Psychotic Disorders. The psychotic symptoms of barbiturate withdrawal can be indistinguishable from those of alcohol-associated delirium tremens. Agitation, delusions, and hallucinations are usually visual, but sometimes tactile or auditory features develop after about 1 week of abstinence. Psychotic symptoms associated with intoxication or withdrawal are more common with barbiturates than with benzodiazepines. They are diagnosed in DSM-5 as sedative, hypnotic, or anxiolytic withdrawal with perceptual disturbances when reality testing is intact (the individual is aware the drug is causing the psychotic symptoms). If reality testing is not intact (the individual believes the hallucinations are real), a diagnosis of substance/medication-induced psychotic disorder is more appropriate. Clinicians can further specify whether delusions or hallucinations are the predominant symptoms, including the type (e.g. auditory, visual, or tactile).

Other Disorders. Sedative and hypnotic use has also been associated with mood disorders, anxiety disorders, sleep disorders, and sexual dysfunctions.

Unspecified Sedative-, Hypnotic-, or Anxiolytic-Related Disorder. When none of the previously discussed diagnostic categories is appropriate for a person with sedative-, hypnotic-, or anxiolytic-related disorder, and he or she does not meet the diagnostic criteria for any general substance-related disorder (see page 621), the appropriate diagnosis is unspecified sedative-, hypnotic-, or anxiolytic-related disorder.

CLINICAL FEATURES

Patterns of Abuse

Oral Use. Sedatives and hypnotics can all be taken orally, either occasionally to achieve a time-limited specific effect or regularly to obtain a constant, usually mild, intoxication state. The occasional use pattern is associated with young persons who take the substance to achieve specific effects—relaxation for an evening, intensification of sexual activities, and a short-lived period of mild euphoria. The user's personality and expectations about the substance's effects and the setting in which the substance is taken also affect the substance-induced experience. The regular use pattern is associated with middle-aged, middle-class persons who usually obtain the substance from a family physician as a prescription for insomnia or anxiety. Abusers of this type may have prescriptions from several physicians, and the pattern of abuse may go undetected until obvious signs of abuse or dependence are noticed by the person's family, coworkers, or physicians.

Intravenous Use. A severe form of abuse involves the intravenous use of this class of substances. The users are mainly young adults who are intimately involved with illegal substances. Intravenous barbiturate use is associated with a pleasant, warm, drowsy feeling, and users may be inclined to use barbiturates more than opioids because barbiturates are less costly. The physical dangers of injection include transmission of the human immunodeficiency virus (HIV), cellulitis, vascular complications from accidental injection into an artery, infections, and allergic reactions to contaminants. Intravenous use is associated with rapid and profound tolerance and dependence and a severe withdrawal syndrome.

Overdose

Benzodiazepines. In contrast to the barbiturates and the barbiturate-like substances, the benzodiazepines have a large margin of safety when taken in overdoses, a feature that has contributed significantly to their rapid acceptance. The ratio of lethal dose to effective dose is about 200 to 1 or higher, because of the minimal degree of respiratory depression associated with the benzodiazepines. A list of equivalent therapeutic doses of benzodiazepines is given in [Table 20.8-2](#). Even when grossly excessive amounts (more than 2 g) are taken in suicide

attempts, the symptoms include only drowsiness, lethargy, ataxia, some confusion, and mild depression of the user's vital signs. A much more serious condition prevails when benzodiazepines are taken in overdose in combination with other sedative-hypnotic substances, such as alcohol. In such cases, small doses of benzodiazepines can cause death. The availability of flumazenil (Romazicon), a specific benzodiazepine antagonist, has reduced the lethality of the benzodiazepines. Flumazenil can be used in emergency rooms to reverse the effects of the benzodiazepines.

