One cream consists of three vasoactive substances known to be absorbed through the skin: aminophylline, isosorbide dinitrate, and co-dergocrine mesylate, which is a mixture of ergot alkaloids. The other is a gel containing alprostadil and an additional ingredient, which temporarily makes the outer layer of the skin more permeable.

In addition, a cream incorporating alprostadil has been developed to treat female sexual arousal disorder; the initial results are promising. In a trial of postmenopausal women with arousal problems who were already on hormonal therapy, vaginally applied phentolamine mesylate, an α -receptor antagonist, significantly increased vasocongestion and a subjective sense of arousal. A drug to increase desire in women, flibanserin, has been resubmitted for approval to the FDA. It was previously denied approval.

The pharmacological treatments described in the preceding text are useful in the treatment of arousal dysfunction of various causes: neurogenic, arterial insufficiency, venous leakage, psychogenic, and mixed. When coupled with insight-oriented or behavioral sex therapy, the use of medications can reverse psychogenic arousal disorder that is resistant to psychotherapy alone, the ultimate goal being pharmacologically unassisted sexual functioning.

Other Pharmacological Agents. Numerous other pharmacological agents have been used to treat the various sexual disorders. Intravenous methohexital sodium (Brevital) has been used in desensitization therapy. Antianxiety agents may have some application in tense patients, although these drugs can interfere with the sexual response. The side effects of antidepressants, in particular the SSRIs and tricyclic drugs, have been used to prolong the sexual response in patients with premature ejaculation. This approach is particularly useful in patients who are refractory to behavioral techniques who may fall into the category of physiologically disposed premature ejaculators. Topical

anesthetic creams are also reported to be helpful in decreasing the intravaginal ejaculation latency time (IELT) in cases of premature ejaculation. Antidepressants are advocated in treatment of patients who are phobic of sex and in those with posttraumatic stress disorder following rape. Trazodone is an antidepressant that improves nocturnal erections. The risks of taking such medications must be carefully weighed against their possible benefits. Bromocriptine (Parlodel) is used in the treatment of hyperprolactinemia, which is frequently associated with hypogonadism. In such patients, it is necessary to rule out pituitary tumors. Bromocriptine, a dopamine agonist, may improve sexual function impaired by hyperprolactinemia.

A number of substances have popular standing as aphrodisiacs; for example, ginseng root and yohimbine (Yocon). Studies, however, have not confirmed any aphrodisiac properties. Yohimbine, an α -receptor antagonist, may cause dilation of the penile artery; however, the American Urologic Association does not recommend its use to treat organic erectile dysfunction. Many recreational drugs, including cocaine, amphetamines, alcohol, and cannabis, are considered enhancers of sexual performance. Although they may provide the user with an initial benefit because of their tranquilizing, disinhibiting, or mood-elevating effects, consistent or prolonged use of any of these substances impairs sexual functioning.

Dopaminergic agents have been reported to increase libido and improve sex function. Those drugs include L-dopa, a dopamine precursor, and bromocriptine, a dopamine agonist. The antidepressant bupropion has dopaminergic effects and has increased sex drive in some patients. Selegiline, an MAOI, is selective for MAO_B and is dopaminergic. It improves sexual functioning in older persons.

HORMONE THERAPY. Androgens increase the sex drive in women and in men with low testosterone concentrations. Women may experience virilizing effects, some of which are irreversible (e.g., deepening of the voice). In men, prolonged use of androgens produces hypertension and prostatic enlargement. Testosterone is most effective when given parenterally; however, effective oral and transdermal preparations are available.

Women who use estrogens for replacement therapy or for contraception may report decreased libido; in such cases, a combined preparation of estrogen and testosterone has been used effectively. Estrogen itself prevents thinning of the vaginal mucous membrane and facilitates lubrication. Several forms of locally delivered estrogen—vaginal rings, vaginal creams, and vaginal tablets—provide alternate administration routes to treat women with arousal problems or genital atrophy. Because tablets, creams, and rings do not significantly increase circulating estrogen levels, these devices may be considered for patients with breast cancer with arousal problems.

ANTIANDROGENS AND ANTIESTROGENS. Estrogens and progesterone are antiandrogens that have been used to treat compulsive sexual behavior in men, usually in sex offenders. Clomiphene (Clomid) and tamoxifen (Nolvadex) are both antiestrogens, and both stimulate gonadotropin-releasing hormone (GnRH) secretion and increase testosterone concentrations, thereby increasing libido. Women being treated for breast cancer with tamoxifen report an increased libido. However, tamoxifen may cause uterine cancer.

MECHANICAL TREATMENT APPROACHES. In male patients with arteriosclerosis (especially of the distal aorta, known as Leriche's syndrome), the erection may be lost during active pelvic thrusting. The need for increased blood in the gluteal muscles and others served by the iliac or hypogastric arteries takes blood away (steals) from the pudendal artery and, thus, interferes with penile blood flow. Relief may be obtained by decreasing pelvic thrusting, which is also aided by the woman's superior coital position.

VACUUM PUMP. Vacuum pumps are mechanical devices that patients without vascular disease can use to obtain erections. The blood drawn into the penis following the creation of the vacuum is kept there by a ring placed around the base of the penis. This device has no adverse effects, but it is cumbersome, and partners must be willing to accept its use. Some women complain that the penis is redder and cooler than when erection is produced by natural circumstances, and they find the process and the result objectionable.

A similar device, called EROS, has been developed to create clitoral erections in women. EROS is a small suction cup that fits over the clitoral region and draws blood into the clitoris. Studies have reported its success in treating female sexual arousal disorder. Vibrators used to stimulate the clitoral area have been successful in treating anorgasmic women.

Surgical Treatment

MALE PROSTHESES. Surgical treatment is infrequently advocated, but penile prosthetic devices are available for men with inadequate erectile responses who are resistant to other treatment methods or who have medically caused deficiencies. The two main types of prostheses are (1) a semi-rigid rod prosthesis that produces a permanent erection that can be positioned close to the body for concealment and (2) an inflatable type that is implanted with its own reservoir and pump for inflation and deflation. The latter type is designed to mimic normal physiological functioning.

VASCULAR SURGERY. When vascular insufficiency is present due to atherosclerosis or other blockage, bypass surgery of penile arteries has been attempted in selected cases with some success.

Outcome

Demonstrating the effectiveness of traditional outpatient psychotherapy is just as difficult when therapy is oriented to sexual problems as it is in general. The more severe the psychopathology associated with a problem of long duration, the more adverse the outcome is likely to be. The results of different treatment methods have varied considerably since Masters and Johnson first reported positive results for their treatment approach in 1970. Masters and Johnson studied the failure rates of their patients (defined as the failure to initiate reversal of the basic symptom of the presenting dysfunction). They compared initial failure rates with 5-year follow-up findings for the same couples. Although some have criticized their definition of the percentage of presumed successes, other studies have confirmed the effectiveness of their approach.

The more difficult treatment cases involve couples with severe marital discord. Desire disorders are particularly difficult to treat. They require longer, more intensive therapy than some other disorders, and their outcomes vary greatly.

When behavioral approaches are used, empirical criteria that predict outcome are more easily isolated. Using these criteria, for instance, couples who regularly practice assigned exercises appear to have a much greater likelihood of success than do more resistant couples or those whose interaction involves sadomasochistic or depressive features or mechanisms of blame and projection. Attitude flexibility is also a positive prognostic factor. Overall, younger couples tend to complete sex therapy more often than older couples. Couples whose interactional difficulties center on their sex problems, such as inhibition, frustration, or fear of performance failure, are also likely to respond well to therapy.

Although most therapists prefer to treat a couple for sexual dysfunction, treatment of individual persons has also been successful. In general, methods that have proved effective singly or in combination include training in behavioral sexual skills, systematic desensitization, directive marital counseling, traditional psychodynamic approaches, group therapy, and pharmacotherapy.

OTHER SPECIFIED SEXUAL DYSFUNCTIONS

Many sexual disorders are not classifiable as sexual dysfunctions or as paraphilias. These unclassified disorders are rare, poorly documented, not easily classified, or not specifically described in DSM-5. ICD-10 has a similar residual category for problems related to sexual development or preference.

Postcoital Dysphoria

Postcoital dysphoria occurs during the resolution phase of sexual activity, when persons normally experience a sense of general well-being and muscular and psychological relaxation. Some persons, however, undergo postcoital dysphoria at this time and, after an otherwise satisfactory sexual experience, become depressed, tense, anxious, and irritable, and show psychomotor agitation. They often want to get away from their partners and may become verbally or even physically abusive. The incidence of the disorder is unknown, but it is more common in men than in women. The causes relate to the person's attitude toward sex in general and toward the partner in particular. The disorder may occur in adulterous sex and in contacts with prostitutes. The fear of acquired immunodeficiency syndrome (AIDS) causes some persons to experience postcoital dysphoria. Treatment requires insight-oriented psychotherapy to help patients understand the unconscious antecedents to their behavior and attitudes.

Couple Problems

At times, a complaint arises from the spousal unit or the couple, rather than from an individual dysfunction. For example, one partner may prefer morning sex, but the other functions more readily at night, or the partners have unequal frequencies of desire.

Unconsummated Marriage

A couple involved in an unconsummated marriage has never had coitus and is typically uninformed and inhibited about sexuality. The partners' feelings of guilt, shame, or inadequacy are increased by their problem, and they experience conflict between their need to seek help and their need to conceal their difficulty. Couples may seek help for the problem after having been married several months or several years. Masters and Johnson reported one unconsummated marriage of 17 years' duration.

Frequently, the couple does not seek help directly; the woman may reveal the problem to her gynecologist on a visit ostensibly concerned with vague vaginal or other somatic complaints. On examining her, the gynecologist may find an intact hymen. In some cases, however, the wife may have undergone a hymenectomy to resolve the problem, but the surgery may aggravate the situation without solving the basic problem. The surgical procedure is another stress and often increases the couple's feelings of inadequacy. The wife may feel put upon, abused, or mutilated, and the husband's concern about his manliness may increase. An inquiry by a physician who is comfortable dealing with sexual problems may be the first opening to a frank discussion of the couple's distress. Often, the pretext of the medical visit is a discussion of contraceptive methods or—even more ironically—a request for an infertility workup. Once presented, the complaint can often be treated successfully. The duration of the problem does not significantly affect the prognosis or the outcome of the case.

The causes of unconsummated marriage are varied: lack of sex education, sexual prohibitions overly stressed by parents or society, problems of an oedipal nature, immaturity in both partners, overdependence on primary families, and problems in sexual identification. Religious orthodoxy, with severe control of sexual and social development, and equating sexuality with sin or uncleanness has also been cited as a dominant cause. Many women involved in an unconsummated marriage have distorted concepts about their vaginas. They may fear that it is too small or too soft, or they may confuse the vagina with the rectum and thus feel unclean. Men may share these distortions about the vagina and perceive it as dangerous to themselves. Similarly, both partners may have distortions about the man's penis and perceive it as a weapon, as too large, or as too small. Many patients can be helped by simple education about genital anatomy and physiology, by suggestions for self-exploration, and by correct information from a physician. The problem of unconsummated marriage is best treated by seeing both members of the couple. Dual-sex therapy involving a male-female cotherapist team has been markedly effective. Other forms of conjoint therapy, marital counseling, traditional psychotherapy on a one-to-one basis, and counseling from a sensitive family physician, gynecologist, or urologist are also helpful.

Body Image Problems

Some persons are ashamed of their bodies and experience feelings of inadequacy related to self-imposed standards of masculinity or femininity. They may insist on sex only during total darkness, not allow certain body parts to be seen or touched, or seek unnecessary operative procedures to deal with their imagined inadequacies. Body dysmorphic disorder should be ruled out.

Sex Addiction and Compulsivity

The concept of sex addiction developed over the last two decades to refer to persons who compulsively seek out sexual experiences and whose behavior becomes impaired if they are unable to gratify their sexual impulses. The concept of sex addiction derived from the model of addiction to such drugs as heroin or addiction to behavioral patterns, such as gambling. Addiction implies psychological dependence, physical dependence, and the presence of a withdrawal syndrome if the substance (e.g., the drug) is unavailable or the behavior (e.g., gambling) is frustrated.

In DSM-5 the terms *sex addiction* or *compulsive sexuality* are not used, nor is it a disorder that is universally recognized or accepted. Nevertheless, the phenomenon of a person whose life revolves around sex-seeking behavior and activities, who spends an excessive amount of time in such behavior, and who often tries to stop such behavior but is unable to do so is well known to clinicians. Such persons show repeated and increasingly frequent attempts to have a sexual experience, deprivation of which gives rise to symptoms of distress. Sex addiction is a useful concept heuristically, in that it can alert the clinician to seek an underlying cause for the manifest behavior. There is interest in making it a new official diagnostic category, which the authors support.

Diagnosis. Sex addicts are unable to control their sexual impulses, which can involve the entire spectrum of sexual fantasy or behavior. Eventually, the need for sexual activity increases, and the person's behavior is motivated largely by the persistent desire to experience the sex act. The history usually reveals a long-standing pattern of such behavior, which the person repeatedly has tried to stop, but without success. Although a patient may have feelings of guilt and remorse after the act, these feelings do not suffice to prevent its recurrence. The patient may report that the need to act out is most severe during stressful periods or when angry, depressed, anxious, or otherwise dysphoric. Most acts culminate in a sexual orgasm. Eventually, the sexual activity interferes with the person's social, vocational, or marital life, which begins to deteriorate. The signs of sexual addiction are listed in [Table 17.2-13](#).

 **Table 17.2-13**
Signs of Sexual Addiction

-
1. Out-of-control behavior
 2. Severe adverse consequences (medical, legal, interpersonal) due to sexual behavior
 3. Persistent pursuit of self-destructive or high-risk sexual behavior
 4. Repeated attempts to limit or stop sexual behavior
 5. Sexual obsession and fantasy as a primary coping mechanism
 6. The need for increasing amounts of sexual activity
 7. Severe mood changes related to sexual activity (e.g., depression, euphoria)
 8. Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experience
 9. Interference of sexual behavior in social, occupational, or recreational activities
-

(Data from Carnes P. *Don't Call It Love*. New York: Bantam Books; 1991.)

Types of Behavioral Patterns. The paraphilias constitute the behavioral patterns most often found in the sex addict. The essential features of a paraphilia are recurrent, intense sexual urges or behaviors, including exhibitionism, fetishism, frotteurism, sadomasochism, cross-dressing, voyeurism, and pedophilia. Paraphilias are associated with clinically significant distress and almost invariably interfere with interpersonal relationships, and they often lead to legal complications. In addition to the paraphilias, however, sex addiction can also include behavior that is considered normal, such as coitus and masturbation, except that it is promiscuous and uncontrolled.

In the 19th century, Krafft-Ebing reported on several cases of abnormally increased sexual desire. One involved a 36-year-old married teacher, the father of seven children, who masturbated repeatedly while sitting at his desk in front of his pupils, after which he was “penitent and filled with shame.” He indulged in coitus three or four times a day in addition to his repeated masturbatory act. In another case, a young woman masturbated almost incessantly and was unable to control her impulses. She had frequent coitus with many men, but neither coitus nor masturbation sufficed, and she eventually was placed in an institution. Krafft-Ebing referred to the condition as “sexual hyperaesthesia,” which he believed could occur in otherwise normal persons. In this case, the clinician would have to differentiate between a diagnosis of sex addiction or Persistent Genital Arousal Disorder (PGAD). This is not a diagnostic category in DSM-5, but has received attention by sex therapists. Women with PGAD complain that their sense of arousal is not satisfied by orgasm or multiple orgasms. The ongoing sense of arousal is distressing, intensely uncomfortable, and has led to one reported case of suicide. In contrast to sex addicts, women with PGAD are not even temporarily satisfied, physically or emotionally, by orgasm. Some theorists suspect a neurologic etiology.

In many cases, sex addiction is the final common pathway of a variety of other disorders. In addition to the paraphilias that are often present, the patient may have an associated major mood disorder or schizophrenia. Antisocial personality disorder and borderline personality disorder are common.

DON JUANISM. Some men who appear to be hypersexual, as manifested by their need to have many sexual encounters or conquests, use their sexual activities to mask deep feelings of inferiority. Some have unconscious homosexual impulses, which they deny by compulsive sexual contacts with women. After having sex, most Don Juans are no longer interested in the woman. The condition is sometimes referred to as *satyriasis* or *sex addiction*.

NYMPHOMANIA. Nymphomania signifies a woman's excessive or pathological desire for coitus. Of the few scientific studies of the condition, those patients who were studied usually have had one or more sexual disorders, often including female orgasmic disorder. The woman often has an intense fear of losing love and, through her actions, attempts to satisfy her dependence needs rather than gratify her sexual impulses. This disorder is a form of sex addiction.

Comorbidity. Comorbidity (dual diagnosis) refers to the presence of an addiction that coexists with another psychiatric disorder. For example, about 50 percent of patients with substance-use disorder also have an additional psychiatric disorder. Similarly, many sex addicts have an associated psychiatric disorder. Dual diagnosis implies that the psychiatric illness and the addiction are separate disorders; one does not cause the other. The diagnosis of comorbidity is often difficult to make because addictive behavior (of all types) can produce extreme anxiety and severe disturbances in mood and affect, especially while the addictive behavior is treated. If, after a period of abstinence, symptoms of a psychiatric disorder remain, the comorbid condition is more easily recognized and diagnosed than during the addictive period. Finally, a high correlation is found between sex addiction and substance-use disorders (up to 80 percent in some studies), which not only complicates the task of diagnosis, but also complicates treatment.

Treatment. Self-help groups based on the 12-step concept used in Alcoholics Anonymous (AA) have been used successfully with many sex addicts. They include such groups as Sexaholics Anonymous (SA), Sex and Love Addicts Anonymous (SLAA), and Sex Addicts Anonymous (SAA). The groups differ in that some are for men or women, or for married persons or couples. All advocate some abstinence from either the addictive behavior or sex in general. Should a substance-use disorder also be present, the patient often requires referral to AA or Narcotics Anonymous (NA) as well. Patients may enter an inpatient treatment unit when they lack sufficient motivation to control their behavior on an outpatient basis or may be a danger to themselves or others. In addition, severe medical or psychiatric symptoms may require careful supervision and treatment best carried out in a hospital.

A 42-year-old married businessman with two children was considered a model of virtue in his community. He was active in his church and on the boards of several charitable organizations. He was living a secret life, however, and would lie to his wife, telling her that he was at a board meeting when he was actually visiting massage parlors for paid sex. He eventually was engaging in the behavior four to five times a day, and although he tried to quit many times, he was unable to do so. He knew that he was harming himself by putting his reputation and marriage at risk.

The patient presented himself to the psychiatric emergency room, stating that he would prefer to be dead rather than continue the behavior described. He was admitted with a diagnosis of major depressive disorder and started on a daily dose of 20 mg of fluoxetine. In addition, he received 100 mg of medroxyprogesterone intramuscularly once a day. His need to masturbate diminished markedly and ceased entirely on the third hospital day, as did his mental preoccupation with sex. The medroxyprogesterone was discontinued on the sixth day, when he was discharged. He continued to take fluoxetine, enrolled in a local SA group, and entered individual and couples psychotherapy. His addictive behavior eventually stopped, he was having satisfactory sexual relations with his wife, and he was no longer suicidal or depressed.

Psychotherapy. Insight-oriented psychotherapy may help patients understand the dynamics of their behavioral patterns. Supportive psychotherapy can help repair the interpersonal, social, or occupational damage that occurs. Cognitive behavioral therapy helps the patient recognize dysphoric states that precipitate sexual acting out. Marital therapy or couples therapy can help the patient regain self-esteem,

which is severely impaired by the time a treatment program is begun. It is also helpful to the partners who need assistance in understanding the disease and dealing with their own complex reactions to the situation. Finally, psychotherapy may be of help in the treatment of any associated psychiatric disorder.

Pharmacotherapy. Most specialists in general addiction avoid the use of psychotropic agents, especially in the early stages of treatment. Substance-dependent persons have a tendency to abuse those agents, especially agents with a high abuse potential, such as the benzodiazepines. Pharmacotherapy is of use in the treatment of associated psychiatric disorders, such as major depressive disorders and schizophrenia.

Certain medications may be of use in treating sex addiction, however, because of their specific effects on reducing the sex drive. SSRIs reduce libido in some persons, a side effect that is used therapeutically. Compulsive masturbation is an example of a behavioral pattern that may benefit from such medication. Medroxyprogesterone acetate diminishes libido in men and, thus, makes it easier to control sexually addictive behavior.

The use of antiandrogens in women to control hypersexuality has not been tested sufficiently, but because androgenic compounds contribute to the sex drive in women, antiandrogens could be of benefit. Antiandrogenic agents (cyproterone acetate) are not available in the United States but are used in Europe with varying success. Use of the antiandrogenic medications is controversial, and objected to by clinicians who see it a chemical castration and believe that is an inappropriate treatment approach.

Persistent and Marked Distress about Sexual Orientation

Distress about sexual orientation is characterized by dissatisfaction with sexual arousal patterns, and it is usually applied to dissatisfaction with homosexual arousal patterns, a desire to increase heterosexual arousal, and strong negative feelings about being homosexual. Occasional statements to the effect that life would be easier if the speaker were not homosexual do not constitute persistent and marked distress about sexual orientation.

Treatment of sexual orientation distress is controversial. One study reported that with a minimum of 350 hours of psychoanalytic therapy, about a third of 100 bisexual and gay men achieved a heterosexual reorientation at a 5-year follow-up; this study has been challenged, however. Behavior therapy and avoidance conditioning techniques have also been used, but these techniques may change behavior only in the laboratory setting. Prognostic factors weighing in favor of heterosexual reorientation for men include being younger than 35 years of age, having some experience of heterosexual arousal, and feeling highly motivated to reorient.

Another and more prevalent style of intervention is directed at enabling persons with persistent and marked distress about sexual orientation to live comfortably with homosexuality without shame, guilt, anxiety, or depression. Gay counseling centers are engaged with patients in such treatment programs. At present, outcome studies of such centers have not been reported in detail.

Few data are available about the treatment of women with persistent and marked distress about sexual orientation, and these are primarily from single-case studies with variable outcomes.

Persistent Genital Arousal Disorder

Persistent genital arousal disorder (PGAD) has previously been called persistent sexual arousal syndrome. It has been diagnosed in women who complain of a continual feeling of sexual arousal, which is uncomfortable, demands release, and interferes with life pleasures and activities. These women masturbate frequently, sometimes incessantly, because climax provides relief. However, the relief is temporary and the sense of arousal returns rapidly and remains. The sense of arousal in these cases is neither pleasurable nor exciting, and the women are not interested in a sexual experience but in relief from their symptoms. Some women have reported masturbating so frequently to alleviate the arousal that they have irritated their genitalia severely. One case of attempted suicide has been reported with this syndrome, with the woman stating that she could no longer tolerate the sensations and that she had masturbated so often that her vulva was raw.

Krafft-Ebing reported a case of a young woman who masturbated almost incessantly and was unable to control her impulses. She had frequent coitus with many men, but neither coitus nor masturbation sufficed, and she was eventually placed in an institution. Krafft-Ebing referred to the condition as "sexual hyperaesthesia," which he believed could occur in otherwise normal persons.

This case would have to be differentiated from sexual addiction (discussed earlier). The differentiating factor would be whether the woman desired an orgasm for itself, and looked forward to having sex, or whether she was seeking relief from incessant and intolerable stimulation. There is some speculation that this disorder is due to nerve damage or anomaly, but the etiology is unknown.

Female Premature Orgasm

Data on female premature orgasm are lacking. A case of multiple spontaneous orgasms without sexual stimulation was seen in a woman; the cause was an epileptogenic focus in the temporal lobe. Instances have been reported of women taking antidepressants (e.g., fluoxetine and clomipramine) who experience spontaneous orgasm associated with yawning.

Postcoital Headache

Postcoital headache, characterized by headache immediately after coitus, may last for several hours. It is usually described as throbbing and is localized in the occipital or frontal area. The cause is unknown. There may be vascular, muscle-contraction (tension), or psychogenic causes. Coitus may precipitate migraine or cluster headaches in predisposed persons.

Orgasmic Anhedonia

Orgasmic anhedonia is a condition in which a person has no physical sensation of orgasm, even though the physiological component (e.g., ejaculation) remains intact. Organic causes, such as sacral and cephalic lesions that interfere with afferent pathways from the genitalia to the cortex, must be ruled out. Psychiatric causes usually relate to extreme guilt about experiencing sexual pleasure. These feelings produce a dissociative response that isolates the affective component of the orgasmic experience from consciousness.

Masturbatory Pain

Persons may experience pain during masturbation. Organic causes should always be ruled out; a small vaginal tear or early Peyronie's disease can produce a painful sensation. The condition should be differentiated from compulsive masturbation. Persons may masturbate to the extent that they do physical damage to their genitals and eventually experience pain during subsequent masturbatory acts. Such cases constitute a separate sexual disorder and should be so classified.

Certain masturbatory practices have resulted in what has been called autoerotic asphyxiation. The practices involve persons masturbating while hanging by the neck to heighten the erotic sensations and the orgasm's intensity through the mechanism of mild hypoxia. Although the persons intend to release themselves from the noose after orgasm, an estimated 500 to 1,000 persons a year accidentally kill themselves by hanging. Most who indulge in the practice are male; transvestism is often associated with the habit, and most deaths occur among adolescents. Such masochistic practices are usually associated with severe mental disorders, such as schizophrenia and major mood disorders.

▲ 17.3 Paraphilic Disorders

Paraphilias or perversions are sexual stimuli or acts that are deviations from normal sexual behaviors, but are necessary for some persons to experience arousal and orgasm. According to the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition* (DSM-5), the term paraphilic disorder is reserved for those cases in which a sexually deviant fantasy or impulse has been expressed behaviorally. Individuals with paraphilic interests can experience sexual pleasure, but they are inhibited from responding to stimuli that are normally considered erotic. The paraphiliac person's sexuality is mainly restricted to specific deviant stimuli or acts. Persons that occasionally experiment with paraphilic behavior (e.g., infrequent episode of bondage or dressing in costumes), but are capable of responding to more typical erotic stimuli, are not seen as having paraphilic disorders.

Paraphilic disorders can range from nearly normal behavior to behavior that is destructive or hurtful only to a person's self or to a person's self and partner, and finally to behavior that is deemed destructive or threatening to the community at large. DSM-5 lists pedophilia, frotteurism, voyeurism, exhibitionism, sexual sadism, sexual masochism, fetishism, and transvestism with explicit diagnostic criteria because of their threat to others and/or because they are relatively common paraphilias. There are many other paraphilias that may be diagnosed. A paraphilia is clinically significant if the person has acted on these fantasies or if these fantasies cause marked distress or interpersonal difficulty or job-related difficulty. However, when the fantasy has not been acted upon, the term paraphilic disorder should not be applied. In the paraphilias listed earlier, with the exception of pedophilia, the specifiers, "in a controlled environment" (where the fantasy cannot easily be acted upon due to circumstances, such as being in an institution) and "in full remission" (when the patient has not acted on the fantasies for 5 years and there has been no impairment in interpersonal or occupational functioning in an uncontrolled environment for 5 years) are added.

A special fantasy with its unconscious and conscious components is the pathognomonic element of the paraphilia, with sexual arousal and orgasm being associated phenomena that *reinforce the fantasy or impulse*. The influence of these fantasies and their behavioral manifestations often extend beyond the sexual sphere to pervade people's lives.

The major functions of human sexual behavior are to assist in bonding, to create mutual pleasure in cooperation with a partner, to express and enhance love between two persons, and to procreate. Paraphilic disorders entail divergent behaviors in that those acts involve aggression, victimization, and extreme one-sidedness. The behaviors exclude or harm others and disrupt the potential for bonding between persons. Moreover, paraphilic sexual scripts often serve other vital psychic functions. They may assuage anxiety, bind aggression, or stabilize identity.

EPIDEMIOLOGY

Paraphilias are practiced by only a small percentage of the population, but the insistent, repetitive nature of the disorders results in a high frequency of such acts. Thus, a large proportion of the population has been victimized by persons with paraphilic disorders. It has been suggested that the prevalence of paraphilias is significantly higher than the number of cases diagnosed in general clinical facilities, based on the large commercial market in paraphilic pornography and paraphernalia. Is not known how many of the consumers of this material act on paraphilic fantasies or cannot respond to typical erotic stimuli.

Among legally identified cases of paraphilic disorders, pedophilia is most common. Of all children, 10 to 20 percent have been molested by age 18. Because a child is the object, the act is taken more seriously, and greater effort is spent tracking down the culprit than in other paraphilic disorders. Persons with exhibitionism who publicly display themselves to young children are also commonly apprehended. Those with voyeurism may be apprehended, but their risk is not great. Of adult females, 20 percent have been the targets of persons with exhibitionism and voyeurism. Sexual masochism and sexual sadism are underrepresented in any prevalence estimates. Sexual sadism usually comes to attention only in sensational cases of rape, brutality, and lust murder. The excretory paraphilic disorders are scarcely reported, because activity usually takes place between consenting adults or between prostitute and client. Persons with fetishism rarely become entangled in the legal system. Those with transvestism may be arrested occasionally for disturbing the peace or on other misdemeanor charges if they are obviously men dressed in women's clothes, but arrest is more common among those with gender identity disorders. Zoophilia as a true paraphilic disorder is rare (Table 17.3-1).

Table 17.3-1

Frequency of Paraphilic Acts Committed by Patients with Paraphilia Seeking Outpatient Treatment

Diagnostic Category	Patients with Paraphilia Seeking Outpatient Treatment (%)	Paraphilic Acts per Patient with Paraphilia ^a
Pedophilia	45	5
Exhibitionism	25	50
Voyeurism	12	17
Frotteurism	6	30
Sexual masochism	3	36
Transvestic fetishism	3	25
Sexual sadism	3	3
Fetishism	2	3
Zoophilia	1	2

^aMedian number.
(Courtesy of Gene G. Abel, M.D.)

As usually defined, the paraphilias seem to be largely male conditions. Fetishism almost always occurs in men. More than 50 percent of all paraphilias have their onset before age 18. Patients with paraphilia frequently have three to five paraphilias, either concurrently or at different times in their lives. This pattern of occurrence is especially the case with exhibitionism, fetishism, sexual masochism, sexual sadism, transvestic fetishism, voyeurism, and zoophilia (see [Table 17.3-1](#)). The occurrence of paraphilic behavior peaks between ages 15 and 25 and gradually declines. DSM-5 suggests the paraphilia designation be reserved for those ages 18 and older to avoid pathologizing normal sexual curiosity and occasional experimentation in adolescence. In men older than 50, criminal paraphilic acts are rare. Those that occur are practiced in isolation or with a cooperative partner.

ETIOLOGY

Psychosocial Factors

In the classic psychoanalytic model, persons with a paraphilia have failed to complete the normal developmental process toward sexual adjustment, but the model has been modified by new psychoanalytic approaches. What distinguishes one paraphilia from another is the method chosen by a person (usually male) to cope with the anxiety caused by the threat of castration by the father and separation from the mother. However bizarre its manifestation, the resulting behavior provides an outlet for the sexual and aggressive drives that would otherwise have been channeled into normal sexual behavior.

Failure to resolve the oedipal crisis by identifying with the father-aggressor (for boys) or mother-aggressor (for girls) results either in improper identification with the opposite-sex parent or in an improper choice of object for libido cathexis. Classic psychoanalytic theory holds that transsexualism and transvestic fetishism are disorders because each involves identification with the opposite-sex parent instead of the same-sex parent; for instance, a man dressing in women's clothes is believed to identify with his mother. Exhibitionism and voyeurism may be attempts to calm anxiety about castration because the reaction of the victim or the arousal of the voyeur reassures the paraphilic person that the penis is intact. Fetishism is an attempt to avoid anxiety by displacing libidinal impulses to inappropriate objects. A person with a shoe fetish unconsciously denies that women have lost their penises through castration by attaching libido to a phallic object, the shoe, which symbolizes the female penis. Persons with pedophilia and sexual sadism have a need to dominate and control their victims to compensate for their feelings of powerlessness during the oedipal crisis. Some theorists believe that choosing a child as a love object is a narcissistic act. Persons with sexual masochism overcome their fear of injury and their sense of powerlessness by showing that they are impervious to harm. Another theory proposes that the masochist directs the aggression inherent in all paraphilias toward herself or himself. Although recent developments in psychoanalysis place more emphasis on treating defense mechanisms than on oedipal traumas, psychoanalytic therapy for patients with a paraphilia remains consistent with Sigmund Freud's theory.

Other theories attribute the development of a paraphilia to early experiences that condition or socialize children into committing a paraphilic act. The first shared sexual experience can be important in that regard. Molestation as a child can predispose a person to accept continued abuse as an adult or, conversely, to become an abuser of others. Also, early experiences of abuse that are not specifically sexual, such as spanking, enemas, or verbal humiliation, can be sexualized by a child and can form the basis for a paraphilia. Such experiences can result in the development of an *erotized child*.

A 34-year-old man presented for treatment with a chief complaint of erectile disorder. He was frequently unable to obtain an erection sufficient for coitus with his wife. The problem disappeared whenever she was willing to act out his bondage fantasy and tie him up with ropes, a scenario he intensely desired. He explained that he felt free to be sexual when he was tied up because it reassured him that he could move vigorously and not hurt the woman. In addition, he gave a history of being tied up "in fun" when he was a child by a babysitter who would then tickle him until he begged her to stop.

The onset of paraphilic acts can result from persons' modeling their behavior on the behavior of others who have carried out paraphilic acts, mimicking sexual behavior depicted in the media, or recalling emotionally laden events from the past, such as their own molestation. Learning theory indicates that because the fantasizing of paraphilic interests begins at an early age and because personal fantasies and thoughts are not shared with others (who could block or discourage them), the use and misuse of paraphilic fantasies and urges continue uninhibited until late in life. Only then do persons begin to realize that such paraphilic interests and urges are inconsistent with societal norms. By that time, however, the repetitive use of such fantasies has become ingrained, and the sexual thoughts and behaviors have become associated with, or conditioned to, paraphilic fantasies.

Biological Factors

Several studies have identified abnormal organic findings in persons with paraphilias. None has used random samples of such persons; instead, they have extensively investigated patients with paraphilia who were referred to large medical centers. Among these patients, those with positive organic findings included 74 percent with abnormal hormone levels, 27 percent with hard or soft neurological signs, 24 percent with chromosomal abnormalities, 9 percent with seizures, 9 percent with dyslexia, 4 percent with abnormal electroencephalography (EEG) studies, 4 percent with major mental disorders, and 4 percent with mental handicaps. The question is whether these abnormalities are causally related to paraphilic interests or are incidental findings that bear no relevance to the development of paraphilia.

Psychophysiological tests have been developed to measure penile volumetric size in response to paraphilic and nonparaphilic stimuli. The procedures may be of use in diagnosis and treatment, but are of questionable diagnostic validity because some men are able to suppress their erectile responses.

DIAGNOSIS AND CLINICAL FEATURES

In DSM-5, the criteria for paraphilic disorder requires the patient to have experienced intense and recurrent arousal from their deviant fantasy for at least 6 months and to have acted on the paraphilic impulse. The presence of a paraphilic fantasy, however, may still distress a patient even if there has been no behavioral elaboration. The fantasy distressing the patient contains unusual sexual material that is

relatively fixed and shows only minor variations. Arousal and orgasm depend on the mental elaboration, if not the behavioral playing out of the fantasy. Sexual activity is ritualized or stereotyped and makes use of degraded, reduced, or dehumanized objects.

Exhibitionism

Exhibitionism is the recurrent urge to expose the genitals to a stranger or to an unsuspecting person. Sexual excitement occurs in anticipation of the exposure, and orgasm is brought about by masturbation during or after the event. In almost 100 percent of cases, those with exhibitionism are men exposing themselves to women. The dynamic of men with exhibitionism is to assert their masculinity by showing their penises and by watching the victims' reactions—fright, surprise, and disgust. In this paraphilic disorder, men unconsciously feel castrated and impotent. Wives of men with exhibitionism often substitute for the mothers to whom the men were excessively attached during childhood, or conversely, by whom they were rejected. In other related paraphilias, the central themes involve derivatives of looking or showing.

A substance-abusing professional was finally able to attain sobriety at age 33 years. With this accomplishment, he met a woman and got married, began to work steadily for the first time in his life, and was able to impregnate his new wife. His preferred sexual activity had been masturbation in semi-public places. The patient had a strong sense that his mother had always thought him to be inadequate, did not like to spend time with him, and constantly made negative comparisons between him and his "all-boy" younger brother. He recalled several times when his father had tried to explain his mother's antipathy: "It is just one of those things son: your mother does not seem to like you." Without substance abuse, he gave up his exhibitionism, but he quickly developed sexual incapacity with his wife and became "addicted" to phone sex. (Courtesy of Stephen B. Levine, M.D.)

Specifiers added to exhibitionistic disorder by DSM-5 differentiate arousal from exposing genitals to prepubertal children, to physically mature individuals, or to both prepubertal children and physically mature individuals.

Fetishism

In fetishism the sexual focus is on objects (e.g., shoes, gloves, pantyhose, and stockings) that are intimately associated with the human body, or on nongenital body parts. The latter focus is sometimes called partialism and is discussed later. DSM-5 applies the diagnosis fetishistic disorder to partialism and attaches the following specifiers to fetishistic disorder: body part(s); non-living parts; other. The particular fetish used is linked to someone closely involved with a patient during childhood and has a quality associated with this loved, needed, or even traumatizing person. Usually, the disorder begins by adolescence, although the fetish may have been established in childhood. Once established, the disorder tends to be chronic.

Sexual activity may be directed toward the fetish itself (e.g., masturbation with or into a shoe), or the fetish may be incorporated into sexual intercourse (e.g., the demand that high-heeled shoes be worn). The disorder is almost exclusively found in men. According to Freud, the fetish serves as a symbol of the phallus to persons with unconscious castration fears. Learning theorists believe that the object was associated with sexual stimulation at an early age.

A 50-year-old man entered treatment with a chief complaint of erectile disorder experienced primarily with his wife. He was suffering from a moderate depression that related to both his marital issues and business problems. He had no erectile problems with women he picked up in bars or knew and arranged to meet in bars. Bars were his chosen venue in part because smoking had been prohibited in other public areas in his city and a woman's act of smoking a cigarette was necessary to his sexual arousal. His family history included an alcoholic mother and an emotionally abusive father who was a chain smoker. On family car trips the father would smoke, with all the car windows up. If the patient complained of feeling nauseous the father would tell him to "shut up." He recalled being very attracted to a Sunday school teacher who smoked when he was 6 years old. He first smoked when he was 13, sneaking and hiding behind his house. His first cigarette was one he stole from a pack on his mother's night table.

Frotteurism

Frotteurism is usually characterized by a man's rubbing his penis against the buttocks or other body parts of a fully clothed woman to achieve orgasm. At other times, he may use his hands to rub an unsuspecting victim. The acts usually occur in crowded places, particularly in subways and buses. Those with frotteurism are extremely passive and isolated, and frottage is often their only source of sexual gratification. The expression of aggression in this paraphilia is readily apparent.

Pedophilia

Pedophilia involves recurrent intense sexual urges toward, or arousal by, children 13 years of age or younger, over a period of at least 6 months. Persons with pedophilia are at least 16 years of age and at least 5 years older than the victims. When a perpetrator is a late adolescent involved in an ongoing sexual relationship with a 12- or 13-year-old, the diagnosis is not warranted.

Most child molestations involve genital fondling or oral sex. Vaginal or anal penetration of children occurs infrequently, except in cases of incest. Although most child victims coming to public attention are girls, this finding appears to be a product of the referral process. Offenders report that when they touch a child, most (60 percent) of the victims are boys. This figure is in sharp contrast to the figure for nontouching victimization of children, such as window peeping and exhibitionism; 99 percent of all such cases are perpetrated against girls. DSM-5 adds the following specifiers to a diagnosis of pedophilic disorder: sexually attracted to males; sexually attracted to females; or sexually attracted to both. Of persons with pedophilia, 95 percent are heterosexual, and 50 percent have consumed alcohol to excess at the time of the incident. In addition to their pedophilia, a significant number of the perpetrators are concomitantly or have previously been involved in exhibitionism, voyeurism, or rape.

Incest is related to pedophilia by the frequent selection of an immature child as a sex object, the subtle or overt element of coercion, and occasionally the preferential nature of the adult-child liaison.

A 62-year-old married janitor had worked as a fourth-grade school teacher for 26 years before he transferred school districts, and finally several years later mysteriously lost his second job. He was referred for help after his family discovered that he had repeatedly fondled the genitals of his 4- and 6-year-old granddaughters. A father of five who had not had sex with his wife for 30 years after strenuously objecting to her cigarette smoking, he was generous, helpful, and cooperative with his children and grandchildren. Intellectually slow, he preferred comic books and had a charming manner of playing with young children "like he was one himself." By his estimate he had touched the buttocks and genitals of at least 300 girl students, thinking only of how they did not know what he was doing because he was being affectionate and they were too young to realize what was happening. He loved the anticipation and excitement of this behavior.

His teaching career ended when parents complained to a principal. The principal discovered that the new teacher had been transferred, not fired from his longstanding teaching job for the same reason. The patient had tried to touch his 12-year-old daughter who angrily warned him to stay away from her, but he had also managed to touch her friends and his best friend's daughters as they neared puberty. (Courtesy of Stephen B. Levine, M.D.)

Sexual Masochism

Masochism takes its name from the activities of Leopold von Sacher-Masoch, a 19th century Austrian novelist whose characters derived sexual pleasure from being abused and dominated by women. According to the DSM-5, persons with sexual masochism have a recurrent preoccupation with sexual urges and fantasies involving the act of being humiliated, beaten, bound, or otherwise made to suffer. A specifier added to this disorder diagnosis is: with asphyxiophilia; also called autoerotic asphyxiation, this is the practice of achieving or heightening sexual arousal with restriction of breathing. Sexual masochistic practices are more common among men than among women. Freud believed masochism resulted from destructive fantasies turned against the self. In some cases, persons can allow themselves to experience sexual feelings only when punishment for the feelings follows. Persons with sexual masochism may have had childhood experiences that convinced them that pain is a prerequisite for sexual pleasure. About 30 percent of those with sexual masochism also have sadistic fantasies. Moral masochism involves a need to suffer, but is not accompanied by sexual fantasies.

A 27-year-old woman presented for an interview with the director of a course to which she had applied and which she was eager to take. She appeared at the interview in the company of a man whom she introduced to the director, saying, "This is my lover." When asked about this unusual behavior during the interview, the applicant stated that her companion had ordered her to bring him and make that introduction. She further explained that she was part of a group that utilized sadomasochistic techniques in their sexual play.

Sexual Sadism

DSM-5 defines sexual sadism as the recurrent and intense sexual arousal from the physical and psychological suffering of another person. A person must have experienced these feelings for at least 6 months, and must have acted on sadistic fantasies to receive a diagnosis of sexual sadism disorder. Persons who deny behavioral elaboration of their paraphilic fantasies and who say they suffer no distress, or interpersonal or social difficulties, as a consequence of their paraphilias are designated as having an ascertained sexual sadism interest.

The onset of the disorder is usually before the age of 18 years, and most persons with sexual sadism are male. According to psychoanalytic theory, sadism is a defense against fears of castration; persons with sexual sadism do to others what they fear will happen to them and derive pleasure from expressing their aggressive instincts. The disorder was named after the Marquis de Sade, an 18th century French author and military officer who was repeatedly imprisoned for his violent sexual acts against women. Sexual sadism is related to rape, although rape is more aptly considered an expression of power. Some sadistic rapists, however, kill their victims after having sex (so-called lust murders). In many cases, these persons have underlying schizophrenia. John Money believes that lust murderers suffer from dissociative disorder and perhaps have a history of head trauma. He lists five contributory causes of sexual sadism: hereditary predisposition, hormonal malfunctioning, pathological relationships, a history of sexual abuse, and the presence of other mental disorders.

Voyeurism

Voyeurism, also known as *scopophilia*, is the recurrent preoccupation with fantasies and acts that involve observing unsuspecting persons who are naked or engaged in grooming or sexual activity. Masturbation to orgasm usually accompanies or follows the event. The first voyeuristic act usually occurs during childhood, and the paraphilia is most common in men. When persons with voyeurism are apprehended, the charge is usually loitering.

Transvestism

Transvestism, formerly called transvestic fetishism, is described as fantasies and sexual urges to dress in opposite gender clothing as a means of arousal and as an adjunct to masturbation or coitus. The diagnosis is given when the transvestic fantasies have been acted upon for at least 6 months. DSM-5 requires specifiers with a diagnosis of transvestic disorder: with fetishism is added if the patient is aroused by fabrics, materials, or garments; with autogynephilia is added if the patient is sexually aroused by thoughts or images of himself as a female.

Transvestism typically begins in childhood or early adolescence. As years pass, some men with transvestism want to dress and live permanently as women. Very rarely, women want to dress and live as men. These persons are classified in DSM-5 as persons with transvestic disorder and gender dysphoria. Usually, a person wears more than one article of opposite sex clothing; frequently, an entire wardrobe is involved. When a man with transvestism is cross-dressed, the appearance of femininity may be striking, although not usually to the degree found in transsexualism. When not dressed in women's clothes, men with transvestism may be hypermasculine in appearance and occupation. Cross-dressing can be graded from solitary, depressed, guilt-ridden dressing to ego-syntonic, social membership in a transvestite subculture.

The overt clinical syndrome of transvestism may begin in latency, but is more often seen around pubescence or in adolescence. Frank dressing in opposite sex clothing usually does not begin until mobility and relative independence from parents are well established.

Other Specified Paraphilic Disorder

This classification includes various paraphilias that cause personal distress and that have been acted upon for 6 months that do not meet the criteria for any of the aforementioned categories. The same definition applies to Unspecified Paraphilic Disorder, with the difference that the clinician does not wish to specify the particular paraphilia for reasons that may include not having sufficient information.

TELEPHONE AND COMPUTER SCATOLOGIA. Telephone scatologia is characterized by obscene phone calling and involves an unsuspecting partner. Tension and arousal begin in anticipation of phoning; the recipient of the call listens while the telephoner (usually male) verbally exposes his preoccupations or induces her to talk about her sexual activity. The conversation is accompanied by masturbation, which is often completed after the contact is interrupted.

Persons also use interactive computer networks, sometimes compulsively, to send obscene messages by electronic mail and to transmit sexually explicit messages and video images. Because of the anonymity of the users in chat rooms who use aliases, on-line or computer sex (cybersex) allows some persons to play the role of the opposite sex ("genderbending"), which represents an alternative method of expressing transvestic or transsexual fantasies. A danger of on-line cybersex is that pedophiles often make contact with children or adolescents who are lured into meeting them and are then molested. Many on-line contacts develop into off-line liaisons. Although some persons report that the off-line encounters develop into meaningful relationships, most such meetings are filled with disappointment and disillusionment, as the fantasized person fails to meet unconscious expectations of the ideal partner. In other situations, when adults meet, rape or even homicide may occur.

NECROPHILIA. Necrophilia is an obsession with obtaining sexual gratification from cadavers. Most persons with this disorder find corpses in

morgues, but some have been known to rob graves or even to murder to satisfy their sexual urges. In the few cases studied, those with necrophilia believed that they were inflicting the greatest conceivable humiliation on their lifeless victims. According to Richard von Krafft-Ebing, the diagnosis of psychosis is, under all circumstances, justified.

PARTIALISM. Persons with the disorder of partialism concentrate their sexual activity on one part of the body to the exclusion of all others. Mouth–genital contact—such as cunnilingus (oral contact with a woman’s external genitals), fellatio (oral contact with the penis), and anilingus (oral contact with the anus)—is normally associated with foreplay; Freud recognized the mucosal surfaces of the body as erotogenic and capable of producing pleasurable sensation. But when a person uses these activities as the sole source of sexual gratification and cannot have or refuses to have coitus, a paraphilia exists. It is also known as *oralism*.

ZOOPHILIA. In zoophilia, animals—which may be trained to participate—are preferentially incorporated into arousal fantasies or sexual activities, including intercourse, masturbation, and oral–genital contact. Zoophilia as an organized paraphilia is rare. For many persons, animals are the major source of relatedness, so it is not surprising that a broad variety of domestic animals are used sensually or sexually.

Sexual relations with animals may occasionally be an outgrowth of availability or convenience, especially in parts of the world where rigid convention precludes premarital sexuality and in situations of enforced isolation. Because masturbation is also available in such situations, however, a predilection for animal contact is probably present in opportunistic zoophilia.

COPROPHILIA AND KLISMAPHILIA. Coprophilia is sexual pleasure associated with the desire to defecate on a partner, to be defecated on, or to eat feces (coprophagia). A variant is the compulsive utterance of obscene words (coprolalia). These paraphilias are associated with fixation at the anal stage of psychosexual development. Similarly, klismaphilia, the use of enemas as part of sexual stimulation, is related to anal fixation.

UROPHILIA. Urophilia, a form of urethral eroticism, is interest in sexual pleasure associated with the desire to urinate on a partner or to be urinated on. In both men and women, the disorder may be associated with masturbatory techniques involving the insertion of foreign objects into the urethra for sexual stimulation.

MASTURBATION. Masturbation is a normal activity that is common in all stages of life from infancy to old age, but this viewpoint was not always accepted. Freud believed that neurasthenia was caused by excessive masturbation. In the early 1900s, masturbatory insanity was a common diagnosis in hospitals for the criminally insane in the United States. Masturbation can be defined as a person’s achieving sexual pleasure—which usually results in orgasm—by himself or herself (autoeroticism). Alfred Kinsey found it to be more prevalent in males than in females, but this difference may no longer exist. The frequency of masturbation varies from three to four times a week in adolescence to one to two times a week in adulthood. It is common among married persons; Kinsey reported that it occurred on the average of once a month among married couples.

The techniques of masturbation vary in both sexes and among persons. The most common technique is direct stimulation of the clitoris or penis with the hand or the fingers. Indirect stimulation can also be used, such as rubbing against a pillow or squeezing the thighs. Kinsey found that 2 percent of women are capable of achieving orgasm through fantasy alone. Men and women have been known to insert objects in the urethra to achieve orgasm. The hand vibrator is now used as a masturbatory device by both sexes.

Masturbation is abnormal when it is the only type of sexual activity performed in adulthood if a partner is or might be available, when its frequency indicates a compulsion or sexual dysfunction, or when it is consistently preferred to sex with a partner (Fig. 17.3-1).

FIGURE 17.3-1

A man who masturbated compulsively with a large electrically powered vibrator by inserting the head of the instrument into his anus was unable to retrieve it when it was inserted too far into the anal canal. (Courtesy of Stephen Baker, M.D.)

HYPOXYPHILIA. Hypoxyphilia is the desire to achieve an altered state of consciousness secondary to hypoxia while experiencing orgasm. Persons may use a drug (e.g., a volatile nitrite or nitrous oxide) to produce hypoxia. Autoerotic asphyxiation is also associated with hypoxic states, but it should be classified as a form of sexual masochism.

DIFFERENTIAL DIAGNOSIS

Clinicians must differentiate a paraphilia from an experimental act that is not recurrent or compulsive and that is done for its novelty. Paraphilic activity most likely begins during adolescence. Some paraphilias (especially the bizarre types) are associated with other mental disorders, such as schizophrenia. Brain diseases can also release perverse impulses.

COURSE AND PROGNOSIS

The difficulty in controlling or curing paraphilic disorders rests in the fact that it is hard for people to give up sexual pleasure with no

assurance that new routes to sexual gratification will be secured. A poor prognosis for paraphilic disorder is associated with an early age of onset, a high frequency of acts, no guilt or shame about the act, and substance abuse. The course and the prognosis are better when patients have a history of coitus in addition to the paraphilia, and when they are self-referred rather than referred by a legal agency.

TREATMENT

Five types of psychiatric interventions are used to treat persons with paraphilic disorder and paraphilic interests: external control, reduction of sexual drives, treatment of comorbid conditions (e.g., depression or anxiety), cognitive-behavioral therapy, and dynamic psychotherapy.

Prison is an external control mechanism for sexual crimes that usually does not contain a treatment element. When victimization occurs in a family or work setting, the external control comes from informing supervisors, peers, or other adult family members of the problem and advising them about eliminating opportunities for the perpetrator to act on urges.

Drug therapy, including antipsychotic or antidepressant medication, is indicated for the treatment of schizophrenia or depressive disorders if the paraphilia is associated with these disorders. Antiandrogens, such as cyproterone acetate in Europe and medroxyprogesterone acetate (Depo-Provera) in the United States, may reduce the drive to behave sexually by decreasing serum testosterone levels to subnormal concentrations. Serotonergic agents, such as fluoxetine (Prozac), have been used with limited success in some patients with paraphilia.

Cognitive-behavioral therapy is used to disrupt learned paraphilic patterns and modify behavior to make it socially acceptable. The interventions include social skills training, sex education, cognitive restructuring (confronting and destroying the rationalizations used to support victimization of others), and development of victim empathy. Imaginal desensitization, relaxation technique, and learning what triggers the paraphilic impulse so that such stimuli can be avoided are also taught. In modified aversive behavior rehearsal, perpetrators are videotaped acting out their paraphilia with a mannequin. Then the patient with paraphilic disorder is confronted by a therapist and a group of other offenders who ask questions about feelings, thoughts, motives associated with the act and repeatedly try to correct cognitive distortions and point out lack of victim empathy to the patient.

Insight-oriented psychotherapy is a long-standing treatment approach. Patients have the opportunity to understand their dynamics and the events that caused the paraphilia to develop. In particular, they become aware of the daily events that cause them to act on their impulses (e.g., a real or fantasized rejection). Treatment helps them deal more effectively with life stresses and enhances their capacity to relate to a life partner. In addition, psychotherapy allows patients to regain self-esteem, which in turn allows them to approach a partner in a more normal sexual manner. Sex therapy is an appropriate adjunct to the treatment of patients with specific sexual dysfunctions when they attempt nondeviant sexual activities.

Good prognostic indicators include the presence of only one paraphilia, normal intelligence, the absence of substance abuse, the absence of nonsexual antisocial personality traits, and the presence of a successful adult attachment. Paraphilic disorders, however, remain significant treatment challenges even under these circumstances.

The term gender dysphoria appears as a diagnosis for the first time in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) to refer to those persons with a marked incongruence between their experienced or expressed gender and the one they were assigned at birth. It was known as gender identity disorder in the previous edition of DSM.

The term gender identity refers to the sense one has of being male or female, which corresponds most often to the person's anatomical sex. Persons with gender dysphoria express their discontent with their assigned sex as a desire to have the body of the other sex or to be regarded socially as a person of the other sex.

The term *transgender* is a general term used to refer to those who identify with a gender different from the one they were born with (sometimes referred to as their assigned gender). Transgender people are a diverse group: There are those who want to have the body of another sex known as transsexuals; those who feel they are between genders, of both genders, or of neither gender known as genderqueer; and those who wear clothing traditionally associated with another gender, but who maintain a gender identity that is the same as their birth-assigned gender known as crossdressers. Contrary to popular belief, most transgender people do not have genital surgery. Some do not desire it and others who do may be unable to afford it. Transgender people may be of any sexual orientation. For example, a transgender man, assigned female at birth, may identify as gay (attracted to other men), straight (attracted to women), or bisexual (attracted to both men and women).

In DSM-5, no distinction is made for the overriding diagnostic term *gender dysphoria* as a function of age. However, criteria for diagnosis in children or adolescents are somewhat different. In children, gender dysphoria can manifest as statements of wanting to be the other sex and as a broad range of sex-typed behaviors conventionally shown by children of the other sex. Gender identity crystallizes in most persons by age 2 or 3 years. A specifier is noted if the gender dysphoria is associated with a disorder of sex development.

EPIDEMIOLOGY

Children

Most children with gender dysphoria are referred for clinical evaluation in early grade school years. Parents, however, typically report that the cross-gender behaviors were apparent before 3 years of age. Among a sample of boys younger than age 12 who were referred for a range of clinical problems, the reported desire to be the other sex was 10 percent. For clinically referred girls younger than age 12, the reported desire to be the other sex was 5 percent. The sex ratio of children referred for gender dysphoria is 4 to 5 boys for each girl, which is hypothesized to be due in part to societal stigma directed toward feminine boys. The sex ratio is equal in adolescents referred for gender dysphoria. Researchers have observed that many children considered to have shown gender nonconforming behavior do not grow up to be transgender adults; conversely many people who later come out as transgender adults report that they were not identified as gender nonconforming during childhood.

Adults

The estimates of gender dysphoria in adults emanate from European hormonal/surgical clinics with a prevalence of 1 in 11,000 male-assigned and 1 in 30,000 female-assigned people. DSM-5 reports a prevalence rate ranging from 0.005 to 0.014 percent for male-assigned and 0.002 to 0.003 percent for female-assigned people. Most clinical centers report a sex ratio of three to five male patients for each female patient. Most adults with gender dysphoria report having felt different from other children of their same sex, although, in retrospect, many could not identify the source of that difference. Many report feeling extensively cross-gender identified from the earliest years, with the cross-gender identification becoming more profound in adolescence and young adulthood. Overall the prevalence of male to female dysphoria is higher than female to male dysphoria. An important factor in diagnosis is that there is greater social acceptance of birth-assigned females dressing and behaving as boys (so-called tomboys) than there is of birth-assigned males acting as females (so-called sissies). Some researchers speculate that one in 500 adults may fall somewhere on a transgender spectrum, based on population data rather than clinical data.

ETIOLOGY

Biological Factors

For mammals, the resting state of tissue is initially female; as the fetus develops, a male is produced only if androgen (set off by the Y chromosome, which is responsible for testicular development) is introduced. Without testes and androgen, female external genitalia develop. Thus, maleness and masculinity depend on fetal and perinatal androgens. Sexual behavior in lower animals is governed by sex steroids, but this effect diminishes as the evolutionary tree is scaled. Sex steroids influence the expression of sexual behavior in mature men or women; that is, testosterone can increase libido and aggressiveness in women, and estrogen can decrease libido and aggressiveness in men. But masculinity, femininity, and gender identity may result more from postnatal life events than from prenatal hormonal organization.

Brain organization theory refers to masculinization or feminization of the brain in utero. Testosterone affects brain neurons that contribute to the masculinization of the brain in such areas as the hypothalamus. Whether testosterone contributes to so-called masculine or feminine behavioral patterns remains a controversial issue.

Genetic causes of gender dysphoria are under study but no candidate genes have been identified, and chromosomal variations are uncommon in transgender populations. Case reports of identical twins have shown some pairs that are concordant for transgender issues and others not so affected.

A variety of other approaches to understanding gender dysphoria are underway. These include imaging studies that have shown changes in white matter tracts, cerebral blood flow, and cerebral activation patterns in patients with gender dysphoria; but such studies have not been replicated. An incidental finding is that transgender persons are likely to be left handed, the significance of which is unknown.

Psychosocial Factors

Children usually develop a gender identity consonant with their assigned sex. The formation of gender identity is influenced by the interaction of children's temperament and parents' qualities and attitudes. Culturally acceptable gender roles exist: Boys are not expected to be effeminate, and girls are not expected to be masculine. There are boys' games (e.g., cops and robbers) and girls' toys (e.g., dolls and dollhouses). These roles are learned, although some investigators believe that some boys are temperamentally delicate and sensitive and that some girls are aggressive and energized—traits that are stereotypically known in today's culture as feminine and masculine, respectively. However, greater tolerance for mild cross-gender activity in children has developed in the last few decades.

Sigmund Freud believed that gender identity problems resulted from conflicts experienced by children within the Oedipal triangle. In his view, these conflicts are fueled by both real family events and children's fantasies. Whatever interferes with a child's loving the opposite-sex parent and identifying with the same-sex parent interferes with normal gender

identity development.

Since Freud, psychoanalysts have postulated that the quality of the mother–child relationship in the first years of life is paramount in establishing gender identity. During this period, mothers normally facilitate their children’s awareness of, and pride in, their gender: Children are valued as little boys and girls. Analysts argue that devaluing, hostile mothering can result in gender problems. At the same time, the separation–individuation process is unfolding. When gender problems become associated with separation–individuation problems, the result can be the use of sexuality to remain in relationships characterized by shifts between a desperate infantile closeness and a hostile, devaluing distance.

Some children are given the message that they would be more valued if they adopted the gender identity of the opposite sex. Rejected or abused children may act on such a belief. Gender identity problems can also be triggered by a mother’s death, extended absence, or depression, to which a young boy may react by totally identifying with her—that is, by becoming a mother to replace her.

The father’s role is also important in the early years, and his presence normally helps the separation–individuation process. Without a father, mother and child may remain overly close. For a girl, the father is normally the prototype of future love objects; for a boy, the father is a model for male identification.

Learning theory postulates that children may be rewarded or punished by parents and teachers on the basis of gendered behavior, thus influencing the way children express their gender identities. Children also learn how to label people according to gender and eventually learn that gender is not dictated by surface appearance such as clothing or hairstyle.

DIAGNOSIS AND CLINICAL FEATURES

Children

The DSM-5 defines gender dysphoria in children as incongruence between expressed and assigned gender, with the most important criterion being a desire to be another gender or insistence that one is another gender (Table 18-1). By emphasizing the importance of the child’s self-perception, the creators of the diagnosis attempt to limit its use to those children who clearly state their wishes to be another gender, rather than encompassing a broader group of children who might be considered by adults to be gender nonconforming. However a child’s behavior may also lead to this diagnosis.

Table 18-1
DSM-5 Diagnostic Criteria for Gender Dysphoria

Gender Dysphoria in Children

- A. A marked incongruence between one’s experienced/expressed gender and assigned gender, of at least 6 months’ duration, as manifested by at least six of the following (one of which must be Criterion A1):
1. A strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one’s assigned gender).
 2. In boys (assigned gender), a strong preference for cross-dressing or simulating female attire; or in girls (assigned gender), a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing.
 3. A strong preference for cross-gender roles in make-believe play or fantasy play.
 4. A strong preference for the toys, games, or activities stereotypically used or engaged in by the other gender.
 5. A strong preference for playmates of the other gender.
 6. In boys (assigned gender), a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play; or in girls (assigned gender), a strong rejection of typically feminine toys, games, and activities.
 7. A strong dislike of one’s sexual anatomy.
 8. A strong desire for the primary and/or secondary sex characteristics that match one’s experienced gender.
- B. The condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning.

Specify if:

With a disorder of sex development (e.g., a congenital adrenogenital disorder such as 255.2 [E25.0] congenital adrenal hyperplasia or 259.50 [E34.50] androgen insensitivity syndrome).

Coding note: Code the disorder of sex development as well as gender dysphoria.

Gender Dysphoria in Adolescents and Adults

- A. A marked incongruence between one’s experienced/expressed gender and assigned gender, of at least 6 months’ duration, as manifested by at least two of the following:
1. A marked incongruence between one’s experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
 2. A strong desire to be rid of one’s primary and/or secondary sex characteristics because of a marked incongruence with one’s experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
 3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
 4. A strong desire to be of the other gender (or some alternative gender different from one’s assigned gender).
 5. A strong desire to be treated as the other gender (or some alternative gender different from one’s assigned gender).
 6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one’s assigned gender).
- B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

With a disorder of sex development (e.g., a congenital adrenogenital disorder such as 255.2 [E25.0] congenital adrenal hyperplasia or 259.50 [E34.50] androgen insensitivity syndrome).

Coding note: Code the disorder of sex development as well as gender dysphoria.

Specify if:

Posttransition: The individual has transitioned to full-time living in the desired gender (with or without legalization of gender change) and has undergone (or is preparing to have) at least one cross-sex medical procedure or treatment regimen—namely, regular cross-sex hormone treatment or gender reassignment surgery confirming the desired gender (e.g., penectomy, vaginoplasty in a natal male; mastectomy or phalloplasty in a natal female).

Many children with gender dysphoria prefer clothing typical of another gender, preferentially choose playmates of another gender, enjoy games and toys associated with another gender, and take on the roles of another gender during play. For a diagnosis to be made, these social characteristics must be accompanied by other traits less likely to be socially influenced, such as a strong desire to be the other gender, dislike of one’s sexual anatomy, or desire for primary or secondary sexual characteristics of the desired gender. Children may express a desire to have different genitals, state that their genitals are going to change, or urinate in the position (standing or sitting) typical of another gender. It is notable that characteristics used to diagnose children with gender dysphoria must be accompanied by clinically significant distress or impairment on the part of the child, and not simply on the part of the adult caregivers, who may be uncomfortable with gender nonconformity.

Differential Diagnosis of Children

Children diagnosed with gender dysphoria, predicted to be more likely than others to identify as transgender as adults, are differentiated from other gender nonconforming children by statements about desired anatomical changes, as well as persistence of the diagnosis over time. Children whose gender dysphoria persists over time may make repeated statements about a desire to be or belief that they are another gender. Other gender nonconforming children may make these statements for short periods but not repeatedly, or may not make these types of statements, and may instead prefer clothing and behaviors associated with another gender, but show contentment with their birth-assigned gender.

The diagnosis of gender dysphoria no longer excludes intersex people, and instead is coded with a specifier in the cases where intersex people are gender dysphoric in relation to their birth-assigned gender. A medical history is important to distinguish between those children with intersex conditions and those without. The standards of care for intersex children have changed dramatically over the last few decades due to activism by intersex adults and supportive medical and mental health professionals. Historically, intersex babies were often subjected to early surgical procedures to create more standard male or female appearances. These procedures had the potential to cause sexual dysfunction, such as inability to orgasm, and permanent sterility. Recently, these practices have changed considerably so that more intersex people are given the chance to make decisions about their bodies later in life.

Adolescents and Adults

Adolescents and adults diagnosed with gender dysphoria must also show an incongruence between expressed and assigned gender. In addition, they must meet at least two of six criteria, half of which are related to their current (or in the cases of early adolescents, future) secondary sex characteristics or desired secondary sex characteristics. Other criteria include a strong desire to be another gender, be treated as another gender, or the belief that one has the typical feelings and reactions of another gender (see [Table 18-1](#)).

In practice, most adults who present to mental health practitioners with reports of gender-related concerns are aware of the concept of transgender identity. They may be interested in therapy to explore gender issues, or may be making contact in order to request a letter recommending hormone treatment or surgery. The cultural trope of being “trapped in the wrong body” does not apply to all, or even most, people who identify as transgender, so clinicians should be aware to use open and affirming approaches, taking language cues from their patients.

The DSM-5 criteria are noticeably open to the idea that some people do not fit into the traditional gender binary, and may desire to be alternative genders, such as genderqueer. Like the diagnosis in childhood, the adolescent and adult diagnosis also requires that those diagnosed be personally distressed or impaired by their feelings, rather than their behaviors or identities being pathologized by others while not upsetting to the people themselves. The adolescent and adult criteria also contain a post-transition specifier, which can be used for those people who live in their affirmed genders. They are required, however, to have undergone or be preparing to undergo at least one medical or surgical procedure in order to qualify for this specifier.

Differential Diagnosis of Adolescents and Adults

Those who meet the criteria for a diagnosis of gender dysphoria must experience clinical distress or impairment related to their gender identity. This excludes from the diagnosis those transgender or gender nonconforming people who are not clinically distressed by their gender identities. There are certain mental illnesses in which transgender identity may be a component of delusional thinking, such as in *schizophrenia*. However, this is extremely rare and can be differentiated from transgender identity or gender dysphoria through the diminishment of transgender feelings with the successful treatment of psychosis versus the persistence of these feelings in periods that are psychosis free. *Body dysmorphic disorder* may be a differential diagnosis for some patients who present with a desire to change gendered body parts. However, those with body dysmorphic disorder generally focus on a body part because of a belief that it is abnormal, rather than due to a desire to change their assigned gender. The *Paraphilic Disorders* chapter of the DSM-5 contains the diagnosis *transvestic disorder*, which is defined as recurrent and intense sexual arousal from cross-dressing that causes clinically significant distress or impairment. This diagnosis is differentiated from gender dysphoria by the patient’s gender identity being consistent with their gender assigned at birth, and by sexual excitement linked to cross-dressing coming to interfere with the person’s life.

COURSE AND PROGNOSIS

Children

Children typically begin to develop a sense of their gender identity around age 3. At this point they may develop gendered behaviors and interests, and some may begin to express a desire to be another gender. It is often around school age that children are first brought for clinical consultations, as this is when they begin to interact heavily with classmates and to be scrutinized by adults other than their caregivers. Some children who will later identify as transgender as adults do not show behaviors consistent with another gender at this age. Some say later that they worked hard to appear stereotypical to their assigned gender, whereas others deny being able to recall gender identity concerns. Approaching puberty, many children diagnosed with gender dysphoria begin to show increased levels of anxiety related to anticipated changes to their bodies.

Children diagnosed with gender dysphoria do not necessarily grow up to identify as transgender adults. A number of studies have demonstrated that more than half of those diagnosed with gender identity disorder, based on the DSM-IV, later identify with their birth-assigned gender once they reach adulthood. Those children who do identify as transgender as adults have been shown to have more extreme gender dysphoria as children. Many studies show increased rates of gay and bisexual identity among those who were gender nonconforming as children.

Comorbidity in Children

Children diagnosed with gender dysphoria show higher rates than other children of depressive disorders, anxiety disorders, and impulse-control disorders. This is likely related to the stigma faced by these children related to their gendered behaviors and identities. There are also reports that those diagnosed with gender dysphoria are more likely than others to fall on the autism spectrum. Some researchers posit that this may be related to intrauterine hormone exposure.

Adults

Some people diagnosed with gender dysphoria as adults recall the continuous development of transgender identity since childhood. In these cases, some have periods of hiding their gender identity, many entering into stereotypic activities and employment in order to convince themselves and others that they do not have gender nonconforming identities. Others do not recall gender identity issues during childhood. Lesbian and gay communities are often havens for gender nonconforming people, and some people identify as gay, lesbian, or bisexual before coming out as transgender.

Comorbidity in Adults

Adults diagnosed with gender dysphoria show higher rates than other adults of depressive disorders, anxiety disorders, suicidality and self-harming behaviors, and substance abuse. The lifetime rate of suicidal thoughts in transgender people is thought to be about 40 percent. The minority stress model predicts increases in mental illness in groups that are stigmatized, discriminated against, harassed, and abused at higher rates than others. DSM-5 reports that persons with late-onset gender dysphoria may have greater fluctuations in the extent of their distress and more ambivalence about and less satisfaction after sex reassignment surgery.

TREATMENT

Children

Treatment of gender identity issues in children typically consists of individual, family, and group therapy that guides children in exploring their gendered interests and identities. There are some providers who practice reparative, or conversion therapy, which attempts to change a person's gender identity or sexual orientation. This type of therapy is contrary to position statements by the American Psychiatric Association and practice guidelines of the American Academy of Child and Adolescent Psychiatry.

Adolescents

As gender-nonconforming children approach puberty, some show intense fear and preoccupation related to the physical changes they anticipate or are beginning to experience. In addition to providing psychotherapy, many clinicians use these adolescents' reactions to the first signs of puberty as a compass to determine if puberty-blocking medications should be a consideration. Puberty-blocking medications are gonadotropin-releasing hormone (GnRH) agonists that can be used to temporarily block the release of hormones that lead to secondary sex characteristics, giving adolescents and their families time to reflect on the best options moving forward. GnRH agonists have been used for many years in other populations (e.g., children with precocious puberty) and are felt to be safe. However, such steps should be considered carefully.

Adults

Treatment of adults who identify as transgender may include psychotherapy to explore gender issues, hormonal treatment, and surgical treatment. Hormonal and surgical interventions may decrease depression and improve quality of life for such persons.

Mental Health Treatment

The history of poor treatment and medicalization of transgender people by mental health providers has led to a decreased interest on the part of trans-identified people in engaging in mental health care. Many surgeons, and some physicians who prescribe transition-related hormones, require a letter from a mental health provider, so many transgender people are engaged with mental health in a gatekeeping model. Many community clinics are now using informed consent models for hormone treatment, thereby decreasing the need for mental health providers to play the role of gatekeepers. The World Professional Association for Transgender Health (WPATH) Standards of Care (SOC) for the health of transsexual, transgender, and gender-nonconforming people have recently become more flexible and open to informed consent models. Some mental health providers are specializing in working with transgender populations, and this is increasing the rate at which transgender people engage in psychotherapy.

Hormones

Hormone treatment of transgender men is primarily accomplished with testosterone, usually taken by injection every week or every other week. Initial changes with testosterone therapy include increased acne, muscle mass, and libido, as well as cessation of menses, usually within the first few months. Subsequent, and more permanent, changes include deepening of the voice, increased body hair, and enlargement of the clitoris. Monitoring includes hemoglobin/hematocrit levels, as testosterone can rarely cause an increase in red blood cell counts that can lead to stroke. Like all steroid hormones, testosterone is processed in the liver, so routine liver function tests should be obtained. Clinicians also want to monitor cholesterol and screen for diabetes, as testosterone treatment may increase the likelihood of lipid abnormalities and diabetes. Those beginning hormone treatments are routinely counseled on fertility, as future fertility may be affected on testosterone.

Transgender women may take estrogen, testosterone-blockers, or progesterone, often in combination. These hormones can cause softening of the skin and redistribution of fat, as well as breast growth. Breast development varies between people, but does not generally exceed bra cup size B. It is generally recommended to be on hormones for 18 to 24 months before having breast augmentation, allowing the breasts to develop to their final size. Sex drive can decrease, as well as erections and ejaculation. Body hair can decrease somewhat, but often not as much as desired, prompting many women to obtain electrolysis. There is no change in voice, as testosterone has permanently altered the vocal cords, and many women seek out voice coaching. Those on estrogen should avoid cigarette smoking, as the combination can lead to increased risk of blood clots. Blood pressure should be monitored, as well as liver function and cholesterol. In addition, providers routinely test prolactin as this hormone can increase on estrogen therapy, and in rare cases transgender women may develop prolactinomas. Reproductive counseling is very important before beginning estrogen treatment because permanent sterility is almost always the outcome.

Surgery

Many fewer people undergo gender-related surgeries than take hormones. Some people do not desire gender-related surgeries. Others cannot afford them, or are not convinced that they will be satisfied with currently available results.

The most common type of surgery for both trans-men and trans-women is "top surgery," or chest surgery. Transgender men may have surgery to construct a male-contoured chest. Trans-women may have breast augmentation.

"Bottom surgery" is less common. Transgender men may have a metoidioplasty, in which the clitoris is freed from the ligament attaching it to the body, and tissue is added, increasing its length and girth. Scrotoplasty, the placement of testicular implants, is another way to create male-appearing genitalia. Phalloplasty, the creation of a penis, is less commonly performed because it is expensive, involves multiple procedures, requires donor skin from another part of the body, and has limited functionality. Bottom surgery for women is typically vaginoplasty, also commonly known as Sex Reassignment Surgery (SRS). In this procedure, the testicles are removed, the penis is reconstructed to form a clitoris, and a vagina is created. Techniques for vaginoplasty are becoming very good, but the procedure remains expensive. Because of this, some women, especially those with less money, may have orchiectomies, where the testes alone are removed. These can be in-office procedures with local anesthetic, and are effective in substantially decreasing the body's production of androgens like testosterone. Less widely discussed, but important to many women, are facial feminization surgeries that alter the cheeks, forehead, nose, and lips to create a more feminine facial appearance. The face is often used by persons to recognize gender in another person and having facial features that match one's affirmed gender can facilitate social interaction and provide safety from harassment and violence. Transgender men rarely undergo facial surgeries, as testosterone typically causes the face to appear more masculine.

Because surgery is inaccessible to many, there are rare cases of self-surgery and some people have surgeries performed under unsafe conditions. Women may inject industrial grade silicone to produce body curves. Silicone injection that is not done under the supervision of a medical professional can result in body mutilation, infection, and even silicone blood clots that can lead to embolism and death.

Other Specified

The category *other specified gender dysphoria* can be used in cases where the presentation causes clinically significant distress or impairment but does not meet the full criteria for gender dysphoria. If this diagnosis is used, the clinician records the specific reason that the full criteria were not met.

Unspecified

The category *unspecified gender dysphoria* can be applied when full criteria are not met and the clinician chooses not to specify why they are not met.

ICD-10/11

In the current iteration of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), gender identity issues appear under Disorders of Adult Behavior and Personality in the category Gender Identity Disorders (F64), and include five diagnoses: transsexualism (F64.0), dual-role transvestism (F64.1), gender identity disorder of childhood (F64.2), other gender identity disorders (F64.3), and gender identity disorder, unspecified (F64.4).

The ICD Working Group on the Classification of Sexual Disorders and Sexual Health is recommending that for ICD-11, gender identity concerns be moved from the psychological sections and is considering options that would list these concerns in their own separate chapter, as medical diagnoses, or as part of a new chapter on sexual health and sexual disorders.

A 27-year-old assigned female at birth was referred to a gender identity clinic reporting having felt different as a child from other girls, although unable then to identify the source. As a young girl, she enjoyed playing sports with girls and boys, but generally preferred the companionship of boys. She preferred wearing unisex or boyish clothes and resisted wearing a skirt or dress. Everyone referred to her as a tomboy. She tried to hide her breast development by wearing loose fitting tops and stooping forward. Menses were embarrassing and poignantly reminded her of her femaleness, which was becoming increasingly alienating. As sexual attractions evolved, they were directed exclusively to female partners. In her late teens, she had one sexual experience with a man, and it was aversive. She began socializing in lesbian circles, but did not feel comfortable there and did not consider herself lesbian, but more a man. For sexual partners, she wanted heterosexual women and wanted to be considered by the partner as a man. As gender dysphoric feelings became increasingly pronounced, she consulted transsexual sites on the Internet and contacted a female-to-male transsexual community support group. She then set into motion the process of clinical referral. She transitioned to living as a man, had a name change, and was administered androgen injections. The patient's voice deepened, facial and body hair grew, menses stopped, and sex drive increased, along with clitoral hypertrophy. After 2 years, the patient underwent bilateral mastectomy and is on the wait list for phalloplasty and hysterectomy-oophorectomy. Employment as a man continues, as does a 3-year relationship with a female partner. The partner has a child from a previous marriage. (Adapted from case of Richard Green, M.D.)

Intersex Conditions

Intersex conditions include a variety of syndromes in which persons are born with anatomies that do not correspond with typical male or female bodies.

Congenital Adrenal Hyperplasia. Congenital adrenal hyperplasia is a condition in which an enzymatic defect in the production of adrenal cortisol, beginning prenatally, leads to overproduction of adrenal androgens and, when the chromosomes are XX, virilization of the female fetus. Postnatally, excessive adrenal androgen can be controlled by steroid administration.

The androgenization can range from mild clitoral enlargement to external genitals that look like a normal scrotal sac, testes, and a penis, but behind these external genitals are a vagina and a uterus. Other parts of the body remain feminized (i.e. there is breast development at puberty). Most people with congenital adrenal hyperplasia are raised female, except in cases of extreme virilization. If the parents are uncertain about the sex of their child, sometimes an intersex identity results. Gender identity usually reflects the rearing practices, but hormones may help determine behavior. Studies showed that sex-disordered children raised as girls had a more intense tomboy quality than that found in a control group. The girls most often had a heterosexual orientation, but higher rates of bisexual or homosexual behavior were reported. In those brought up female, about 5% show severe gender dysphoria, whereas about 12% of those assigned male are gender dysphoric.

Androgen Insensitivity Syndrome. Androgen insensitivity syndrome was formerly called *testicular feminization*. In persons with complete androgen insensitivity and the XY karyotype, tissue cells are unable to use testosterone or other androgens. Therefore, the person appears to be a normal female at birth and is raised as a girl. She is later found to have cryptorchid testes, which produce the testosterone to which the tissues do not respond, and minimal or absent internal sexual organs. Secondary sex characteristics at puberty are female because of the small, but sufficient, amount of estrogens, which results from the conversion of testosterone into estradiol. The patients usually sense themselves as females and are feminine. However, some experience gender conflicts and distress. In partial androgen insensitivity, persons may have a range of anatomical structures and gender identities.

TURNER'S SYNDROME. In Turner's syndrome, one sex chromosome is missing, such that the sex karyotype is simply X. Persons with Turner's syndrome have female genitalia, are short, and sometimes have anomalies such as a shield-shaped chest and a webbed neck. As a consequence of dysfunctional ovaries, they require exogenous estrogen to develop female secondary sex characteristics. Gender identity is typically female (Fig. 18-1).

FIGURE 18-1 Turner's syndrome in a patient aged 23. Note webbed neck, increased carrying angle, failure of breast development, and lack of pubic hair. (From Douthwaite AH, ed. *French's Index of Differential Diagnosis*. 7th ed. Baltimore: Williams & Wilkins; 234.)

KLINFELTER'S SYNDROME. An extra X chromosome is present in Klinefelter's syndrome, such that the karyotype is XXY . At birth, persons with Klinefelter's appear to be normal males. Excessive gynecomastia may occur in adolescence. Testes are small, usually without sperm production. They are tall, and body habitus is eunuchoid. Reports suggest a higher rate of gender dysphoria.

5- α -Reductase Deficiency. In 5- α -reductase deficiency, an enzymatic defect prevents the conversion of testosterone to dihydrotestosterone, which is required for prenatal virilization of the genitalia. At birth, the affected person appears to be female, although some variance is visible. In earlier generations, before childhood identification of the disorder was common, these persons, raised as girls, virilized at puberty and usually changed their gender identity to male. Later generations were expected to virilize and, thus, may have been raised with ambiguous gender. Over half of those with 5- α -reductase deficiency identify as male as adults. There are reports of a small number of patients for whom early removal of the testes and socialization as girls have resulted in a female gender identity.

Treatment. Because intersex conditions are present at birth, treatment must be timely. The appearance of the genitalia in diverse conditions is often ambiguous, and a decision must be made about the assigned sex (boy or girl) and how the child should be reared.

Intersex conditions should be addressed as early as possible, so that the entire family can regard the child in a consistent, relaxed manner. This is particularly important because intersex patients may have gender identity problems because of complicated biological influences and familial confusion about their actual sex. When intersex conditions are discovered, a panel of pediatric, urological, and psychiatric experts works with the family to determine the sex of rearing on the basis of clinical examination, urological studies, buccal smears, chromosomal analyses, and assessment of the parental wishes.

Education of parents and presentation of the range of options open to them is essential, because parents respond to the infant's genitalia in ways that promote the formation of gender identity. Although the label of boy or girl may be assigned to the infant on the basis of chromosomal and urological examination, the parents can then react to the child according to sex role assignment with leeway to adjust the sex assignment should the child act definitively as a member of the sex different from the one designated. Some studies have shown that an equal number of persons assigned to be female at birth choose to become male as adults as do those assigned to be male at birth who choose to become female. In general, the sex of rearing is the best predictor of later gender identity.

In the past, many intersex infants underwent surgical procedures at an early age in order to normalize genital appearance. It is easier to surgically assign a child to be female than to assign one to be male, because male-to-female genital surgical procedures are far more advanced than female-to-male procedures. That is an insufficient reason, however, to assign a chromosomal male to be female.

The standards of care related to intersex infants have changed considerably due to work by intersex people and their allies, so that it is no longer recommended that infants have immediate surgical procedures performed. Instead, families are encouraged to choose a sex of rearing that is flexible, and to wait for the intersex person to decide on their own later whether to have surgery. Early surgeries are typically avoided now because they may interfere with later reproductive capacity and sexual functioning.

Transvestic Disorder

Transvestic disorder appears in the DSM-5 section on *Paraphilic Disorders*, and is defined as a period of at least 6 months of recurrent and intense sexual arousal from cross-dressing that causes clinically significant distress or impairment. Those who cross-dress are diverse, and many use cross-dressing as a form of entertainment or pleasure that does not cause distress, and therefore do not meet the criteria for this diagnosis. Cross-dressing does not imply gender dysphoria—many people who cross-dress do so while retaining a gender identity that matches their assigned gender. Cross-dressers do not necessarily have a preoccupation with getting rid of their primary and secondary sex characteristics and acquiring the sex characteristics of the other sex. However, there are those who may be diagnosed with both gender dysphoria and transvestic disorder.

The prevalence of transvestic disorder is unknown. It is more common in males and extremely rarely diagnosed in females, most likely due to comparable societal acceptance of women dressing in male-typical clothing. Those diagnosed with transvestic disorder often remember a fascination with female clothing in childhood. They may have periods of stress-related cross-dressing that produces sexual excitement, but also reduces tension and anxiety. There may be periods where the person buys a number of articles of clothing, wears them for sexual excitement, and then becomes distressed by their behavior and throws them out. Transvestic disorder can coexist with other paraphilic disorders, most commonly *sexual masochism disorder* and *fetishistic disorder*.

Treatment. A combined approach, using psychotherapy and pharmacotherapy, is often useful in the treatment of transvestic disorder. The stress factors that precipitate the behavior are identified in therapy. The goal is to help patients cope with the stressors appropriately and, if possible, eliminate them. Intrapsychic dynamics about attitudes toward men and women are examined, and unconscious conflicts are identified. Medication, such as anti-anxiety and antidepressant agents, is used to treat the symptoms. Because cross-dressing can occur impulsively, medications that reinforce impulse control may be helpful, such as fluoxetine (Prozac). Behavior therapy and hypnosis are alternative methods that may be of use in selected patients.

Preoccupation with Castration

Preoccupation with castration does not appear in the DSM-5 but can be serious and life-threatening if castration is carried out without medical supervision. This preoccupation occurs at times in people who do not have a desire to acquire the sex characteristics of the other sex, but may be uncomfortable with their assigned sex, and their lives are driven by the fantasy of what it would be like to be a different gender. They may be asexual and lack sexual interest in either men or women.

Disruptive, Impulse-Control, and Conduct Disorders

Five conditions comprise the category of *disruptive, impulse-control, and conduct disorders*. They include two that are associated with childhood: (1) oppositional defiant disorder and (2) conduct disorder, both of which are discussed in the child psychiatry section of this text in Sections 32.12d and 32.12e, respectively. The remaining three disorders are intermittent explosive disorder, kleptomania, and pyromania, which are discussed in subsequent text of this chapter. Each disorder is characterized by the inability to resist an intense impulse, drive, or temptation to perform a particular act that is obviously harmful to self or others, or both. Before the event, the individual usually experiences mounting tension and arousal, sometimes—but not consistently—mingled with conscious anticipatory pleasure. Completing the action brings immediate gratification and relief. Within a variable time afterward, the individual experiences a conflation of remorse, guilt, self-reproach, and dread. These feelings may stem from obscure unconscious conflicts or awareness of the deed's impact on others (including the possibility of serious legal consequences in syndromes such as kleptomania). Shameful secretiveness about the repeated impulsive activity frequently expands to pervade the individual's entire life, often significantly delaying treatment.

ETIOLOGY

Psychodynamic, psychosocial, and biological factors all play an important role in impulse-control disorders; however, the primary causal factor remains unknown. Some impulse-control disorders may have common underlying neurobiological mechanisms. Fatigue, incessant stimulation, and psychic trauma can lower a person's resistance to control impulses.

Psychodynamic Factors

An impulse is a disposition to act to decrease heightened tension caused by the buildup of instinctual drives or by diminished ego defenses against the drives. The impulse disorders have in common an attempt to bypass the experience of disabling symptoms or painful affects by acting on the environment. In his work with adolescents who were delinquent, August Aichhorn described impulsive behavior as related to a weak superego and weak ego structures associated with psychic trauma produced by childhood deprivation.

Otto Fenichel linked impulsive behavior to attempts to master anxiety, guilt, depression, and other painful affects by means of action. He thought that such actions defend against internal danger and that they produce a distorted aggressive or sexual gratification. To observers, impulsive behaviors may appear irrational and motivated by greed, but they may actually be endeavors to find relief from pain.

Heinz Kohut considered many forms of impulse-control problems, including gambling, kleptomania, and some paraphilic behaviors, to be related to an incomplete sense of self. He observed that when patients do not receive the validating and affirming responses that they seek from persons in significant relationships with them, the self might fragment. As a way of dealing with this fragmentation and regaining a sense of wholeness or cohesion in the self, persons may engage in impulsive behaviors that to others appear self-destructive. Kohut's formulation has some similarities to Donald Winnicott's view that impulsive or deviant behavior in children is a way for them to try to recapture a primitive maternal relationship. Winnicott saw such behavior as hopeful in that the child searches for affirmation and love from the mother rather than abandoning any attempt to win her affection.

Patients attempt to master anxiety, guilt, depression, and other painful affects by means of actions, but such actions aimed at obtaining relief seldom succeed even temporarily.

Psychosocial Factors

Psychosocial factors implicated causally in impulse-control disorders are related to early life events. The growing child may have had improper models for identification, such as parents who had difficulty controlling impulses. Other psychosocial factors associated with the disorders include exposure to violence in the home, alcohol abuse, promiscuity, and antisocial behavior.

Biological Factors

Many investigators have focused on possible organic factors in the impulse-control disorders, especially for patients with overtly violent behavior. Experiments have shown that impulsive and violent activity is associated with specific brain regions, such as the limbic system, and that the inhibition of such behaviors is associated with other brain regions. A relation has been found between low cerebrospinal fluid (CSF) levels of 5-hydroxyindoleacetic acid (5-HIAA) and impulsive aggression. Certain hormones, especially testosterone, have also been associated with violent and aggressive behavior. Some reports have described a relation between temporal lobe epilepsy and certain impulsive violent behaviors, as well as an association of aggressive behavior in patients who have histories of head trauma with increased numbers of emergency room visits and other potential organic antecedents. A high incidence of mixed cerebral dominance may be found in some violent populations.

Considerable evidence indicates that the serotonin neurotransmitter system mediates symptoms evident in impulse-control disorders. Brainstem and CSF levels of 5-HIAA are decreased, and serotonin-binding sites are increased in persons who have committed suicide. The dopaminergic and noradrenergic systems have also been implicated in impulsivity.

Impulse-control disorder symptoms can continue into adulthood in persons whose disorder has been diagnosed as childhood attention-deficit/hyperactivity disorder (ADHD). Lifelong or acquired mental deficiency, epilepsy, and even reversible brain syndromes have long been implicated in lapses in impulse control.

INTERMITTENT EXPLOSIVE DISORDER

Intermittent explosive disorder manifests as discrete episodes of losing control of aggressive impulses; these episodes can result in serious assault or the destruction of property. The aggressiveness expressed is grossly out of proportion to any stressors that may have helped elicit the episodes. The symptoms, which patients may describe as spells or attacks, appear within minutes or hours and, regardless of duration, remit spontaneously and quickly. After each episode, patients usually show genuine regret or self-reproach, and signs of generalized impulsivity or aggressiveness are absent between episodes. The diagnosis of intermittent explosive disorder should not be made if the loss of control can be accounted for by schizophrenia, antisocial or borderline personality disorder, ADHD, conduct disorder, or substance intoxication.

The term *epileptoid personality* has been used to convey the seizure-like quality of the characteristic outbursts, which are not typical of the patient's usual behavior, and to convey the suspicion of an organic disease process, for example, damage to the central nervous system. Several associated features suggest the possibility of an epileptoid state: the presence of auras; postictal-like changes in the sensorium, including partial or spotty amnesia; and hypersensitivity to photic, aural, or auditory stimuli.

Epidemiology

Intermittent explosive disorder is underreported. The disorder appears to be more common in men than in women. The men are likely to be found in correctional institutions and the women in psychiatric facilities. In one study, about 2 percent of all persons admitted to a university hospital psychiatric service had disorders that were diagnosed as intermittent explosive disorder; 80 percent were men.

Evidence indicates that intermittent explosive disorder is more common in first-degree biological relatives of persons with the disorder than in the general population. Many factors other than a simple genetic explanation may be responsible.

Comorbidity

High rates of fire setting in patients with intermittent explosive disorder have been reported. Other disorders of impulse control and substance use and mood, anxiety, and eating disorders have also been associated with intermittent explosive disorder.

Etiology

Psychodynamic Factors. Psychoanalysts have suggested that explosive outbursts occur as a defense against narcissistic injurious events. Rage outbursts serve as interpersonal distance and protect against any further narcissistic injury.

Psychosocial Factors. Typical patients have been described as physically large, but dependent, men whose sense of masculine identity is poor. A sense of being useless and impotent or of being unable to change the environment often precedes an episode of physical violence, and a high level of anxiety, guilt, and depression usually follows an episode.

An unfavorable childhood environment often filled with alcohol dependence, beatings, and threats to life is usual in these patients. Predisposing factors in infancy and childhood include perinatal trauma, infantile seizures, head trauma, encephalitis, minimal brain dysfunction, and hyperactivity. Investigators who have concentrated on psychogenesis as causing episodic explosiveness have stressed identification with assaultive parental figures as symbols of the target for violence. Early frustration, oppression, and hostility have been noted as predisposing factors. Situations that are directly or symbolically reminiscent of early deprivations (e.g., persons who directly or indirectly evoke the image of the frustrating parent) become targets for destructive hostility.

Biological Factors. Some investigators suggest that disordered brain physiology, particularly in the limbic system, is involved in most cases of episodic violence. Compelling evidence indicates that serotonergic neurons mediate behavioral inhibition. Decreased serotonergic transmission, which can be induced by inhibiting serotonin synthesis or by antagonizing its effects, decreases the effect of punishment as a deterrent to behavior. The restoration of serotonin activity, by administering serotonin precursors such as L-tryptophan or drugs that increase synaptic serotonin levels, restores the behavioral effect of punishment. Restoring serotonergic activity by administration of L-tryptophan or drugs that increase synaptic serotonergic levels appears to restore control of episodic violent tendencies. Low levels of CSF 5-HIAA have been correlated with impulsive aggression. High CSF testosterone concentrations are correlated with aggressiveness and interpersonal violence in men. Antiandrogenic agents have been shown to decrease aggression.

Familial and Genetic Factors. First-degree relatives of patients with intermittent explosive disorder have higher rates of impulse-control disorders, depressive disorders, and substance use disorders. Biological relatives of patients with the disorder were more likely to have histories of temper or explosive outbursts than the general population.

Diagnosis and Clinical Features

The diagnosis of intermittent explosive disorder should be the result of history-taking that reveals several episodes of loss of control associated with aggressive outbursts (Table 19-1). One discrete episode does not justify the diagnosis. The histories typically describe a childhood in an atmosphere of alcohol dependence, violence, and emotional instability. Patients' work histories are poor; they report job losses, marital difficulties, and trouble with the law. Most patients have sought psychiatric help in the past but to no avail. Anxiety, guilt, and depression usually follow an outburst, but this is not a constant finding. Neurological examination sometimes reveals soft neurological signs, such as left-right ambivalence and perceptual reversal. Electroencephalography (EEG) findings are frequently normal or show nonspecific changes.

 **Table 19-1**
DSM-5 Diagnostic Criteria for Intermittent Explosive Disorder

- A. Recurrent behavioral outbursts representing a failure to control aggressive impulses as manifested by either of the following:
1. Verbal aggression (e.g., temper tantrums, tirades, verbal arguments or fights) or physical aggression towards property, animals, or other individuals, occurring twice weekly, on average, for a period of 3 months. The physical aggression does not result in damage or destruction of property and does not result in physical injury to animals or other individuals.
 2. Three behavioral outbursts involving damage or destruction of property and/or physical assault involving physical injury against animals or other individuals occurring within a 12-month period.
- B. The magnitude of aggressiveness expressed during the recurrent outbursts is grossly out of proportion to the provocation or to any precipitating psychosocial stressors.
- C. The recurrent aggressive outbursts are not premeditated (i.e., they are impulsive and/or anger-based) and are not committed to achieve some tangible objective (e.g., money, power, intimidation).
- D. The recurrent aggressive outbursts cause either marked distress in the individual or impairment in occupational or interpersonal functioning, or are associated with financial or legal consequences.
- E. Chronological age is at least 6 years (or equivalent developmental level).
- F. The recurrent aggressive outbursts are not better explained by another mental disorder (e.g., major depressive disorder, bipolar disorder, disruptive mood dysregulation disorder, a psychotic disorder, antisocial personality disorder, borderline personality disorder) and are not attributable to another medical condition (e.g., head trauma, Alzheimer's disease) or the physiological effects of a substance (e.g., a drug of abuse, a medication). For children ages 6–18 years, aggressive behavior that occurs as part of an adjustment disorder should not be considered for this diagnosis.
- Note:** This diagnosis can be made in addition to the diagnosis of attention-deficit/hyperactivity disorder, conduct disorder, oppositional defiant disorder, or autism spectrum disorder when recurrent impulsive aggressive outbursts are in excess of those usually seen in these disorders and warrant independent clinical attention.

A 36-year-old real estate agent sought assistance for difficulty with his anger. He was quite competent at his job, although he frequently lost clients when he became enraged over their indecisiveness. On a number of occasions, he became verbally abusive, leading clients to find ways out of escrow closings. The impulsive aggression also led to termination of multiple relationships because sudden angry outbursts contained demeaning accusations toward his girlfriends. This occurred frequently in the absence of any clear conflict. On multiple occasions, the patient became so uncontrollably enraged that he threw things across the room, including books, his desk, and the contents of the refrigerator. Between episodes, he was a kind and likable individual with many friends. He enjoyed drinking on the weekends and had a history of two arrests for driving while intoxicated. On one of these occasions, he became involved in a verbal altercation with a police officer. He had a history of drug experimentation in college that included cocaine and marijuana.

Mental status examination revealed a generally cooperative patient. However, he became quite defensive when questioned about his anger and easily felt accused and blamed by the interviewer for his past behaviors. He had no significant medical history and no signs of neurological problems. He had never been in psychiatric treatment prior to this evaluation. He was on no medications. He denied any symptoms of a mood disorder or any other antisocial activity.

Treatment included the use of carbamazepine (Tegretol) and a combination of supportive and cognitive-behavioral psychotherapy. The patient's angry outbursts improved as he became aware of early signs that he was about to lose control. He learned techniques to avoid confrontation when he was faced with these warning signs. (Courtesy of Vivien K. Burt, M.D., Ph.D., and Jeffrey William Katzman, M.D.)

Physical Findings and Laboratory Examination

Persons with the disorder have a high incidence of soft neurological signs (e.g., reflex asymmetries), nonspecific EEG findings, abnormal neuropsychological testing results (e.g., letter reversal difficulties), and accident susceptibility. Blood chemistry (liver and thyroid function tests, fasting blood glucose, electrolytes), urinalysis (including drug toxicology), and syphilis serology may help rule out other causes of aggression. Magnetic resonance imaging (MRI) may reveal changes in the prefrontal cortex, which is associated with loss of impulse control.

Differential Diagnosis

The diagnosis of intermittent explosive disorder can be made only after disorders associated with the occasional loss of control of aggressive impulses have been ruled out as the primary cause. These other disorders include psychotic disorders, personality change because of a general medical condition, antisocial or borderline personality disorder, and substance intoxication (e.g., alcohol, barbiturates, hallucinogens, and amphetamines), epilepsy, brain tumors, degenerative diseases, and endocrine disorders.

Conduct disorder is distinguished from intermittent explosive disorder by its repetitive and resistant pattern of behavior, as opposed to an episodic pattern. Intermittent explosive disorder differs from the antisocial and borderline personality disorders because, in the personality disorders, aggressiveness and impulsivity are part of patients' characters and, thus, are present between outbursts. In paranoid and catatonic schizophrenia, patients may display violent behavior in response to delusions and hallucinations, and they show gross impairments in reality testing. Hostile patients with mania may be impulsively aggressive, but the underlying diagnosis is generally apparent from their mental status examinations and clinical presentations.

Amok is an episode of acute violent behavior for which the person claims amnesia. Amok is usually seen in southeastern Asia, but it has been reported in North America. Amok is distinguished from intermittent explosive disorder by a single episode and prominent dissociative features.

Course and Prognosis

Intermittent explosive disorder may begin at any stage of life, but usually appears between late adolescence and early adulthood. The onset can be sudden or insidious, and the course can be episodic or chronic. In most cases, the disorder decreases in severity with the onset of middle age, but heightened organic impairment can lead to frequent and severe episodes.

Treatment

A combined pharmacological and psychotherapeutic approach has the best chance of success. Psychotherapy with patients who have intermittent explosive disorder is difficult, however, because of their angry outbursts. Therapists may have problems with countertransference and limit-setting. Group psychotherapy may be helpful, and family therapy is useful, particularly when the explosive patient is an adolescent or a young adult. A goal of therapy is to have the patient recognize and verbalize the thoughts or feelings that precede the explosive outbursts instead of acting them out.

Anticonvulsants have long been used, with mixed results, in treating explosive patients. Lithium (Eskalith) has been reported useful in generally lessening aggressive behavior, and carbamazepine, valproate (Depakene) or divalproex (Depakote), and phenytoin (Dilantin) have been reported helpful. Some clinicians have also used other anticonvulsants (e.g., gabapentin [Neurontin]). Benzodiazepines are sometimes used but have been reported to produce a paradoxical reaction of dyscontrol in some cases.

Antipsychotics (e.g., phenothiazines and serotonin-dopamine antagonists) and tricyclic drugs have been effective in some cases, but clinicians must then question whether schizophrenia or a mood disorder is the true diagnosis. With a likelihood of subcortical seizure-like activity, medications that lower the seizure threshold can aggravate the situation. Selective serotonin reuptake inhibitors (SSRIs), trazodone (Desyrel), and buspirone (BuSpar) are useful in reducing impulsivity and aggression.

Propranolol (Inderal) and other β -adrenergic receptor antagonists and calcium channel inhibitors have also been effective in some cases. Some neurosurgeons have performed operative treatments for intractable violence and aggression. No evidence indicates that such treatment is effective.

KLEPTOMANIA

The essential feature of kleptomania is a recurrent failure to resist impulses to steal objects not needed for personal use or for monetary value. The objects taken are often given away, returned surreptitiously, or kept and hidden. Persons with kleptomania usually have the money to pay for the objects they impulsively steal.

As with other impulse-control disorders, kleptomania is characterized by mounting tension before the act, followed by gratification and lessening of tension with or without guilt, remorse, or depression after the act. The stealing is not planned and does not involve others. Although the thefts do not occur when immediate arrest is probable, persons with kleptomania do not always consider their chances of being apprehended, although repeated arrests lead to pain and humiliation. These persons may feel guilt and anxiety after the theft, but they do not feel anger or vengeance. Furthermore, when the object stolen is the goal, the diagnosis is not kleptomania; in kleptomania, the act of stealing is itself the goal.

Epidemiology

The prevalence of kleptomania is not known, but it is estimated to be about 0.6 percent. The range varies from 3.8 to 24 percent of those arrested for shoplifting. There are reports that it occurs in fewer than 5 percent of identified shoplifters. The male-to-female ratio is 1:3 in clinical samples.

Comorbidity

Patients with kleptomania are said to have a high lifetime comorbidity of major mood disorders (usually, but not exclusively, depressive) and various anxiety disorders. Associated conditions also include other disorders such as pathological gambling and compulsive shopping, eating disorders, and substance use disorders, alcoholism in particular.

Etiology

Psychosocial Factors. The symptoms of kleptomania tend to appear in times of significant stress, for example, losses, separations, and endings of important relationships. Some psychoanalytic writers have stressed the expression of aggressive impulses in kleptomania; others have discerned a libidinal aspect. Those who focus on symbolism see meaning in the act itself, the object stolen, and the victim of the theft.

Analytic writers have focused on stealing by children and adolescents. Anna Freud pointed out that the first thefts from mother's purse indicate the degree to which all stealing is rooted in the oneness between mother and child. Karl Abraham wrote of the central feeling of being neglected, injured, or unwanted. One theoretician established seven categories of stealing in chronically acting-out children:

1. As a means of restoring the lost mother-child relationship

2. As an aggressive act
3. As a defense against fears of being damaged (perhaps a search by girls for a penis or a protection against castration anxiety in boys)
4. As a means of seeking punishment
5. As a means of restoring or adding to self-esteem
6. In connection with, and as a reaction to, a family secret
7. As excitement (*lust angst*) and a substitute for a sexual act

One or more of these categories can also apply to adult kleptomania.

Biological Factors. Brain diseases and mental retardation have been associated with kleptomania, as they have with other disorders of impulse control. Focal neurological signs, cortical atrophy, and enlarged lateral ventricles have been found in some patients. Disturbances in monoamine metabolism, particularly of serotonin, have been postulated.

Family and Genetic Factors. In one study, 7 percent of first-degree relatives had obsessive-compulsive disorder (OCD). In addition, a higher rate of mood disorders has been reported in family members.

Diagnosis and Clinical Features

The essential feature of kleptomania is recurrent, intrusive, and irresistible urges or impulses to steal unneeded objects. Patients with kleptomania may also be distressed about the possibility or actuality of being apprehended and may manifest signs of depression and anxiety. Patients feel guilty, ashamed, and embarrassed about their behavior. They often have serious problems with interpersonal relationships and often show signs of personality disturbance. In one study of patients with kleptomania, the frequency of stealing ranged from less than 1 to 120 episodes a month. Most patients with kleptomania steal from retail stores, but they may also steal from family members in their own households.

Jane was a 42-year-old, highly successful, single executive from a wealthy background. She called herself a “shop-’til-you-drop type” and had always been able to afford the expensive designer clothing that she loved. Since college, her “legit” shopping had been paralleled by “boosting” cheap panties and brassieres from discount stores. She did not wear the stolen items; indeed, she considered them “sleazy.” She could never bring herself to get rid of them either and kept boxes filled with pilfered lingerie in a storage facility.

Jane talked or bought her way out of trouble until her 30s, when she was arrested while stealing pantyhose from the same K-Mart for the third time in as many months. As a condition of probation, she was ordered to see a psychiatrist. Her attendance was sporadic, and several more thefts occurred over the next 2 years. She also experienced substantial depression, which she tried to alleviate by heavy drinking.

Jane finally began taking her problem seriously after yet another arrest precipitated a suicidal gesture. She began keeping appointments regularly and consented to taking citalopram (Celexa) and naltrexone (ReVia). She believes that her participation in an Alcoholics Anonymous (AA) group for high-pressured executives has been at least as effective—if not more so—in controlling her stealing. (Courtesy of Harvey Roy Greenberg, M.D.)

Differential Diagnosis

Episodes of theft occasionally occur during psychotic illness, for example, acute mania, major depression with psychotic features, or schizophrenia. Psychotic stealing is obviously a product of pathological elevation or depression of mood or command hallucinations or delusions. Theft in individuals with antisocial personality disorder is deliberately undertaken for personal gain, with some degree of premeditation and planning, often executed with others. Antisocial stealing regularly involves the threat of harm or actual violence, particularly to elude capture. Guilt and remorse are distinctively lacking, or patients are patently insincere. Shoplifting has become a national epidemic. Few shoplifters have true kleptomania; most are teenagers and young adults who “boost” in pairs or small groups for “kicks,” as well as goods, and do not have a major psychiatric disorder. Acute intoxication with drugs or alcohol may precipitate theft in an individual with another psychiatric disorder or without significant psychopathology. Patients with Alzheimer’s disease or other dementing organic illness may leave a store without paying, owing to forgetfulness rather than larcenous intent. Malingering kleptomania is common in apprehended antisocial types, as well as nonantisocial youthful shoplifters. Given a sufficiently intelligent perpetrator, the fictive version can be difficult to distinguish from the genuine disorder.

Course and Prognosis

Kleptomania may begin in childhood, although most children and adolescents who steal do not become kleptomaniac adults. The onset of the disorder generally is late adolescence. Women are more likely than men to present for psychiatric evaluation or treatment. Men are more likely to be sent to prison. Men tend to present with the disorder at about 50 years of age; women present at about 35 years of age. In quiescent cases, new bouts of the disorder may be precipitated by loss or disappointment.

The course of the disorder waxes and wanes, but tends to be chronic. Persons sometimes have bouts of being unable to resist the impulse to steal, followed by free periods that last for weeks or months. The spontaneous recovery rate of kleptomania is unknown.

Serious impairment and complications are usually secondary to being caught, particularly to being arrested. Many persons seem never to have consciously considered the possibility of facing the consequences of their acts, a feature that agrees with some descriptions of patients with kleptomania (sometimes, as persons who feel wronged and therefore entitled to steal). Often, the disorder in no way impairs a person’s social or work functioning.

The prognosis with treatment can be good, but few patients come for help of their own accord.

Treatment

Because true kleptomania is rare, reports of treatment tend to be individual case descriptions or a short series of cases. Insight-oriented psychotherapy and psychoanalysis have been successful, but depend on patients’ motivations. Those who feel guilt and shame may be helped by insight-oriented psychotherapy because of their increased motivation to change their behavior.

Behavior therapy, including systematic desensitization, aversive conditioning, and a combination of aversive conditioning and altered social contingencies, has been reported successful, even when motivation was lacking. The reports cite follow-up studies of up to 2 years. SSRIs, such as fluoxetine (Prozac) and fluvoxamine (Luvox), appear to be effective in some patients with kleptomania. Case reports indicated successful treatment with tricyclic drugs, trazodone, lithium, valproate, naltrexone, and electroconvulsive therapy.

PYROMANIA

Pyromania is the recurrent, deliberate, and purposeful setting of fires. Associated features include tension or affective arousal before setting

the fires; fascination with, interest in, curiosity about, or attraction to fire and the activities and equipment associated with firefighting; and pleasure, gratification, or relief when setting fires or when witnessing or participating in their aftermath. Patients may make considerable advance preparations before starting a fire. Pyromania differs from arson in that the latter is done for financial gain, revenge, or other reasons and is planned beforehand.

Epidemiology

No information is available on the prevalence of pyromania, but only a small percentage of adults who set fires can be classified as having pyromania. The disorder is found far more often in men than in women, with a male-to-female ratio of approximately 8:1. More than 40 percent of arrested arsonists are younger than 18 years of age.

Comorbidity

Pyromania is significantly associated with substance abuse disorder (especially alcoholism); affective disorders, depressive or bipolar; other impulse control disorders, such as kleptomania in female fire setters; and various personality disturbances, such as inadequate and borderline personality disorders. Attention-deficit/hyperactivity disorder and learning disabilities may be conspicuously associated with childhood pyromania; this constellation frequently persists into adulthood. Persons who set fires are more likely to be mildly retarded than are those in the general population. Some studies have noted an increased incidence of alcohol use disorders in persons who set fires. Fire setters also tend to have a history of antisocial traits, such as truancy, running away from home, and delinquency. Enuresis has been considered a common finding in the history of fire setters, although controlled studies have failed to confirm this. Studies, however, have found an association between cruelty to animals and fire setting. Childhood and adolescent fire setting is often associated with ADHD or adjustment disorders.

Etiology

Psychosocial. Freud saw fire as a symbol of sexuality. He believed the warmth radiated by fire evokes the same sensation that accompanies a state of sexual excitation, and a flame's shape and movements suggest a phallus in activity. Other psychoanalysts have associated pyromania with an abnormal craving for power and social prestige. Some patients with pyromania are volunteer firefighters who set fires to prove themselves brave, to force other firefighters into action, or to demonstrate their power to extinguish a blaze. The incendiary act is a way to vent accumulated rage over frustration caused by a sense of social, physical, or sexual inferiority. Several studies have noted that the fathers of patients with pyromania were absent from the home. Thus, one explanation of fire setting is that it represents a wish for the absent father to return home as a rescuer, to put out the fire, and to save the child from a difficult existence.

Female fire setters, in addition to being much fewer in number than male fire setters, do not start fires to put firefighters into action as men frequently do. Frequently noted delinquent trends in female fire setters include promiscuity without pleasure and petty stealing, often approaching kleptomania.

Biological Factors. Significantly low CSF levels of 5-HIAA and 3-methoxy-4-hydroxyphenylglycol (MHPG) have been found in fire setters, which suggests possible serotonergic or adrenergic involvement. The presence of reactive hypoglycemia, based on blood glucose concentrations on glucose tolerance tests, has been put forward as a cause of pyromania. Further studies are needed, however.

Diagnosis and Clinical Features

Persons with pyromania often regularly watch fires in their neighborhoods, frequently set off false alarms, and show interest in firefighting paraphernalia. Their curiosity is evident, but they show no remorse and may be indifferent to the consequences for life or property. Fire setters may gain satisfaction from the resulting destruction; frequently, they leave obvious clues. Commonly associated features include alcohol intoxication, sexual dysfunctions, below-average intelligence quotient (IQ), chronic personal frustration, and resentment toward authority figures. Some fire setters become sexually aroused by the fire.

Differential Diagnosis

Clinicians should have little trouble distinguishing between pyromania and the fascination of many young children with matches, lighters, and fire as part of the normal investigation of their environments. Pyromania must also be separated from incendiary acts of sabotage carried out by dissident political extremists or by "paid torchers", termed arsonists in the legal system.

When fire setting occurs in conduct disorder and antisocial personality disorder, it is a deliberate act, not a failure to resist an impulse. Fires may be set for profit, sabotage, or retaliation. Patients with schizophrenia or mania may set fires in response to delusions or hallucinations. Patients with brain dysfunction (e.g., dementia), mental retardation, or substance intoxication may set fires because of a failure to appreciate the consequences of the act.

Course and Prognosis. Although fire setting often begins in childhood, the typical age of onset of pyromania is unknown. When the onset is in adolescence or adulthood, the fire setting tends to be deliberately destructive. Fire setting in pyromania is episodic and may wax and wane in frequency. The prognosis for treated children is good, and complete remission is a realistic goal. The prognosis for adults is guarded, because they frequently deny their actions, refuse to take responsibility, are dependent on alcohol, and lack insight.

Treatment

Little has been written about the treatment of pyromania, and treating fire setters has been difficult because of their lack of motivation. No single treatment has been proved effective; thus a number of modalities, including behavioral approaches, should be tried. Because of the recurrent nature of pyromania, any treatment program should include supervision of patients to prevent a repeated episode of fire setting. Incarceration may be the only method of preventing a recurrence. Behavior therapy can then be administered in the institution.

Fire setting by children must be treated with the utmost seriousness. Intensive interventions should be undertaken when possible, but as therapeutic and preventive measures, not as punishment. In the case of children and adolescents, treatment of pyromania or fire setting should include family therapy.

OTHER SPECIFIED OR UNSPECIFIED DISORDERS

This DSM-5 diagnostic category is a residual category for disorders that do not meet the criteria for the disorders described earlier. Some of the disorders listed below stand at the borderline between impulsive and compulsive disorders. Important, although subtle, distinctions exist between the two terms. An *impulse* is a tension state that can exist without an action; a *compulsion* is a tension state that always has an action component. The disorders are classified here as compulsions because the patients feel "compelled" to act out their pathological behavior; they cannot resist the impulse to do so. Impulses are acted on with the expectation of receiving pleasure; compulsions are usually ego-dystonic; for example, the patient does not like having to perform the act even though compelled to do so. An exception to the rule that impulses are associated with pleasure involves those cases in which feelings of guilt follow the act and disturb the sense of pleasure.

Similarly, not all compulsions are ego-dystonic; for example, certain compulsive video game playing may have a pleasurable component. Both impulsive and compulsive behaviors are characterized by their repetitive nature; however, the repeated acting out of impulses leads to psychosocial impairment, whereas compulsive behavior does not always carry that risk. Because of the repetitive and pleasurable nature of many of the behavioral patterns in this group of disorders, they are often referred to as addictions.

Internet Compulsion

Also called *Internet Addiction*, such persons spend almost all their waking hours at the computer terminal. Their patterns of use are repetitive and constant, and they are unable to resist strong urges to use the computer or to “surf the Web.” Internet addicts may gravitate to certain sites that meet specific needs (e.g., shopping, sex, and interactive games, among others). In DSM-5 there is a condition proposed for further study called “Internet gaming disorder,” which refers to persons who continually use the Internet to play games to the extent that it interferes with social relations and work performance. But as mentioned earlier, the disorder need not be limited to games. Other activities may be involved.

Internet Use and Abuse. Web sites and organizations offer opportunities for people with similar interests to find one another and begin relationships. The Internet has been useful as a matchmaker, with millions of subscribers to dating services. People meet on the Internet, fall in love, and may even marry. During this process some fact fudging is not uncommon. In Second Life and similar alternate universe games, creative identity deception is expected. This use can become problematic and thus can be termed “abuse” in various ways.

victims. Deception can take a malignant turn as sexual predators deceive their victims with false identities only to exploit and harm them when they meet. These contacts are unregulated and difficult to detect except by monitoring and checking the computers used. There are weekly reports of minors having been lured into sometimes lethal situations by sexual predators. Occasionally there is a report of a couple that met to marry only to discover they had missed verifying crucial details, such as each other’s sex.

Some people who make little use of the Internet nonetheless become victims and enter treatment. The suicide of one teenager after reading untruths entered by a peer’s malicious mother (“cyberbullying”) has inspired laws to criminalize such behavior. Internet identity theft is also rampant. An underreported and growing problem, medical identity theft, is harder to detect and remedy, often requiring painstaking record correction.

The combination of anonymity, convenience, and escape (the ACE model) promotes the Internet as a focus of psychopathology. Internet addiction is mentioned on 385,000 Web pages, a 180-fold increase in 4 years, with those at risk suffering from depression, bipolar disorder, anxiety, low self-esteem, or addiction to substances, at least previously. Online surveys find that 4 to 10 percent of users meet criteria for “Internet addiction,” defined as having at least five of the following signs and symptoms: (1) preoccupation with the Internet; (2) increasing amount of time spent online; (3) failure to cut back use with concomitant restlessness; (4) moodiness or depression; (5) staying online longer than originally intended; (6) running the risk of losing a job, relationship, or other opportunity because of Internet use; and (7) lying to conceal the extent of Internet use and/or using the Internet to escape negative feelings. General population surveys show a prevalence of .3 to .7 percent, with higher rates when family members are queried. The “addicted” averaged 38.5 hours per week on a computer, whereas others averaged 4.9 hours per week. Forty percent got less than 4 hours of sleep per night because of Internet use. Impairment was evident in increased divorce rates, vocational impairment, legal problems, and personal distress. Subgroups on Internet use include (1) cybersex addiction (viewing pornography); (2) cyber-relational addiction (online relationships become more important than those in one’s physical world); online gaming (gambling, stock trading), compulsive, debt-inducing shopping, and others; (3) information overload; (4) net compulsivity; and (5) computer (non-Internet) addiction (e.g., computer games). About 30 percent of those “addicted” reported using the Internet to escape negative feelings and because it was always available at low cost. It is possible to lose real money on the Internet, gambling constantly and continually without being seen to do so. More money is made on sex via the Internet than through the sale of anything else. Combinations abound, as in the 873,000 sites mentioning both “cybersex” and “casino.”

TREATMENT FOR INTERNET ADDICTS. A subset of Web pages offer a chance to evaluate one’s Internet use as possibly pathological and offer both education and online counseling, with some urging face-to-face counseling as a way of becoming less involved with the Internet. A rough idea of the ratio of what is offered as possible sources of help online is the number of sites mentioning “cybersex” (close 4 million) compared to those mentioning “cybersex addiction” (about 20 thousand). There are many mentions and variants on “Center for Internet Addiction” often represented only by single practitioners with some ancillary staff.

Mobile or Cell Phone Compulsion

Some persons compulsively use mobile phones to call others—friends, acquaintances, or business associates. They justify their need to contact others by giving plausible reasons for calling; but underlying conflicts may be expressed in the behavior, such as fear of being alone, the need to satisfy unconscious dependency needs, or undoing a hostile wish toward a loved one, among others (e.g., “I just want to make sure you are OK.”).

Repetitive Self-Mutilation

Persons who repeatedly cut themselves or do damage to their bodies may do so in a compulsive manner. In all cases, another disorder will be found. Parasuicidal behavior is common in borderline personality disorder. Compulsive body piercing or tattooing may be a symptom of a paraphilia or a depressive equivalent.

In DSM-5 there is a proposed diagnosis called “non-suicidal self injury” to refer to persons who repeatedly damage their bodies, who, however, do not wish to die, contrasted with those persons who harm themselves with true suicidal intent. There is secondary gain to this self-injurious behavior such as getting the attention of others, the so-called “cry for help,” or obtaining relief from dysphoric states. It has been postulated that cutting the skin or inflicting bodily pain may release endorphins or raise dopamine levels in the brain, both of which contribute to a euthymic or elated mood, thus alleviating depressed states of mind in those who practice self-mutilation.

Compulsive Sexual Behavior

Some persons repeatedly seek out sexual gratification, often in perverse ways (e.g., exhibitionism). They are unable to control their behavior and may not experience feelings of guilt after an episode of acting-out behavior. Sometimes called *sexual addiction*, this condition is discussed extensively in Section 17.2.

Substance Use and Addictive Disorders

20.1 Introduction and Overview

The most commonly used drugs have been part of human existence for thousands of years. For example, opium has been used for medicinal purposes for at least 3,500 years, references to cannabis (marijuana) as a medicinal can be found in ancient Chinese herbals, wine is mentioned frequently in the Bible, and the natives of the Western Hemisphere smoked tobacco and chewed coca leaves. As new drugs were discovered and new routes of administration developed, new problems related to their use emerged. Substance use disorders are complicated psychiatric conditions and like other psychiatric disorders, both biological factors and environmental circumstances are etiologically significant.

This chapter covers substance dependence and substance abuse with descriptions of the clinical phenomena associated with the use of 11 designated classes of pharmacological agents: alcohol; amphetamines or similarly acting agents; caffeine; cannabis; cocaine; hallucinogens; inhalants; nicotine; opioids; phencyclidine (PCP) or similar agents; and a group that includes sedatives, hypnotics, and anxiolytics. A residual 12th category includes a variety of agents not in the 11 designated classes, such as anabolic steroids and nitrous oxide.

TERMINOLOGY

Various terms have been used over the years to refer to drug abuse. For example, the term *dependence* has been and is used in one of two ways when discussing substance use disorders. In *behavioral dependence*, substance-seeking activities and related evidence of pathological use patterns are emphasized, whereas *physical dependence* refers to the physical (physiological) effects of multiple episodes of substance use. Psychological dependence, also referred to as habituation, is characterized by a continuous or intermittent craving (i.e., intense desire) for the substance to avoid a dysphoric state. Behavioral, physical, and psychological dependence are the hallmark of substance use disorders.

Somewhat related to dependence are the related words addiction and addict. The word *addict* has acquired a pejorative connotation that ignores the concept of substance abuse as a medical disorder. *Addiction* has also been trivialized in popular usage, as in the terms *TV addiction* and *money addiction*; however, the term still has value. There are common neurochemical and neuroanatomical substrates found among all addictions, whether it is to substances or to gambling, sex, stealing, or eating. These various addictions may have similar effects on the activities of specific reward areas of the brain, such as the ventral tegmental area, the locus ceruleus, and the nucleus accumbens.

Other Terms

Codependence. The terms *coaddiction* and, more commonly, *codependency* or *codependence* are used to designate the behavioral patterns of family members who have been significantly affected by another family member's substance use or addiction. The terms have been used in various ways and no established criteria for codependence exist.

Enabling. Enabling was one of the first, and more agreed on, characteristics of codependence or coaddiction. Sometimes, family members feel that they have little or no control over the enabling acts. Either because of the social pressures for protecting and supporting family members or because of pathological interdependencies, or both, enabling behavior often resists modification. Other characteristics of codependence include unwillingness to accept the notion of addiction as a disease. The family members continue to behave as if the substance-using behavior were voluntary and willful (if not actually spiteful), and the user cares more for alcohol and drugs than for family members. This results in feelings of anger, rejection, and failure. In addition to those feelings, family members may feel guilty and depressed because addicts, in an effort to deny loss of control over drugs and to shift the focus of concern away from their use, often try to place the responsibility for such use on other family members, who often seem willing to accept some or all of it.

Denial. Family members, as with the substance users themselves, often behave as if the substance use that is causing obvious problems were not really a problem; that is, they engage in denial. The reasons for the unwillingness to accept the obvious vary. Sometimes denial is self-protecting, in that the family members believe that if a drug or alcohol problem exists, then they are responsible.

As with the addicts themselves, codependent family members seem unwilling to accept the notion that outside intervention is needed and, despite repeated failures, continue to believe that greater willpower and greater efforts at control can restore tranquility. When additional efforts at control fail, they often attribute the failure to themselves rather than to the addict or the disease process, and along with failure come feelings of anger, lowered self-esteem, and depression. A summary of some key terms related to substance use disorders is given in [Table 20.1-1](#).

Table 20.1-1
Terms Used in Substance-Related Disorders

Dependence The repeated use of a drug or chemical substance, with or without physical dependence. Physical dependence indicates an altered physiologic state caused by repeated administration of a drug, the cessation of which results in a specific syndrome.

Abuse Use of any drug, usually by self-administration, in a manner that deviates from approved social or medical patterns.

Misuse Similar to abuse, but usually applies to drugs prescribed by physicians that are not used properly.

Addiction The repeated and increased use of a substance, the deprivation of which gives rise to symptoms of distress and an irresistible urge to use the agent again and which leads also to physical and mental deterioration.

Intoxication A reversible syndrome caused by a specific substance (e.g., alcohol) that affects one or more of the following mental functions: memory, orientation, mood, judgment, and behavioral, social, or occupational functioning.

Withdrawal A substance-specific syndrome that occurs after stopping or reducing the amount of the drug or substance that has been used regularly over a prolonged period. The syndrome is characterized by physiological signs and symptoms in addition to psychological changes, such as disturbances in thinking, feeling, and behavior. Also called *abstinence syndrome* or *discontinuation syndrome*.

Tolerance Phenomenon in which, after repeated administration, a given dose of drug produces a decreased effect or increasingly larger doses must be administered to obtain the effect observed with the original dose. *Behavioral tolerance* reflects the ability of the person to perform tasks despite the effects of the drug.

Cross-tolerance Refers to the ability of one drug to be substituted for another, each usually producing the same physiological and psychological effect (e.g., diazepam and barbiturates). Also known as *cross-dependence*.

Neuroadaptation Neurochemical or neurophysiologic changes in the body that result from the repeated administration of a drug. Neuroadaptation accounts for the phenomenon of tolerance. *Pharmacokinetic adaptation* refers to adaptation of the metabolizing system in the body. *Cellular or pharmacodynamic adaptation* refers to the ability of the nervous system to function despite high blood levels of the offending substance.

Codependence Term used to refer to family members affected by or influencing the behavior of the substance abuser. Related to the term *enabler*, which is a person who facilitates the abuser's addictive behavior (e.g., providing drugs directly or money to buy drugs). Enabling also includes the unwillingness of a family member to accept addiction as a medical-psychiatric disorder or to deny that person is abusing a substance.

EPIDEMIOLOGY

The National Institute of Drug Abuse (NIDA) and other agencies, such as the National Survey of Drug Use and Health (NSDUH), conduct periodic surveys of the use of illicit drugs in the United States. As of 2012, it is estimated that more than 22 million persons older than the age of 12 years (about 10 percent of the total US population) were classified as having a substance-related disorder. Of this group, almost 15 million were dependent on, or abused, alcohol (Fig. 20.1-1).

FIGURE 20.1-1

Substance dependence or abuse in the past year among persons age 12 or over: 2002–2012. (From Substance Abuse and Mental Health Services Administration, *Results from the 2012 National Survey on Drug Use and Health: Summary of National Findings*, NSDUH Series H-46, HHS Publication No. (SMA) 13-4795. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2013.)

Figure 20.1-2 shows data from the surveys on the percentage of respondents who reported using various drugs. In 2012, 669,000 persons were dependent on, or abused, heroin; 1.7 percent (4.3 million) abused marijuana; 0.4 percent (1 million) abused cocaine; and 2 million were classified as dependent on, or abuse of, pain relievers.

FIGURE 20.1-2

Dependence on, or abuse of, specific illicit drugs within the past year among persons age 12 or older: 2010. (From Substance Abuse and Mental Health Services Administration, *Results from the 2012 National Survey on Drug Use and Health: Summary of National Findings*, NSDUH Series H-46, HHS Publication No. (SMA) 13-4795. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2013.)

With regard to age at first use, those who started to use drugs at an earlier age (14 years or younger) were more likely to become addicted than those who started at a later age. This applied to all substances of abuse, but particularly to alcohol. Among adults aged 21 or older who first tried alcohol at age 14 or younger, 15 percent were classified as alcoholics compared with only 3 percent who first used alcohol at age 21 or older.

Rates of abuse also varied according to age (Table 20.1-2). In 2012, the rate for dependence or abuse is highest among adults age 18 to 25 (19 percent) compared to youths age 12 to 17 (6 percent) and adults age 26 or older (7 percent). After age 21, a general decline occurred with age. By age 65, only about 1 percent of persons have used an illicit substance within the past year, which lends credence to the clinical observation that addicts tend to “burn out” as they age.

Table 20.1-2
Illicit Drug Use in Lifetime, Past Year, and Past Month, by Detailed Age Category: Percentages, 2011 and 2012

Age Category	Time Period					
	Lifetime		Past Year		Past Month	
	2011	2012	2011	2012	2011	2012
TOTAL	47.0	48.0	14.9 ^b	16.0	8.7	9.2
12	9.2	8.1	5.3	5.0	2.7	2.5
13	14.0	12.9	8.7	8.8	3.9	4.6
14	20.1	19.1	14.5	13.3	6.8	6.8
15	29.4	27.1	22.9 ^b	19.3	11.7 ^a	9.5

(From SAMHSA, Center for Behavioral Health Statistics and Quality, National Survey on Drug Use and Health, 2011 and 2012.)

Table 20.1-3 summarizes data about the demographic characteristics of those who use illicit drugs. More men than women use drugs; the highest lifetime rate is among American Indian or Alaska Natives; whites are more affected than blacks or African Americans; those with some college education use more substances than those with less education; and the unemployed have higher rates than those with either part-time or full-time employment.

¹The Other Employment category includes retired persons, disabled persons, homemakers, students, or other persons not in the labor force. (From SAMHSA, Office of Applied Studies, National Survey on Drug Use and Health, 2011 and 2012, with permission.)

Rates of substance dependence or abuse varied by region in the United States. In 2010, rates were slightly higher in the West (9 percent) and Midwest (9 percent) than in the Northeast (8 percent) and South (8 percent). Rates were similar in small metropolitan counties and large metropolitan counties (both at 9 percent) and were lowest in completely rural counties (7 percent). Rates are also higher among persons on parole or on supervised release from jail (34 percent vs. 9 percent). The number of persons driving while under the influence of drugs or alcohol is on a decline. The percentage driving under the influence of alcohol decreased from 14 percent in 2002 to 11 percent in 2010, and those driving under the influence of drugs decreased from 5 percent to 4 percent during the same period. A comprehensive survey of drug use and trends in the United States is available at www.samhsa.gov.

ETIOLOGY

The model of substance use disorders is the result of a process in which multiple interacting factors influence drug-using behavior and the loss of judgment with respect to decisions about using a given drug. Although the actions of a given drug are critical in the process, it is not assumed that all people who become dependent on the same drug experience its effects in the same way or are motivated by the same set of factors. Furthermore, it is postulated that different factors may be more or less important at different stages of the process. Thus, drug availability, social acceptability, and peer pressures may be the major determinants of initial experimentation with a drug, but other factors, such as personality and individual biology, probably are more important in how the effects of a given drug are perceived and the degree to which repeated drug use produces changes in the central nervous system (CNS). Still other factors, including the particular actions of the drug, may be primary determinants of whether drug use progresses to drug dependence, whereas still others may be important influences on the likelihood that drug use (1) leads to adverse effects or (2) to successful recovery from dependence.

It has been asserted that addiction is a “brain disease,” that the critical processes that transform voluntary drug-using behavior to compulsive drug use are changes in the structure and neurochemistry of the brain of the drug user. Sufficient evidence now indicates that such changes in relevant parts of the brain do occur. The perplexing and unanswered question is whether these changes are both necessary and sufficient to account for the drug-using behavior. Many argue that they are not, that the capacity of drug-dependent individuals to modify their drug-using behavior in response to positive reinforcers or aversive contingencies indicates that the nature of addiction is more complex and requires the interaction of multiple factors.

Figure 20.1-3 illustrates how various factors might interact in the development of drug dependence. The central element is the drug-using behavior itself. The decision to use a drug is influenced by immediate social and psychological situations as well as by the person’s more remote history. Use of the drug initiates a sequence of consequences that can be rewarding or aversive and which, through a process of learning, can result in a greater or lesser likelihood that the drug-using behavior will be repeated. For some drugs, use also initiates the biological processes associated with tolerance, physical dependence, and (not shown in the figure) sensitization. In turn, tolerance can reduce some of the adverse effects of the drug, permitting or requiring the use of larger doses, which then can accelerate or intensify the development of physical dependence. Above a certain threshold, the aversive qualities of a withdrawal syndrome provide a distinct recurrent motive for further drug use. Sensitization of motivational systems can increase the salience of drug-related stimuli.

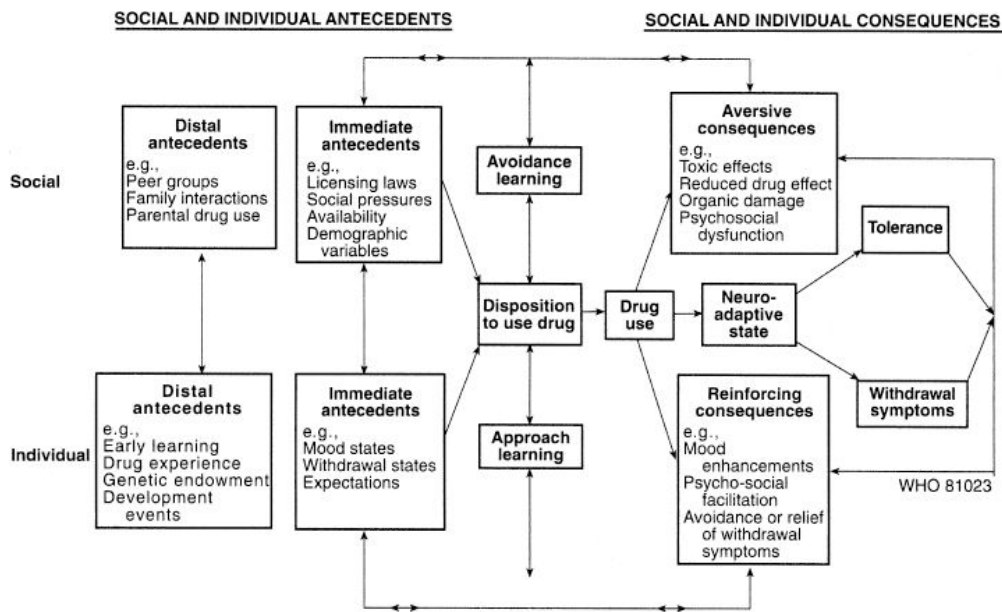

FIGURE 20.1-3

World Health Organization schematic model of drug use and dependence. (From Edwards G, Arif A, Hodgson R. Nomenclature and classification of drug-and alcohol-related problems. A WHO memorandum. *Bull WHO*. 1981;59:225, with permission.)

Psychodynamic Factors

The range of psychodynamic theories about substance abuse reflects the various popular theories during the last 100 years. According to classic theories, substance abuse is a masturbatory equivalent (some heroin users describe the initial “rush” as similar to a prolonged sexual orgasm), a defense against anxious impulses, or a manifestation of oral regression (i.e., dependency). Recent psychodynamic formulations relate substance use as a reflection of disturbed ego functions (i.e., the inability to deal with reality). As a form of self-medication, alcohol may be used to control panic, opioids to diminish anger, and amphetamines to alleviate depression. Some addicts have great difficulty recognizing their inner emotional states, a condition called *alexithymia* (i.e., being unable to find words to describe their feelings).

Learning and Conditioning.

Drug use, whether occasional or compulsive, can be viewed as behavior maintained by its consequences. Drugs can reinforce antecedent behaviors by terminating some noxious or aversive state such as pain, anxiety, or depression. In some social situations, the drug use, apart from its pharmacological effects, can be reinforcing if it results in special status or the approval of friends. Each use of the drug evokes rapid positive reinforcement, either as a result of the rush (the drug-induced euphoria), alleviation of disturbed affects, alleviation of withdrawal symptoms, or any combination of these effects. In addition, some drugs may sensitize neural systems to the reinforcing effects of the drug. Eventually, the paraphernalia (needles, bottles, cigarette packs) and behaviors associated with substance use can become secondary reinforcers, as well as cues signaling availability of the substance, and in their presence, craving or a desire to experience the effects increases.

Drug users respond to the drug-related stimuli with increased activity in limbic regions, including the amygdala and the anterior cingulate. Such drug-related activation of limbic areas has been demonstrated with a variety of drugs, including cocaine, opioids, and cigarettes (nicotine). Of interest, the same regions activated by cocaine-related stimuli in cocaine users are activated by sexual stimuli in both normal controls and cocaine users.

In addition to the operant reinforcement of drug-using and drug-seeking behaviors, other learning mechanisms probably play a role in dependence and relapse. Opioid and alcohol withdrawal phenomena can be conditioned (in the Pavlovian or classic sense) to environmental or interoceptive stimuli. For a long time after withdrawal (from opioids, nicotine, or alcohol), the addict exposed to environmental stimuli previously linked with substance use or withdrawal may experience conditioned withdrawal, conditioned craving, or both. The increased feelings of craving are not necessarily accompanied by symptoms of withdrawal. The most intense craving is elicited by conditions associated with the availability or use of the substance, such as watching someone else use heroin or light a cigarette or being offered some drug by a friend. Those learning and conditioning phenomena can be superimposed on any preexisting psychopathology, but preexisting difficulties are not required for the development of powerfully reinforced substance-seeking behavior.

Genetic Factors

Strong evidence from studies of twins, adoptees, and siblings brought up separately indicates that the cause of alcohol abuse has a genetic component. Many less conclusive data show that other types of substance abuse or substance dependence have a genetic pattern in their development. Researchers recently have used restriction fragment length polymorphism (RFLP) in the study of substance abuse and substance dependence, and associations to genes that affect dopamine production have been postulated.

Neurochemical Factors

Receptors and Receptor Systems.

With the exception of alcohol, researchers have identified particular neurotransmitters or neurotransmitter receptors involved with most substances of abuse. Some researchers base their studies on such hypotheses. The opioids, for example, act on opioid receptors. A person with too little endogenous opioid activity (e.g., low concentrations of endorphins) or with too much activity of an endogenous opioid antagonist may be at risk for developing opioid dependence. Even in a person with completely normal endogenous receptor function and neurotransmitter concentration, the long-term use of a particular substance of abuse may eventually modulate receptor systems in the brain so that the presence of the exogenous substance is needed to maintain homeostasis. Such a receptor-level process may be the mechanism for developing tolerance within the CNS. Demonstrating modulation of neurotransmitter release and neurotransmitter receptor function has proved difficult, however, and recent research focuses on the effects of substances on the second-messenger system and on gene regulation.

Pathways and Neurotransmitters

The major neurotransmitters possibly involved in developing substance abuse and substance dependence are the opioid, catecholamine (particularly dopamine), and γ -aminobutyric acid (GABA) systems. The dopaminergic neurons in the ventral tegmental area are particularly

important. These neurons project to the cortical and limbic regions, especially the nucleus accumbens. This pathway is probably involved in the sensation of reward and may be the major mediator of the effects of such substances as amphetamine and cocaine. The locus ceruleus, the largest group of adrenergic neurons, probably mediates the effects of the opiates and the opioids. These pathways have collectively been called the *brain-reward circuitry*.

COMORBIDITY

Comorbidity is the occurrence of two or more psychiatric disorders in a single patient at the same time. A high prevalence of additional psychiatric disorders is found among persons seeking treatment for alcohol, cocaine, or opioid dependence; some studies have shown that up to 50 percent of addicts have a comorbid psychiatric disorder. Although opioid, cocaine, and alcohol abusers with current psychiatric problems are more likely to seek treatment, those who do not seek treatment are not necessarily free of comorbid psychiatric problems; such persons may have social supports that enable them to deny the impact that drug use is having on their lives. Two large epidemiological studies have shown that even among representative samples of the population, those who meet the criteria for alcohol or drug abuse and dependence (excluding tobacco dependence) are also far more likely to meet the criteria for other psychiatric disorders also.

In various studies, a range of 35 to 60 percent of patients with substance abuse or substance dependence also meets the diagnostic criteria for antisocial personality disorder. The range is even higher when investigators include persons who meet all the antisocial personality disorder diagnostic criteria, except the requirement that the symptoms started at an early age. That is, a high percentage of patients with substance abuse or substance dependence diagnoses have a pattern of antisocial behavior, whether it was present before the substance use started or developed during the course of the substance use. Patients with substance abuse or substance dependence diagnoses who have antisocial personality disorder are likely to use more illegal substances; to have more psychopathology; to be less satisfied with their lives; and to be more impulsive, isolated, and depressed than patients with antisocial personality disorders alone.

Depression and Suicide. Depressive symptoms are common among persons diagnosed with substance abuse or substance dependence. About one third to one half of all those with opioid abuse or opioid dependence and about 40 percent of those with alcohol abuse or alcohol dependence meet the criteria for major depressive disorder sometime during their lives. Substance use is also a major precipitating factor for suicide. Persons who abuse substances are about 20 times more likely to die by suicide than the general population. About 15 percent of persons with alcohol abuse or alcohol dependence have been reported to commit suicide. This frequency of suicide is second only to the frequency in patients with major depressive disorder.

DIAGNOSTIC CLASSIFICATION

There are four major diagnostic categories in the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5): (1) Substance Use Disorder; (2) Substance Intoxication; (3) Substance Withdrawal; and (4) Substance-Induced Mental Disorder.

Substance Use Disorder

Substance use disorder is the diagnostic term applied to the specific substance abused (e.g., alcohol use disorder, opioid use disorder) that results from the prolonged use of the substance. The following points should be considered in making this diagnosis. These criteria apply to all substances of abuse.

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by 2 (or more) of the following, occurring within a 12-month period:

1. recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)
4. tolerance, as defined by either of the following:
 - a. a need for markedly increased amounts of the substance to achieve intoxication or desired effect
 - b. markedly diminished effect with continued use of the same amount of the substance
5. withdrawal, as manifested by either of the following:
 - a. the characteristic withdrawal syndrome for the substance
 - b. the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
6. the substance is often taken in larger amounts or over a longer period than was intended
7. there is a persistent desire or unsuccessful efforts to cut down or control substance use
8. a great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
9. important social, occupational, or recreational activities are given up or reduced because of substance use
10. the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance
11. craving or a strong desire or urge to use a specific substance.

Substance Intoxication

Substance intoxication is the diagnosis used to describe a syndrome (e.g., alcohol intoxication or simple drunkenness) characterized by specific signs and symptoms resulting from recent ingestion or exposure to the substance. A general description of substance intoxication includes the following points:

- ▶ The development of a reversible substance-specific syndrome due to recent ingestion of (or exposure to) a substance. **Note:** Different substances may produce similar or identical syndromes.
- ▶ Clinically significant maladaptive behavioral or psychological changes that are due to the effect of the substance on the central nervous system (e.g., belligerence, mood lability, cognitive impairment, impaired judgment, impaired social or occupational functioning) and develop during or shortly after use of the substance.
- ▶ The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Substance Withdrawal

Substance withdrawal is the diagnosis used to describe a substance specific syndrome that results from the abrupt cessation of heavy and prolonged use of a substance (e.g., opioid withdrawal). A general description of substance withdrawal requires the following criteria to be

met:

- ▶ The development of a substance-specific syndrome due to the cessation of (or reduction in) substance use that has been heavy and prolonged.
- ▶ The substance-specific syndrome causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- ▶ The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

In the discussion of each substance in the sections that follow, the generic tables listed above, derived from the DSM-5 can be applied. Thus, in place of the word substance, the clinician should indicate the specific substance or drug that is used or that caused intoxication or withdrawal.

TREATMENT AND REHABILITATION

Some persons who develop substance-related problems recover without formal treatment, especially as they age. For those patients with less severe disorders, such as nicotine addiction, relatively brief interventions are often as effective as more intensive treatments. Because these brief interventions do not change the environment, alter drug-induced brain changes, or provide new skills, a change in the patient's motivation (cognitive change) probably has the best impact on the drug-using behavior. For those individuals who do not respond or whose dependence is more severe, a variety of interventions described below appear to be effective.

It is useful to distinguish among specific procedures or techniques (e.g., individual therapy, family therapy, group therapy, relapse prevention, and pharmacotherapy) and treatment programs. Most programs use a number of specific procedures and involve several professional disciplines as well as nonprofessionals who have special skills or personal experience with the substance problem being treated. The best treatment programs combine specific procedures and disciplines to meet the needs of the individual patient after a careful assessment.

No classification system is generally accepted for either the specific procedures used in treatment or programs using various combinations of procedures. This lack of standardized terminology for categorizing procedures and programs presents a problem, even when the field of interest is narrowed from substance problems in general to treatment for a single substance, such as alcohol, tobacco, or cocaine. Except in carefully monitored research projects, even the definitions of specific procedures (e.g., individual counseling, group therapy, and methadone maintenance) tend to be so imprecise that usually just what transactions are supposed to occur cannot be inferred. Nevertheless, for descriptive purposes, programs are often broadly grouped on the basis of one or more of their salient characteristics: whether the program is aimed at merely controlling acute withdrawal and consequences of recent drug use (detoxification) or is focused on longer-term behavioral change; whether the program makes extensive use of pharmacological interventions; and the degree to which the program is based on individual psychotherapy, Alcoholics Anonymous (AA) or other 12-step principles, or therapeutic community principles. For example, government agencies recently categorized publicly funded treatment programs for drug dependence as (1) methadone maintenance (mostly outpatient), (2) outpatient drug-free programs, (3) therapeutic communities, or (4) short-term inpatient programs.

Selecting a Treatment

Not all interventions are applicable to all types of substance use or dependence, and some of the more coercive interventions used for illicit drugs are not applicable to substances that are legally available, such as tobacco. Addictive behaviors do not change abruptly, but through a series of stages. Five stages in this gradual process have been proposed: precontemplation, contemplation, preparation, action, and maintenance. For some types of addictions the therapeutic alliance is enhanced when the treatment approach is tailored to the patient's stage of readiness to change. Interventions for some drug use disorders may have a specific pharmacological agent as an important component; for example, disulfiram, naltrexone (ReVia), or acamprosate for alcoholism; methadone (Dolophine), levomethadyl acetate (ORLAAM), or buprenorphine (Buprenex) for heroin addiction; and nicotine delivery devices or bupropion (Zyban) for tobacco dependence. Not all interventions are likely to be useful to health care professionals. For example, many youthful offenders with histories of drug use or dependence are now remanded to special facilities (boot camps); other programs for offenders (and sometimes for employees) rely almost exclusively on the deterrent effect of frequent urine testing; and a third group are built around religious conversion or rededication in a specific religious sect or denomination. In contrast to the numerous studies suggesting some value for brief interventions for smoking and for problem drinking, few controlled studies are conducted of brief interventions for those seeking treatment for dependence on illicit drugs.

In general, brief interventions (e.g., a few weeks of detoxification, whether in or out of a hospital) used for persons who are severely dependent on illicit opioids have limited effect on outcome measured a few months later. Substantial reductions in illicit drug use, antisocial behaviors, and psychiatric distress among patients dependent on cocaine or heroin are much more likely following treatment lasting at least 3 months. Such a time-in-treatment effect is seen across very different modalities, from residential therapeutic communities to ambulatory methadone maintenance programs. Although some patients appear to benefit from a few days or weeks of treatment, a substantial percentage of users of illicit drugs drop out (or are dropped) from treatment before they have achieved significant benefits.

Some of the variance in treatment outcomes can be attributed to differences in the characteristics of patients entering treatment and by events and conditions following treatment. Programs based on similar philosophical principles and using what seem to be similar therapeutic procedures vary greatly in effectiveness, however. Some of the differences among programs that seem to be similar reflect the range and intensity of services offered. Programs with professionally trained staffs that provide more comprehensive services to patients with more severe psychiatric difficulties are more likely able to retain those patients in treatment and help them make positive changes. Differences in the skills of individual counselors and professionals can strongly affect outcomes.

Such generalizations concerning programs serving illicit drug users may not hold for programs dealing with those seeking treatment for alcohol, tobacco, or even cannabis problems uncomplicated by heavy use of illicit drugs. In such cases, relatively brief periods of individual or group counseling can produce long-lasting reductions in drug use. The outcomes usually considered in programs dealing with illicit drugs have typically included measures of social functioning, employment, and criminal activity, as well as decreased drug-using behavior.

Treatment of Comorbidity

Treatment of the severely mentally ill (primarily those with schizophrenia and schizoaffective disorders) who are also drug dependent continues to pose problems for clinicians. Although some special facilities have been developed that use both antipsychotic drugs and therapeutic community principles, for the most part, specialized addiction agencies have difficulty treating these patients. Generally, integrated treatment in which the same staff can treat both the psychiatric disorder and the addiction is more effective than either parallel treatment (a mental health and a specialty addiction program providing care concurrently) or sequential treatment (treating either the addiction or the psychiatric disorder first and then dealing with the comorbid condition).

Services and Outcome

The extension of managed care into the public sector has produced a major reduction in the use of hospital-based detoxification and virtual disappearance of residential rehabilitation programs for alcoholics. Managed-care organizations, however, tend to assume that the relatively brief courses of outpatient counseling that are effective with private-sector alcoholic patients are also effective with patients who are

dependent on illicit drugs and who have minimal social supports. For the present, the trend is to provide the care that costs the least over the short term and to ignore studies showing that more services can produce better long-term outcomes.

Treatment is often a worthwhile social expenditure. For example, treatment of antisocial illicit drug users in outpatient settings can decrease antisocial behavior and reduce rates of human immunodeficiency virus (HIV) seroconversion that more than offset the treatment cost. Treatment in a prison setting can decrease post-release costs associated with drug use and rearrests. Despite such evidence, problems exist in maintaining public support for treatment of substance dependence in both the public and private sectors. This lack of support suggests that these problems continue to be viewed, at least in part, as moral failings rather than as medical disorders.

20.2 Alcohol-Related Disorders

Alcoholism is among the most common psychiatric disorders observed in the Western world. Alcohol-related problems in the United States contribute to 2 million injuries each year, including 22,000 deaths. Recent years have witnessed a blossoming of clinically relevant research regarding alcohol abuse and dependence, including information on specific genetic influences, the clinical course of these conditions, and the development of new and helpful treatments.

Alcohol is a potent drug that causes both acute and chronic changes in almost all neurochemical systems. Thus alcohol abuse can produce serious temporary psychological symptoms including depression, anxiety, and psychoses. Long-term, escalating levels of alcohol consumption can produce tolerance as well as such intense adaptation of the body that cessation of use can precipitate a withdrawal syndrome usually marked by insomnia, evidence of hyperactivity of the autonomic nervous system, and feelings of anxiety. Therefore, in an adequate evaluation of life problems and psychiatric symptoms in a patient, the clinician must consider the possibility that the clinical situation reflects the effects of alcohol.

EPIDEMIOLOGY

Psychiatrists need to be concerned about alcoholism because this condition is common; intoxication and withdrawal mimic many major psychiatric disorders, and the usual person with alcoholism does not fit the stereotype (i.e., so called “nasty knock-down drinkers”).

Prevalence of Drinking

At some time during life, 90 percent of the population in the United States drinks, with most people beginning their alcohol intake in the early to middle teens (Table 20.2-1). By the end of high school, 80 percent of students have consumed alcohol, and more than 60 percent have been intoxicated. At any time, two of three men are drinkers, with a ratio of persisting alcohol intake of approximately 1.3 men to 1.0 women, and the highest prevalence of drinking from the middle or late teens to the mid-20s.

**Table 20.2-1
Alcohol Epidemiology**

Condition	Population (%)
Ever had a drink	90
Current drinker	60–70
Temporary problems	40+
Abuse ^a	Male: 10+ Female: 5+
Dependence ^a	Male: 10 Female: 3–5

^aTwenty percent to 30 percent of psychiatric patients.

Men and women with higher education and income are most likely to imbibe, and, among religious denominations, Jews have the highest proportion who consume alcohol but among the lowest rates of alcohol dependence. Other ethnicities, such as the Irish, have higher rates of severe alcohol problems, but they also have significantly higher rates of abstentions. Some estimates show that more than 60 percent of men and women in some Native American and Inuit tribes have been alcohol dependent at some time. In the United States, the average adult consumes 2.2 gallons of absolute alcohol a year, a decrease from 2.7 gallons per capita in 1981.

Drinking alcohol-containing beverages is generally considered an acceptable habit in the United States. About 90 percent of all US residents have had an alcohol-containing drink at least once in their lives, and about 51 percent of all US adults are current users of alcohol. After heart disease and cancer, alcohol-related disorders constitute the third largest health problem in the United States today. Beer accounts for about one half of all alcohol consumption, liquor for about one third, and wine for about one sixth. About 30 to 45 percent of all adults in the United States have had at least one transient episode of an alcohol-related problem, usually an alcohol-induced amnesic episode (e.g., a blackout), driving a motor vehicle while intoxicated, or missing school or work because of excessive drinking. About 10 percent of women and 20 percent of men have met the diagnostic criteria for alcohol abuse during their lifetimes, and 3 to 5 percent of women and 10 percent of men have met the diagnostic criteria for the more serious diagnosis of alcohol dependence during their lifetimes. About 200,000 deaths each year are directly related to alcohol abuse. The common causes of death among persons with the alcohol-related disorders are

suicide, cancer, heart disease, and hepatic disease. Although persons involved in automotive fatalities do not always meet the diagnostic criteria for an alcohol-related disorder, drunk drivers are involved in about 50 percent of all automotive fatalities, and this percentage increases to about 75 percent when only accidents occurring in the late evening are considered. Alcohol use and alcohol-related disorders are associated with about 50 percent of all homicides and 25 percent of all suicides. Alcohol abuse reduces life expectancy by about 10 years, and alcohol leads all other substances in substance-related deaths. [Table 20.2-2](#) lists other epidemiological data about alcohol use.

 **Table 20.2-2**
Epidemiological Data for Alcohol-Related Disorders

Race and Ethnicity	<ul style="list-style-type: none"> ▶ Whites have the highest rate of alcohol use ▶ Hispanics and blacks have similar rate of binge use, but the rate is lower among blacks than among whites
Gender	<ul style="list-style-type: none"> ▶ Men are much more likely than women to be binge drinkers and heavy drinkers
Region and Urbanicity	<ul style="list-style-type: none"> ▶ Alcohol use is highest in western states and lowest in southern states ▶ North-central and northeast regions are about the same ▶ The rate of past month alcohol use was 56 percent in large metropolitan areas, 52 percent in small metropolitan areas, and 46 percent in nonmetropolitan areas. ▶ Little variation seen in binge and heavy alcohol use rates by population density.
Education	<ul style="list-style-type: none"> ▶ About 70 percent of adults with college degrees are current drinkers, compared with only 40 percent of those with less than a high school education. ▶ Binge alcohol use rates are similar across different levels of education.
Socioeconomic Class	<ul style="list-style-type: none"> ▶ Alcohol-related disorders appear among persons of all socioeconomic classes. ▶ Persons who are stereotypical skid-row alcoholics constitute less than 5 percent of those with alcohol-related disorders.

COMORBIDITY

The psychiatric diagnoses most commonly associated with the alcohol-related disorders are other substance-related disorders, antisocial personality disorder, mood disorders, and anxiety disorders. Although the data are somewhat controversial, most suggest that persons with alcohol-related disorders have a markedly higher suicide rate than the general population.

Antisocial Personality Disorder

A relation between antisocial personality disorder and alcohol-related disorders has frequently been reported. Some studies suggest that antisocial personality disorder is particularly common in men with an alcohol-related disorder and can precede the development of the alcohol-related disorder. Other studies, however, suggest that antisocial personality disorder and alcohol-related disorders are completely distinct entities that are not causally related.

Mood Disorders

About 30 to 40 percent of persons with an alcohol-related disorder meet the diagnostic criteria for major depressive disorder sometime during their lifetimes. Depression is more common in women than in men with these disorders. Several studies reported that depression is likely to occur in patients with alcohol-related disorders who have a high daily consumption of alcohol and a family history of alcohol abuse. Persons with alcohol-related disorders and major depressive disorder are at great risk for attempting suicide and are likely to have other substance-related disorder diagnoses. Some clinicians recommend antidepressant drug therapy for depressive symptoms that remain after 2 to 3 weeks of sobriety. Patients with bipolar I disorder are thought to be at risk for developing an alcohol-related disorder; they may use alcohol to self-medicate their manic episodes. Some studies have shown that persons with both alcohol-related disorder and depressive disorder diagnoses have concentrations of dopamine metabolites (homovanillic acid) and γ -aminobutyric acid (GABA) in their cerebrospinal fluid (CSF).

Anxiety Disorders

Many persons use alcohol for its efficacy in alleviating anxiety. Although the comorbidity between alcohol-related disorders and mood disorders is fairly widely recognized, it is less well known that perhaps 25 to 50 percent of all persons with alcohol-related disorders also meet the diagnostic criteria for an anxiety disorder. Phobias and panic disorder are particularly frequent comorbid diagnoses in these patients. Some data indicate that alcohol may be used in an attempt to self-medicate symptoms of agoraphobia or social phobia, but an alcohol-related disorder is likely to precede the development of panic disorder or generalized anxiety disorder.

Suicide

Most estimates of the prevalence of suicide among persons with alcohol-related disorders range from 10 to 15 percent, although alcohol use itself may be involved in a much higher percentage of suicides. Some investigators have questioned whether the suicide rate among persons with alcohol-related disorders is as high as the numbers suggest. Factors that have been associated with suicide among persons with alcohol-related disorders include the presence of a major depressive episode, weak psychosocial support systems, a serious coexisting medical condition, unemployment, and living alone.

ETIOLOGY

Many factors affect the decision to drink, the development of temporary alcohol-related difficulties in the teenage years and the 20s, and the development of alcohol dependence. The initiation of alcohol intake probably depends largely on social, religious, and psychological factors, although genetic characteristics might also contribute. The factors that influence the decision to drink or those that contribute to temporary problems might differ, however, from those that add to the risk for the severe, recurring problems of alcohol dependence.

A similar interplay between genetic and environmental influences contributes to many medical and psychiatric conditions, and, thus, a review of these factors in alcoholism offers information about complex genetic disorders overall. Dominant or recessive genes, although important, explain only relatively rare conditions. Most disorders have some level of genetic predisposition that usually relates to a series of different genetically influenced characteristics, each of which increases or decreases the risk for the disorder.

It is likely that a series of genetic influences combine to explain approximately 60 percent of the proportion of risk for alcoholism, with environment responsible for the remaining proportion of the variance. The divisions offered in this section, therefore, are more heuristic than real, because it is the combination of a series of psychological, sociocultural, biological, and other factors that are responsible for the

development of severe, repetitive alcohol-related life problems.

Psychological Theories

A variety of theories relate to the use of alcohol to reduce tension, increase feelings of power, and decrease the effects of psychological pain. Perhaps the greatest interest has been paid to the observation that people with alcohol-related problems often report that alcohol decreases their feelings of nervousness and helps them cope with the day-to-day stresses of life. The psychological theories are built, in part, on the observation among nonalcoholic people that the intake of low doses of alcohol in a tense social setting or after a difficult day can be associated with an enhanced feeling of well-being and an improved ease of interactions. In high doses, especially at falling blood alcohol levels, however, most measures of muscle tension and psychological feelings of nervousness and tension are increased. Thus, tension-reducing effects of this drug might have an impact most on light to moderate drinkers or add to the relief of withdrawal symptoms, but play a minor role in causing alcoholism. The theories that focus on alcohol's potential to enhance feelings of being powerful and sexually attractive and to decrease the effects of psychological pain are difficult to evaluate definitively.

Psychodynamic Theories

Perhaps related to the disinhibiting or anxiety-lowering effects of lower doses of alcohol is the hypothesis that some people may use this drug to help them deal with self-punitive harsh superegos and to decrease unconscious stress levels. In addition, classic psychoanalytical theory hypothesizes that at least some alcoholic people may have become fixated at the oral stage of development and use alcohol to relieve their frustrations by taking the substance by mouth. Hypotheses regarding arrested phases of psychosexual development, although heuristically useful, have had little effect on the usual treatment approaches and are not the focus of extensive ongoing research. Similarly, most studies have not been able to document an "addictive personality" present in most alcoholics and associated with a propensity to lack control of intake of a wide range of substances and foods. Although pathological scores on personality tests are often seen during intoxication, withdrawal, and early recovery, many of these characteristics are not found to predate alcoholism, and most disappear with abstinence. Similarly, prospective studies of children of alcoholics who themselves have no co-occurring disorders usually document high risks mostly for alcoholism. As is described later in this text, one partial exception occurs with the extreme levels of impulsivity seen in the 15 to 20 percent of alcoholic men with antisocial personality disorder, because they have high risks for criminality, violence, and multiple substance dependencies.

Behavioral Theories

Expectations about the rewarding effects of drinking, cognitive attitudes toward responsibility for one's behavior, and subsequent reinforcement after alcohol intake all contribute to the decision to drink again after the first experience with alcohol and to continue to imbibe despite problems. These issues are important in efforts to modify drinking behaviors in the general population, and they contribute to some important aspects of alcoholic rehabilitation.

Sociocultural Theories

Sociocultural theories are often based on extrapolations from social groups that have high and low rates of alcoholism. Theorists hypothesize that ethnic groups, such as Jews, who introduce children to modest levels of drinking in a family atmosphere and eschew drunkenness have low rates of alcoholism. Some other groups, such as Irish men or some American Indian tribes with high rates of abstinence but a tradition of drinking to the point of drunkenness among drinkers, are believed to have high rates of alcoholism. These theories, however, often depend on stereotypes that tend to be erroneous, and prominent exceptions to these rules exist. For example, some theories based on observations of the Irish and the French have incorrectly predicted high rates of alcoholism among the Italians.

Yet, environmental events, presumably including cultural factors, account for as much as 40 percent of the alcoholism risk. Thus, although these are difficult to study, it is likely that cultural attitudes toward drinking, drunkenness, and personal responsibility for consequences are important contributors to the rates of alcohol-related problems in a society. In the final analysis, social and psychological theories are probably highly relevant, because they outline factors that contribute to the onset of drinking, the development of temporary alcohol-related life difficulties, and even alcoholism. The problem is how to gather relatively definitive data to support or refute the theories.

Childhood History

Researchers have identified several factors in the childhood histories of persons with later alcohol-related disorders and in children at high risk for having an alcohol-related disorder because one or both of their parents are affected. In experimental studies, children at high risk for alcohol-related disorders have been found to possess, on average, a range of deficits on neurocognitive testing, low amplitude of the P300 wave on evoked potential testing, and a variety of abnormalities on electroencephalography (EEG) recordings. Studies of high-risk offspring in their 20s have also shown a generally blunted effect of alcohol compared with that seen in persons whose parents have not been diagnosed with alcohol-related disorder. These findings suggest that a heritable biological brain function may predispose a person to an alcohol-related disorder. A childhood history of attention-deficit/hyperactivity disorder (ADHD), conduct disorder, or both, increases a child's risk for an alcohol-related disorder as an adult. Personality disorders, especially antisocial personality disorder, as noted earlier, also predispose a person to an alcohol-related disorder.

Genetic Theories

Importance of Genetic Influences. Four lines of evidence support the conclusion that alcoholism is genetically influenced. First, a threefold to fourfold increased risk for severe alcohol problems is seen in close relatives of alcoholic people. The rate of alcohol problems increases with the number of alcoholic relatives, the severity of their illness, and the closeness of their genetic relationship to the person under study. The family investigations do little to separate the importance of genetics and environment, and the second approach, twin studies, takes the data a step further. The rate of similarity, or concordance, for severe alcohol-related problems is significantly higher in identical twins of alcoholic individuals than in fraternal twins in most investigations, which estimate that genes explain 60 percent of the variance, with the remainder relating to nonshared, probably adult environmental influences. Third, the adoption-type studies have all revealed a significantly enhanced risk for alcoholism in the offspring of alcoholic parents, even when the children had been separated from their biological parents close to birth and raised without any knowledge of the problems within the biological family. The risk for severe alcohol-related difficulties is not further enhanced by being raised by an alcoholic adoptive family. Finally, studies in animals support the importance of a variety of yet-to-be-identified genes in the free-choice use of alcohol, subsequent levels of intoxication, and some consequences.

EFFECTS OF ALCOHOL

The term *alcohol* refers to a large group of organic molecules that have a hydroxyl group (-OH) attached to a saturated carbon atom. Ethyl alcohol, also called *ethanol*, is the common form of alcohol; sometimes referred to as *beverage alcohol*, ethyl alcohol is used for drinking. The chemical formula for ethanol is CH₃-CH₂-OH.

The characteristic tastes and flavors of alcohol-containing beverages result from their methods of production, which produce various congeners in the final product, including methanol, butanol, aldehydes, phenols, tannins, and trace amounts of various metals. Although the congeners may confer some differential psychoactive effects on the various alcohol-containing beverages, these differences are minimal compared with the effects of ethanol itself. A single drink is usually considered to contain about 12 g of ethanol, which is the content of 12 ounces of beer (7.2 proof, 3.6 percent ethanol in the United States), one 4-ounce glass of nonfortified wine, or 1 to 1.5 ounces of an 80-proof (40 percent ethanol) liquor (e.g., whiskey or gin). In calculating patients' alcohol intake, however, clinicians should be aware that beers vary in their alcohol content, that beers are available in

small and large cans and mugs, that glasses of wine range from 2 to 6 ounces, and that mixed drinks at some bars and in most homes contain 2 to 3 ounces of liquor. Nonetheless, using the moderate sizes of drinks, clinicians can estimate that a single drink increases the blood alcohol level of a 150-pound man by 15 to 20 mg/dL, which is about the concentration of alcohol that an average person can metabolize in 1 hour.

The possible beneficial effects of alcohol have been publicized, especially by the makers and the distributors of alcohol. Most attention has been focused on some epidemiological data that suggest that one or two glasses of red wine each day lower the incidence of cardiovascular disease; these findings, however, are highly controversial.

Absorption

About 10 percent of consumed alcohol is absorbed from the stomach, and the remainder from the small intestine. Peak blood concentration of alcohol is reached in 30 to 90 minutes and usually in 45 to 60 minutes, depending on whether the alcohol was ingested on an empty stomach (which enhances absorption) or with food (which delays absorption). The time to peak blood concentration also depends on the time during which the alcohol was consumed; rapid drinking reduces the time to peak concentration, slower drinking increases it. Absorption is most rapid with beverages containing 15 to 30 percent alcohol (30 to 60 proof). There is some dispute about whether carbonation (e.g., in champagne and in drinks mixed with seltzer) enhances the absorption of alcohol.

The body has protective devices against inundation by alcohol. For example, if the concentration of alcohol in the stomach becomes too high, mucus is secreted and the pyloric valve closes. These actions slow the absorption and keep the alcohol from passing into the small intestine, where there are no significant restraints on absorption. Thus, a large amount of alcohol can remain unabsorbed in the stomach for hours. Furthermore, pylorospasm often results in nausea and vomiting.

Once alcohol is absorbed into the bloodstream, it is distributed to all body tissues. Because alcohol is uniformly dissolved in the body's water, tissues containing a high proportion of water receive a high concentration of alcohol. The intoxicating effects are greater when the blood alcohol concentration is rising than when it is falling (the Mellanby effects). For this reason, the rate of absorption bears directly on the intoxication response.

Metabolism

About 90 percent of absorbed alcohol is metabolized through oxidation in the liver; the remaining 10 percent is excreted unchanged by the kidneys and lungs. The rate of oxidation by the liver is constant and independent of the body's energy requirements. The body can metabolize about 15 mg/dL per hour, with a range of 10 to 34 mg/dL per hour. That is, the average person oxidizes three fourths of an ounce of 40 percent (80 proof) alcohol in an hour. In persons with a history of excessive alcohol consumption, upregulation of the necessary enzymes results in rapid alcohol metabolism.

Alcohol is metabolized by two enzymes: alcohol dehydrogenase (ADH) and aldehyde dehydrogenase. ADH catalyzes the conversion of alcohol into acetaldehyde, which is a toxic compound; aldehyde dehydrogenase catalyzes the conversion of acetaldehyde into acetic acid. Aldehyde dehydrogenase is inhibited by disulfiram (Antabuse), often used in the treatment of alcohol-related disorders. Some studies have shown that women have a lower ADH blood content than men; this fact may account for woman's tendency to become more intoxicated than men after drinking the same amount of alcohol. The decreased function of alcohol-metabolizing enzymes in some Asian persons can also lead to easy intoxication and toxic symptoms.

Effects on the Brain

Biochemistry. In contrast to most other substances of abuse with identified receptor targets—such as the *N*-methyl-D-aspartate (NMDA) receptor of phencyclidine (PCP)—no single molecular target has been identified as the mediator for the effects of alcohol. The longstanding theory about the biochemical effects of alcohol concerns its effects on the membranes of neurons. Data support the hypothesis that alcohol produces its effects by intercalating itself into membranes and, thus, increasing fluidity of the membranes with short-term use. With long-term use, however, the theory hypothesizes that the membranes become rigid or stiff. The fluidity of the membranes is critical to normal functioning of receptors, ion channels, and other membrane-bound functional proteins. In recent studies, researchers have attempted to identify specific molecular targets for the effects of alcohol. Most attention has been focused on the effects of alcohol at ion channels. Specifically, studies have found that alcohol ion channel activities associated with the nicotinic acetylcholine, serotonin 5-hydroxytryptamine₃ (5-HT₃), and GABA type A (GABA_A) receptors are enhanced by alcohol, whereas ion channel activities associated with glutamate receptors and voltage-gated calcium channels are inhibited.

Behavioral Effects. As the net result of the molecular activities, alcohol functions as a depressant much like the barbiturates and the benzodiazepines, with which alcohol has some cross-tolerance and cross-dependence. At a level of 0.05 percent alcohol in the blood, thought, judgment, and restraint are loosened and sometimes disrupted. At a concentration of 0.1 percent, voluntary motor actions usually become perceptibly clumsy. In most states, legal intoxication ranges from 0.1 to 0.15 percent blood alcohol level. At 0.2 percent, the function of the entire motor area of the brain is measurably depressed, and the parts of the brain that control emotional behavior are also affected. At 0.3 percent, a person is commonly confused or may become stuporous; at 0.4 to 0.5 percent, the person falls into a coma. At higher levels, the primitive centers of the brain that control breathing and heart rate are affected, and death ensues secondary to direct respiratory depression or the aspiration of vomitus. Persons with long-term histories of alcohol abuse, however, can tolerate much higher concentrations of alcohol than can alcohol-naïve persons; their alcohol tolerance may cause them to falsely appear less intoxicated than they really are.

Sleep Effects. Although alcohol consumed in the evening usually increases the ease of falling asleep (decreased sleep latency), alcohol also has adverse effects on sleep architecture. Specifically, alcohol use is associated with a decrease in rapid eye movement sleep (REM or dream sleep) and deep sleep (stage 4) and more sleep fragmentation, with more and longer episodes of awakening. Therefore, the idea that drinking alcohol helps persons fall asleep is a myth.

Other Physiological Effects

Liver. The major adverse effects of alcohol use are related to liver damage. Alcohol use, even as short as week-long episodes of increased drinking, can result in an accumulation of fats and proteins, which produce the appearance of a fatty liver, sometimes found on physical examination as an enlarged liver. The association between fatty infiltration of the liver and serious liver damage remains unclear. Alcohol use, however, is associated with the development of alcoholic hepatitis and hepatic cirrhosis.

Gastrointestinal System. Long-term heavy drinking is associated with developing esophagitis, gastritis, achlorhydria, and gastric ulcers. The development of esophageal varices can accompany particularly heavy alcohol abuse; the rupture of the varices is a medical emergency often resulting in death by exsanguination. Disorders of the small intestine occasionally occur, and pancreatitis, pancreatic insufficiency, and pancreatic cancer are also associated with heavy alcohol use. Heavy alcohol intake can interfere with the normal processes of food digestion and absorption; as a result, consumed food is inadequately digested. Alcohol abuse also appears to inhibit the intestine's capacity to absorb various nutrients, such as vitamins and amino acids. This effect, coupled with the often poor dietary habits of those with alcohol-related disorders, can cause serious vitamin deficiencies, particularly of the B vitamins.

Other Bodily Systems. Significant intake of alcohol has been associated with increased blood pressure, dysregulation of lipoprotein and triglyceride metabolism, and increased risk for myocardial infarction and cerebrovascular disease. Alcohol has been shown to affect the hearts of nonalcoholic persons who do not usually drink, increasing the resting cardiac output, the heart rate, and the myocardial oxygen

consumption. Evidence indicates that alcohol intake can adversely affect the hematopoietic system and can increase the incidence of cancer, particularly head, neck, esophageal, stomach, hepatic, colonic, and lung cancer. Acute intoxication may also be associated with hypoglycemia, which, when unrecognized, may be responsible for some of the sudden deaths of persons who are intoxicated. Muscle weakness is another side effect of alcoholism. Recent evidence shows that alcohol intake raises the blood concentration of estradiol in women. The increase in estradiol correlates with the blood alcohol level.

Laboratory Tests. The adverse effects of alcohol appear in common laboratory tests, which can be useful diagnostic aids in identifying persons with alcohol-related disorders. The γ -glutamyl transpeptidase levels are high in about 80 percent of those with alcohol-related disorders, and the mean corpuscular volume (MCV) is high in about 60 percent, more so in women than in men. Other laboratory test values that may be high in association with alcohol abuse are those of uric acid, triglycerides, aspartate aminotransferase (AST), and alanine aminotransferase (ALT).

Drug Interactions

The interaction between alcohol and other substances can be dangerous, even fatal. Certain substances, such as alcohol and phenobarbital (Luminal), are metabolized by the liver, and their prolonged use can lead to acceleration of their metabolism. When persons with alcohol-related disorders are sober, this accelerated metabolism makes them unusually tolerant to many drugs such as sedatives and hypnotics; when they are intoxicated, however, these drugs compete with the alcohol for the same detoxification mechanisms, and potentially toxic concentrations of all involved substances can accumulate in the blood.

The effects of alcohol and other central nervous system (CNS) depressants are usually synergistic. Sedatives, hypnotics, and drugs that relieve pain, motion sickness, head colds, and allergy symptoms must be used with caution by persons with alcohol-related disorders. Narcotics depress the sensory areas of the cerebral cortex and can produce pain relief, sedation, apathy, drowsiness, and sleep; high doses can result in respiratory failure and death. Increasing the dosages of sedative-hypnotic drugs, such as chloral hydrate (Noctec) and benzodiazepines, especially when they are combined with alcohol, produces a range of effects from sedation to motor and intellectual impairment to stupor, coma, and death. Because sedatives and other psychotropic drugs can potentiate the effects of alcohol, patients should be instructed about the dangers of combining CNS depressants and alcohol, particularly when they are driving or operating machinery.

DISORDERS

Alcohol Use Disorder

Diagnosis and Clinical Features. In the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), all substance use disorders use the same general criteria for dependence and abuse (see [Section 20.1](#)). A need for daily use of large amounts of alcohol for adequate functioning, a regular pattern of heavy drinking limited to weekends, and long periods of sobriety interspersed with binges of heavy alcohol intake lasting for weeks or months strongly suggest alcohol dependence and alcohol abuse. The drinking patterns are often associated with certain behaviors: the inability to cut down or stop drinking; repeated efforts to control or reduce excessive drinking by “going on the wagon” (periods of temporary abstinence) or by restricting drinking to certain times of the day; binges (remaining intoxicated throughout the day for at least 2 days); occasional consumption of a fifth of spirits (or its equivalent in wine or beer); amnesic periods for events occurring while intoxicated (blackouts); the continuation of drinking despite a serious physical disorder that the person knows is exacerbated by alcohol use; and drinking nonbeverage alcohol, such as fuel and commercial products containing alcohol. In addition, persons with alcohol dependence and alcohol abuse show impaired social or occupational functioning because of alcohol use (e.g., violence while intoxicated, absence from work, job loss), legal difficulties (e.g., arrest for intoxicated behavior and traffic accidents while intoxicated), and arguments or difficulties with family members or friends about excessive alcohol consumption.

Mark, a 45-year-old divorced man, was examined in a hospital emergency room because he had been confused and unable to care for himself of the preceding 3 days. His brother, who brought him to the hospital, reported that the patient has consumed large quantities of beer and wine daily for more than 5 years. His home and job lives were reasonably stable until his divorce 5 years prior. The brother indicated that Mark's drinking pattern since the divorce has been approximately 5 beers and a fourth of wine a day. Mark often experienced blackouts from drinking and missed days of work frequently. As a result, Mark has lost several jobs in the past 5 years. Although he usually provides for himself marginally with small jobs, 3 days earlier he ran out of money and alcohol and resorted to panhandling on the streets for cash to buy food. Mark had been poorly nourished, having one meal per day at best and was evidently relying on beer as his prime source of nourishment.

On examination, Mark alternates between apprehension and chatty, superficial warmth. He is pretty keyed up and talks constantly in a rambling and unfocused manner. His recognition of the physician varies; at times he recognizes him and other times he becomes confused and believes the doctor to be his other brother who lives in another state. On two occasions he referred to the physician by said brother's name and asked when he arrived in town, evidently having lost track of the interview up to that point. He has a gross hand tremor at rest and is disoriented to time. He believes he's in a parking lot rather than a hospital. Efforts at memory and calculation testing fail because Mark's attention shifts so rapidly.

Subtypes of Alcohol Dependence. Various researchers have attempted to divide alcohol dependence into subtypes based primarily on phenomenological characteristics. One recent classification notes that type A alcohol dependence is characterized by late onset, few childhood risk factors, relatively mild dependence, few alcohol-related problems, and little psychopathology. Type B alcohol dependence is characterized by many childhood risk factors, severe dependence, an early onset of alcohol-related problems, much psychopathology, a strong family history of alcohol abuse, frequent polysubstance abuse, a long history of alcohol treatment, and a lot of severe life stresses. Some researchers have found that type A persons who are alcohol dependent may respond to interactional psychotherapies, whereas type B persons who are alcohol dependent may respond to training in coping skills.

Other subtyping schemes of alcohol dependence have received fairly wide recognition in the literature. One group of investigators proposed three subtypes: earlystage problem drinkers, who do not yet have complete alcohol dependence syndromes; affiliative drinkers, who tend to drink daily in moderate amounts in social settings; and schizoid-isolated drinkers, who have severe dependence and tend to drink in binges and often alone.

Another investigator described gamma alcohol dependence, which is thought to be common in the United States and represents the alcohol dependence seen in those who are active in Alcoholics Anonymous (AA). This variant concerns control problems in which persons are unable to stop drinking once they start. When drinking is terminated as a result of ill health or lack of money, these persons can abstain for varying periods. In delta alcohol dependence, perhaps more common in Europe than in the United States, persons who are alcohol dependent must drink a certain amount each day but are unaware of a lack of control. The alcohol use disorder may not be discovered until a person who must stop drinking for some reason exhibits withdrawal symptoms.

Another researcher has suggested a *type I, male-limited* variety of alcohol dependence, characterized by late onset, more evidence of psychological than of physical dependence, and the presence of guilt feelings. *Type II, male-limited* alcohol dependence is characterized by

onset at an early age, spontaneous seeking of alcohol for consumption, and a socially disruptive set of behaviors when intoxicated.

Four subtypes of alcoholism were postulated by still another investigator. The first is *antisocial alcoholism*, typically with a predominance in men, a poor prognosis, early onset of alcohol-related problems, and a close association with antisocial personality disorder. The second is *developmentally cumulative alcoholism*, with a primary tendency for alcohol abuse that is exacerbated with time as cultural expectations foster increased opportunities to drink. The third is *negative-affect alcoholism*, which is more common in women than in men; according to this hypothesis, women are likely to use alcohol for mood regulation and to help ease social relationships. The fourth is *developmentally limited alcoholism*, with frequent bouts of consuming large amounts of alcohol; the bouts become less frequent as persons age and respond to the increased expectations of society about their jobs and families.

Alcohol Intoxication

The DSM-5 diagnostic criteria for alcohol intoxication (also called simple drunkenness) are based on evidence of recent ingestion of ethanol, maladaptive behavior, and at least one of several possible physiological correlates of intoxication (Table 20.2-3). As a conservative approach to identifying blood levels that are likely to have major effects on driving abilities, the legal definition of intoxication in most states in the United States requires a blood concentration of 80 or 100 mg ethanol per deciliter of blood (mg/dL), which is the same as 0.08 to 0.10 g/dL. The following is an outline of the rough estimates of the levels of impairment likely to be seen at various blood alcohol concentrations, for most people. Evidence of behavioral changes, a slowing in motor performance, and a decrease in the ability to think clearly occurs at doses as low as 20 to 30 mg/dL, as shown in Table 20.2-4. Blood concentrations between 100 and 200 mg/dL are likely to increase the impairment in coordination and judgment to severe problems with coordination (ataxia), increasing lability of mood, and progressively greater levels of cognitive deterioration. Anyone who does not show significant levels of impairment in motor and mental performance at approximately 150 mg/dL probably has significant pharmacodynamic tolerance. In that range, most people without significant tolerance also experience relatively severe nausea and vomiting. With blood alcohol concentrations in the 200 to 300 mg/dL range, the slurring of speech is likely to become more intense, and memory impairment (*anterograde amnesia* or *alcoholic blackouts*) becomes pronounced. Further increases in blood alcohol concentration result in the first level of anesthesia, and the nontolerant person who reaches 400 mg/dL or more risks respiratory failure, coma, and death.

 **Table 20.2-3**
Signs of Alcohol Intoxication

1. Slurred speech
2. Dizziness
3. Incoordination
4. Unsteady gait
5. Nystagmus
6. Impairment in attention or memory
7. Stupor or coma
8. Double vision

 **Table 20.2-4**
Impairment Likely to be Seen at Different Blood Alcohol Concentrations

Level	Likely Impairment
20–30 mg/dL	Slowed motor performance and decreased thinking ability
30–80 mg/dL	Increases in motor and cognitive problems
80–200 mg/dL	Increases in incoordination and judgment errors Mood lability Deterioration in cognition
200–300 mg/dL	Nystagmus, marked slurring of speech, and alcoholic blackouts
>300 mg/dL	Impaired vital signs and possible death

Alcohol Withdrawal

Alcohol withdrawal, even without delirium, can be serious; it can include seizures and autonomic hyperactivity. Conditions that may predispose to, or aggravate, withdrawal symptoms include fatigue, malnutrition, physical illness, and depression. The DSM-5 criteria for alcohol withdrawal require the cessation or reduction of alcohol use that was heavy and prolonged as well as the presence of specific physical or neuropsychiatric symptoms. The diagnosis also allows for the specification “with perceptual disturbances.” One positron emission tomography (PET) study of blood flow during alcohol withdrawal in otherwise healthy persons with alcohol dependence reported a globally low rate of metabolic activity, although, with further inspection of the data, the authors concluded that activity was especially low in the left parietal and right frontal areas.

The classic sign of alcohol withdrawal is tremulousness, although the spectrum of symptoms can expand to include psychotic and perceptual symptoms (e.g., delusions and hallucinations), seizures, and the symptoms of delirium tremens (DTs), called alcohol delirium in DSM-5. Tremulousness (commonly called the “shakes” or the “jitters”) develops 6 to 8 hours after the cessation of drinking, the psychotic and perceptual symptoms begin in 8 to 12 hours, seizures in 12 to 24 hours, and DTs anytime during the first 72 hours, although physicians should watch for the development of DTs for the first week of withdrawal. The syndrome of withdrawal sometimes skips the usual progression and, for example, goes directly to DTs.

The tremor of alcohol withdrawal can be similar to either physiological tremor, with a continuous tremor of great amplitude and of more than 8 Hz, or familial tremor, with bursts of tremor activity slower than 8 Hz. Other symptoms of withdrawal include general irritability, gastrointestinal symptoms (e.g., nausea and vomiting), and sympathetic autonomic hyperactivity, including anxiety, arousal, sweating, facial flushing, mydriasis, tachycardia, and mild hypertension. Patients experiencing alcohol withdrawal are generally alert but may startle easily.

Twenty-nine-year-old Mr. F had been a heavy drinker for 8 years. One evening after work, he started drinking with friends and drank throughout the evening. He fell asleep in the early morning hours and upon awakening had a strong desire to drink and decided not to attend work. He had several Bloody Marys instead of food because food did not appeal to him. He went to a local bar in the afternoon and consumed large quantities of beer. That evening he met with some friends and continued to drink.

This drinking pattern continued for the next week. The beginning of the following week he attempted to have a cup of coffee and found that his hands were shaking so much that he could not get the cup to his mouth to drink. He eventually managed to pour himself some wine in a glass and drank as much as he could. His hands then became less shaky, but he now felt nauseous and began having dry heaves. He tried to drink repeatedly but he could not keep the alcohol down. He felt very ill and anxious so he contacted his physician who recommended he report to a hospital.

Upon evaluation, Mr. F was alert. He had a marked resting and intention tremor of the hands, and his tongue and eyelids were tremulous. He was oriented and had no memory impairment. When inquired about his drinking, Mr. F admits to drinking several drinks each day for the past 8 years, but claims that his drinking never interfered with his work or his relations with colleagues or friends. He denies having any aftereffects from his drinking other than mild hangovers. He denies ever having a binge such as this before and denies ever needing to drink daily in order to function adequately. He admits, however, that he has never tried to reduce or stop drinking.

Withdrawal Seizures. Seizures associated with alcohol withdrawal are stereotyped, generalized, and tonic-clonic in character. Patients often have more than one seizure 3 to 6 hours after the first seizure. Status epilepticus is relatively rare and occurs in less than 3 percent of patients. Although anticonvulsant medications are not required in the management of alcohol withdrawal seizures, the cause of the seizures is difficult to establish when a patient is first assessed in the emergency room; thus, many patients with withdrawal seizures receive anticonvulsant medications, which are then discontinued once the cause of the seizures is recognized. Seizure activity in patients with known alcohol abuse histories should still prompt clinicians to consider other causative factors, such as head injuries, CNS infections, CNS neoplasms, and other cerebrovascular diseases; long-term severe alcohol abuse can result in hypoglycemia, hyponatremia, and hypomagnesemia—all of which can also be associated with seizures.

Treatment. The primary medications to control alcohol withdrawal symptoms are the benzodiazepines (Table 20.2-5). Many studies have found that benzodiazepines help control seizure activity, delirium, anxiety, tachycardia, hypertension, diaphoresis, and tremor associated with alcohol withdrawal. Benzodiazepines can be given either orally or parenterally; neither diazepam (Valium) nor chlordiazepoxide (Librium), however, should be given intramuscularly (IM) because of their erratic absorption by this route. Clinicians must titrate the dosage of the benzodiazepine, starting with a high dosage and lowering the dosage as the patient recovers. Sufficient benzodiazepines should be given to keep patients calm and sedated but not so sedated that they cannot be aroused for clinicians to perform appropriate procedures, including neurological examinations.

Table 20.2-5
Drug Therapy for Alcohol Intoxication and Withdrawal

Clinical Problem	Drug	Route	Dosage	Comment
Tremulousness and mild to moderate agitation	Chlordiazepoxide	Oral	25–100 mg every 4–6 hrs	Initial dose can be repeated every 2 hrs until patient is calm; subsequent doses must be individualized and titrated
	Diazepam	Oral	5–20 mg every 4–6 hrs	
Hallucinosi	Lorazepam	Oral	2–10 mg every 4–6 hrs	Give until patient is calm; subsequent doses must be individualized and titrated
Extreme agitation	Chlordiazepoxide	Intravenous	0.5 mg/kg at 12.5 mg/min	
Withdrawal seizures	Diazepam	Intravenous	0.15 mg/kg at 2.5 mg/min	
Delirium tremens	Lorazepam	Intravenous	0.1 mg/kg at 2.0 mg/min	

(Adapted from Koch-Weser J, Sellers EM, Kalant J. Alcohol intoxication and withdrawal. *N Engl J Med.* 1976;294:757.)

Although benzodiazepines are the standard treatment for alcohol withdrawal, studies have shown that carbamazepine (Tegretol) in daily doses of 800 mg is as effective as benzodiazepines and has the added benefit of minimal abuse liability. Carbamazepine use is gradually becoming common in the United States and Europe. The β -adrenergic receptor antagonists and clonidine (Catapres) have also been used to block the symptoms of sympathetic hyperactivity, but neither drug is an effective treatment for seizures or delirium.

Delirium

Diagnosis and Clinical Features. Patients with recognized alcohol withdrawal symptoms should be carefully monitored to prevent progression to alcohol withdrawal delirium, the most severe form of the withdrawal syndrome, also known as DTs. Alcohol withdrawal delirium is a medical emergency that can result in significant morbidity and mortality. Patients with delirium are a danger to themselves and to others. Because of the unpredictability of their behavior, patients with delirium may be assaultive or suicidal or may act on hallucinations or delusional thoughts as if they were genuine dangers. Untreated, DTs has a mortality rate of 20 percent, usually as a result of an intercurrent medical illness such as pneumonia, renal disease, hepatic insufficiency, or heart failure. Although withdrawal seizures commonly precede the development of alcohol withdrawal delirium, delirium can also appear unheralded. The essential feature of the syndrome is delirium occurring within 1 week after a person stops drinking or reduces the intake of alcohol. In addition to the symptoms of delirium, the features of alcohol intoxication delirium include autonomic hyperactivity such as tachycardia, diaphoresis, fever, anxiety, insomnia, and hypertension; perceptual distortions, most frequently visual or tactile hallucinations; and fluctuating levels of psychomotor activity, ranging from hyperexcitability to lethargy.

About 5 percent of persons with alcohol-related disorders who are hospitalized have DTs. Because the syndrome usually develops on the third hospital day, a patient admitted for an unrelated condition may unexpectedly have an episode of delirium, the first sign of a previously undiagnosed alcohol-related disorder. Episodes of DTs usually begin in a patient's 30s or 40s after 5 to 15 years of heavy drinking, typically of the binge type. Physical illness (e.g., hepatitis or pancreatitis) predisposes to the syndrome; a person in good physical health rarely has DTs during alcohol withdrawal.

Mr. R, a 40-year-old man, was admitted to the orthopedic department of a general hospital after experiencing a fall down stairs and breaking his leg. On the third day of his hospital stay, he became increasingly nervous and started to tremble. He was unable to sleep at night, talked incoherently, and was obviously very anxious. Mr. R, when asked, denied an alcohol problem other than an occasional glass of wine.

When asked directly, his wife admitted that Mr. R drank large quantities of wine for over 4 years. During the previous year, his drinking would begin every evening when he came home from work and would not end until he fell asleep. On the evening of admittance, the fall occurred before he was able to consume any alcohol.

During the few weeks prior to his admittance, Mr. R had eaten very little. On several occasions, Mrs. R noticed that Mr. R was unable to recall even important events from the previous day. He had a car accident 3 years prior but without major injury. Mr. R had no other major health problems. His relationship with Mrs. R became very difficult after he began drinking and Mrs. R was seriously contemplating divorce. Mr. R had a tense relationship with his four children and he often argued with them. Recently, the children tried to avoid Mr. R as much as possible.

On examination, Mr. R's speech was rambling and incoherent. He believed that he was still at work and that he had a job to finish. At times he thought the physicians and nurses were his co-workers. At times he picked at bugs that he could see on his bed sheets. He was disoriented in time and was startled easily by sounds from outside the room. He sweat profusely and could not hold a glass without spilling some of the contents.

Treatment. The best treatment for DTs is prevention. Patients withdrawing from alcohol who exhibit withdrawal phenomena should receive a benzodiazepine, such as 25 to 50 mg of chlordiazepoxide every 2 to 4 hours until they seem to be out of danger. Once the delirium appears, however, 50 to 100 mg of chlordiazepoxide should be given every 4 hours orally, or lorazepam (Ativan) should be given intravenously (IV) if oral medication is not possible (Table 20.2-5). Antipsychotic medications that may reduce the seizure threshold in patients should be avoided. A high-calorie, high-carbohydrate diet supplemented by multivitamins is also important.

Physically restraining patients with the DTs is risky; they may fight against the restraints to a dangerous level of exhaustion. When patients are disorderly and uncontrollable, a seclusion room can be used. Dehydration, often exacerbated by diaphoresis and fever, can be corrected with fluids given by mouth or IV. Anorexia, vomiting, and diarrhea often occur during withdrawal. Antipsychotic medications should be avoided because they can reduce the seizure threshold in the patient. The emergence of focal neurological symptoms, lateralizing seizures, increased intracranial pressure, or evidence of skull fractures or other indications of CNS pathology should prompt clinicians to examine a patient for additional neurological disease. Nonbenzodiazepine anticonvulsant medication is not useful in preventing or treating alcohol withdrawal convulsions, although benzodiazepines are generally effective.

Warm, supportive psychotherapy in the treatment of DTs is essential. Patients are often bewildered, frightened, and anxious because of their tumultuous symptoms, and skillful verbal support is imperative.

Alcohol-Induced Persisting Dementia

Alcohol-induced persisting dementia is a poorly studied, heterogeneous long-term cognitive problem that can develop in the course of alcoholism. Global decreases in intellectual functioning, cognitive abilities, and memory are observed, but recent memory difficulties are consistent with the global cognitive impairment, an observation that helps to distinguish this from alcohol-induced persisting amnesic disorder. Brain functioning tends to improve with abstinence, but perhaps half of all affected patients have long-term and even permanent disabilities in memory and thinking. Approximately 50 to 70 percent of these patients evidence increased size of the brain ventricles and shrinkage of the cerebral sulci, although these changes appear to be partially or completely reversible during the first year of complete abstinence.

Alcohol-Induced Persisting Amnesic Disorder

Diagnosis and Clinical Features. The essential feature of alcohol-induced persisting amnesic disorder is a disturbance in short-term memory caused by prolonged heavy use of alcohol. Because the disorder usually occurs in persons who have been drinking heavily for many years, the disorder is rare in persons younger than age 35.

Wernicke-Korsakoff Syndrome. The classic names for alcohol-induced persisting amnesic disorder are Wernicke's encephalopathy (a set of acute symptoms) and Korsakoff's syndrome (a chronic condition). Whereas Wernicke's encephalopathy is completely reversible with treatment, only about 20 percent of patients with Korsakoff's syndrome recover. The pathophysiological connection between the two syndromes is thiamine deficiency, caused either by poor nutritional habits or by malabsorption problems. Thiamine is a cofactor for several important enzymes and may also be involved in conduction of the axon potential along the axon and in synaptic transmission. The neuropathological lesions are symmetrical and paraventricular, involving the mammillary bodies, the thalamus, the hypothalamus, the midbrain, the pons, the medulla, the fornix, and the cerebellum.

Wernicke's encephalopathy, also called *alcoholic encephalopathy*, is an acute neurological disorder characterized by ataxia (affecting primarily the gait), vestibular dysfunction, confusion, and a variety of ocular motility abnormalities, including horizontal nystagmus, lateral orbital palsy, and gaze palsy. These eye signs are usually bilateral but not necessarily symmetrical. Other eye signs may include a sluggish reaction to light and anisocoria. Wernicke's encephalopathy may clear spontaneously in a few days or weeks or may progress into Korsakoff's syndrome.

Treatment. In the early stages, Wernicke's encephalopathy responds rapidly to large doses of parenteral thiamine, which is believed to be effective in preventing the progression into Korsakoff's syndrome. The dosage of thiamine is usually initiated at 100 mg by mouth two to three times daily and is continued for 1 to 2 weeks. In patients with alcohol-related disorders who are receiving IV administration of glucose solution, it is good practice to include 100 mg of thiamine in each liter of the glucose solution.

Korsakoff's syndrome is the chronic amnesic syndrome that can follow Wernicke's encephalopathy, and the two syndromes are believed to be pathophysiologically related. The cardinal features of Korsakoff's syndrome are impaired mental syndrome (especially recent memory) and anterograde amnesia in an alert and responsive patient. The patient may or may not have the symptom of confabulation. Treatment of Korsakoff's syndrome is also thiamine given 100 mg by mouth two to three times daily; the treatment regimen should continue for 3 to 12 months. Few patients who progress to Korsakoff's syndrome ever fully recover, although many have some improvement in their cognitive abilities with thiamine and nutritional support.

Blackouts. Blackouts are similar to episodes of transient global amnesia in that they are discrete episodes of anterograde amnesia that occur in association with alcohol intoxication. The periods of amnesia can be particularly distressing when persons fear that they have unknowingly harmed someone or behaved imprudently while intoxicated. During a blackout, persons have relatively intact remote memory but experience a specific short-term memory deficit in which they are unable to recall events that happened in the previous 5 or 10 minutes. Because their other intellectual faculties are well preserved, they can perform complicated tasks and appear normal to casual observers. The neurobiological mechanisms for alcoholic blackouts are now known at the molecular level; alcohol blocks the consolidation of new memories into old memories, a process that is thought to involve the hippocampus and related temporal lobe structures.

Alcohol-Induced Psychotic Disorder

Diagnosis and Clinical Features. Approximately 3 percent of alcoholic persons experience auditory hallucinations or paranoid delusions in the context of heavy drinking or withdrawal. The most common auditory hallucinations are voices, but they are often unstructured. The voices are characteristically maligning, reproachful, or threatening, although some patients report that the voices are pleasant and nondisruptive. The hallucinations usually last less than a week, but during that week impaired reality testing is common. After the episode, most patients realize the hallucinatory nature of the symptoms.

Hallucinations after alcohol withdrawal are considered rare, and the syndrome is distinct from alcohol withdrawal delirium. The hallucinations can occur at any age, but usually appear in persons abusing alcohol for a long time. Although the hallucinations usually resolve within a week, some linger; in these cases, clinicians must consider other psychotic disorders in the differential diagnosis. Alcohol withdrawal-related hallucinations are differentiated from the hallucinations of schizophrenia by the temporal association with alcohol withdrawal, the absence of a classic history of schizophrenia, and their usually short-lived duration. Alcohol withdrawal-related hallucinations are differentiated from the DTs by the presence of a clear sensorium in patients.

Mr. G was a 40-year-old unemployed man living alone in a studio apartment and was brought to the hospital by the police. He contacted them complaining that he heard voices of men on the street below his window talking about him and threatening to kill him.

He stated that every time he looked out the window the men had always disappeared.

Mr. G had a 15-year history of almost daily alcohol use. He was intoxicated each day and often experienced shakes upon awakening in the morning. On the previous day, he had only one glass of beer instead of his usual four because of gastrointestinal problems. He was fully alert and oriented.

Treatment. The treatment of alcohol withdrawal-related hallucinations is much like the treatment of DTs—benzodiazepines, adequate nutrition, and fluids, if necessary. If this regimen fails or for long-term cases, antipsychotics may be used.

Alcohol-Induced Mood Disorder

Heavy intake of alcohol over several days results in many of the symptoms observed in major depressive disorder, but the intense sadness markedly improves within several days to 1 month of abstinence. Eighty percent of people with alcoholism report histories of intense depression, including 30 to 40 percent who were depressed for 2 or more weeks at a time. However, only 10 to 15 percent of alcoholic persons have ever had depression that meets the criteria for major depressive disorder when they have not been drinking heavily.

Even severe substance-induced depressions are likely to improve fairly rapidly with abstinence, without medication or intensive psychotherapy aimed at the depressive symptoms. A logical approach for these substance-induced conditions is to teach the patient how to best view and deal with the temporary sadness through education and cognitive-behavioral treatment, and to watch and wait at least 2 to 4 weeks before starting antidepressant medications.

A consultation was requested on a 42-year-old woman with alcohol dependence who complained of persisting severe depressive symptoms despite 5 days of abstinence. In the initial stage of the interview, she noted that she had “always been depressed” and felt that she “drank to cope with the depressive symptoms.” Her current complaint included a prominent sadness that had persisted for several weeks, difficulties concentrating, initial and terminal insomnia, and a feeling of hopelessness and guilt. In an effort to distinguish between an alcohol-induced mood disorder and an independent major depressive episode, a time-line-based history was obtained. This focused on the age of onset of alcohol dependence, periods of abstinence that extended for several months or more since the onset of dependence, and the ages of occurrence of clear major depressive episodes lasting several weeks or more at a time. Despite this patient’s original complaints, it became clear that there had been no major depressive episodes prior to her mid-20s when alcohol dependence began, and that during a 1-year period of abstinence related to the gestation and neonatal period of her son, her mood had significantly improved. A provisional diagnosis of an alcohol-induced mood disorder was made. The patient was offered education, reassurance, and cognitive therapy to help her to deal with the depressive symptoms, but no antidepressant medications were prescribed. The depressive symptoms remained at their original intensity for several additional days and then began to improve. By approximately 3 weeks abstinent the patient no longer met criteria for a major depressive episode, although she demonstrated mood swings similar to dysphemia for several additional weeks. This case is a fairly typical example of an alcohol-induced mood disorder in an individual with alcohol dependence. (Courtesy of Marc A. Shuckit, M.D.)

Alcohol-Induced Anxiety Disorder

Anxiety symptoms fulfilling the diagnostic criteria for alcohol-induced anxiety disorder are also common in the context of acute and protracted alcohol withdrawal. Almost 80 percent of alcoholic persons report panic attacks during at least one acute withdrawal episode; their complaints can be sufficiently intense for the clinician to consider diagnosing panic disorder. Similarly, during the first 4 weeks or so of abstinence, people with severe alcohol problems are likely to avoid some social situations for fear of being overwhelmed by anxiety (i.e., they have symptoms resembling social phobia); their problems can at times be severe enough to resemble agoraphobia. However, when psychological or physiological symptoms of anxiety are observed in alcoholic persons only in the context of heavy drinking or within the first several weeks or month of abstinence, the symptoms are likely to diminish and subsequently disappear with time alone.

A 48-year-old woman was referred for evaluation and treatment of her recent onset of panic attacks. These episodes occurred two to three times per week over the preceding 6 months, with each lasting typically between 10 and 20 minutes. Panic symptoms occurred regardless of levels of life stress and could not be explained by current medications or medical conditions. The workup included an evaluation of her laboratory test values, which revealed a carbohydrate-deficient transferrin (CDT) level of 28 U/L, a uric acid level of 7.1 mg, and a γ -glutamyltransferase value of 47. All other blood tests were within normal limits.

The atypical age of onset of the panic attacks, along with the blood results, encouraged the clinician to probe further regarding the pattern of alcohol-related life problems with both the patient and, separately, her spouse. This step documented a history of alcohol dependence with an onset at approximately 35 years of age, with no evidence of panic disorder before that date. Nor did the patient have repetitive panic attacks beyond 2 weeks of abstinence during her frequent periods of nondrinking, which often lasted for 3 or 4 months. A working diagnosis of alcohol dependence with an alcohol-induced anxiety disorder characterized by panic attacks was made, and the patient was encouraged to abstain and was appropriately treated for possible withdrawal symptoms. Over the subsequent 3 weeks after a taper of benzodiazepines used for the treatment of withdrawal, the panic symptoms diminished in intensity and subsequently disappeared. (Courtesy of Marc A. Schuckit, M.D.)

Alcohol-Induced Sexual Dysfunction

The formal diagnosis of symptoms of sexual dysfunction associated with alcohol intoxication is alcohol-induced sexual dysfunction (see Section 17.2).

Alcohol-Induced Sleep Disorder

The diagnostic criteria for alcohol-induced sleep disorders with an onset during either alcohol intoxication or alcohol withdrawal are found in the sleep disorders section (see Section 16.2).

Unspecified Alcohol-Related Disorder

The diagnosis of unspecified alcohol-related disorder is used for alcohol-related disorders that do not meet the diagnostic criteria for any of the other diagnoses.

Idiosyncratic Alcohol Intoxication

Whether there is such a diagnostic entity as idiosyncratic alcohol intoxication is under debate. Several well-controlled studies of persons who supposedly have the disorder have raised questions about the validity of the designation. The condition has been variously called pathologic, complicated, atypical, and paranoid alcohol intoxication; all these terms indicate that a severe behavioral syndrome develops rapidly after a person consumes a small amount of alcohol that would have minimal behavioral effects on most persons. The diagnosis is important in the forensic arena because alcohol intoxication is not generally accepted as a reason for judging persons not responsible for their activities. Idiosyncratic alcohol intoxication, however, can be used in a person's defense if a defense lawyer can argue successfully that the defendant has an unexpected, idiosyncratic, pathological reaction to a minimal amount of alcohol.

In anecdotal reports, persons with idiosyncratic alcohol intoxication have been described as confused and disoriented and as experiencing illusions, transitory delusions, and visual hallucinations. Persons may display greatly increased psychomotor activity and impulsive, aggressive behavior. They can be dangerous to others and they may also exhibit suicidal ideation and make suicide attempts. The disorder, usually described as lasting for a few hours, terminates in prolonged sleep, and those affected cannot recall the episodes on awakening. The cause of the condition is unknown, but it is reported to be most common in persons with high levels of anxiety. According to one hypothesis, alcohol causes sufficient disorganization and loss of control to release aggressive impulses. Another suggestion is that brain damage, particularly encephalitic or traumatic damage, predisposes some persons to an intolerance for alcohol and thus to abnormal behavior after they ingest only small amounts. Other predisposing factors may include advancing age, using sedative-hypnotic drugs, and feeling fatigued. A person's behavior while intoxicated tends to be atypical; after one weak drink, a quiet, shy person becomes belligerent and aggressive.

In treating idiosyncratic alcohol intoxication, clinicians must help protect patients from harming themselves and others. Physical restraint may be necessary, but is difficult because of the abrupt onset of the condition. Once a patient has been restrained, injection of an antipsychotic drug, such as haloperidol (Haldol), is useful for controlling assaultiveness. This condition must be differentiated from other causes of abrupt behavioral change, such as complex partial epilepsy. Some persons with the disorder reportedly showed temporal lobe spiking on an EEG after ingesting small amounts of alcohol.

Other Alcohol-Related Neurological Disorders

Only the major neuropsychiatric syndromes associated with alcohol use have been discussed here. The complete list of neurological syndromes is lengthy (Table 20.2-6). Alcoholic pellagra encephalopathy is one diagnosis of potential interest to psychiatrists presented with a patient who appears to have Wernicke-Korsakoff syndrome but who does not respond to thiamine treatment. The symptoms of alcoholic pellagra encephalopathy include confusion, clouding of consciousness, myoclonus, oppositional hypertonias, fatigue, apathy, irritability, anorexia, insomnia, and sometimes delirium. Patients have a niacin (nicotinic acid) deficiency, and the specific treatment is 50 mg of niacin by mouth four times daily or 25 mg parenterally two to three times daily.

Table 20.2-6
Neurological and Medical Complications of Alcohol Use

Alcohol intoxication	Cardiovascular diseases
Acute intoxication	Cardiomyopathy with potential cardiogenic emboli and cerebrovascular disease
Pathological intoxication (atypical, complicated, unusual)	Arrhythmias and abnormal blood pressure leading to cerebrovascular disease
Blackouts	Hematological disorders
Alcohol withdrawal syndromes	Anemia, leukopenia, thrombocytopenia (could possibly lead to hemorrhagic cerebrovascular disease)
Tremulousness (the shakes or the jitters)	Infectious disease, especially meningitis (especially pneumococcal and meningococcal)
Alcoholic hallucinosis (horrors)	Hypothermia and hyperthermia
Withdrawal seizures (rum fits)	Hypotension and hypertension
Delirium tremens (shakes)	Respiratory depression and associated hypoxia
Nutritional diseases of the nervous system secondary to alcohol abuse	Toxic encephalopathies, including alcohol and other substances
Wernicke-Korsakoff syndrome	Electrolyte imbalances leading to acute confusional states and, rarely, local neurological signs and symptoms
Cerebellar degeneration	Hypoglycemia
Peripheral neuropathy	Hyperglycemia
Optic neuropathy (tobacco-alcohol amblyopia)	Hyponatremia
Pellagra	Hypercalcemia
Alcoholic diseases of uncertain pathogenesis	Hypomagnesemia
Central pontine myelinolysis	Hypophosphatemia
Marchiafava-Bignami disease	Increased incidence of trauma
Fetal alcohol syndrome	Epidural, subdural, and intracerebral hematoma
Myopathy	Spinal cord injury
Alcoholic dementia	Posttraumatic seizure disorders
Alcoholic cerebral atrophy	Compressive neuropathies and brachial plexus injuries (Saturday night palsies)
Systemic diseases due to alcohol with secondary neurological complications	Posttraumatic symptomatic hydrocephalus (normal pressure hydrocephalus)
Liver disease	Muscle crush injuries and compartmental syndromes
Hepatic encephalopathy	
Acquired (non-Wilsonian) chronic hepatocerebral degeneration	
Gastrointestinal diseases	
Malabsorption syndromes	
Postgastrectomy syndromes	
Possible pancreatic encephalopathy	

(From Rubino FA. Neurologic complications of alcoholism. *Psychiatr Clin North Am.* 1992;15:361, with permission.)

Fetal Alcohol Syndrome. Data indicate that women who are pregnant or are breast-feeding should not drink alcohol. Fetal alcohol syndrome, the leading cause of intellectual disability in the United States, occurs when mothers who drink alcohol expose fetuses to alcohol in utero. The alcohol inhibits intrauterine growth and postnatal development. Microcephaly, craniofacial malformations, and limb and heart defects are common in affected infants. Short adult stature and development of a range of adult maladaptive behaviors have also been associated with fetal alcohol syndrome.

Women with alcohol-related disorders have a 35 percent risk of having a child with defects. Although the precise mechanism of the damage to the fetus is unknown, the damage seems to result from exposure in utero to ethanol or to its metabolites; alcohol may also cause hormone imbalances that increase the risk of abnormalities.

PROGNOSIS

Between 10 and 40 percent of alcoholic persons enter some kind of formal treatment program during the course of their alcohol problems. A number of prognostic signs are favorable. First is the absence of preexisting antisocial personality disorder or a diagnosis of other substance abuse or dependence. Second, evidence of general life stability with a job, continuing close family contacts, and the absence of severe legal problems also bodes well for the patient. Third, if the patient stays for the full course of the initial rehabilitation (perhaps 2 to

4 weeks), the chances of maintaining abstinence are good. The combination of these three attributes predicts at least a 60 percent chance for 1 or more years of abstinence. Few studies have documented the long-term course, but researchers agree that 1 year of abstinence is associated with a good chance for continued abstinence over an extended period. Alcoholic persons with severe drug problems (especially intravenous drug use or cocaine or amphetamine dependence) and those who are homeless may have only a 10 to 15 percent chance of achieving 1 year of abstinence, however.

Accurately predicting whether any specific person will achieve or maintain abstinence is impossible, but the prognostic factors listed earlier are associated with an increased likelihood of abstinence. The factors reflecting life stability, however, probably explain only 20 percent or less of the course of alcohol use disorders. Many forces that are difficult to measure affect the clinical course significantly; they are likely to include such intangibles as motivational level and the quality of the patient's social support system.

In general, alcoholic persons with preexisting independent major psychiatric disorders—such as antisocial personality disorder, schizophrenia, and bipolar I disorder—are likely to run the course of their independent psychiatric illness. Thus, for example, clinicians must treat the patient with bipolar I disorder who has secondary alcoholism with appropriate psychotherapy and lithium (Eskalith), use relevant psychological and behavioral techniques for the patient with antisocial personality disorder, and offer appropriate antipsychotic medications on a long-term basis to the patient with schizophrenia. The goal is to minimize the symptoms of the independent psychiatric disorder in the hope that greater life stability will be associated with a better prognosis for the patient's alcohol problems.

TREATMENT AND REHABILITATION

Three general steps are involved in treating the alcoholic person after the disorder has been diagnosed: intervention, detoxification, and rehabilitation. These approaches assume that all possible efforts have been made to optimize medical functioning and to address psychiatric emergencies. Thus, for example, an alcoholic person with symptoms of depression sufficiently severe to be suicidal requires inpatient hospitalization for at least several days until the suicidal ideation disappears. Similarly, a person presenting with cardiomyopathy, liver difficulties, or gastrointestinal bleeding first needs adequate treatment of the medical emergency.

The patient with alcohol abuse or dependence must then be brought face-to-face with the reality of the disorder (intervention), be detoxified if needed, and begin rehabilitation. The essentials of these three steps for an alcoholic person with independent psychiatric syndromes closely resemble the approaches used for the primary alcoholic person without independent psychiatric syndromes. In the former case, however, the treatments are applied after the psychiatric disorder has been stabilized to the extent possible.

Intervention

The goal in the intervention step, which has also been called *confrontation*, is to break through feelings of denial and help the patient recognize the adverse consequences likely to occur if the disorder is not treated. Intervention is a process aimed at maximizing the motivation for treatment and continued abstinence.

This step often involves convincing patients that they are responsible for their own actions while reminding them of how alcohol has created significant life impairments. The psychiatrist often finds it useful to take advantage of the person's chief presenting complaint, whether it is insomnia, difficulties with sexual performance, an inability to cope with life stresses, depression, anxiety, or psychotic symptoms. The psychiatrist can then explain how alcohol has either created or contributed to these problems and can reassure the patient that abstinence can be achieved with a minimum of discomfort.

JP, a 47-year-old physician, was confronted regarding his alcohol-related behaviors by his wife and 21-year-old daughter. They told him about his slurred speech on several recent occasions when the daughter called home, as well as a large number of wine bottles in the trash each week. JP's wife complained of the hours he spent alone in his study and his practice of staying up after she went to bed, retiring later with alcohol on his breath. She also related her concern about his consumption of about 10 or 12 drinks at a recent party, with the resulting tendency to isolate himself from the other guests. She then reminded him of his need to pack liquor when they go on trips where alcohol may not be readily available, and the tremor of his hands some mornings after being drunk the night before. The family shared their concern directly with JP at a time when he was not actively intoxicated, emphasizing specific times and events when his impairment with alcohol occurred. They had also made an appointment with the clinician at an alcohol and drug treatment program so that a next step could be established if the intervention was successful. (Adapted from Marc A. Schuckit, M.D.)

A physician intervening with a patient can use the same nonjudgmental but persistent approach each time an alcohol-related impairment is identified. It is the persistence rather than exceptional interpersonal skills that usually gets results. A single intervention is rarely sufficient. Most alcoholic persons need a series of reminders of how alcohol contributed to each developing crisis before they seriously consider abstinence as a long-term option.

Family

The family can be of great help in the intervention. Family members must learn not to protect the patient from the problems caused by alcohol; otherwise, the patient may not be able to gather the energy and the motivation necessary to stop drinking. In addition, during the intervention stage, the family can suggest that the patient meet with persons who are recovering from alcoholism, perhaps through AA, and family members can meet with groups, such as Al-Anon, that reach out to family members. Those support groups for families meet many times a week and help family members and friends see that they are not alone in their fears, worry, and feelings of guilt. Participants share coping strategies and help each other find community resources. The groups can be most useful in helping family members rebuild their lives, even if the alcoholic person refuses to seek help.

Detoxification

Most persons with alcohol dependence have relatively mild symptoms when they stop drinking. If the patient is in relatively good health, is adequately nourished, and has a good social support system, the depressant withdrawal syndrome usually resembles a mild case of the flu. Even intense withdrawal syndromes rarely approach the severity of symptoms described by some early textbooks in the field.

The essential first step in detoxification is a thorough physical examination. In the absence of a serious medical disorder or combined drug abuse, severe alcohol withdrawal is unlikely. The second step is to offer rest, adequate nutrition, and multiple vitamins, especially those containing thiamine.

Mild or Moderate Withdrawal. Withdrawal develops because the brain has physically adapted to the presence of a brain depressant and cannot function adequately in the absence of the drug. Giving sufficient brain depressant on the first day to diminish symptoms and then weaning the patient off the drug over the next 5 days offers most patients optimal relief and minimizes the possibility that severe withdrawal will develop. Any depressant—including alcohol, barbiturates, or any of the benzodiazepines—can work, but most clinicians choose a benzodiazepine for its relative safety. Adequate treatment can be given with either short-acting drugs (e.g., lorazepam), or long-acting substances (e.g., chlordiazepoxide and diazepam).

An example of treatment is the administration of 25 mg of chlordiazepoxide by mouth three or four times a day on the first day, with a notation to skip a dose if the patient is asleep or feeling sleepy. An additional one or two 25-mg doses can be given during the first 24 hours if the patient is jittery or shows signs of increasing tremor or autonomic dysfunction. Whatever benzodiazepine dosage is required on the first day can be decreased by 20 percent each subsequent day, with a resulting need for no further medication after 4 or 5 days. When giving a long-acting agent, such as chlordiazepoxide, the clinician must avoid producing excessive sleepiness through overmedication; if the patient is sleepy, the next scheduled dose should be omitted. When taking a short-acting drug, such as lorazepam, the patient must not miss any dose because rapid changes in benzodiazepine concentrations in the blood can precipitate severe withdrawal.

A social model program of detoxification saves money by avoiding medications while using social supports. This less-expensive regimen can be helpful for mild or moderate withdrawal syndromes. Some clinicians have also recommended β -adrenergic receptor antagonists (e.g., propranolol [Inderal]) or α -adrenergic receptor agonists (e.g., clonidine), although these medications do not appear to be superior to the benzodiazepines. Unlike the brain depressants, these other agents do little to decrease the risk of seizures or delirium.

Severe Withdrawal. For the approximately 1 percent of alcoholic patients with extreme autonomic dysfunction, agitation, and confusion—that is, those with alcoholic withdrawal delirium, or DTs—no optimal treatment has yet been developed. The first step is to ask why such a severe and relatively uncommon withdrawal syndrome has occurred; the answer often relates to a severe concomitant medical problem that needs immediate treatment. The withdrawal symptoms can then be minimized through the use of either benzodiazepines (in which case high doses are sometimes required) or antipsychotic agents, such as haloperidol. Once again, on the first or second day, doses are used to control behavior, and the patient can be weaned off the medication by about the fifth day.

Another 1 percent of patients may have a single grand mal convulsion; the rare person has multiple fits, with the peak incidence on the second day of withdrawal. Such patients require neurological evaluation, but in the absence of evidence of a seizure disorder, they do not benefit from anticonvulsant drugs.

Protracted Withdrawal. Symptoms of anxiety, insomnia, and mild autonomic overactivity are likely to continue for 2 to 6 months after the acute withdrawal has disappeared. Although no pharmacological treatment for this syndrome appears appropriate, it is possible that some of the medications used for the rehabilitation phase, especially acamprosate (Campral), may work by diminishing some of these symptoms. It is important that the clinician warn the patient that some level of sleep problems or feelings of nervousness might remain after acute withdrawal and discuss cognitive and behavioral approaches that might be appropriate to helping the patient feel more comfortable. These protracted withdrawal symptoms may enhance the probability of relapse.

Rehabilitation

For most patients, rehabilitation includes three major components: (1) continued efforts to increase and maintain high levels of motivation for abstinence; (2) work to help the patient readjust to a lifestyle free of alcohol; and (3) relapse prevention. Because these steps are carried out in the context of acute and protracted withdrawal syndromes and life crises, treatment requires repeated presentations of similar materials that remind the patient how important abstinence is and that help the patient develop new day-to-day support systems and coping styles.

No single major life event, traumatic life period, or identifiable psychiatric disorder is known to be a unique cause of alcoholism. In addition, the effects of any causes of alcoholism are likely to have been diluted by the effects of alcohol on the brain and the years of an altered lifestyle, so that the alcoholism has developed a life of its own. This is true even though many alcoholic persons believe that the cause was depression, anxiety, life stress, or pain syndromes. Research, data from records, and resource persons usually reveal that alcohol contributed to the mood disorder, accident, or life stress, not vice versa.

The same general treatment approach is used in inpatient and outpatient settings. Selection of the more expensive and intensive inpatient mode often depends on evidence of additional severe medical or psychiatric syndromes, the absence of appropriate nearby outpatient groups and facilities, and the patient's history of having failed in outpatient care. The treatment process in either setting involves intervention, optimizing physical and psychological functioning, enhancing motivation, reaching out to family, and using the first 2 to 4 weeks of care as an intensive period of help. Those efforts must be followed by at least 3 to 6 months of less frequent outpatient care. Outpatient care uses a combination of individual and group counseling, judicious avoidance of psychotropic medications unless needed for independent disorders, and involvement in such self-help groups as AA.

Counseling. Counseling efforts in the first several months should focus on day-to-day life issues to help patients maintain a high level of motivation for abstinence and to enhance their functioning. Psychotherapy techniques that provoke anxiety or that require deep insights have not been shown to be of benefit during the early months of recovery and, at least theoretically, may actually impair efforts at maintaining abstinence. Thus, this discussion focuses on the efforts likely to characterize the first 3 to 6 months of care.

Counseling or therapy can be carried out in an individual or group setting; few data indicate that either approach is superior. The technique used is not likely to matter greatly and usually boils down to simple day-to-day counseling or almost any behavioral or psychotherapeutic approach focusing on the here and now. To optimize motivation, treatment sessions should explore the consequences of drinking, the likely future course of alcohol-related life problems, and the marked improvement that can be expected with abstinence. Whether in an inpatient or an outpatient setting, individual or group counseling is usually offered a minimum of three times a week for the first 2 to 4 weeks, followed by less intense efforts, perhaps once a week, for the subsequent 3 to 6 months.

Much time in counseling deals with how to build a lifestyle free of alcohol. Discussions cover the need for a sober peer group, a plan for social and recreational events without drinking, and approaches for reestablishing communication with family members and friends.

The third major component, relapse prevention, first identifies situations in which the risk for relapse is high. The counselor must help the patient develop modes of coping to be used when the craving for alcohol increases or when any event or emotional state makes a return to drinking likely. An important part of relapse prevention is reminding the patient about the appropriate attitude toward slips. Short-term experiences with alcohol can never be used as an excuse for returning to regular drinking. The efforts to achieve and maintain a sober lifestyle are not a game in which all benefits are lost with that first sip. Rather, recovery is a process of trial and error; patients use slips that occur to identify high-risk situations and to develop more appropriate coping techniques.

Most treatment efforts recognize the effects that alcoholism has on the significant persons in the patient's life, and an important aspect of recovery involves helping family members and close friends understand alcoholism and realize that rehabilitation is an ongoing process that lasts for 6 to 12 or more months. Couples and family counseling and support groups for relatives and friends help the persons involved to rebuild relationships, to learn how to avoid protecting the patient from the consequences of any drinking in the future, and to be as supportive as possible of the alcoholic patient's recovery program.

Medications. If detoxification has been completed and the patient is not one of the 10 to 15 percent of alcoholic persons who have an independent mood disorder, schizophrenia, or anxiety disorder, little evidence favors prescribing psychotropic medications for the treatment of alcoholism. Lingering levels of anxiety and insomnia as part of a reaction to life stresses and protracted abstinence should be treated with behavior modification approaches and reassurance. Medications for these symptoms (including benzodiazepines) are likely to lose their effectiveness much faster than the insomnia disappears; thus, the patient may increase the dose and have subsequent problems. Similarly, sadness and mood swings can linger at low levels for several months. Controlled clinical trials, however, indicate no benefit in prescribing antidepressant medications or lithium to treat the average alcoholic person who has no independent or long-lasting psychiatric disorder. The mood disorder will clear before the medications can take effect, and patients who resume drinking while on the medications face significant

potential dangers. With little or no evidence that the medications are effective, the dangers significantly outweigh any potential benefits from their routine use.

One possible exception to the proscription against the use of medications is the alcohol-sensitizing agent disulfiram. Disulfiram is given in daily doses of 250 mg before the patient is discharged from the intensive first phase of outpatient rehabilitation or from inpatient care. The goal is to place the patient in a condition in which drinking alcohol precipitates an uncomfortable physical reaction, including nausea, vomiting, and a burning sensation in the face and stomach. Few data prove that disulfiram is more effective than a placebo, however, probably because most persons stop taking the disulfiram when they resume drinking. Many clinicians have stopped routinely prescribing the agent, partly in recognition of the dangers associated with the drug itself: mood swings, rare instances of psychosis, the possibility of increased peripheral neuropathies, the relatively rare occurrence of other significant neuropathies, and potentially fatal hepatitis. Moreover, patients with preexisting heart disease, cerebral thrombosis, diabetes, and a number of other conditions cannot be given disulfiram because an alcohol reaction to the disulfiram could be fatal.

Two additional promising pharmacological interventions have recently been studied. The first involves the opioid antagonist naltrexone (ReVia), which at least theoretically is believed possibly to decrease the craving for alcohol or blunt the rewarding effects of drinking. In any event, two relatively small (approximately 90 patients on the active drug across the studies) and short-term (3 months of active treatment) investigations using 50 mg per day of this drug had potentially promising results. Evaluating the full impact of this medication, however, will require longer-term studies of relatively large groups of more diverse patients.

The second medication of interest, acamprosate (Campral), has been tested in more than 5,000 alcohol-dependent patients in Europe. This drug is not yet available in the United States. Used in dosages of approximately 2,000 mg per day, this medication was associated with approximately 10 to 20 percent more positive outcomes than placebo when used in the context of the usual psychological and behavioral treatment regimens for alcoholism. The mechanism of action of acamprosate is not known, but it may act directly or indirectly at GABA receptors or at NMDA sites, the effects of which alter the development of tolerance or physical dependence on alcohol. A summary of medications used for alcohol dependence is given in Table 20.2-7.

Table 20.2-7
Medications for Treating Alcohol Dependence

	Disulfiram (Antabuse)	Naltrexone (ReVia)	Acamprosate (Campral)
Action	Inhibits intermediate metabolism of alcohol, causing a build-up of acetaldehyde and a reaction of flushing, sweating, nausea, and tachycardia if a patient drinks alcohol	Blocks opioid receptors, resulting in reduced craving and reduced reward in response to drinking	Affects glutamate and GABA neurotransmitter systems, but its alcohol-related action is unclear
Contraindications	Concomitant use of alcohol or alcohol-containing preparations or metronidazole; coronary artery disease; severe myocardial disease	Currently using opioids or in acute opioid withdrawal; anticipated need for opioid analgesics; acute hepatitis or liver failure	Severe renal impairment (CrCl* ≤ 30 mL/min)
Precautions	High impulsivity—likely to drink while using it; psychoses (current or history); diabetes mellitus; epilepsy; hepatic dysfunction; hypothyroidism; renal impairment; rubber contact dermatitis	Other hepatic disease; renal impairment; history of suicide attempts. If opioid analgesia is required, larger doses may be required, and respiratory depression may be deeper and more prolonged.	Moderate renal impairment (dose adjustment for CrCl* between 30 and 50 mL/min); depression or suicidality
Serious Adverse Reactions	Hepatitis; optic neuritis; peripheral neuropathy; psychotic reactions. Pregnancy Category C.	Will precipitate severe withdrawal if patient is dependent on opioids; hepatotoxicity (uncommon at usual doses). Pregnancy Category C.	Anxiety; depression. Rare events include the following: suicide attempt, acute kidney failure, heart failure, mesenteric arterial occlusion, cardiomyopathy, deep thrombophlebitis, and shock. Pregnancy Category C.
Common Side Effects	Metallic aftertaste; dermatitis	Nausea; abdominal pain; constipation; dizziness; headache; anxiety; fatigue	Diarrhea; flatulence; nausea; abdominal pain; headache; back pain; infection; flu syndrome; chills; somnolence; decreased libido; amnesia; confusion
Examples of Drug Interactions	Amitriptyline; anticoagulants such as warfarin; diazepam; isoniazid; metronidazole; phenytoin; theophylline; warfarin; any nonprescription drug containing alcohol	Opioid analgesics (blocks action); yohimbine (use with naltrexone increases negative drug effects)	No clinically relevant interactions known
Usual Adult Dosage	<i>Oral dose:</i> 250 mg daily (range 125–500 mg) <i>Before prescribing:</i> (1) warn that the patient should not take disulfiram for at least 12 hours after drinking and that a disulfiram-alcohol reaction can occur up to 2 weeks after the last dose; and (2) warn about alcohol in the diet (e.g., sauces and vinegars) and in medications and toiletries <i>Follow-up:</i> Monitor liver function tests periodically	<i>Oral dose:</i> 50 mg daily <i>Before prescribing:</i> Evaluate for possible current opioid use; consider a urine toxicology screen for opioids, including synthetic opioids. Obtain liver function tests <i>Follow-up:</i> Monitor liver function tests periodically	<i>Oral dose:</i> 666 mg (two 333 mg tablets) three times daily <i>or</i> , for patients with moderate renal impairment (CrCl* 30–50 mL/min), reduce to 333 mg (one tablet) three times daily <i>Before prescribing:</i> Establish abstinence

*CrCl, creatinine clearance; GABA, γ-aminobutyric acid.

Another medication with potential promise in the treatment of alcoholism is the nonbenzodiazepine antianxiety drug buspirone (BuSpar), although the effect of this drug on alcohol rehabilitation is inconsistent between studies. No evidence exists that antidepressant medications, such as the selective serotonin reuptake inhibitors (SSRIs), lithium, or antipsychotic medications, are significantly effective in the treatment of alcoholism.

Alcoholics Anonymous. Clinicians must recognize the potential importance of self-help groups such as AA. Members of AA have help available 24 hours a day, associate with a sober peer group, learn that it is possible to participate in social functions without drinking, and are given a model of recovery by observing the accomplishments of sober members of the group.

Learning about AA usually begins during inpatient or outpatient rehabilitation. The clinician can play a major role in helping patients understand the differences between specific groups. Some are composed only of men or women, and others are mixed; some meetings are composed mostly of blue collar men and women, whereas others are mostly for professionals; some groups place great emphasis on religion, and others are eclectic. Patients with coexisting psychiatric disorders may need some additional education about AA. The clinician should remind them that some members of AA may not understand their special need for medications and should arm the patients with

ways of coping when group members inappropriately suggest that the required medications be stopped. Although difficult to evaluate using double-blind controls, most studies indicate that participation in AA is associated with improved outcomes, and incorporation into treatment programs saves money.

20.3 Caffeine-Related Disorders

Caffeine is the most widely consumed psychoactive substance in the world. Caffeine is found in more than 60 species of plants and belongs to the methylxanthine class of alkaloids, which also includes theobromine (found in chocolate) and theophylline (often used in the treatment of asthma). In the United States, 87 percent of children and adults consume foods and beverages containing caffeine. Caffeine affects various neurobiological and physiological systems and produces significant psychological effects. Caffeine is not associated with any life-threatening illnesses, but its use can result in psychiatric symptoms and disorders. The habitual use of caffeine and its widely accepted integration into daily customs can lead to an underestimation of the role that caffeine may play in one's daily life and can make the recognition of caffeine-associated disorders particularly challenging. Hence, it is important for the clinician to be familiar with caffeine, its effects, and problems that can be associated with its use.

Caffeine use is associated with five disorders: caffeine use disorder, caffeine intoxication, caffeine withdrawal, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder.

EPIDEMIOLOGY

Caffeine is contained in drinks, foods, prescription medicines, and over-the-counter medicines (Table 20.3-1). An adult in the United States consumes about 200 mg of caffeine per day on average, although 20 to 30 percent of all adults consume more than 500 mg per day. The per capita use of coffee in the United States is 10.2 pounds per year. A cup of coffee generally contains 100 to 150 mg of caffeine; tea contains about one third as much. Many over-the-counter medications contain one third to one half as much caffeine as a cup of coffee, and some migraine medications and over-the-counter stimulants contain more caffeine than a cup of coffee. Cocoa, chocolate, and soft drinks contain significant amounts of caffeine, enough to cause some symptoms of caffeine intoxication in small children when they ingest a candy bar and a 12-ounce cola drink.

Table 20.3-1
Common Sources of Caffeine and Representative Decaffeinated Products

Source	Caffeine per Unit (mg)
Beverages and foods (5–6 oz)	
Fresh drip coffee, brewed coffee	90–140
Instant coffee	66–100
Tea (leaf or bagged)	30–100
Cocoa	5–50
Decaffeinated coffee	2–4
Chocolate bar or ounce of baking chocolate	25–35
Soft drinks (8–12 oz)	
Pepsi, Coke, Tab, Royal Crown Cola, Dr. Pepper, Mountain Dew	25–50
Canada Dry Ginger Ale, Caffeine-Free Coke, Caffeine-Free Pepsi, 7-Up, Sprite, Squirt, Caffeine-Free Tab	0
Prescription medications (1 tablet or capsule)	
Cafergot, Migralam	100
Anoquan, Aspir-code, BAC, Darvon, Fiorinal	32–50
Over-the-counter analgesics and cold preparations (1 tablet or capsule)	
Excedrin	60
Aspirin compound, Anacin, B-C powder, Capron, Cope, Dolor, Midol, Nilain, Norgesic, PAC, Trigesic, Vanquish	~30
Advil, aspirin, Empirin, Midol 200, Nuprin, Pamprin	0
Over-the-counter stimulants and appetite suppressants (1 tablet or capsule)	
Caffin-TD, Caffedrine	250
Vivarin, Ver	200
Quick-Pep	140–150
Amostant, Anorexin, Appedrine, Nodoz, Wakoz	100

(Adapted from table by Jerome H. Jaffe, M.D.)

Caffeine consumption also varies by age. The average daily caffeine consumption of caffeine consumers of all ages is 2.79 mg/kg of body weight in the United States. A substantial amount of caffeine is consumed even by young children (i.e., more than 1 mg/kg for children between the ages of 1 and 5 years). Worldwide, estimates place the average daily per capita caffeine consumption at about 70 mg. Up to 85 percent of adults consume caffeine in any given year.

COMORBIDITY

Persons with caffeine-related disorders are more likely to have additional substance-related disorders than are those without diagnoses of caffeine-related disorders. About two thirds of those who consume large amounts of caffeine daily also use sedative and hypnotic drugs.

ETIOLOGY

After exposure to caffeine, continued caffeine consumption can be influenced by several different factors, such as the pharmacological effects of caffeine, caffeine's reinforcing effects, genetic predispositions to caffeine use, and personal attributes of the consumer.

Neuropharmacology

Caffeine, a methylxanthine, is more potent than another commonly used methylxanthine, theophylline (Primatene). The half-life of caffeine in the human body is 3 to 10 hours, and the time of peak concentration is 30 to 60 minutes. Caffeine readily crosses the blood–brain barrier. Caffeine acts primarily as an antagonist of the adenosine receptors. Adenosine receptors activate an inhibitory G protein (Gi) and, thus, inhibit the formation of the second-messenger cyclic adenosine monophosphate (cAMP). Caffeine intake, therefore, results in an increase in intraneuronal cAMP concentrations in neurons with adenosine receptors. Three cups of coffee are estimated to deliver so much caffeine to the brain that about 50 percent of the adenosine receptors are occupied by caffeine. Several experiments indicate that caffeine, especially at high doses or concentrations, can affect dopamine and noradrenergic neurons. Specifically, dopamine activity may be enhanced by caffeine, a hypothesis that could explain clinical reports associating caffeine intake with an exacerbation of psychotic symptoms in patients with schizophrenia. Activation of noradrenergic neurons has been hypothesized to be involved in the mediation of some symptoms of caffeine withdrawal.

Subjective Effects and Reinforcement

Single low to moderate doses of caffeine (i.e., 20 to 200 mg) can produce a profile of subjective effects in humans that is generally identified as pleasurable. Thus, studies have shown that such doses of caffeine result in increased ratings on measures such as well-being, energy and concentration, and motivation to work. In addition, these doses of caffeine produce decreases in ratings of feeling sleepy or tired. Doses of caffeine in the range of 300 to 800 mg (the equivalent of several cups of brewed coffee ingested at once) produce effects that are often rated as being unpleasant, such as anxiety and nervousness. Although animal studies have generally found it difficult to demonstrate that caffeine functions as a reinforcer, well-controlled studies in humans have shown that people choose caffeine over placebo when given the choice under controlled experimental conditions. In habitual users, the reinforcing effects of caffeine are potentiated by the ability to suppress low-grade withdrawal symptoms after overnight abstinence. Thus, the profile of caffeine's subjective effects and its ability to function as a reinforcer contribute to the regular use of caffeine.

Genetics and Caffeine Use

Some genetic predisposition may exist to continued coffee use after exposure to coffee. Investigations comparing coffee or caffeine use in monozygotic and dizygotic twins have shown higher concordance rates for monozygotic twins for total caffeine consumption, heavy use, caffeine tolerance, caffeine withdrawal, and caffeine intoxication, with heritabilities ranging between 35 and 77 percent. Multivariate structural equation modeling of caffeine use, cigarette smoking, and alcohol use suggests that a common genetic factor—polysubstance use—underlies use of these three substances.

Age, Sex, and Race

The relationship between long-term chronic caffeine use and demographical features, such as age, sex, and race, has not been widely studied. Some evidence suggests that middle-aged people may use more caffeine, although caffeine use in adolescents is not uncommon. No known evidence indicates that caffeine use differs between men and women, and no data specifically address caffeine use for different races. Some evidence suggests that, for both children and adults in the United States, whites consume more caffeine than blacks.

Special Populations

Cigarette smokers consume more caffeine than nonsmokers. This observation may reflect a common genetic vulnerability to caffeine use and cigarette smoking. It may also be related to increased rates of caffeine elimination in cigarette smokers. Preclinical and clinical studies indicate that regular caffeine use can potentiate the reinforcing effects of nicotine.

Heavy use and clinical dependence on alcohol is associated with heavy use and clinical dependence on caffeine as well. Individuals with anxiety disorders tend to report lower levels of caffeine use, although one study showed that a greater proportion of heavy caffeine consumers also use benzodiazepines. Several studies have also shown high daily amounts of caffeine use in psychiatric in-patients. For example, several studies have found that such patients consume the equivalent of an average of five or more cups of brewed coffee each day. Finally, high daily caffeine consumption has also been noted in prisoners.

Personality

Although attempts have been made to link preferential use of caffeine to particular personality types, results from these studies do not suggest that any particular personality type is especially linked to caffeine use.

Effects on Cerebral Blood Flow

Most studies have found that caffeine results in global cerebral vasoconstriction, with a resultant decrease in cerebral blood flow (CBF), although this effect may not occur in persons over 65 years of age. According to one recent study, tolerance does not develop to these vasoconstrictive effects, and the CBF shows a rebound increase after withdrawal from caffeine. Some clinicians believe that caffeine use can cause a similar constriction in the coronary arteries and produce angina in the absence of atherosclerosis.

DIAGNOSIS

The diagnosis of caffeine intoxication or other caffeine-related disorders depends primarily on a comprehensive history of a patient's intake of caffeine-containing products. The history should cover whether a patient has experienced any symptoms of caffeine withdrawal during periods when caffeine consumption was either stopped or severely reduced. The differential diagnosis for caffeine-related disorders should include the following psychiatric diagnoses: generalized anxiety disorder, panic disorder with or without agoraphobia, bipolar II disorder, attention-deficit/hyperactivity disorder (ADHD), and sleep disorders. The differential diagnosis should include the abuse of caffeine-containing over-the-counter medications, anabolic steroids, and other stimulants, such as amphetamines and cocaine. A urine sample may be needed to screen for these substances. The differential diagnosis should also include hyperthyroidism and pheochromocytoma.

Caffeine Intoxication

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) diagnostic criteria for caffeine intoxication includes the recent consumption of caffeine, usually in excess of 250 mg. The annual incidence of caffeine intoxication is an estimated 10 percent, although some clinicians and investigators suspect that the actual incidence is much higher. The common symptoms associated with caffeine intoxication include anxiety, psychomotor agitation, restlessness, irritability, and psychophysiological complaints such as muscle twitching, flushed face, nausea, diuresis, gastrointestinal distress, excessive perspiration, tingling in the fingers and toes, and insomnia. Consumption of more than 1 g of caffeine can produce rambling speech, confused thinking, cardiac arrhythmias, incoherence, marked agitation, tinnitus, and mild visual hallucinations (light flashes). Consumption of more than 10 g of caffeine can cause generalized tonic-clonic seizures, respiratory failure, and death.

Ms. B, a 30-year-old, went for consultation due to "anxiety attacks." The attacks occurred mid- to late afternoon, when Ms. B became restless, nervous, and easily excited and sometimes was noticed to be flushed, sweating, and, according to coworkers, "talking a mile a minute." In response to questioning, Ms. B admitted to consuming six to seven cups of coffee each day before the time the attacks usually occurred.

Caffeine Withdrawal

The appearance of withdrawal symptoms reflects the tolerance and physiological dependence that develop with continued caffeine use. Several epidemiological studies have reported symptoms of caffeine withdrawal in 50 to 75 percent of all caffeine users studied. The most common symptoms are headache and fatigue; other symptoms include anxiety, irritability, mild depressive symptoms, impaired psychomotor performance, nausea, vomiting, craving for caffeine, and muscle pain and stiffness. The number and severity of the withdrawal symptoms are correlated with the amount of caffeine ingested and the abruptness of the withdrawal. Caffeine withdrawal symptoms have their onset 12 to 24 hours after the last dose; the symptoms peak in 24 to 48 hours and resolve within 1 week.

The induction of caffeine withdrawal can sometimes be iatrogenic. Physicians often ask their patients to discontinue caffeine intake before certain medical procedures, such as endoscopy, colonoscopy, and cardiac catheterization. In addition, physicians often recommend that patients with anxiety symptoms, cardiac arrhythmias, esophagitis, hiatal hernias, fibrocystic disease of the breast, and insomnia stop caffeine intake. Some persons simply decide that it would be good for them to stop using caffeine-containing products. In all these situations, caffeine users should taper the use of caffeine-containing products over a 7- to 14-day period rather than stop abruptly.

Mr. F was a 43-year-old attorney who was brought for a psychiatric consultation by his wife. Mr. F had been complaining of fatigue, loss of motivation, sleepiness, headache, nausea, and difficulty concentrating. His symptoms occurred mostly over the weekends. He withdrew from weekend social activities due to his symptoms, which worried Mrs. F because he seems fine during the week. Mr. F is in good health with no recent history of medical disorders.

Mr. F worked in a very busy law practice, many times working 60-hour weeks, and barely sees his family during the week. At work he is often anxious, restless, and constantly busy. He worries about his job so much that he has difficulty sleeping on weeknights. He denies any marital or family problems, other than those caused by his not wanting to do anything over the weekend.

At work, Mr. F regularly consumes approximately 4 to 5 cups of coffee per day. He cut out coffee on the weekends because he felt that it may be contributing to his anxiety and sleeplessness.

Caffeine-Induced Anxiety Disorder

The anxiety related to caffeine use can resemble that of generalized anxiety disorder. Patients with the disorder may be perceived as "wired," overly talkative, and irritable; they may complain of not sleeping well and of having energy to burn. Caffeine can induce and exacerbate panic attacks in persons with a panic disorder, and although a causative association between caffeine and a panic disorder has not yet been demonstrated, patients with panic disorder should avoid caffeine.

Mr. B was a 28-year-old single African American male graduate student who was in good health and had no history of previous psychiatric evaluation or treatment. He took no medications, did not smoke or consume alcohol, and had no current or past history of illicit drug use.

His chief complaint was that he had begun feeling mounting “anxiety” when working in the laboratory where he was pursuing his graduate studies. His work had been progressive well, he felt his relationship with his advisor was good and supportive, and he could not identify any problems with staff or peers that might explain his anxiety. He had been working long hours, but found the work interesting and had recently had his first paper accepted for publication.

Despite these successes, he reported feeling a “crescendoing anxiety” as his day would progress. He noted that by the afternoon he would be experiencing palpitations, bursts of his heart racing, tremors in his hands, and an overall feeling of “being on the edge.” He also noted a nervous energy in the afternoons. These experiences were occurring daily and seemed confined to the laboratory (although he admitted he was in the laboratory every day of the week).

When reviewing Mr. B’s caffeine intake, it was found that he was consuming excessive amounts of coffee. Staff made a large urn of caffeinated coffee each morning, and Mr. B routinely started with a large mug of coffee. Over the course of the morning he would consume three to four mugs of coffee (the equivalent of about six or eight 6-oz cups of coffee), and continued this level of use throughout the afternoon. He occasionally had a single can of a caffeinated soft drink, and used no other forms of caffeine on a regular basis. Mr. B estimated that he drank a total of six to eight or more mugs of coffee per day (which was estimated to be at least 1,200 mg of caffeine per day). Once pointed out to him, he realized that this level of caffeine consumption was considerably higher than at any other time in his life. He admitted he liked the taste of coffee and felt a burst of energy in the morning when he drank coffee that helped him start his day.

Mr. B and his physician developed a plan to decrease his caffeine use by tapering off caffeine. Mr. B was successful in decreasing his caffeine use and had good resolution of his anxiety symptoms once his daily caffeine use had markedly decreased. (Courtesy of Laura M. Juliano, Ph.D., and Roland R. Griffiths, Ph.D.)

Caffeine-Induced Sleep Disorder

Caffeine is associated with delay in falling asleep, inability to remain asleep, and early morning awakening.

Caffeine Use Disorder

A diagnosis of caffeine use disorder can be given in some people with problematic caffeine consumption. It is included in Section III of DSM-5, which is reserved for conditions that require further research. No studies have examined the course and prognosis for patients with a diagnosis of caffeine use disorder. Subjects with caffeine use disorder have reported continued use of caffeine despite repeated efforts to discontinue their caffeine use.

Ms. G was a 35-year-old married, white homemaker with three children, aged 8, 6, and 2. She took no prescription medications, took a multivitamin and vitamins C and E on a daily basis, did not smoke, and had no history of psychiatric problems. She drank moderate amounts of alcohol on the weekends, had smoked marijuana in college but had not used it since, and had no other history of illicit drug use.

She had started consuming caffeinated beverages while in college, and her current beverage of choice was caffeinated diet cola. Ms. G had her first soft drink early in the morning, shortly after getting out of bed, and she jokingly called it her “morning hit.” She spaced out her bottles of soft drinks over the course of the day, with her last bottle at dinnertime. She typically drank four to five 20-oz bottles of caffeinated diet cola each day.

She and her husband had argued about her caffeinated soft drink use in the past, and her husband had believed she should not drink caffeinated soft drinks while pregnant. However, she had continued to do so during each of her pregnancies. Despite a desire to stop drinking caffeinated soft drinks, she was unable to do so. She described having a strong desire to drink caffeinated soft drinks, and if she resisted this desire, she found that she could not think of anything else. She drank caffeinated soft drinks in her car, which had a manual transmission, and noted that she fumbled while shifting and holding the soft drink and spilled it in the car. She also noted that her teeth had become yellowed, and she suspected this was related to her tendency to swish soft drink in her mouth before swallowing it. When asked to describe a time when she stopped using soft drinks, she reported that she had run out of it on the day one of her children was to have a birthday party, and she did not have time to leave her home to buy more. In the early afternoon of that day, a few hours before the scheduled start of the party, she felt extreme lethargy, a severe headache, irritability, and craving for a soft drink. She called her husband and told him she planned to cancel the party. She then went to the grocery store to buy soft drinks, and after drinking two bottles, she felt well enough to host the party.

Although initially expressing interest in decreasing or stopping her caffeinated soft drink use, Ms. G did not attend scheduled follow-up appointments after her first evaluation. When finally contacted at home, she reported she had only sought help initially at her husband’s request, and she had decided to try to cut down on her caffeine use on her own. (Courtesy of Eric Stain, M.D.)

Caffeine-Related Disorder Not Elsewhere Classified

This category is used for caffeine-related disorders that do not meet the criteria for caffeine use disorder, caffeine intoxication, caffeine withdrawal, caffeine-induced anxiety disorder, or caffeine-induced sleep disorder.

CLINICAL FEATURES

Signs and Symptoms

After the ingestion of 50 to 100 mg of caffeine, common symptoms include increased alertness, a mild sense of well-being, and a sense of improved verbal and motor performance. Caffeine ingestion is also associated with diuresis, cardiac muscle stimulation, increased intestinal peristalsis, increased gastric acid secretion, and (usually mildly) increased blood pressure.

Caffeine Use and Nonpsychiatric Illnesses

Despite numerous studies examining the relationship between caffeine use and physical illness, significant health risk from nonreversible pathological consequences of caffeine use, such as cancer, heart disease, and human reproduction, has not been conclusively demonstrated. Nonetheless, caffeine use is often considered to be contraindicated for various conditions, including generalized anxiety disorder, panic disorder, primary insomnia, gastroesophageal reflux, and pregnancy. In addition, the modest ability of caffeine to increase blood pressure and the documented cholesterol-elevating compounds of unfiltered coffee have raised the issue of the relationship of caffeine and coffee use

to cardiovascular disease. Finally, there may be a mild association between higher daily caffeine use in women and delayed conception and slightly lower birth weight. Studies, however, have not found such associations, and effects, when found, are usually with relatively high daily dosages of caffeine (e.g., the equivalent of five cups of brewed coffee per day). For a woman who is considering pregnancy, especially if there is some difficulty in conceiving, it may be useful to counsel the elimination of caffeine use. Similarly, for a woman who becomes pregnant and has moderate to high daily caffeine consumption, a discussion about decreasing her daily caffeine use may be warranted.

TREATMENT

Analgesics, such as aspirin, almost always can control the headaches and muscle aches that may accompany caffeine withdrawal. Rarely do patients require benzodiazepines to relieve withdrawal symptoms. If benzodiazepines are used for this purpose, they should be used in small dosages for a brief time, about 7 to 10 days at the longest.

The first step in reducing or eliminating caffeine use is to have patients determine their daily consumption of caffeine. This can best be accomplished by having the patient keep a daily food diary. The patient must recognize all sources of caffeine in the diet, including forms of caffeine (e.g., beverages, medications), and accurately record the amount consumed. After several days of keeping such a diary, the clinician can meet with the patient, review the diary, and determine the average daily caffeine dose in milligrams.

The patient and clinician should then decide on a fading schedule for caffeine consumption. Such a schedule could involve a decrease in increments of 10 percent every few days. Because caffeine is typically consumed in beverage form, the patient can use a substitution procedure in which a decaffeinated beverage is gradually used in place of the caffeinated beverage. The diary should be maintained during this time, so that the patient's progress can be monitored. The fading should be individualized for each patient, so that the rate of decrease in caffeine consumption minimizes withdrawal symptoms. The patient should probably avoid stopping all caffeine use abruptly, because withdrawal symptoms are likely to develop with sudden discontinuation of all caffeine use.

20.4 Cannabis-Related Disorders

Cannabis is the most widely used illegal drug in the world, with an estimate 19 million users in 2012. Over the last 30 years cannabis has become a common part of youth culture in most developed societies, with first use now occurring in the mid- to late teenage years. Cannabis is the fourth most commonly used psychoactive drug among adults in the United States, after caffeine, alcohol, and nicotine.

CANNABIS PREPARATIONS

Cannabis preparations are obtained from the plant *Cannabis sativa* (Fig. 20.4-1), which has been used in China, India, and the Middle East for approximately 8,000 years, primarily for its fibers and secondarily for its medicinal properties. The plant occurs in male and female forms. The female plant contains the highest concentrations of more than 60 cannabinoids that are unique to the plant. Delta-9-tetrahydrocannabinol (Δ^9 -THC) is the cannabinoid that is primarily responsible for the psychoactive effects of cannabis. The most potent forms of cannabis come from the flowering tops of the plants or from the dried, black-brown, resinous exudate from the leaves, which are referred to as hashish or hash. The cannabis plant is usually cut, dried, chopped, and rolled into cigarettes (commonly called “joints”), which are then smoked. The common names for cannabis are marijuana, grass, pot, weed, tea, and Mary Jane. Other names, which describe cannabis types of various strengths, are hemp, chasra, bhang, ganja, dagga, and sinsemilla. The potency of marijuana preparations has increased in recent years because of improved agricultural techniques used in cultivation so that plants may contain up to 15 or 20 percent THC.

FIGURE 20.4-1
 Marijuana (*Cannabis sativa*).

EPIDEMIOLOGY

Prevalence and Recent Trends

Based on the 2012 National Surveys on Drug Use and Health (NSDUH), an estimated 19 million persons age 12 years and older (7 percent) had used marijuana in the past month. Of this age group, 2.4 million initiated use within the last year, 57 percent of which initiated use before age 18 years.

The *Monitoring the Future* survey of adolescents in school indicates recent increases in lifetime, annual, current (within the past 30 days), and daily use of marijuana by eighth and tenth graders, continuing a trend that began in the early 1990s. In 1996, about 23 percent of eighth graders and about 40 percent of tenth graders reported having used marijuana and, in 1998 and 1999, more than a quarter of marijuana initiates were aged 14 years or younger. The average age was 17. In 2012, approximately 1 percent of eighth graders, 4 percent of tenth graders, and 7 percent of twelfth graders reported daily use of marijuana.

Demographic Correlates

The rate of past year and current marijuana use by males was almost twice the rate for females overall among those aged 26 and older. This gap between the sexes narrows with younger users; at ages 12 to 17, there are no significant differences.

Race and ethnicity were also related to marijuana use, but the relationships varied by age group. Among those aged 12 to 17, whites had higher rates of lifetime and past-year marijuana use than blacks. Among those 17 to 34 years of age, whites reported higher levels of lifetime use than blacks and Hispanics. But among those 35 and older, whites and blacks reported the same levels of use. The lifetime rates for black adults were significantly higher than those for Hispanics.

NEUROPHARMACOLOGY

As stated above, the principal component of cannabis is Δ^9 -THC; however, the cannabis plant contains more than 400 chemicals, of which about 60 are chemically related to Δ^9 -THC. In humans, Δ^9 -THC is rapidly converted into 11-hydroxy- Δ^9 -THC, the metabolite that is active in the central nervous system (CNS).

A specific receptor for the cannabinoids has been identified, cloned, and characterized. The cannabinoid receptor, a member of the G-protein-linked family of receptors, is linked to the inhibitory G protein (G_i), which is linked to adenylyl cyclase in an inhibitory fashion. The cannabinoid receptor is found in highest concentrations in the basal ganglia, the hippocampus, and the cerebellum, with lower concentrations in the cerebral cortex (Figure 20.4-2). This receptor is not found in the brainstem, a fact consistent with cannabis's minimal effects on respiratory and cardiac functions. Studies in animals have shown that the cannabinoids affect the monoamine and γ -aminobutyric acid (GABA) neurons.

FIGURE 20.4-2

Autoradiography of cannabinoid receptor distribution in a sagittal section of rat brain. Binding of tritiated ligand is dense in the hippocampus (*Hipp*), the globus pallidus (*GP*), the entopeduncular nucleus (*EP*), the substantia nigra pars reticulata (*SNr*), and the cerebellum (*Cer*). Binding is moderate in the cerebral cortex (*Cx*) and the caudate putamen (*CP*) and sparse in the brainstem (*Br St*) and spinal cord. (From Howlett AC, Bidaut-Russell M, Devane WA, Melvin LS, Johnson MR, Herkenham M. The cannabinoid receptor: Biochemical anatomical, and behavioral characterization. *Trends Neurosci.* 1990;13:422, with permission.)

According to most studies, animals do not self-administer cannabinoids as they do most other substances of abuse. Moreover, some debate questions whether the cannabinoids stimulate the so-called reward centers of the brain, such as the dopaminergic neurons of the ventral tegmental area. Tolerance to cannabis does develop, however, and psychological dependence has been found, although the evidence for physiological dependence is not strong. Withdrawal symptoms in humans are limited to modest increases in irritability, restlessness, insomnia, and anorexia and mild nausea; all these symptoms appear only when a person abruptly stops taking high doses of cannabis.

When cannabis is smoked, the euphoric effects appear within minutes, peak in about 30 minutes, and last 2 to 4 hours. Some motor and cognitive effects last 5 to 12 hours. Cannabis can also be taken orally when it is prepared in food, such as brownies and cakes. About two to three times as much cannabis must be taken orally to be as potent as cannabis taken by inhaling its smoke. Many variables affect the psychoactive properties of cannabis, including the potency of the cannabis used, the route of administration, the smoking technique, the effects of pyrolysis on the cannabinoid content, the dose, the setting, and the user's past experience, expectations, and unique biological vulnerability to the effects of cannabinoids.

DIAGNOSIS AND CLINICAL FEATURES

The most common physical effects of cannabis are dilation of the conjunctival blood vessels (red eye) and mild tachycardia. At high doses, orthostatic hypotension may appear. Increased appetite—often referred to as “the munchies”—and dry mouth are common effects of cannabis intoxication. That no clearly documented case of death caused by cannabis intoxication alone reflects the substance's lack of effect on the respiratory rate. The most serious potential adverse effects of cannabis use are those caused by inhaling the same carcinogenic hydrocarbons present in conventional tobacco, and some data indicate that heavy cannabis users are at risk for chronic respiratory disease and lung cancer. The practice of smoking cannabis-containing cigarettes to their very ends, so-called “roaches,” further increases the intake of tar (particulate matter). Many reports indicate that long-term cannabis use is associated with cerebral atrophy, seizure susceptibility, chromosomal damage, birth defects, impaired immune reactivity, alterations in testosterone concentrations, and dysregulation of menstrual cycles; these reports, however, have not been conclusively replicated, and the association between these findings and cannabis use is uncertain.

Cannabis Use Disorder

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes the diagnosis of cannabis use disorder. People who use cannabis daily over weeks to months are most likely to become dependent. The risk of developing dependence is around one in ten for anyone who uses cannabis. The earlier the age of first use, the more often cannabis has been used, and the longer it has been used, the higher the risk of dependence.

Cannabis Intoxication

Cannabis intoxication commonly heightens users' sensitivities to external stimuli, reveals new details, makes colors seem brighter and richer, and subjectively slows the appreciation of time. In high doses, users may experience depersonalization and derealization. Motor skills are impaired by cannabis use, and the impairment in motor skills remains after the subjective, euphoriant effects have resolved. For 8 to 12 hours after using cannabis, users' impaired motor skills interfere with the operation of motor vehicles and other heavy machinery. Moreover, these effects are additive to those of alcohol, which is commonly used in combination with cannabis.

Mr. M was an unemployed 20-year-old man who lived with his parents. He was brought to a hospital by some friends in a state of anxiety and agitation. He had been out for the evening with some friends at a restaurant, and after a couple of beers, he decided to have some cannabis. He had smoked cannabis on previous occasions; however, this time he ate a lump of cannabis despite warnings from his friends. After about half an hour, Mr. M appeared tense and anxious and complained that everything was changing. He could see the faces of his friends increasing to about three times their natural size. The room became distorted, and its proportions and colors kept altering. He felt that the other guests in the restaurant were talking about him and his friends in a menacing way, so he suddenly rushed outside because he felt that he was in danger. He became increasingly agitated and started running down the middle of the street, dodging in and out among the traffic. Eventually, his friends were able to catch him. They were unable to quiet his anxiety, however, and had a hard time persuading him to go with them to the hospital.

On examination Mr. M appeared tense and apprehensive, looking around the room as if he felt uneasy with the surroundings, but he denied perceptual symptoms and did not really believe that he was the subject of persecution. He was fully aware of his surroundings, but his attention was fleeting, and he did not always answer questions. There was no marked impairment of memory, and he was fully oriented.

Physical examination revealed conjunctival injection and an increased pulse rate of 120 beats per minute, but otherwise no

abnormalities were found. Neurological examination also revealed no abnormalities. In the course of a few hours, he quieted down. When he felt recovered, he left the hospital with his friends.

Cannabis Intoxication Delirium

The delirium associated with cannabis intoxication is characterized by marked impairment on cognition and performance tasks. Even modest doses of cannabis impair memory, reaction time, perception, motor coordination, and attention. High doses that also impair users' levels of consciousness have marked effects on cognitive measures.

Cannabis Withdrawal

Studies have shown that cessation of use in daily cannabis users results in withdrawal symptoms within 1 to 2 weeks of cessation. Withdrawal symptoms include irritability, cannabis cravings, nervousness, anxiety, insomnia, disturbed or vivid dreaming, decreased appetite, weight loss, depressed mood, restlessness, headache, chills, stomach pain, sweating, and tremors.

Cannabis-Induced Psychotic Disorder

Cannabis-induced psychotic disorder is diagnosed in the presence of a cannabis-induced psychosis. Cannabis-induced psychotic disorder is rare; transient paranoid ideation is more common.

Florid psychosis is somewhat common in countries in which some persons have long-term access to cannabis of particularly high potency. The psychotic episodes are sometimes referred to as “hemp insanity.” Cannabis use rarely causes a “bad-trip” experience, which is often associated with hallucinogen intoxication. When cannabis-induced psychotic disorder does occur, it may be correlated with a preexisting personality disorder in the affected person.

Cannabis-Induced Anxiety Disorder

Cannabis-induced anxiety disorder is a common diagnosis for acute cannabis intoxication, which in many persons induces short-lived anxiety states often provoked by paranoid thoughts. In such circumstances, panic attacks may be induced, based on ill-defined and disorganized fears. The appearance of anxiety symptoms is correlated with the dose and is the most frequent adverse reaction to the moderate use of smoked cannabis. Inexperienced users are much more likely to experience anxiety symptoms than are experienced users.

A 35-year-old white married male who was naïve to cannabis use was given two “joints” by a friend. He smoked the first of the two in the same manner that he normally smoked a cigarette (in about 3 to 5 minutes). Noting no major effects, he proceeded immediately to smoke the second in the same amount of time. Within 30 minutes, he began to experience rapid heartbeat, dry mouth, mounting anxiety and the delusional belief that his throat was closing up and that he was going to die. That belief induced further panic and the patient was brought to the emergency room in the midst of the experience. Reassurance that he would not die had no effect. He was sedated with diazepam and some of his anxiety diminished. He eventually went to sleep and on awakening in about 5 hours he was asymptomatic with full recall of previous events.

Unspecified Cannabis-Related Disorders

DSM-5 includes the category unspecified cannabis-related disorders for cannabis disorders that cannot be classified as cannabis use disorder, cannabis intoxication, cannabis intoxication delirium, cannabis withdrawal, cannabis-induced psychotic disorder, or cannabis-induced anxiety disorder. Cannabis intoxication can be associated with depressive symptoms, although such symptoms may suggest long-term cannabis use. Hypomania, however, is a common symptom in cannabis intoxication.

When either sleep disorder or sexual dysfunction symptoms are related to cannabis use, they almost always resolve within days or a week after cessation of cannabis use.

Flashbacks. There are case reports of persons who have experienced—at times significantly—sensations related to cannabis intoxication after the short-term effects of the substance have disappeared. Continued debate concerns whether flashbacks are related to cannabis use alone or to the concomitant use of hallucinogens or of cannabis tainted with phencyclidine (PCP).

Cognitive Impairment. Clinical and experimental evidence indicates that the long-term use of cannabis may produce subtle forms of cognitive impairment in the higher cognitive functions of memory, attention, and organization and in the integration of complex information. This evidence suggests that the longer the period of heavy cannabis use, the more pronounced the cognitive impairment. Nonetheless, because the impairments in performance are subtle, it remains to be determined how significant they are for everyday functioning. It also remains to be investigated whether these impairments can be reversed after an extended period of abstinence from cannabis.

Amotivational Syndrome. A controversial cannabis-related syndrome is *amotivational syndrome*. Whether the syndrome is related to cannabis use or reflects characterological traits in a subgroup of persons regardless of cannabis use is under debate. Traditionally, the amotivational syndrome has been associated with long-term heavy use and has been characterized by a person's unwillingness to persist in a task—be it at school, at work, or in any setting that requires prolonged attention or tenacity. Persons are described as becoming apathetic and anergic, usually gaining weight, and appearing slothful.

TREATMENT AND REHABILITATION

Treatment of cannabis use rests on the same principles as treatment of other substances of abuse—abstinence and support. Abstinence can be achieved through direct interventions, such as hospitalization, or through careful monitoring on an outpatient basis by the use of urine drug screens, which can detect cannabis for up to 4 weeks after use. Support can be achieved through the use of individual, family, and group psychotherapies. Education should be a cornerstone for both abstinence and support programs. A patient who does not understand the intellectual reasons for addressing a substance-abuse problem has little motivation to stop. For some patients, an anti-anxiety drug may be useful for short-term relief of withdrawal symptoms. For other patients, cannabis use may be related to an underlying depressive disorder that may respond to specific antidepressant treatment.

Medical Use of Marijuana

Marijuana has been used as a medicinal herb for centuries, and cannabis was listed in the US Pharmacopeia until the end of the 19th century as a remedy for anxiety, depression, and gastrointestinal disorders, among others. Currently, cannabis is a controlled substance with a high

potential for abuse and no medical use recognized by the Drug Enforcement Agency (DEA); however, it is used to treat various disorders, such as the nausea secondary to chemotherapy, multiple sclerosis (MS) chronic pain, acquired immune deficiency syndrome (AIDS), epilepsy, and glaucoma. In 1996, California residents approved the California Compensation Use Act that allowed state residents to grow and use marijuana for these disorders: in 2001, however, the U.S. Supreme Court ruled 8 to 0 that the manufacture and distribution of marijuana are illegal under any circumstances. In addition, the Court held that patients using marijuana for medical purposes can be prosecuted; however, as of 2013, 20 states—Alaska, Arizona, California, Colorado, Connecticut, Delaware, Hawaii, Illinois, Maine, Massachusetts, Michigan, Montana, Nevada, New Hampshire, New Jersey, New Mexico, Oregon, Rhode Island, Vermont and Washington—and the District of Columbia have passed laws exempting patients who use cannabis under a physician’s supervision from state criminal penalties.

In addition to the Supreme Court ruling, periodically the federal government attempts to prosecute doctors who prescribe the drug for medical use with the threat of loss of licensure or jail sentences. In a strongly worded editorial, the *New England Journal of Medicine* urged that “Federal authorities should rescind their prohibition of the medical use of marijuana for seriously ill patients and allow physicians to decide which patients to treat.” The editorial concluded by commenting on the role of the physician: “Some physicians will have the courage to challenge the continued proscription of marijuana for the sick. Eventually, their actions will force the courts to adjudicate between the rights of those at death’s door and the absolute power of bureaucrats whose decisions are based more on reflexive ideology and political correctness than on compassion.”

Dronabinol, a synthetic form of THC, has been approved by the U.S. Food and Drug Administration (FDA); some researchers believe, however, that when taken orally, it is not as effective as smoking the entire plant product. In 2006, regulatory officials authorized the first U.S. clinical trial investigating the efficacy of Sativex, an oral spray consisting of natural cannabis extracts, for the treatment of cancer pain. Sativex is currently available by prescription in Canada and on a limited basis in Spain and Great Britain for patients with neuropathic pain, multiple sclerosis, and other conditions. Sativex can be prescribed in the United States only with a special exemption granted by the FDA for use in certain patients. In 2013, a product called Epidiolex which contains cannabidiol was granted orphan drug status for the treatment of certain rare, intractable types of epilepsy in children.

20.5 Hallucinogen-Related Disorders

Hallucinogens, by definition, are intoxicants. The use of hallucinogenic drugs is associated with panic attacks, hallucinogen persisting perception disorder (flashbacks), psychosis, delirium, and mood and anxiety disorders. Hallucinogens have been used for thousands of years, and drug-induced hallucinogenic states have been part of social and religious rituals. The discovery of lysergic acid diethylamide (LSD) in 1943 increased the use and misuse of hallucinogens because such synthetic hallucinogens are easily made, easily distributed, sold cheaply, and much more potent than their botanical counterparts. This paved the way to the abuse of synthetic hallucinogens and the development of several associated psychiatric disorders that are now seen in psychiatric practice.

PREPARATIONS

Hallucinogens are natural and synthetic substances that are variously called *psychedelics* or *psychotomimetics* because, in addition to inducing hallucinations, they produce a loss of contact with reality and an experience of expanded and heightened consciousness. The hallucinogens are classified as Schedule I controlled substances; the US Food and Drug Administration (FDA) has decreed that they have no medical use and a high abuse potential.

The classic, naturally occurring hallucinogens are psilocybin (from some mushrooms) and mescaline (from peyote cactus); others are harmine, harmaline, ibogaine, and dimethyltryptamine (DMT). The classic synthetic hallucinogen is LSD, synthesized in 1938 by Albert Hoffman, who later accidentally ingested some of the drug and experienced the first LSD-induced hallucinogenic episode. Some researchers classify the substituted or so-called designer amphetamines, such as 3,4-methylenedioxyamphetamine (MDMA), as hallucinogens. Because these drugs are structurally related to amphetamines, this textbook classifies them as stimulant substances, and they are covered in Section 20.9. Table 20.5-1 lists some representative hallucinogens.

 **Table 20.5-1**
Overview of Representative Hallucinogens

Agent	Locale	Chemical Classification	Biological Sources	Common Route	Typical Dose	Duration of Effects	Adverse Reactions
Lysergic acid diethylamide (LSD)	Globally distributed, semisynthetic	Indolealkylamine	Fungus in rye yields lysergic acid	Oral	100 µg	6–12 hr	Extensive, including pandemic 1965–1975
Mescaline	Southwestern U.S.	Phenethylamine	Peyote cactus, <i>L. williamsii</i>	Oral	200–400 mg or 4–6 cactus buttons	10–12 hr	Little or none verified
Methylenedioxyamphetamine (MDA)	U.S., synthetic	Phenethylamine	Synthetic	Oral	80–160 mg	8–12 hr	Documented
Methylenedioxymethamphetamine (MDMA)	U.S., synthetic	Phenethylamine	Synthetic	Oral	80–150 mg	4–6 hr	Documented
Psilocybin	Southern U.S., Mexico, South America	Phosphorylated hydroxylated DMT	Psilocybin mushrooms	Oral	4–6 mg or 5–10 g of dried mushroom	4–6 hr	Psychosis
Ibogaine	West Central Africa	Indolealkylamine	Tabernanthe iboga	Eating powdered root	200–400 mg	8–48 hr	CNS excitation, death?
Ayahuasca	South American tropics	Harmine, other β-carbolines	Bark or leaves of <i>Banisteriopsis caapi</i>	As a tea	300–400 mg	4–8 hr	None reported
Dimethyltryptamine	South America, synthetic	Substituted tryptamine	Leaves of <i>Viola calophylla</i>	As a snuff, IV	0.2 mg/kg IV	30 min	None reported
Morning glory	American tropics and warm zones	D-Lysergic acid alkaloids	Seeds of <i>L. violacea</i> , <i>T. corymbosa</i>	Orally as infusion	7–13 seeds	3 hr	Toxic delirium
Nutmeg and mace	Warm zones of Europe, Africa, Asia	Myristicin and aromatic ethers	Fruit of <i>M. fragrans</i> , commercial species	Orally or as a snuff	1 teaspoon, 5–15 g	Unknown	Similar to atropinism, with seizures, death
Yopo/Cohoba	Northern South America, Argentina	β-Carbolines and tryptamines	Beans of <i>Anadenanthera peregrina</i>	Smoked or as a snuff	Unknown	Unknown	Ataxia, hallucinations, seizures?
Bufotenin	Northern South America, Argentina	5-OH-Dimethyl-tryptamine	Skin glands of toads; seeds of <i>A. peregrina</i>	As a snuff or IV	Unknown	15 min	None reported
Phencyclidine (PCP)	U.S., synthetic	1-phenylcyclohexylpiperidine	Synthetic	Oral, Smoked, as a snuff, IV	5–10 mg	4–6 hr	Psychotic
Ketamine	U.S., synthetic	(+/-)-2-(2-chlorophenyl)-2-(methylamino)-cyclohexanone	Synthetic	Oral, snorted, IV		1–2 hr	Psychotic

(Adapted from Henry David Abraham, M.D.)

Phencyclidine (PCP; 1-1 [phenylcyclohexyl] piperidine), also known as *angel dust*, was first developed as a novel anesthetic in the late 1950s. This drug and the closely related compound ketamine were termed *dissociative anesthetics*, because they produced a condition in which subjects were awake but apparently insensitive to, or dissociated from, the environment. Phencyclidine and ketamine exert their unique behavioral effects by blocking *N*-methyl-D-aspartate (NMDA)-type receptors for the excitatory neurotransmitter glutamate. Their intoxication can present with a variety of symptoms, from anxiety to psychosis. Phencyclidine and ketamine are classified as Schedule II and Schedule III controlled substances, respectively. Although different in pharmacology and clinical effects, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes PCP and ketamine within the hallucinogen category due to their hallucinogenic effects.

EPIDEMIOLOGY

The incidence of hallucinogen use has exhibited two notable periods of increase. Between 1965 and 1969, there was a tenfold increase in the estimated annual number of initiates. This increase was driven primarily by the use of LSD. The second period of increase in first-time hallucinogen use occurred from around 1992 until 2000, fueled mainly by increases in use of ecstasy (i.e., MDMA). Decreases in initiation of both LSD and ecstasy were evident between then and 2013, coinciding with an overall drop in hallucinogen incidence from 1.6 million to 1.1 million.

The National Survey on Drug Use and Health (NSDUH) found that approximately 10 percent of persons age 12 years or older reported lifetime use of hallucinogens. Of this group, 9 percent reported lifetime use of LSD, 6 percent reported lifetime use of ecstasy, and 3 percent reported lifetime use of PCP. The highest rates of current use are among 18 to 25 year olds (2 percent) followed by 12 to 17 year olds (0.9 percent) and adults 25 years or older (0.2 percent). Males (9 percent) are more likely than females (11 percent) to use hallucinogens. Approximately 331,000 persons age 12 years or older were dependent on or abused hallucinogens within the past year.

Hallucinogen use is most common among young (15 to 35 years of age) white men. The ratio of whites to blacks who have used a hallucinogen is 2:1; the white to Hispanic ratio is about 1.5:1. Men represent 62 percent of those who have used a hallucinogen at some time and 75 percent of those who have used a hallucinogen in the preceding month. Persons 26 to 34 years of age show the highest use of hallucinogens, with 16 percent having used a hallucinogen at least once. Persons 18 to 25 years of age have the highest recent use of a hallucinogen.

Cultural factors influence the use of hallucinogens; their use in the western United States is significantly higher than in the southern United States. Hallucinogen use is associated with less morbidity and less mortality than use of some other substances. For example, one study found that only 1 percent of substance-related emergency room visits were related to hallucinogens, compared with 40 percent for cocaine-related problems. Of persons visiting the emergency room for hallucinogen-related reasons, however, more than 50 percent were younger than 20 years of age. Resurgence in the popularity of hallucinogens has been reported.

Phencyclidine

Phencyclidine and some related substances are relatively easy to synthesize in illegal laboratories and relatively inexpensive to buy on the street. The variable quality of the laboratories, however, results in a range of potency and purity. PCP use varies most markedly with geography. Most users of PCP also use other substances, particularly alcohol, but also opiates, opioids, marijuana, amphetamines, and cocaine. PCP is frequently added to marijuana, with severe untoward effects on users. The actual rate of PCP dependence and abuse is not known, but PCP is associated with 3 percent of substance abuse deaths and 32 percent of substance-related emergency room visits nationally.

In the United States, 2.5 percent of those ages 12 and older acknowledged ever using PCP. The highest lifetime prevalence was in those aged 26 to 34 years (4 percent), whereas the highest proportion using PCP in the prior year (0.7 percent) was in those aged 12 to 17 years.

Some areas of some cities have a tenfold higher usage rate of PCP than other areas. The highest PCP use in the United States is in Washington, DC, where PCP accounts for 18 percent of all substance-related deaths and more than 1,000 emergency room visits per year. In

Los Angeles, Chicago, and Baltimore, the comparable figure is 6 percent. Overall, most users are between 18 and 25 years of age and they account for 50 percent of cases. Patients are more likely to be male rather than female, especially those who visit emergency rooms. There are twice as many white as blacks users, although blacks account for more visits to hospitals for PCP-related disorders than do whites. PCP use appears to be rising, with some reports showing a 50 percent increase, particularly in urban areas.

NEUROPHARMACOLOGY

Although most hallucinogenic substances vary in their pharmacological effects, LSD can serve as a hallucinogenic prototype. The pharmacodynamic effect of LSD remains controversial, although it is generally agreed that the drug acts on the serotonergic system, either as an antagonist or as an agonist. Data at this time suggest that LSD acts as a partial agonist at postsynaptic serotonin receptors.

Most hallucinogens are well absorbed after oral ingestion, although some are ingested by inhalation, smoking, or intravenous injection. Tolerance for LSD and other hallucinogens develops rapidly and is virtually complete after 3 or 4 days of continuous use. Tolerance also reverses quickly, usually in 4 to 7 days. Neither physical dependence nor withdrawal symptoms occur with hallucinogens, but a user can develop a psychological dependence on the insight-inducing experiences of episodes of hallucinogen use.

Phencyclidine

Phencyclidine and its related compounds are variously sold as a crystalline powder, paste, liquid, or drug-soaked paper (blotter). PCP is most commonly used as an additive to a cannabis- or parsley-containing cigarette. Experienced users report that the effects of 2 to 3 mg of smoked PCP occur in about 5 minutes and plateau in 30 minutes. The bioavailability of PCP is about 75 percent when taken by intravenous administration and about 30 percent when smoked. The half-life of PCP in humans is about 20 hours, and the half-life of ketamine in humans is about 2 hours.

The primary pharmacodynamic effect of PCP and ketamine is as an antagonist at the NMDA subtype of glutamate receptors. PCP binds to a site within the NMDA-associated calcium channel and prevents the influx of calcium ions. PCP also activates the dopaminergic neurons of the ventral tegmental area, which project to the cerebral cortex and the limbic system. Activation of these neurons is usually involved in mediating the reinforcing qualities of PCP.

Tolerance for the effects of PCP occurs in humans, although physical dependence generally does not occur. In animals that are administered more PCP per pound for longer times than most humans, PCP does induce physical dependence, however, with marked withdrawal symptoms of lethargy, depression, and craving. Physical symptoms of withdrawal in humans are rare, probably as a function of dose and duration of use. Although physical dependence on PCP is rare in humans, psychological dependence on both PCP and ketamine are common, and some users become psychologically dependent on the PCP-induced psychological state.

That PCP is made in illicit laboratories contributes to the increased likelihood of impurities in the final product. One such contaminant is 1-piperidenocyclohexane carbonitrite, which releases hydrogen cyanide in small quantities when ingested. Another contaminant is piperidine, which can be recognized by its strong, fishy odor.

DIAGNOSIS

Hallucinogen Use Disorder

Long-term hallucinogen use is not common. Some long-term users of PCP are said to be “crystallized,” a syndrome characterized by dulled thinking, decreased reflexes, loss of memory, loss of impulse control, depression, lethargy, and impaired concentration. Although psychological dependence occurs, it is rare, in part because each LSD experience is different and in part because there is no reliable euphoria.

B, a 16-year-old boy from divorced parents, was admitted to the psychiatric unit of a local hospital. He had slashed his wrists with a knife, severing nerves and tendons in his left hand, and drifted in and out of consciousness during the night. He finally contacted the mother of a friend who lived nearby in the morning who immediately brought him to the hospital.

B had a history of juvenile delinquency from the age of 13 when he began hanging out with some older boys at his junior high school. He and his friends shoplifted, stole, smoked marijuana, and took LSD. B's grades dropped and he got in trouble at school on two occasions for getting into fights with other students.

On admission, B stated that he did not intend on committing suicide when he slashed his wrist. After some questioning, he revealed that he had been “dropping acid” with some friend and after they left he thought he heard the sirens of police cars approaching his home. He did not wish to get arrested, so he slashed his wrist and then lost consciousness. He denies feeling depressed, although he claims his life is pointless and that he felt it made no difference whether he lived or died.

Hallucinogen Intoxication

Intoxication with hallucinogens is characterized by maladaptive behavioral and perceptual changes and by certain physiological signs (Table 20.5-2). The differential diagnosis for hallucinogen intoxication includes anticholinergic and amphetamine intoxication and alcohol withdrawal. The preferred treatment for hallucinogen intoxication is talking down the patient; during this process, guides can reassure patients that the symptoms are drug induced, that they are not going crazy, and that the symptoms will resolve shortly. In the most severe cases, dopaminergic antagonists—for example, haloperidol (Haldol)—or benzodiazepines—for example, diazepam (Valium)—can be used for a limited time. Hallucinogen intoxication usually lacks a withdrawal syndrome.

 **Table 20.5-2**
Physiological Changes from Hallucinogens

1. Pupillary dilation
2. Tachycardia
3. Sweating
4. Palpitations
5. Blurring of vision
6. Tremors
7. Incoordination

Short-term PCP intoxication can have potentially severe complications and must often be considered a psychiatric emergency. Some patients may be brought to psychiatric attention within hours of ingesting PCP, but often 2 to 3 days elapse before psychiatric help is sought. Persons who lose consciousness are brought for help earlier than those who remain conscious. Most patients recover completely within a day or two, but some remain psychotic for as long as 2 weeks. Patients who are first seen in a coma often exhibit disorientation,

hallucinations, confusion, and difficulty communicating on regaining consciousness. These symptoms may also be seen in noncomatose patients, but their symptoms appear to be less severe than those of comatose patients. Behavioral disturbances sometimes are severe; they can include public masturbation, stripping off clothes, violence, urinary incontinence, crying, and inappropriate laughing. Patients frequently have amnesia for the entire period of the psychosis. A 17-year-old male patient was brought to the emergency room by the police, having been found disoriented on the street. As the police attempted to question him, he became increasingly agitated; when they attempted to restrain him, he became assaultive. Attempts to question or to examine him in the emergency department evoked increased agitation.

Initially, it was impossible to determine vital signs or to draw blood. Based on the observation of horizontal, vertical, and rotator nystagmus, a diagnosis of PCP intoxication was entertained. Within a few minutes of being placed in a darkened examination room, his agitation markedly decreased. Blood pressure was 170/100; other vital signs were within normal limits. Blood was drawn for toxicological examination. The patient agreed to take 20 mg of diazepam (Valium) orally. Thirty minutes later, he was less agitated and could be interviewed, although he responded to questions in a fragmented fashion and was slightly dysarthric. He stated that he must have inadvertently taken a larger-than-usual dose of “dust,” which he reported having used once or twice a week for several years. He denied use of any other substance and any history of mental disorder. He was disoriented to time and place. The qualitative toxicology screen revealed PCP and no other drugs. Results of neurological examination were within normal limits, but brisk deep tendon reflexes were noted. Some 90 minutes after arrival, his temperature, initially normal, was elevated to 38°C, his blood pressure had increased to 182/110, and he was poorly responsive to stimulation. He was admitted to a medical bed. His blood pressure and level of consciousness continued to fluctuate over the ensuing 18 hours. Results of hematological and biochemical analyses of blood, as well as urinalyses, remained within normal limits. A history obtained from his family revealed that the patient had had multiple emergency room visits for complications from PCP use during the previous several years. He had completed a 30-day residential treatment program and had participated in several outpatient programs but had consistently relapsed. The patient was discharged after vital signs and level of consciousness had been within normal limits for 8 hours. At discharge, nystagmus and dysarthria were no longer present. A referral to an outpatient treatment program was made. (Courtesy of Daniel C. Javitt, M.D., Ph.D., and Stephen R. Zukin, M.D.)

Hallucinogen Persisting Perception Disorder

Long after ingesting a hallucinogen, a person can experience a flashback of hallucinogenic symptoms. This syndrome is diagnosed as *hallucinogen persisting perception disorder* in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). According to studies, from 15 to 80 percent of users of hallucinogens report having experienced flashbacks. The differential diagnosis for flashbacks includes migraine, seizures, visual system abnormalities, and posttraumatic stress disorder. The following can trigger a flashback: emotional stress; sensory deprivation, such as monotonous driving; or use of another psychoactive substance, such as alcohol or marijuana.

Flashbacks are spontaneous, transitory recurrences of the substance-induced experience. Most flashbacks are episodes of visual distortion, geometric hallucinations, hallucinations of sounds or voices, false perceptions of movement in peripheral fields, flashes of color, trails of images from moving objects, positive afterimages and halos, macropsia, micropsia, time expansion, physical symptoms, or relived intense emotion. The episodes usually last a few seconds to a few minutes, but sometimes last longer. Most often, even in the presence of distinct perceptual disturbances, the person has insight into the pathological nature of the disturbance. Suicidal behavior, major depressive disorder, and panic disorders are potential complications.

A 20-year-old undergraduate presented with a chief complaint of seeing the air. The visual disturbance consisted of perception of white pinpoint specks too numerous to count in both the central and peripheral visual fields. They were constantly present and were accompanied by the perception of trails of moving objects left behind as they passed through the patient's visual field. Attending a hockey game was difficult, as the brightly dressed players left streaks of their own images against the white of the ice for seconds at a time. The patient also described the false perception of movement in stable objects, usually in his peripheral visual fields; halos around objects; and positive and negative afterimages. Other symptoms included mild depression, daily bitemporal headache, and a loss of concentration in the last year.

The visual syndrome had gradually emerged over the last 3 months following experimentation with the hallucinogenic drug LCD-25 on three separate occasions. He feared he had sustained some kind of “brain damage” from the drug experience. He denied use of any other agents, including amphetamines, phencyclidine, narcotics, or alcohol, to excess. He had smoked marijuana twice a week for a period of 7 months at age 17.

The patient had consulted two ophthalmologists, both of whom confirmed that the white pinpoint specks were not vitreous floaters (diagnostically insignificant particulate matter floating in the vitreous humor of the eye that can cause the perception of “specks”). A neurologist's examination also proved negative. A therapeutic trial of an anticonvulsant medication resulted in a 50 percent improvement in the patient's visual symptoms and remission of his depression.

Hallucinogen Intoxication Delirium

Hallucinogen intoxication delirium is a relatively rare disorder beginning during intoxication in those who have ingested pure hallucinogens. An estimated 25 percent of all PCP-related emergency room patients may meet the criteria for hallucinogen intoxication delirium. Hallucinogens are often mixed with other substances, however, and the other components or their interactions with the hallucinogens can produce clinical delirium.

Hallucinogen-Induced Psychotic Disorders

If psychotic symptoms are present in the absence of retained reality testing, a diagnosis of hallucinogen-induced psychotic disorder may be warranted. The most common adverse effect of LSD and related substances is a “bad trip,” an experience resembling the acute panic reaction to cannabis but sometimes more severe; a bad trip can occasionally produce true psychotic symptoms. The bad trip generally ends when the immediate effects of the hallucinogen wear off, but its course is variable. Occasionally, a protracted psychotic episode is difficult to distinguish from a nonorganic psychotic disorder. Whether a chronic psychosis after drug ingestion is the result of the drug ingestion, is unrelated to the drug ingestion, or is a combination of both the drug ingestion and predisposing factors is currently unanswerable.

Occasionally, the psychotic disorder is prolonged, a reaction thought to be most common in persons with preexisting schizoid personality disorder and prepsychotic personalities, an unstable ego balance, or much anxiety. Such persons cannot cope with the perceptual changes, body-image distortions, and symbolic unconscious material stimulated by the hallucinogen. The rate of previous mental instability in persons hospitalized for LSD reactions is high. Adverse reactions occurred in the late 1960s when LSD was being promoted as a self-prescribed psychotherapy for emotional crises in the lives of seriously disturbed persons. Now that this practice is less frequent, prolonged adverse reactions are less common.

A 22-year-old female photography student presented to the hospital with inappropriate mood and bizarre thinking. She had no prior psychiatric history. Nine days before admission, she ingested one or two psilocybin mushrooms. Following the immediate ingestion, the patient began to giggle. She then described euphoria, which progressed to auditory hallucinations and belief in the ability to broadcast her thoughts on the media. Two days later she repeated the ingestion, and continued to exhibit psychotic symptoms to the day of admission. When examined she heard voices telling her she could be president, and reported the sounds of “lambs crying.” She continued to giggle inappropriately, bizarrely turning her head from side to side ritualistically. She continued to describe euphoria, but with an intermittent sense of hopelessness in a context of thought blocking. Her self-description was “feeling lucky.” She was given haloperidol, 10 mg twice a day, along with benztropine (Cogentin) 1 mg three times a day and lithium carbonate (Eskalith) 300 mg twice a day. On this regimen her psychosis abated after 5 days.

Hallucinogen-Induced Mood Disorder

Unlike cocaine-induced mood disorder and amphetamine-induced mood disorder, in which the symptoms are somewhat predictable, mood disorder symptoms accompanying hallucinogen abuse can vary. Abusers may experience manic-like symptoms with grandiose delusions or depression-like feelings and ideas or mixed symptoms. As with the hallucinogen-induced psychotic disorder symptoms, the symptoms of hallucinogen-induced mood disorder usually resolve once the drug has been eliminated from the person's body.

Hallucinogen-Induced Anxiety Disorder

Hallucinogen-induced anxiety disorder also varies in its symptom pattern, but few data about symptom patterns are available. Anecdotally, emergency room physicians who treat patients with hallucinogen-related disorders frequently report panic disorder with agoraphobia. Anxiety is probably the most common symptom causing a PCP-intoxicated person to seek help in an emergency room.

Unspecified Hallucinogen-Related Disorder

When a patient with a hallucinogen-related disorder does not meet the diagnostic criteria for any of the standard hallucinogen-related disorders, the patient may be classified as having unspecified hallucinogen-related disorder. DSM-5 does not have a diagnostic category of hallucinogen withdrawal, but some clinicians anecdotally report a syndrome with depression and anxiety after cessation of frequent hallucinogen use. Such a syndrome may best fit the diagnosis of unspecified hallucinogen-related disorder.

CLINICAL FEATURES

Lysergic Acid Diethylamide

A large class of hallucinogenic compounds with well-studied structure–activity relationships is represented by the prototype LSD. LSD is a synthetic base derived from the lysergic acid nucleus from the ergot alkaloids. That family of compounds was discovered in rye fungus and was responsible for lethal outbreaks of St. Anthony's fire in the Middle Ages. The compounds are also present in morning glory seeds in low concentrations. Many homologs and analogs of LSD have been studied. None of them has potency exceeding that of LSD.

Physiological symptoms from LSD are typically few and relatively mild. Dilated pupils, increased deep tendon motor reflexes and muscle tension, and mild motor incoordination and ataxia are common. Increased heart rate, respiration, and blood pressure are modest in degree and variable, as are nausea, decreased appetite, and salivation.

The usual sequence of changes follows a pattern of somatic symptoms appearing first, then mood and perceptual changes, and, finally, psychological changes, although effects overlap and, depending on the particular hallucinogen, the time of onset and offset varies. The intensity of LSD effects in a nontolerant user generally is proportional to dose, with 25 µg as an approximate threshold dose.

The syndrome produced by LSD resembles that produced by mescaline, psilocybin, and some of the amphetamine analogs. The major difference among LSD, psilocybin, and mescaline is potency. A 1.5 µg/kg dose of LSD is roughly equivalent to 225 µg/kg of psilocybin, which is equivalent to 5 mg/kg of mescaline. With mescaline, onset of symptoms is slower and more nausea and vomiting occurs but in general, the perceptual effects are more similar than different.

Tolerance, particularly to the sensory and other psychological effects, is evident as soon as the second or third day of successive LSD use. Four to 6 days free of LSD are necessary to lose significant tolerance. Tolerance is associated with frequent use of any of the hallucinogens. Cross-tolerance among mescaline, psilocybin, and LSD occurs, but not between amphetamine and LSD, despite the chemical similarity of amphetamine and mescaline.

Previously distributed as tablets, liquid, powder, and gelatin squares, in recent years, LSD has been commonly distributed as “blotter acid.” Sheets of paper are soaked with LSD, and dried and perforated into small squares. Popular designs are stamped on the paper. Each sheet contains as many as a few hundred squares; one square containing 30 to 75 µg of LSD is one chewed dose, more or less. Planned massive ingestion is uncommon but massive ingestion happens by accident.

The onset of action of LSD occurs within an hour, peaks in 2 to 4 hours, and lasts 8 to 12 hours. The sympathomimetic effects of LSD include tremors, tachycardia, hypertension, hyperthermia, sweating, blurring of vision, and mydriasis. Death caused by cardiac or cerebrovascular pathology related to hypertension or hyperthermia can occur with hallucinogenic use. A syndrome similar to neuroleptic malignant syndrome has reportedly been associated with LSD. Death can also be caused by a physical injury when LSD use impairs judgment about traffic or a person's ability to fly, for example. The psychological effects are usually well tolerated, but when persons cannot recall experiences or appreciate that the experiences are substance induced, they may fear the onset of insanity.

With hallucinogen use, perceptions become unusually brilliant and intense. Colors and textures seem to be richer, contours sharpened, music more emotionally profound, and smells and tastes heightened. Synesthesia is common; colors may be heard or sounds seen. Changes in body image and alterations of time and space perception also occur. Hallucinations are usually visual, often of geometric forms and figures, but auditory and tactile hallucinations are sometimes experienced. Emotions become unusually intense and may change abruptly and often; two seemingly incompatible feelings may be experienced at the same time. Suggestibility is greatly heightened, and sensitivity or detachment from other persons may arise. Other common features are a seeming awareness of internal organs, the recovery of lost early memories, the release of unconscious material in symbolic form, and regression and the apparent reliving of past events, including birth. Introspective reflection and feelings of religious and philosophical insight are common. The sense of self is greatly changed, sometimes to the point of depersonalization, merging with the external world, separation of self from body, or total dissolution of the ego in mystical ecstasy.

There is no clear evidence of a drastic personality change or chronic psychosis produced by long-term LSD use by moderate users not otherwise predisposed to these conditions. Some heavy users of hallucinogens, however, may experience chronic anxiety or depression and may benefit from a psychological or pharmacological approach that addresses the underlying problem.

Many persons maintain that a single experience with LSD has given them increased creative capacity, new psychological insight, relief from neurotic or psychosomatic symptoms, or a desirable change in personality. In the 1950s and 1960s, psychiatrists showed great interest in LSD and related substances, both as potential models for functional psychosis and as possible pharmacotherapeutic agents. The availability of these compounds to researchers in the basic neurosciences has led to many scientific advances.

Phenethylamines

Phenethylamines are compounds with chemical structures similar to those of the neurotransmitters dopamine and norepinephrine. Mescaline (3,4,5-trimethoxyphenethylamine), a classic hallucinogen in every sense of the term, was the first hallucinogen isolated from the peyote cactus that grows in the southwestern United States and northern Mexico. Mescaline human pharmacology was characterized in 1896 and its structure verified by synthesis 23 years later. Although many psychoactive plants have been recognized dating to before recorded history, mescaline was the only structurally identified hallucinogen until LSD was described in 1943.

Mescaline

Mescaline is usually consumed as peyote “buttons,” picked from the small blue-green cacti *Lophophora williamsii* and *Lophophora diffusa*. The buttons are the dried, round, fleshy cacti tops. Mescaline is the active hallucinogenic alkaloid in the buttons. Use of peyote is legal for the Native American Church members in some states. Adverse reactions to peyote are rare during structured religious use. Peyote usually is not consumed casually because of its bitter taste and sometimes severe nausea and vomiting that precede the hallucinogenic effects.

Many structural variations of mescaline have been investigated and structural activity relationships fairly well characterized. One analog, 2,5-dimethoxy-4-methylamphetamine (DOM), also known as STP, an unusually potent amphetamine with hallucinogen properties, had a relatively brief period of illicit popularity and notoriety in the 1960s, but it appears to have disappeared from the illicit market.

Another series of phenethylamine analogs with hallucinogenic properties is the 3,4-methylenedioxymphetamine (MDA)-related amphetamines. The currently most popular and, to society, most troublesome member of this large family of drugs is MDMA, or ecstasy, more a relatively mild stimulant than hallucinogen. MDMA produces an altered state of consciousness with sensory changes and, most important for some users, a feeling of enhanced personal interactions.

Many plants contain N,N-dimethyltryptamine (DMT), which is also found normally in human biofluids at very low concentrations. When DMT is taken parenterally or by sniffing, a brief, intense hallucinogenic episode can result. As with mescaline in the phenethylamine group, DMT is one of the oldest, best documented, but least potent of the tryptamine hallucinogens. Synthesized homologs of DMT have been evaluated in humans and structure activity relationships have been reasonably well described.

Psilocybin Analogs

An unusual collection of tryptamines has its origin in the world of fungi. The natural prototype is psilocybin itself. That and related homologs have been found in as many as 100 species of mushroom, largely of the *Psilocybe* genus.

Psilocybin is usually ingested as mushrooms. Many species of psilocybin-containing mushrooms are found worldwide. In the United States, large *Psilocybe cubensis* (gold caps) grow in Florida and Texas and are easily grown with cultivation kits advertised in drug-oriented magazines and on the Internet. The tiny *Psilocybe semilanceata* (liberty cap) grows in lawns and pastures in the Pacific Northwest. Psilocybin remains active when the mushrooms are dried or cooked into omelets or other foods.

Psilocybin mushrooms are used in religious activities by Mexican Indians. They are valued in Western society by users who prefer to ingest a mushroom rather than a synthetic chemical. Of course, one danger of eating wild mushrooms is misidentification and ingestion of a poisonous variety. At a large American university, 24 percent of students reported using psychedelic mushrooms or mescaline, compared with 17 percent who reported LSD use. Psilocybin sold as pills or capsules usually contains phencyclidine (PCP) or LSD instead.

Studies are underway in several medical centers in the United States (including New York University) to examine the use of psilocybin in terminally ill patients.

Preliminary reports indicate that the psilocybin is helpful in reducing morbid anxiety about death and dying. It may play an important role in palliative care medicine in the future.

Phencyclidine

The amount of PCP varies greatly from PCP-laced cigarette to cigarette; 1 g may be used to make as few as four or as many as several dozen cigarettes. Less than 5 mg of PCP is considered a low dose, and doses above 10 mg are considered high. Dose variability makes it difficult to predict the effect, although smoking PCP is the easiest and most reliable way for users to titrate the dose.

Persons who have just taken PCP are frequently uncommunicative, appear to be oblivious, and report active fantasy production. They experience speedy feelings, euphoria, bodily warmth, tingling, peaceful floating sensations, and, occasionally, feelings of depersonalization, isolation, and estrangement. Sometimes, they have auditory and visual hallucinations. They often have striking alterations of body image, distortions of space and time perception, and delusions. They may experience intensified dependence feelings, confusion, and disorganization of thought. Users may be sympathetic, sociable, and talkative at one moment but hostile and negative at another. Anxiety is sometimes reported; it is often the most prominent presenting symptom during an adverse reaction. Nystagmus, hypertension, and hyperthermia are common effects of PCP. Head-rolling movements, stroking, grimacing, muscle rigidity on stimulation, repeated episodes of vomiting, and repetitive chanting speech are sometimes observed.

The short-term effects last 3 to 6 hours and sometimes give way to a mild depression in which the user becomes irritable, somewhat paranoid, and occasionally belligerent, irrationally assaultive, suicidal, or homicidal. The effects can last for several days. Users sometimes find that it takes 1 to 2 days to recover completely; laboratory tests show that PCP can remain in the patient's blood and urine for more than a week.

Ketamine

Ketamine is a dissociative anesthetic agent, originally derived from PCP, which is available for use in human and veterinary medicine. It has become a drug of abuse, with sources exclusively from stolen supplies. It is available as a powder or in solution for intranasal, oral, inhalational, or (rarely) intravenous use. Ketamine functions by working at the NMDA receptor and, as with PCP, can cause hallucinations and a dissociated state in which the patient has an altered sense of the body and reality and little concern for the environment.

Ketamine causes cardiovascular stimulation and no respiratory depression. On physical examination, the patient may be hypertensive and tachycardic, have increased salivation and bidirectional or rotary nystagmus, or both. The onset of action is within seconds when used intravenously, and analgesia lasting 40 minutes and dissociative effects lasting for hours have been described. Cardiovascular status should be monitored and supportive care administered. A dystonic reaction has been described, as have flashbacks, but a more common complication is related to a lack of concern for the environment or personal safety.

Ketamine has a briefer duration of effect than PCP. Peak ketamine levels occur approximately 20 minutes after intramuscular injection. After intranasal administration, the duration of effect is approximately 1 hour. Ketamine is N-demethylated by liver microsomal cytochrome P450 (CYP), especially CYP3A, into norketamine. Ketamine, norketamine, and dehydronorketamine can be detected in urine, with half-lives of 3, 4, and 7 hours, respectively. Urinary ketamine and norketamine levels vary widely from individual to individual and can range from 10 to 7,000 ng/mL after intoxication. As of yet, the relationship between serum ketamine levels and clinical symptoms has not been formally studied. Ketamine is often used in combination with other drugs of abuse, especially cocaine. Ketamine does not appear to interfere with, and may enhance, cocaine metabolism. Ketamine is being studied for use in the treatment of depression.

ADDITIONAL HALLUCINOGENS

Canthinones

Cathinones are alkaloids similar to amphetamines naturally found in the khat plant and synthetically made and known as "bath salts." They are CNS stimulants that cause a massive release of dopamine, and a single dose can last up to 8 hours. They produce profound toxic effects that can lead to seizures, strokes, and/or death. Hallucinations and delusions are common. They are swallowed, injected, or "snorted" to produce the desired euphoric effect.

Ibogaine

Ibogaine is a complex alkaloid found in the African shrub *Tabernanthe iboga*. Ibogaine is a hallucinogen at the 400 mg dose range. The plant originates in Africa and traditionally is used in sacramental initiation ceremonies. Although it has not been a popular hallucinogen because of its unpleasant somatic effects when taken at hallucinogenic doses, patients exposed to ibogaine may be encountered by a psychiatrist because of the therapeutic claims.

Ayahuasca

Ayahuasca, much discussed on Internet hallucinogen websites, originally referred to a decoction from one or more South American plants. The substance contains the alkaloids harmaline and harmine. Both of those β -carboline alkaloids have hallucinogenic properties, but the resulting visual sensory alterations are accompanied by considerable nausea. Amazon native tribes discovered that adding leaves from plants containing substantial amounts of DMT markedly enhanced the visual and sacramental impact of ayahuasca. Thus, neither component in the ayahuasca plant mixture works well alone but when taken in combination an extremely effective hallucinogenic agent results.

In recent years, the term *ayahuasca* has evolved to a less specific term to refer to any mixture of two things that are hallucinogenic when taken in combination. For example, harmine and harmaline are available as fine chemicals and when taken along with many botanicals containing DMT result in a mixture with hallucinogen properties, initially intense but usually of brief duration.

Salvia Divinorum

American Indians in northern Oaxaca, Mexico, have used *Salvia divinorum* as a medicine and as a sacred sacrament, which is now widely discussed, advertised, and sold on the Internet. When the plant is chewed or dried leaves smoked, it produces hallucinogen effects. Salvinorin-A, an active component in the plant, is parenterally potent, active at 250- μ g doses when smoked, and of scientific and potential medical interest because it binds to the opioid κ -receptor.

TREATMENT

Hallucinogen Intoxication

A basic principle in treatment is providing reassurance and supportive care. Patients experiencing intense and unpleasant hallucinogen intoxication can be helped by a quiet environment, verbal reassurance, and the passage of time. More rapid relief of intense anxiety is likely after oral administration of 20 mg of diazepam (Valium) or, if oral administration presents problems, an equivalent parenteral dose of a benzodiazepine. Anxiety and other symptoms generally diminish within 20 minutes of medication administration, compared to hours with only psychological and environmental support; however, perceptual symptoms may persist. Patients may need gentle restraint if they are in danger to themselves or others, but restraints should be avoided if possible. Neuroleptic medications, particularly if given at excessive doses, may worsen symptoms and are best avoided unless the diagnosis remains unclear and behavior cannot otherwise be managed. The marketing of lower doses of LSD and a more sophisticated approach to treatment of casualties by drug users themselves have combined to reduce the appearance of this once-common disorder in psychiatric treatment facilities.

Hallucinogen Persisting Disorder

Treatment for hallucinogen persisting perception disorder is palliative. The first step in the process is correct identification of the disorder; it is not uncommon for the patient to consult a number of specialists before the diagnosis is made. Pharmacological approaches include long-lasting benzodiazepines, such as clonazepam (Klonopin) and, to a lesser extent, anticonvulsants including valproic acid (Depakene) and carbamazepine (Tegretol). Currently, no drug is completely effective in ablating symptoms. Antipsychotic agents should be used only in the treatment of hallucinogen-induced psychoses, because they may have a paradoxical effect and exacerbate symptoms. A second dimension of treatment is behavioral. The patient must be instructed to avoid gratuitous stimulation in the form of over-the-counter drugs, caffeine, and alcohol, and avoidable physical and emotional stressors. Marijuana smoke is a particularly strong intensifier of the disorder, even when passively inhaled. Finally, three comorbid conditions are associated with hallucinogen persisting perception disorder: panic disorder, major depression, and alcohol dependence. All these conditions require primary prevention and early intervention.

Hallucinogen-Induced Psychosis

Treatment of hallucinogen-induced psychosis does not differ from conventional treatment for other psychoses. In addition to antipsychotic medications, a number of agents are reportedly effective, including lithium carbonate, carbamazepine, and electroconvulsive therapy. Antidepressant drugs, benzodiazepines, and anticonvulsant agents may each have a role in treatment as well. One hallmark of this disorder is that, as opposed to schizophrenia, in which negative symptoms and poor interpersonal relatedness may commonly be found, patients with hallucinogen-induced psychosis exhibit the positive symptoms of hallucinations and delusions while retaining the ability to relate to the psychiatrist. Medical therapies are best applied in a context of supportive, educational, and family therapies. The goals of treatment are the control of symptoms, a minimal use of hospitals, daily work, the development and preservation of social relationships, and the management of comorbid illnesses such as alcohol dependence.

Phencyclidine

Treatment of PCP intoxication aims to reduce systemic PCP levels and to address significant medical, behavioral, and psychiatric issues. For intoxication and PCP-induced psychotic disorder, although resolution of current symptoms and signs is paramount, the long-term goal of treatment is to prevent relapse to PCP use. PCP levels can fluctuate over many hours or even days, especially after oral administration. A prolonged period of clinical observation is therefore mandatory before concluding that no serious or life-threatening complications will ensue.

Trapping of ionized PCP in the stomach has led to the suggestion of continuous nasogastric suction as a treatment for PCP intoxication. This strategy, however, can be needlessly intrusive and can induce electrolyte imbalances. Administration of activated charcoal is safer, and it binds PCP and diminishes toxic effects of PCP in animals.

Trapping of ionized PCP in urine has led to the suggestion of urinary acidification as an aid to drug elimination. This strategy, however, may be ineffective and is potentially dangerous. Only a small portion of PCP is excreted in urine, metabolic acidosis itself carries significant risks, and acidic urine can increase the risk of renal failure secondary to rhabdomyolysis. Because of the extremely large volume of distribution of PCP, neither hemodialysis nor hemoperfusion can significantly promote drug clearance.

No drug is known to function as a direct PCP antagonist. Any compound binding to the PCP receptor, which is located within the ion channel of the NMDA receptor, would block NMDA receptor-mediated ion fluxes as does PCP itself. NMDA-receptor mechanisms predict that pharmacological strategies promoting NMDA receptor activation (e.g., administration of a glycine site agonist drug) would promote rapid dissociation of PCP from its binding sites. No clinical trials of NMDA agonists for PCP or ketamine intoxication in humans have been

carried out to date. Treatment must therefore be supportive and directed at specific symptoms and signs of toxicity. Classic measures should be used for medical crises, including seizures, hypothermia, and hypertensive crisis.

Because PCP disrupts sensory input, environmental stimuli can cause unpredictable, exaggerated, distorted, or violent reactions. A cornerstone of treatment, therefore, is minimization of sensory inputs to PCP-intoxicated patients. Patients should be evaluated and treated in an environment that is as quiet and isolated as possible. Precautionary physical restraint is recommended by some authorities, with the risk of rhabdomyolysis from struggle against the restraints balanced by the avoidance of violent or disruptive behavior. Pharmacological sedation can be accomplished with oral or intramuscular (IM) antipsychotics or benzodiazepines; no convincing evidence indicates that either class of compounds is clinically superior. Because of the anticholinergic actions of PCP at high doses, neuroleptics with potent intrinsic anticholinergic properties should be avoided.

20.6 Inhalant-Related Disorders

Inhalant drugs (also called *volatile substances* or *solvents*) are volatile hydrocarbons that vaporize to gaseous fumes at room temperature and are inhaled through the nose or mouth to enter the bloodstream via the transpulmonary route. These compounds are commonly found in many household products and are divided into four commercial classes: (1) solvents for glues and adhesives; (2) propellants (e.g., for aerosol paint sprays, hair sprays, and shaving cream); (3) thinners (e.g., for paint products and correction fluids); and (4) fuels (e.g., gasoline, propane). These drugs are believed to share some similar pharmacological properties despite their chemical differences.

Persons, especially adolescents, like to inhale these products for their intoxicating effect. Inhalants are associated with a number of problems including conduct disorder, mood disorders, suicidality, and physical and sexual abuse or neglect. In some cases, an early time-limited use of inhalants may signal a lifelong problem with externalizing behaviors and risk-taking propensity. A smaller subgroup use inhalants chronically and such use has been associated with multiple sequelae, including major behavioral and organ pathology from the drugs' toxicity.

The fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) excludes anesthetic gases (e.g., nitrous oxide and ether) and short-acting vasodilators (e.g., amyl nitrite) from the inhalant-related disorders, which are classified as other (or unknown) substance-related disorders and are discussed in Section 20.12.

EPIDEMIOLOGY

Inhalant substances are easily available, legal, and inexpensive. These three factors contribute to the high use of inhalants among poor persons and young persons. Approximately 6 percent of persons in the United States had used inhalants at least once, and about 1 percent of persons are current users. Among young adults 18 to 25 years of age, 11 percent had used inhalants at least once, and 2 percent were current users. Among adolescents 12 to 17 years of age, 7 percent had used inhalants at least once, and 1.1 percent were current users. In one study of high school seniors, 18 percent reported having used inhalants at least once, and 2.7 percent reported having used inhalants within the preceding month. White users of inhalants are more common than either black or Hispanic users. Most users (up to 80 percent) are male. Some data suggest that inhalant use may be more common in suburban communities in the United States than in urban communities.

Inhalant use accounts for 1 percent of all substance-related deaths and less than 0.5 percent of all substance-related emergency room visits. About 20 percent of the emergency room visits for inhalant use involve persons younger than 18 years of age. Inhalant use among adolescents may be most common in those whose parents or older siblings use illegal substances. Inhalant use among adolescents is also associated with an increased likelihood of conduct disorder or antisocial personality disorder.

NEUROPHARMACOLOGY

Inhalants most used by American adolescents are (in descending order) gasoline, glue (which usually contains toluene), spray paint, solvents, cleaning fluids, and assorted other aerosols. Sniffing vapor through the nose or huffing (taking deep breaths) through the mouth leads to transpulmonary absorption with very rapid drug access to the brain. Breathing through a solvent-soaked cloth, inhaling fumes from a glue-containing bag, huffing vapor sprayed into a plastic bag, or breathing vapor from a gasoline can are common. Approximately 15 to 20 breaths of 1 percent gasoline vapor produce several hours of intoxication. Inhaled toluene concentrations from a glue-containing bag may reach 10,000 ppm, and vapors from several tubes of glue may be inhaled each day. By comparison, one study of just 100 ppm of toluene showed that a 6-hour exposure produced a temporary neuropsychological performance decrement of approximately 10 percent.

Inhalants generally act as a central nervous system (CNS) depressant. Tolerance for inhalants can develop, although withdrawal symptoms are usually fairly mild.

Inhalants are rapidly absorbed through the lungs and rapidly delivered to the brain. The effects appear within 5 minutes and can last for

30 minutes to several hours, depending on the inhalant substance and the dose. The concentrations of many inhalant substances in blood are increased when used in combination with alcohol, perhaps because of competition for hepatic enzymes. Although about one fifth of an inhalant substance is excreted unchanged by the lungs, the remainder is metabolized by the liver. Inhalants are detectable in the blood for 4 to 10 hours after use, and blood samples should be taken in the emergency room when inhalant use is suspected.

Much like alcohol, inhalants have specific pharmacodynamic effects that are not well understood. Because their effects are generally similar and additive to the effects of other CNS depressants (e.g., ethanol, barbiturates, and benzodiazepines), some investigators have suggested that inhalants operate by enhancing the γ -aminobutyric acid (GABA) system. Other investigators have suggested that inhalants work through membrane fluidization, which has also been hypothesized to be a pharmacodynamic effect of ethanol.

DIAGNOSIS

Inhalant Use Disorder

Most persons probably use inhalants for a short time without developing a pattern of long-term use resulting in dependence and abuse. Nonetheless, dependence and abuse of inhalants occur and are diagnosed according to the DSM-5 (see page 621).

Inhalant Intoxication

The diagnostic criteria for inhalant intoxication specify the presence of maladaptive behavioral changes and at least two physical symptoms. The intoxicated state is often characterized by apathy, diminished social and occupational functioning, impaired judgment, and impulsive or aggressive behavior, and it can be accompanied by nausea, anorexia, nystagmus, depressed reflexes, and diplopia. With high doses and long exposures, a user's neurological status can progress to stupor and unconsciousness, and a person may later be amnesic for the period of intoxication. Clinicians can sometimes identify a recent user of inhalants by rashes around the patient's nose and mouth; unusual breath odors; the residue of the inhalant substances on the patient's face, hands, or clothing; and irritation of the patient's eyes, throat, lungs, and nose. The disorder can be chronic, as in the following case.

A 16-year-old single Hispanic female was referred to a university substance-treatment program for evaluation. The patient had been convicted for auto theft, menacing with a weapon, and being out of control by her family. By age 15, she had regularly been using inhalants and drinking alcohol heavily. She had tried typewriter-erasing fluid, bleach, tile cleaner, hairspray, nail polish, glue, and gasoline, but preferred spray paint. She had sniffed paint many times each day for about 6 months at age 15, using a maximum of eight paint cans per day. The patient said, "It blacks out everything." Sometimes she had lost consciousness, and she believed that the paint had impaired her memory and made her "dumb." (Courtesy of Thomas J. Crowley, M.D.)

Inhalant Intoxication Delirium

Delirium can be induced by the effects of the inhalants themselves, by pharmacodynamic interactions with other substances, and by the hypoxia that may be associated with either the inhalant or its method of inhalation. If the delirium results in severe behavioral disturbances, short-term treatment with a dopamine receptor antagonist, such as haloperidol (Haldol), may be necessary. Benzodiazepines should be avoided because of the possibility of increasing the patient's respiratory depression.

Inhalant-Induced Persisting Dementia

Inhalant-induced persisting dementia, as with delirium, may result from the neurotoxic effects of the inhalants themselves; the neurotoxic effects of the metals (e.g., lead) commonly used in inhalants; or the effects of frequent and prolonged periods of hypoxia. The dementia caused by inhalants is likely to be irreversible in all but the mildest cases.

Inhalant-Induced Psychotic Disorder

Clinicians can specify hallucinations or delusions as the predominant symptoms. Paranoid states are probably the most common psychotic syndromes during inhalant intoxication.

Inhalant-Induced Mood Disorder and Inhalant-Induced Anxiety Disorder

Inhalant-induced mood disorder and inhalant-induced anxiety disorder allow the classification of inhalant-related disorders characterized by prominent mood and anxiety symptoms. Depressive disorders are the most common mood disorders associated with inhalant use, and panic disorders and generalized anxiety disorder are the most common anxiety disorders.

Other Inhalant-Induced Disorders

Other Inhalant-Induced Disorder is the recommended DSM-5 diagnosis for inhalant-related disorders that do not fit into one of the diagnostic categories discussed earlier.

CLINICAL FEATURES

In small initial doses, inhalants can be disinhibiting and produce feelings of euphoria and excitement as well as pleasant floating sensations, the effects for which persons presumably use the drugs. High doses of inhalants can cause psychological symptoms of fearfulness, sensory illusions, auditory and visual hallucinations, and distortions of body size. The neurological symptoms can include slurred speech, decreased speed of talking, and ataxia. Long-term use can be associated with irritability, emotional lability, and impaired memory.

Tolerance for the inhalants does develop for some users; a withdrawal syndrome can accompany the cessation of inhalant use. The withdrawal syndrome does not occur frequently; when it does, it can be characterized by sleep disturbances, irritability, jitteriness, sweating, nausea, vomiting, tachycardia, and (sometimes) delusions and hallucinations.

Organ Pathology and Neurological Effects

Inhalants are associated with many potentially serious adverse effects. The most serious of these is death, which can result from respiratory depression, cardiac arrhythmias, asphyxiation, aspiration of vomitus, or accident or injury (e.g., driving while intoxicated with inhalants). Placing an inhalant-soaked rag and one's head into a plastic bag, a common procedure for inhalant users, can cause coma and suffocation.

Chronic inhalant users may have numerous neurological problems. Computed tomography (CT) and magnetic resonance imaging (MRI) reveal diffuse cerebral, cerebellar, and brainstem atrophy with white matter disease, a leukoencephalopathy. Single photon emission CT (SPECT) of former solvent-abusing adolescents showed both increases and decreases of blood flow in different cerebral areas. Several studies of house painters and factory workers who have been exposed to solvents for long periods also have found evidence of brain atrophy on CT

scans, with decreased cerebral blood flow.

Neurological and behavioral signs and symptoms can include hearing loss, peripheral neuropathy, headache, paresthesias, cerebellar signs, persisting motor impairment, parkinsonism, apathy, poor concentration, memory loss, visual-spatial dysfunction, impaired processing of linguistic material, and lead encephalopathy. White matter changes, or pontine atrophy on MRI, have been associated with worse intelligence quotient (IQ) test results. The combination of organic solvents with high concentrations of copper, zinc, and heavy metals has been associated with the development of brain atrophy, temporal lobe epilepsy, decreased IQ, and a variety of electroencephalography (EEG) changes.

Other serious adverse effects associated with long-term inhalant use include irreversible hepatic disease or renal damage (tubular acidosis) and permanent muscle damage associated with rhabdomyolysis. Additional adverse effects include cardiovascular and pulmonary symptoms (e.g., chest pain and bronchospasm) as well as gastrointestinal (GI) symptoms (e.g., pain, nausea, vomiting, and hematemesis). There are several clinical reports of *toluene embryopathy*, with signs such as those of fetal alcohol syndrome. These include low birth weight, microcephaly, shortened palpebral fissures, small face, low-set ears, and other dysmorphic signs. These babies reportedly develop slowly, show hyperactivity, and have cerebellar dysfunction. No convincing evidence indicates, however, that toluene, the best-studied inhalant, produces genetic damage in somatic cells.

TREATMENT

Inhalant intoxication, as with alcohol intoxication, usually requires no medical attention and resolves spontaneously. However, effects of the intoxication, such as coma, bronchospasm, laryngospasm, cardiac arrhythmias, trauma, or burns, need treatment. Otherwise, care primarily involves reassurance, quiet support, and attention to vital signs and level of consciousness. Sedative drugs, including benzodiazepines, are contraindicated because they worsen inhalant intoxication.

No established treatment exists for the cognitive and memory problems of inhalant-induced persisting dementia. Street outreach and extensive social service support have been offered to severely deteriorated, inhalant-dependent, homeless adults. Patients may require extensive support within their families or in foster or domiciliary care.

The course and treatment of inhalant-induced psychotic disorder are like those of inhalant intoxication. The disorder is brief, lasting a few hours to (at most) a very few weeks beyond the intoxication. Appropriate is vigorous treatment of such life-threatening complications as respiratory or cardiac arrest, together with conservative management of the intoxication itself. Confusion, panic, and psychosis mandate special attention to patient safety. Severe agitation may require cautious control with haloperidol (5 mg intramuscularly per 70 kg body weight). Sedative drugs should be avoided because they may aggravate the psychosis. Inhalant-induced anxiety and mood disorders may precipitate suicidal ideation, and patients should be carefully evaluated for that possibility. Antianxiety medications and antidepressants are not useful in the acute phase of the disorder; they may be of use in cases of a coexisting anxiety or depressive illness.

Day Treatment and Residential Programs

Day treatment and residential programs have been used successfully, especially for adolescent abusers with combined substance dependence and other psychiatric disorders. Treatment addresses the comorbid state which, in most cases, is conduct disorder or, in other instances, may be attention-deficit/hyperactivity disorder (ADHD), major depressive disorder, dysthymic disorder, and posttraumatic stress disorder (PTSD). Attention is also directed to experiences of abuse or neglect, which is very common in these patients. Both group and individual therapy are used that are behaviorally oriented, with immediate rewards for progress toward objectively defined goals in treatment and punishments for lapses to previous behaviors. Patients attend on-site schools with special education teachers, together with planned recreational activities, and the programs provide birth control consultations. The patients' families, often very chaotic, are engaged in modifications of structural family therapy or multisystemic therapy, both of which have good empirical support. Participation in 12-step programs is required. Treatment interventions are coordinated closely with interventions by community social workers and probation officers. Progress is monitored with urine and breath samples analyzed for alcohol and other drugs at intake and frequently during treatment.

Treatment usually lasts 3 to 12 months. Termination is considered successful if the youth has practiced a plan to stay abstinent; is showing fewer antisocial behaviors; has a plan to continue any needed psychiatric treatment (e.g., treatment for comorbid depression); has a plan to live in a supportive, drug-free environment; is interacting with the family in a more productive way; is working or attending school; and is associating with drug-free, nondelinquent peers.

20.7 Opioid-Related Disorders

Opioids have been used for analgesic and other medicinal purposes for thousands of years, but they also have a long history of misuse for their psychoactive effects. Continued opioid misuse can result in syndromes of abuse and dependence and cause disturbances in mood, behavior, and cognition that can mimic other psychiatric disorders. In developed countries, the opioid drug most frequently associated with abuse and dependence is heroin; however, there is growing public health concern about prescription opioids, which are widely available, have significant abuse liability, and are used increasingly for purposes. Opioid addiction affects the young and the old, the wealthy and the poor, and the professional and the unemployed. Over the last few decades there have been significant advances in treatment and understanding of opioid dependence. It is increasingly accepted that opioid dependence is often a chronic, relapsing disorder amenable to

medical treatment and intervention. Table 20.7-1 lists various opioids that are used therapeutically in the United States, with the exception of heroin.

Table 20.7-1
Opioids

Proprietary Name	Trade Name
Morphine	
Heroin (diacetylmorphine)	
Hydromorphone (dihydromorphinone)	Dilaudid
Oxymorphone (dihydrohydroxymorphinone)	Numorphan
Levorphanol	Levo-Dromoran
Methadone	Dolophine
Meperidine (pethidine)	Demerol, Pethadol
Fentanyl	Sublimaze
Codeine	
Hydrocodone (dihydrocodeinone)	Hycodan, others
Drocode (dihydrocodeine)	Synalgos-DC, Compal
Oxycodone (dihydrohydroxycodone)	Roxicodone, OxyContin, Percodan, Percocet, Vicodin
Propoxyphene	Darvon, others
Buprenorphine	Buprenex
Pentazocine	Talwin
Nalbuphine	Nubain
Butorphanol	Stadol

Opioid dependence is a cluster of physiological, behavioral, and cognitive symptoms, which together indicate repeated and continuing use of opioid drugs, despite significant problems related to such use. Drug dependence, in general, has been defined by the World Health Organization (WHO) as a syndrome in which the use of a drug or class of drugs takes on a much higher priority for a given person than other behaviors that once had a higher value. These brief definitions each have as their central features an emphasis on the drug-using behavior itself, its maladaptive nature, and how the choice to engage in that behavior shifts and becomes constrained as a result of interaction with the drug over time.

Opioid abuse is a term used to designate a pattern of maladaptive use of an opioid drug leading to clinically significant impairment or distress and occurring within a 12-month period, but one in which the symptoms have never met the criteria for opioid dependence.

The opioid-induced disorders include such common phenomena as opioid use disorder, opioid intoxication, opioid withdrawal, opioid-induced sleep disorder, and opioid-induced sexual dysfunction. Opioid intoxication delirium is occasionally seen in hospitalized patients. Opioid-induced psychotic disorder, opioid-induced mood disorder, and opioid-induced anxiety disorder, by contrast, are quite uncommon with μ -agonist opioids, but have been seen with certain mixed agonist-antagonist opioids acting at other receptors. The diagnosis of opioid-related disorder not elsewhere classified is used for situations that do not meet the criteria for any of the other opioid-related disorders.

In addition to the morbidity and mortality associated directly with the opioid-related disorders, the association between the transmission of the human immunodeficiency virus (HIV) and intravenous opioid and opiate use is now recognized as a leading national health concern. The words *opiate* and *opioid* come from the word opium, the juice of the opium poppy, *Papaver somniferum*, which contains approximately 20 opium alkaloids, including morphine.

Many synthetic opioids have been manufactured, including meperidine (Demerol), methadone (Dolophine), pentazocine (Talwin), and propoxyphene (Darvon). Methadone is the current gold standard in the treatment of opioid dependence. Opioid antagonists have been synthesized to treat opioid overdose and opioid dependence. This class of drugs includes naloxone (Narcan), naltrexone (ReVia), nalorphine, levallorphan, and apomorphine. Compounds with mixed agonist and antagonist activity at opioid receptors have been synthesized and include pentazocine, butorphanol (Stadol), and buprenorphine (Buprenex). Studies have found buprenorphine to be an effective treatment for opioid dependence.

EPIDEMIOLOGY

The use and dependence rates derived from national surveys do not accurately reflect fluctuations in drug use among opioid-dependent and previously opioid-dependent populations. When the supply of illicit heroin increases in purity or decreases in price, use among that vulnerable population tends to increase, with subsequent increases in adverse consequences (emergency room visits) and requests for treatment. The number of current heroin users in the United States has been estimated to be between 600,000 and 800,000. The number of people estimated to have used heroin at any time in their lives (lifetime users) is estimated at approximately 3 million.

In 2010, an estimated 140,000 persons had used heroin for the first time within the past 12 months. The average age of first use among recent initiates was 21.3 years in 2010. Opioid use in the United States experienced a resurgence in the 1990s, with emergency department visits related to heroin abuse doubling between 1990 and 1995. This increase in heroin use was associated with an increase in heroin purity and a decrease in its street price. In the late 1990s, heroin use increased among people who were 18 to 25 years of age, and a brief upsurge was seen in the use of oxycodone (OxyContin). Methods of administration other than injecting, such as smoking and snorting, increased in popularity. In 2010, the number of new nonmedical users of psychiatry of oxycodone was 598,000, with an average age at first use of 22.8 years. Comparable data on past year oxycodone initiation are not available for prior years, but calendar year estimates of oxycodone initiation show a steady increase in the number of initiates from 1995, the year this drug was first available, through 2003. The male-to-female ratio of persons with heroin dependence is about 3:1. Users of opioids typically started to use substances in their teens and early 20s; currently, most persons with opioid dependence are in their 30s and 40s. The tendency for dependence to remit generally begins after age 40 years and has been called “maturing out.” Many persons, however, have remained opioid dependent for 50 years or longer. In the United States, persons tend to experience their first opioid-induced experience in their early teens or even as young as 10 years of age. Early induction into the drug culture is likely in communities in which substance abuse is rampant and in families in which the parents are substance abusers. A heroin habit can cost a person hundreds of dollars a day; thus, a person with opioid dependence needs to obtain money through criminal activities and prostitution. The involvement of persons with opioid dependence in prostitution accounts for much of the spread of HIV. The lifetime prevalence for heroin use is about 1 percent, with 0.2 percent having taken the drug during the prior year.

NEUROPHARMACOLOGY

The primary effects of the opioid drugs are mediated via the opioid receptors, which were discovered in the first half of the 1970s (published in 1973). The μ -opioid receptors are involved in the regulation and mediation of analgesia, respiratory depression, constipation, and drug dependence; the κ -opioid receptors, with analgesia, diuresis, and sedation; and the Δ -opioid receptors, with analgesia.

In 1975, the enkephalins, two endogenous pentapeptides with opioid-like actions, were identified. This discovery led to the identification

of three classes of endogenous opioids within the brain, including the endorphins, the dynorphins, and the enkephalins. The term “endorphin” (a contraction of “endogenous” and “morphine”) was coined by Dr. Eric Simon, Professor of psychiatry at NYU School of Medicine, one of the scientists who discovered the opioid receptors, to serve as a generic name for all molecules with morphine-like activity found in the brain. Endorphins are involved in neural transmission and pain suppression. They are released naturally in the body when a person is physically hurt or severely stressed and are thought to account for the absence of pain during acute injuries.

The endogenous opioids also have significant interactions with other neuronal systems, such as the dopaminergic and noradrenergic neurotransmitter systems. Several types of data indicate that the addictive rewarding properties of opioids are mediated through activation of the ventral tegmental area dopaminergic neurons that project to the cerebral cortex and the limbic system (Fig. 20.7-1).

FIGURE 20.7-1

Scheme illustrating opioid actions in the locus ceruleus (LC). Opioids acutely inhibit LC neurons by increasing the conductance of a K^+ channel (light cross-hatch) via coupling with subtypes of G_i and/or G_o and by decreasing an Na^+ -dependent inward current (dark cross-hatch) via coupling with $G_{i/o}$ and the consequent inhibition of adenylyl cyclase. Reduced levels of cAMP decrease PKA and the phosphorylation of the responsible channel or pump. Inhibition of the cyclic adenosine monophosphate (cAMP) pathway also decreases phosphorylation of numerous other proteins and thereby affects many additional processes in the neuron. For example, it reduces the phosphorylation state of CREB, which may initiate some of the longer-term changes in LC function. *Upper bold arrows* summarize effects of repeated morphine administration in the LC. Repeated morphine administration increases levels of adenylyl cyclase, PKA, and several phosphoproteins, including CREB. These changes contribute to the altered phenotype of the drug-addicted state. For example, the intrinsic excitability of LC neurons is increased via enhanced activity of the cAMP pathway and Na^+ -dependent inward current, which contributes to the tolerance, dependence, and withdrawal exhibited by these neurons. This altered phenotypic state appears to be maintained, in part, by upregulation of CREB expression. (From Nestler EJ. Molecular mechanisms underlying opiate addiction: Implications for medications development. *Semin Neurosci.* 1997;9:84, with permission.)

Heroin, the most commonly abused opioid, is more lipid soluble than morphine. This allows it to cross the blood–brain barrier faster and have a more rapid and pleasurable onset than morphine. Heroin was first introduced as a treatment for morphine addiction, but heroin, in fact, is more dependence producing than morphine. Codeine, which occurs naturally as about 0.5 percent of the opiate alkaloids in opium, is absorbed easily through the gastrointestinal tract and is subsequently transformed into morphine in the body. Results of at least one study using positron emission tomography (PET) have suggested that one effect of all opioids is decreased cerebral blood flow in selected brain regions in persons with opioid dependence. There is interesting evidence indicating that the endorphins are involved in other addictions, such as alcoholism, cocaine, and cannabinoid addiction. The opioid antagonist, naltrexone, has shown value in mitigating alcohol addiction.

The discovery of this new endorphinergic neuromodulatory system has led to the discovery of an endogenous cannabinoid system and has stimulated many outstanding laboratories to do research toward improved pain management and prevention and treatment of narcotic addiction.

Tolerance and Dependence

Tolerance to all actions of opioid drugs does not develop uniformly. Tolerance to some actions of opioids can be so high that a 100-fold increase in dose is required to produce the original effect. For example, terminally ill cancer patients may need 200 to 300 mg a day of morphine, whereas a dose of 60 mg can easily be fatal to an opioid-naive person. The symptoms of opioid withdrawal do not appear unless a person has been using opioids for a long time or when cessation is particularly abrupt, as occurs functionally when an opioid antagonist is given. The long-term use of opioids results in changes in the number and sensitivity of opioid receptors, which mediate at least some of the effects of tolerance and withdrawal. Although long-term use is associated with increased sensitivity of the dopaminergic, cholinergic, and serotonergic neurons, the effect of opioids on the noradrenergic neurons is probably the primary mediator of the symptoms of opioid withdrawal. Short-term use of opioids apparently decreases the activity of the noradrenergic neurons in the locus ceruleus; long-term use activates a compensatory homeostatic mechanism within the neurons; and opioid withdrawal results in rebound hyperactivity. This hypothesis also provides an explanation for why clonidine (Catapres), an α_2 -adrenergic receptor agonist that decreases the release of norepinephrine, is useful in the treatment of opioid withdrawal symptoms.

COMORBIDITY

About 90 percent of persons with opioid dependence have an additional psychiatric disorder. The most common comorbid psychiatric diagnoses are major depressive disorder, alcohol use disorders, antisocial personality disorder, and anxiety disorders. About 15 percent of persons with opioid dependence attempt to commit suicide at least once. The high prevalence of comorbidity with other psychiatric diagnoses (Table 20.7-2) highlights the need to develop a broad-based treatment program that also addresses patients' associated psychiatric disorders.

Table 20.7-2
Non-Substance-Related Psychiatric Disorders in Opioid Users

Diagnostic Category*	Lifetime Rates % (Current Rates %)		
	Men (N = 378)	Women (N = 338)	Total
Mood disorder	11.4 (2.1)	27.5 (5.3)	19.0 (3.6)
Major depressive disorder	8.7 (1.3)	23.7 (5.3)	15.8 (3.2)
Dysthymic disorder	2.4 (2.4)	4.4 (4.4)	3.4 (3.4)
Bipolar I disorder	0.8 (0.8)	0.0 (0.0)	0.4 (0.4)
Anxiety disorder	6.1 (3.4)	10.7 (6.8)	8.2 (5.0)
Simple phobia	1.9 (1.9)	5.3 (3.6)	3.5 (2.7)
Social phobia	1.9 (0.8)	3.6 (2.7)	2.7 (1.7)
Panic disorder	2.1 (0.3)	1.8 (0.9)	2.0 (0.6)
Agoraphobia	0.0 (0.0)	0.6 (0.3)	0.3 (0.1)
Obsessive-compulsive disorder	0.5 (0.5)	0.0 (0.0)	0.3 (0.3)
General anxiety disorder	0.8 (0.8)	0.0 (0.0)	0.1 (0.1)

 Psychiatric and substance use comorbidity among treatment-seeking
 opioid abusers. *Arch Gen Psychiatry*. 1997;54:71.)

ETIOLOGY

Psychosocial Factors

Opioid dependence is not limited to low socioeconomic status (SES), although the incidence of opioid dependence is greater in these groups than in higher SES groups. Social factors associated with urban poverty probably contribute to opioid dependence. About 50 percent of urban heroin users are children of single parents or divorced parents and are from families in which at least one other member has a substance-related disorder. Children from such settings are at high risk for opioid dependence, especially if they also evidence behavioral problems in school or other signs of conduct disorder.

Some consistent behavior patterns seem to be especially pronounced in adolescents with opioid dependence. These patterns have been called the *heroin behavior syndrome*: underlying depression, often of an agitated type and frequently accompanied by anxiety symptoms; impulsiveness expressed by a passive-aggressive orientation; fear of failure; use of heroin as an antianxiety agent to mask feelings of low self-esteem, hopelessness, and aggression; limited coping strategies and low frustration tolerance, accompanied by the need for immediate gratification; sensitivity to drug contingencies, with a keen awareness of the relation between good feelings and the act of drug taking; feelings of behavioral impotence counteracted by momentary control over the life situation by means of substances; disturbances in social and interpersonal relationships with peers maintained by mutual substance experiences.

Biological and Genetic Factors

Evidence now exists for common and drug-specific, genetically transmitted vulnerability factors that increase the likelihood of developing drug dependence. Individuals who abuse a substance from any category are more likely to abuse substances from other categories. Monozygotic twins are more likely than dizygotic twins to be concordant for opioid dependence. Multivariate modeling techniques have indicated that not only was the genetic contribution high for heroin abuse in this group, but also a higher proportion of the variance because of genetic factors was not shared with the common vulnerability factor—that is, it was specific for opioids.

A person with an opioid-related disorder may have had genetically determined hypoactivity of the opiate system. Researchers are investigating the possibility that such hypoactivity may be caused by too few, or less-sensitive, opioid receptors, by release of too little endogenous opioid, or by overly high concentrations of a hypothesized endogenous opioid antagonist. A biological predisposition to an opioid-related disorder may also be associated with abnormal functioning in either the dopaminergic or the noradrenergic neurotransmitter system.

Psychodynamic Theory

In psychoanalytic literature, the behavior of persons addicted to narcotics has been described in terms of libidinal fixation, with regression to pregenital, oral, or even more archaic levels of psychosexual development. The need to explain the relation of drug abuse, defense mechanisms, impulse control, affective disturbances, and adaptive mechanisms led to the shift from psychosexual formulations to formulations emphasizing ego psychology. Serious ego pathology, often thought to be associated with substance abuse, is considered to indicate profound developmental disturbances. Problems of the relation between the ego and affects emerge as a key area of difficulty.

DIAGNOSIS

Opioid Use Disorder

Opioid use disorder is a pattern of maladaptive use of an opioid drug, leading to clinically significant impairment or distress and occurring within a 12-month period.

A 42-year-old executive in a public relations firm was referred for psychiatric consultation by his surgeon, who discovered him sneaking large quantities of a codeine-containing cough medicine into the hospital. The patient had been a heavy cigarette smoker for 20 years and had a chronic, hacking cough. He had come into the hospital for a hernia repair and found the pain from the incision unbearable when he coughed.

An back operation 5 years previously had led his doctors to prescribe codeine to help relieve the incisional pain at that time. Over the intervening 5 years, however, the patient had continued to use codeine-containing tablets and had increased his intake to 60–90 mg daily. He stated that he often “just took them by the handful—not to feel good, you understand, just to get by.” He spent considerable time and effort developing a circle of physicians and pharmacists to whom he would “make the rounds” at least three times a week to obtain new

supplies of pills. He had tried several times to stop using codeine, but had failed. During this period he lost two jobs because of lax work habits and was divorced by his wife of 11 years.

Opioid Intoxication

Opioid intoxication includes maladaptive behavioral changes and specific physical symptoms of opioid use. In general, altered mood, psychomotor retardation, drowsiness, slurred speech, and impaired memory and attention in the presence of other indicators of recent opioid use strongly suggest a diagnosis of opioid intoxication.

Opioid Withdrawal

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) diagnostic criteria for opioid withdrawal are listed in [Table 20.7-3](#). The general rule about the onset and duration of withdrawal symptoms is that substances with short durations of action tend to produce short, intense withdrawal syndromes and substances with long durations of action produce prolonged, but mild, withdrawal syndromes. An exception to the rule, narcotic antagonist-precipitated withdrawal after long-acting opioid dependence can be severe.

 **Table 20.7-3**
DSM-5 Diagnostic Criteria for Opioid Withdrawal

- A. Presence of either of the following:
1. Cessation of (or reduction in) opioid use that has been heavy and prolonged (i.e., several weeks or longer).
 2. Administration of an opioid antagonist after a period of opioid use.
- B. Three (or more) of the following developing within minutes to several days after Criterion A:
1. Dysphoric mood.
 2. Nausea or vomiting.
 3. Muscle aches.
 4. Lacrimation or rhinorrhea.
 5. Pupillary dilation, piloerection, or sweating.
 6. Diarrhea.
 7. Yawning.
 8. Fever.
 9. Insomnia.
- C. The signs or symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The signs or symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication or withdrawal from another substance.
- Coding note:** The ICD-9-CM code is 292.0. The ICD-10-CM code for opioid withdrawal is F11.23. Note that the ICD-10-CM code indicates the comorbid presence of a moderate or severe opioid use disorder, reflecting the fact that opioid withdrawal can only occur in the presence of a moderate or severe opioid use disorder. It is not permissible to code a comorbid mild opioid use disorder with opioid withdrawal.

An abstinence syndrome can be precipitated by administration of an opioid antagonist. The symptoms can begin within seconds of such an intravenous injection and peak in about 1 hour. Opioid craving rarely occurs in the context of analgesic administration for pain from physical disorders or surgery. The full withdrawal syndrome, including intense craving for opioids, usually occurs only secondary to abrupt cessation of use in persons with opioid dependence.

Morphine and Heroin. The morphine and heroin withdrawal syndrome begins 6 to 8 hours after the last dose, usually after a 1- to 2-week period of continuous use or after the administration of a narcotic antagonist. The withdrawal syndrome reaches its peak intensity during the second or third day and subsides during the next 7 to 10 days, but some symptoms may persist for 6 months or longer.

Meperidine. The withdrawal syndrome from meperidine begins quickly, reaches a peak in 8 to 12 hours, and ends in 4 to 5 days.

Methadone. Methadone withdrawal usually begins 1 to 3 days after the last dose and ends in 10 to 14 days.

Symptoms. Opioid withdrawal consists of severe muscle cramps and bone aches, profuse diarrhea, abdominal cramps, rhinorrhea, lacrimation, piloerection or gooseflesh (from which comes the term *cold turkey* for the abstinence syndrome), yawning, fever, pupillary dilation, hypertension, tachycardia, and temperature dysregulation, including hypothermia and hyperthermia. Persons with opioid dependence seldom die from opioid withdrawal, unless they have a severe preexisting physical illness such as cardiac disease. Residual symptoms—such as insomnia, bradycardia, temperature dysregulation, and a craving for opioids—can persist for months after withdrawal. Associated features of opioid withdrawal include restlessness, irritability, depression, tremor, weakness, nausea, and vomiting. At any time during the abstinence syndrome, a single injection of morphine or heroin eliminates all the symptoms.

Opioid Intoxication Delirium

Opioid intoxication delirium is most likely to happen when opioids are used in high doses, are mixed with other psychoactive compounds, or are used by a person with preexisting brain damage or a central nervous system (CNS) disorder (e.g., epilepsy).

Opioid-Induced Psychotic Disorder

Opioid-induced psychotic disorder can begin during opioid intoxication. Clinicians can specify whether hallucinations or delusions are the predominant symptoms.

Opioid-Induced Mood Disorder

Opioid-induced mood disorder can begin during opioid intoxication. Opioid-induced mood disorder symptoms can have a manic, depressed, or mixed nature, depending on a person's response to opioids. A person coming to psychiatric attention with opioid-induced mood disorder

usually has mixed symptoms, combining irritability, expansiveness, and depression.

Opioid-Induced Sleep Disorder and Opioid-Induced Sexual Dysfunction

Hypersomnia is likely to be more common with opioids than insomnia. The most common sexual dysfunction is likely to be impotence.

Unspecified Opioid-Related Disorder

The DSM-5 includes diagnoses for other opioid-related disorders with symptoms of delirium, abnormal mood, psychosis, abnormal sleep, and sexual dysfunction. Clinical situations that do not fit into these categories exemplify appropriate cases for the use of the DSM-5 diagnosis of unspecified opioid-related disorder.

CLINICAL FEATURES

Opioids can be taken orally, snorted intranasally, and injected intravenously or subcutaneously (Fig. 20.7-2). Opioids are subjectively addictive because of the euphoric high (the rush) that users experience, especially those who take the substances intravenously. The associated symptoms include a feeling of warmth, heaviness of the extremities, dry mouth, itchy face (especially the nose), and facial flushing. The initial euphoria is followed by a period of sedation, known in street parlance as “nodding off.” Opioid use can induce dysphoria, nausea, and vomiting in opioid-naive persons.

FIGURE 20.7-2

Skin popper. Circular depressed scars, often with underlying chronic abscesses, can result from skin popping. (Courtesy of Michael Baden, M.D.)

The physical effects of opioids include respiratory depression, pupillary constriction, smooth muscle contraction (including the ureters and the bile ducts), constipation, and changes in blood pressure, heart rate, and body temperature. The respiratory depressant effects are mediated at the level of the brainstem.

Adverse Effects

The most common and most serious adverse effect associated with the opioid-related disorders is the potential transmission of hepatitis and HIV through the use of contaminated needles by more than one person. Persons can experience idiosyncratic allergic reactions to opioids, which result in anaphylactic shock, pulmonary edema, and death if they do not receive prompt and adequate treatment. Another serious adverse effect is an idiosyncratic drug interaction between meperidine and monoamine oxidase inhibitors (MAOIs), which can produce gross autonomic instability, severe behavioral agitation, coma, seizures, and death. Opioids and MAOIs should not be given together for this reason.

Opioid Overdose

Death from an overdose of an opioid is usually attributable to respiratory arrest from the respiratory depressant effect of the drug. The symptoms of overdose include marked unresponsiveness, coma, slow respiration, hypothermia, hypotension, and bradycardia. When presented with the clinical triad of coma, pinpoint pupils, and respiratory depression, clinicians should consider opioid overdose as a primary diagnosis. They can also inspect the patient's body for needle tracks in the arms, legs, ankles, groin, and even the dorsal vein of the penis.

MPTP-Induced Parkinsonism

In 1976, after ingesting an opioid contaminated with methyl-phenyltetrahydropyridine (MPTP), several persons developed a syndrome of irreversible parkinsonism. The mechanism for the neurotoxic effect is as follows: MPTP is converted into 1-methyl-4-phenylpyridinium (MPP⁺) by the enzyme monoamine oxidase and is then taken up by dopaminergic neurons. Because MPP⁺ binds to melanin in substantia nigra neurons, MPP⁺ is concentrated in these neurons and eventually kills the cells. PET studies of persons who ingested MPTP but remained asymptomatic have shown a decreased number of dopamine-binding sites in the substantia nigra. This decrease reflects a loss in the number of dopaminergic neurons in that region.

TREATMENT AND REHABILITATION

Overdose Treatment

The first task in overdose treatment is to ensure an adequate airway. Tracheopharyngeal secretions should be aspirated; an airway may be inserted. The patient should be ventilated mechanically until naloxone, a specific opioid antagonist, can be given. Naloxone is administered intravenously at a slow rate—initially about 0.8 mg per 70 kg of body weight. Signs of improvement (increased respiratory rate and pupillary dilation) should occur promptly. In opioid-dependent patients, too much naloxone may produce signs of withdrawal as well as reversal of overdosage. If no response to the initial dosage occurs, naloxone administration may be repeated after intervals of a few minutes. Previously, it was thought that if no response was observed after 4 to 5 mg, the CNS depression was probably not caused solely by opioids. The duration of action of naloxone is short compared with that of many opioids, such as methadone and levomethadyl acetate, and repeated administration may be required to prevent recurrence of opioid toxicity.

Medically Supervised Withdrawal and Detoxification

Opioid Agents for Treating Opioid Withdrawal

METHADONE. Methadone is a synthetic narcotic (an opioid) that substitutes for heroin and can be taken orally. When given to addicts to replace their usual substance of abuse, the drug suppresses withdrawal symptoms. A daily dose of 20 to 80 mg suffices to stabilize a patient, although daily doses of up to 120 mg have been used. The duration of action for methadone exceeds 24 hours; thus, once-daily dosing is adequate. Methadone maintenance is continued until the patient can be withdrawn from methadone, which itself causes dependence. An abstinence syndrome occurs with methadone withdrawal, but patients are detoxified from methadone more easily than from heroin. Clonidine (0.1 to 0.3 mg three to four times a day) is usually given during the detoxification period.

Methadone maintenance has several advantages. First, it frees persons with opioid dependence from using injectable heroin and, thus, reduces the chance of spreading HIV through contaminated needles. Second, methadone produces minimal euphoria and rarely causes drowsiness or depression when taken for a long time. Third, methadone allows patients to engage in gainful employment instead of criminal activity. The major disadvantage of methadone use is that patients remain dependent on a narcotic.

Other Opioid Substitutes

LEVOMETHADYL (LAAM). LAAM is an opioid agonist that suppresses opioid withdrawal. It is no longer used, however, because some patients developed prolonged QT intervals associated with potentially fatal arrhythmias (*torsades de pointes*).

BUPRENORPHINE. As with methadone and LAAM, buprenorphine is an opioid agonist approved for opioid dependence in 2002. It can be dispensed on an outpatient basis, but prescribing physicians must demonstrate that they have received special training in its use. Buprenorphine in a daily dose of 8 to 10 mg appears to reduce heroin use. Buprenorphine also is effective in thrice-weekly dosing because of its slow dissociation from opioid receptors. After repeated administration, it attenuates or blocks the subjective effects of parenterally administered opioids such as heroin or morphine. A mild opioid withdrawal syndrome occurs if the drug is abruptly discontinued after chronic administrations.

Opioid Antagonists. Opioid antagonists block or antagonize the effects of opioids. Unlike methadone, they do not exert narcotic effects and do not cause dependence. Opioid antagonists include naloxone, which is used in the treatment of opioid overdose because it reverses the effects of narcotics, and naltrexone, the longest-acting (72 hours) antagonist. The theory for using an antagonist for opioid-related disorders is that blocking opioid agonist effects, particularly euphoria, discourages persons with opioid dependence from substance-seeking behavior and, thus, deconditions this behavior. The major weakness of the antagonist treatment model is the lack of any mechanism that compels a person to continue to take the antagonist.

Pregnant Women with Opioid Dependence

Neonatal addiction is a significant problem. About three fourths of all infants born to addicted mothers experience the withdrawal syndrome.

Neonatal Withdrawal. Although opioid withdrawal rarely is fatal for the otherwise healthy adult, it is hazardous to the fetus and can lead to miscarriage or fetal death. Maintaining a pregnant woman with opioid dependence on a low dose of methadone (10 to 40 mg daily) may be the least hazardous course to follow. At this dose, neonatal withdrawal is usually mild and can be managed with low doses of paregoric. If pregnancy begins while a woman is taking high doses of methadone, the dosage should be reduced slowly (e.g., 1 mg every 3 days), and fetal movements should be monitored. If withdrawal is necessary or desired, it is least hazardous during the second trimester.

Fetal AIDS Transmission. Acquired immune deficiency syndrome (AIDS) is the other major risk to the fetus of a woman with opioid dependence. Pregnant women can pass HIV, the causative agent of AIDS, to the fetus through the placental circulation. An HIV-infected mother can also pass HIV to the infant through breast-feeding. The use of zidovudine (Retrovir) alone or in combination with other anti-HIV medication in infected women can decrease the incidence of HIV in newborns.

Psychotherapy

The entire range of psychotherapeutic modalities is appropriate for treating opioid-related disorders. Individual psychotherapy, behavioral therapy, cognitive-behavioral therapy, family therapy, support groups (e.g., Narcotics Anonymous [NA]), and social skills training may all prove effective for specific patients. Social skills training should be particularly emphasized for patients with few social skills. Family therapy is usually indicated when the patient lives with family members.

Therapeutic Communities

Therapeutic communities are residences in which all members have a substance abuse problem. Abstinence is the rule; to be admitted to such a community, a person must show a high level of motivation. The goals are to effect a complete change of lifestyle, including abstinence from substances; to develop personal honesty, responsibility, and useful social skills; and to eliminate antisocial attitudes and criminal behavior.

The staff members of most therapeutic communities are persons with former substance dependence who often put prospective candidates through a rigorous screening process to test their motivation. Self-help through the use of confrontational groups and isolation from the outside world and from friends associated with the drug life are emphasized. The prototypical community for persons with substance dependence is Phoenix House, where the residents live for long periods (usually 12 to 18 months) while receiving treatment. They are allowed to return to their old environments only when they have demonstrated their ability to handle increased responsibility within the therapeutic community. Therapeutic communities can be effective but require large staffs and extensive facilities. Moreover, dropout rates are high; up to 75 percent of those who enter therapeutic communities leave within the first month.

Education and Needle Exchange. Although the essential treatment of opioid use disorders is encouraging persons to abstain from opioids, education about the transmission of HIV must receive equal attention. Persons with opioid dependence who use intravenous or subcutaneous routes of administration must be taught available safe-sex practices. Free needle-exchange programs are often subject to intense political and societal pressures but, where allowed, should be made available to persons with opioid dependence. Several studies have indicated that unsafe needle sharing is common when it is difficult to obtain enough clean needles and is also common in persons with legal difficulties, severe substance problems, and psychiatric symptoms. These are just the persons most likely to be involved in transmitting HIV.

Narcotics Anonymous

Narcotics Anonymous is a self-help group of abstinent drug addicts modeled on the 12-step principles of Alcoholics Anonymous (AA). Such groups now exist in most large cities and can provide useful group support. The outcome for patients treated in 12-step programs is generally good, but the anonymity that is at the core of the 12-step model has made detailed evaluation of its efficacy in treating opioid

dependence difficult.

20.8 Sedative-, Hypnotic-, or Anxiolytic-Related Disorders

The drugs discussed in this section are referred to as *anxiolytic* or *sedative-hypnotic* drugs. Their sedative or calming effects are on a continuum with their hypnotic or sleep-inducing effects. In addition to their psychiatric indications, these drugs are also used as antiepileptics, muscle relaxants, anesthetics, and anesthetic adjuvants. Alcohol and all drugs of this class are cross-tolerant, and their effects are additive. Physical and psychological dependence develops to these drugs, and all are associated with withdrawal symptoms. In the practice of psychiatry and addiction medicine, the drug class that is most important clinically is the benzodiazepines.

The three major groups of drugs associated with this class of substance-related disorders are benzodiazepines, barbiturates, and barbiturate-like substances. Each group is discussed below.

BENZODIAZEPINES

Many benzodiazepines, differing primarily in their half-lives, are available in the United States. Examples of benzodiazepines are diazepam, flurazepam (Dalmane), oxazepam (Serax), and chlordiazepoxide (Librium). Benzodiazepines are used primarily as anxiolytics, hypnotics, antiepileptics, and anesthetics, as well as for alcohol withdrawal. After their introduction in the United States in the 1960s, benzodiazepines rapidly became the most prescribed drugs; about 15 percent of all persons in the United States have had a benzodiazepine prescribed by a physician. Increasing awareness of the risks for dependence on benzodiazepines and increased regulatory requirements, however, have decreased the number of benzodiazepine prescriptions. The Drug Enforcement Agency (DEA) classifies all benzodiazepines as Schedule IV controlled substances.

Flunitrazepam (Rohypnol), a benzodiazepine used in Mexico, South America, and Europe but not available in the United States, has become a drug of abuse. When taken with alcohol, it has been associated with promiscuous sexual behavior and rape. It is illegal to bring flunitrazepam into the United States. Although misused in the United States, it remains a standard anxiolytic in many countries.

Non-benzodiazepine sedatives such as zolpidem (Ambien) zaleplon (Sonata), and eszopiclone (Lunesta)—the so called Z drugs—have clinical effects similar to the benzodiazepines and are also subject to misuse and dependence.

BARBITURATES

Before the introduction of benzodiazepines, barbiturates were frequently prescribed, but because of their high abuse potential, their use is much rarer today. Secobarbital (popularly known as “reds,” “red devils,” “seggies,” and “downers”), pentobarbital (Nembutal) (known as “yellow jackets,” “yellows,” and “nembies”), and a secobarbital–amobarbital combination (known as “reds and blues,” “rainbows,” “double-trouble,” and “tooies”) are easily available on the street from drug dealers. Pentobarbital, secobarbital, and amobarbital (Amytal) are now under the same federal legal controls as morphine.

The first barbiturate, barbital (Veronal), was introduced in the United States in 1903. Barbital and phenobarbital (Solfoton, Luminal), which was introduced shortly thereafter, are long-acting drugs with half-lives of 12 to 24 hours. Amobarbital is an intermediate-acting barbiturate with a half-life of 6 to 12 hours. Pentobarbital and secobarbital are short-acting barbiturates with half-lives of 3 to 6 hours. Although barbiturates are useful and effective sedatives, they are highly lethal with only ten times the normal dose producing coma and death.

BARBITURATE-LIKE SUBSTANCES

The most commonly abused barbiturate-like substance is methaqualone, which is no longer manufactured in the United States. It is often used by young persons who believe that the substance heightens the pleasure of sexual activity. Abusers of methaqualone commonly take one or two standard tablets (usually 300 mg per tablet) to obtain the desired effects. The street names for methaqualone include “mandrakes” (from the United Kingdom preparation Mandrax) and “soapers” (from the brand name Sopor). “Luding out” (from the brand name Quaalude) means getting high on methaqualone, which is often combined with excessive alcohol intake.

Other barbiturate-like substances include meprobamate (Equanil), a carbamate derivative that has weak efficacy as an antianxiety agent but has muscle-relaxant effects and is used for that purpose; chloral hydrate, a hypnotic that is highly toxic to the gastrointestinal (GI) system and, when combined with alcohol, is known as a “mickey finn”; and ethchlorvynol, a rapidly acting sedative agent with anticonvulsant and

muscle-relaxant properties. All are subject to abuse.

EPIDEMIOLOGY

About 6 percent of individuals have used either sedatives or tranquilizers illicitly, including 0.3 percent who reported illicit use of sedatives in the prior year and 0.1 percent who reported use of sedatives in the prior month. The age group with the highest lifetime prevalence of sedative (3 percent) or tranquilizer (6 percent) use was 26 to 34 years of age, and those aged 18 to 25 were most likely to have used sedatives or tranquilizers in the prior year. About one fourth to one third of all substance-related emergency room visits involve substances of this class. The patients have a female-to-male ratio of 3:1 and a white-to-black ratio of 2:1. Some persons use benzodiazepines alone, but persons who use cocaine often use benzodiazepines to reduce withdrawal symptoms, and opioid abusers use them to enhance the euphoric effects of opioids. Because they are easily obtained, benzodiazepines are also used by abusers of stimulants, hallucinogens, and phencyclidine (PCP) to help reduce the anxiety that can be caused by those substances.

Whereas barbiturate abuse is common among mature adults who have long histories of abuse of these substances, benzodiazepines are abused by a younger age group, usually those under 40 years of age. This group may have a slight male predominance and has a white-to-black ratio of about 2:1. Benzodiazepines are probably not abused as frequently as other substances for the purpose of getting “high,” or inducing a euphoric feeling. Rather, they are used when a person wishes to experience a general relaxed feeling.

NEUROPHARMACOLOGY

The benzodiazepines, barbiturates, and barbiturate-like substances all have their primary effects on the γ -aminobutyric acid (GABA) type A ($GABA_A$) receptor complex, which contains a chloride ion channel, a binding site for GABA, and a well-defined binding site for benzodiazepines. The barbiturates and barbiturate-like substances are also believed to bind somewhere on the $GABA_A$ receptor complex.

When a benzodiazepine, barbiturate, or barbiturate-like substance does bind to the complex, the effect is to increase the affinity of the receptor for its endogenous neurotransmitter, GABA, and to increase the flow of chloride ions through the channel into the neuron. The influx of negatively charged chloride ions into the neuron is inhibitory, and hyperpolarizes the neuron relative to the extracellular space.

Although all the substances in this class induce tolerance and physical dependence, the mechanisms behind these effects are best understood for the benzodiazepines. After long-term benzodiazepine use, the receptor effects caused by the agonist are attenuated. Specifically, GABA stimulation of the $GABA_A$ receptors results in less chloride influx than was caused by GABA stimulation before the benzodiazepine administration. This downregulation of receptor response is not caused by a decrease in receptor number or by decreased affinity of the receptor for GABA. The basis for the downregulation seems to be in the coupling between the GABA binding site and the activation of the chloride ion channel. This decreased efficiency in coupling may be regulated within the $GABA_A$ receptor complex itself or by other neuronal mechanisms.

DIAGNOSIS

Sedative, Hypnotic, or Anxiolytic Use Disorder

Sedative, hypnotic, or anxiolytic use disorder is diagnosed according to the general criteria in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) for substance use disorder (see page 621).

Sedative, Hypnotic, or Anxiolytic Intoxication

The intoxication syndromes induced by all these drugs are similar, and include incoordination, dysarthria, nystagmus, impaired memory, gait disturbance, and in severe cases stupor, coma, or death. The diagnosis of intoxication by one of this class of substances is best confirmed by obtaining a blood sample for substance screening.

Benzodiazepines. Benzodiazepine intoxication can be associated with behavioral disinhibition, potentially resulting in hostile or aggressive behavior in some persons. The effect is perhaps most common when benzodiazepines are taken in combination with alcohol. Benzodiazepine intoxication is associated with less euphoria than is intoxication by other drugs in this class. This characteristic is the basis for the lower abuse and dependence potential of benzodiazepines than of barbiturates.

Barbiturates and Barbiturate-like Substances. When barbiturates and barbiturate-like substances are taken in relatively low doses, the clinical syndrome of intoxication is indistinguishable from that associated with alcohol intoxication. The symptoms include sluggishness, incoordination, difficulty thinking, poor memory, slow speech and comprehension, faulty judgment, disinhibited sexual aggressive impulses, narrowed range of attention, emotional lability, and exaggerated basic personality traits. The sluggishness usually resolves after a few hours, but depending primarily on the half-life of the abused substance, impaired judgment, distorted mood, and impaired motor skills may remain for 12 to 24 hours. Other potential symptoms are hostility, argumentativeness, moroseness, and, occasionally, paranoid and suicidal ideation. The neurological effects include nystagmus, diplopia, strabismus, ataxic gait, positive Romberg’s sign, hypotonia, and decreased superficial reflexes.

Sedative, Hypnotic, or Anxiolytic Withdrawal

Benzodiazepines. The severity of the withdrawal syndrome associated with the benzodiazepines varies significantly depending on the average dose and the duration of use, but a mild withdrawal syndrome can follow even short-term use of relatively low doses of benzodiazepines. A significant withdrawal syndrome is likely to occur at cessation of dosages in the range of 40 mg a day for diazepam, for example, although 10 to 20 mg a day, taken for a month, can also result in a withdrawal syndrome when drug administration is stopped. The onset of withdrawal symptoms usually occurs 2 to 3 days after the cessation of use, but with long-acting drugs, such as diazepam, the latency before onset can be 5 or 6 days. The symptoms include anxiety, dysphoria, intolerance for bright lights and loud noises, nausea, sweating, muscle twitching, and sometimes seizures (generally at dosages of 50 mg a day or more of diazepam). [Table 20.8-1](#) lists the signs and symptoms of benzodiazepine withdrawal.

Table 20.8-1

Signs and Symptoms of the Benzodiazepine Discontinuation Syndrome

The following signs and symptoms may be seen when benzodiazepine therapy is discontinued; they reflect the return of the original anxiety symptoms (recurrence), worsening of the original anxiety symptoms (rebound), or emergence of new symptoms (true withdrawal):

- ▶ *Disturbances of mood and cognition*
Anxiety, apprehension, dysphoria, pessimism, irritability, obsessive rumination, and paranoid ideation
 - ▶ *Disturbances of sleep*
Insomnia, altered sleep–wake cycle, and daytime drowsiness
 - ▶ *Physical signs and symptoms*
Tachycardia, elevated blood pressure, hyperreflexia, muscle tension, agitation/motor restlessness, tremor, myoclonus, muscle and joint pain, nausea, coryza, diaphoresis, ataxia, tinnitus, and grand mal seizures
 - ▶ *Perceptual disturbances*
Hyperacusis, depersonalization, blurred vision, illusions, and hallucinations
-

Barbiturates and Barbiturate-like Substances. The withdrawal syndrome for barbiturate and barbiturate-like substances ranges from mild symptoms (e.g., anxiety, weakness, sweating, and insomnia) to severe symptoms (e.g., seizures, delirium, cardiovascular collapse, and death). Persons who have been abusing phenobarbital in the range of 400 mg a day may experience mild withdrawal symptoms; those who have been abusing the substance in the range of 800 mg a day can experience orthostatic hypotension, weakness, tremor, and severe anxiety. About 75 percent of these persons have withdrawal-related seizures. Users of dosages higher than 800 mg a day may experience anorexia, delirium, hallucinations, and repeated seizures.

Most symptoms appear in the first 3 days of abstinence, and seizures generally occur on the second or third day, when the symptoms are worst. If seizures do occur, they always precede the development of delirium. The symptoms rarely occur more than a week after stopping the substance. A psychotic disorder, if it develops, starts on the third to eighth day. The various associated symptoms generally run their course within 2 to 3 days, but can last as long as 2 weeks. The first episode of the syndrome usually occurs after 5 to 15 years of heavy substance use.

Other Sedative-, Hypnotic-, or Anxiolytic-Induced Disorders

Delirium. Delirium that is indistinguishable from delirium tremens associated with alcohol withdrawal is seen more commonly with barbiturate withdrawal than with benzodiazepine withdrawal. Delirium associated with intoxication can be seen with either barbiturates or benzodiazepines if the dosages are sufficiently high.

Persisting Dementia. The existence of the sedative/hypnotic-induced persisting dementia is controversial, because uncertainty exists whether a persisting dementia is caused by the substance use itself or by associated features of the substance use.

Persisting Amnestic Disorder. Amnestic disorders associated with sedatives and hypnotics may be underdiagnosed. One exception is the increased number of reports of amnestic episodes associated with short-term use of benzodiazepines with short half-lives (e.g., triazolam [Halcion]).