Table 20.8-2
Approximate Therapeutic Equivalent Doses of Benzodiazepines

Generic Name	Trade Name	Dose (mg)
Alprazolam	Xanax	1
Chlordiazepoxide	Librium	25
Clonazepam	Klonopin	0.5–1.0
Clorazepate	Tranxene	15
Diazepam	Valium	10
Estazolam	ProSom	1
Flurazepam	Dalmane	30
Lorazepam	Ativan	2
Oxazepam	Serax	30
Temazepam	Restoril	20
Triazolam	Halcion	0.25
Quazepam	Doral	15
Zolpidem	Ambien	10
Zaleplon	Sonata	10

Barbiturates. Barbiturates are lethal when taken in overdose because they induce respiratory depression. In addition to intentional suicide attempts, accidental or unintentional overdoses are common. Barbiturates in home medicine cabinets are a common cause of fatal drug overdoses in children. As with benzodiazepines, the lethal effects of the barbiturates are additive to those of other sedatives or hypnotics, including alcohol and benzodiazepines. Barbiturate overdose is characterized by the induction of coma, respiratory arrest, cardiovascular failure, and death.

The lethal dose varies with the route of administration and the degree of tolerance for the substance after a history of long-term abuse. For the most commonly abused barbiturates, the ratio of lethal dose to effective dose ranges between 3:1 and 30:1. Dependent users often take an average daily dose of 1.5 g of a short-acting barbiturate, and some have been reported to take as much as 2.5 g a day for months.

The lethal dose is not much greater for the long-term abuser than for the neophyte. Tolerance develops quickly, to the point at which withdrawal in a hospital becomes necessary to prevent accidental death from overdose.

Barbiturate-like Substances. The barbiturate-like substances vary in their lethality and are usually intermediate between the relative safety of the benzodiazepines and the high lethality of the barbiturates. An overdose of methaqualone, for example, can result in restlessness, delirium, hypertonia, muscle spasms, convulsions, and, in very high doses, death. Unlike barbiturates, methaqualone rarely causes severe cardiovascular or respiratory depression, and most fatalities result from combining methaqualone with alcohol.

TREATMENT AND REHABILITATION

Withdrawal

Benzodiazepines. Because some benzodiazepines are eliminated from the body slowly, symptoms of withdrawal can continue to develop for several weeks. To prevent seizures and other withdrawal symptoms, clinicians should gradually reduce the dosage. Several reports indicate that carbamazepine (Tegretol) may be useful in the treatment of benzodiazepine withdrawal. Table 20.8-3 lists guidelines for treating benzodiazepine withdrawal.

Table 20.8-3
Guidelines for Treatment of Benzodiazepine Withdrawal

- Evaluate and treat concomitant medical and psychiatric conditions.
- Obtain drug history and urine and blood samples for drug and ethanol assay.
- Determine required dose of benzodiazepine or barbiturate for stabilization, guided by history, clinical presentation, drug-ethanol assay, and (in some cases) challenge dose.
- Detoxification from supratherapeutic dosages:
 - Hospitalize if there are medical or psychiatric indications, poor social supports, or polysubstance dependence, or the patient is unreliable.
 - Some clinicians recommend switching to longer-acting benzodiazepine for withdrawal (e.g., diazepam, clonazepam); others recommend stabilizing on the drug that patient was taking or on phenobarbital.
 - After stabilization reduce dosage by 30 percent on the second or third day and evaluate the response, keeping in mind that symptoms that occur after decreases in benzodiazepines with short elimination half-lives (e.g., lorazepam) appear sooner than with those with longer elimination half-lives (e.g., diazepam)
 - Reduce dosage further by 10 to 25 percent every few days if tolerated.
 - Use adjunctive medications if necessary—carbamazepine, β -adrenergic receptor antagonists, valproate, clonidine, and sedative antidepressants have been used but their efficacy in the treatment of the benzodiazepine abstinence syndrome has not been established.
- Detoxification from therapeutic dosages:
 - Initiate 10 to 25 percent dose reduction and evaluate response.
 - Dose, duration of therapy, and severity of anxiety influence the rate of taper and need for adjunctive medications.
 - Most patients taking therapeutic doses have uncomplicated discontinuation.
- Psychological interventions may assist patients in detoxification from benzodiazepines and in the long-term management of anxiety.

Barbiturates. To avoid sudden death during barbiturate withdrawal, clinicians must follow conservative clinical guidelines. Clinicians should not give barbiturates to a comatose or grossly intoxicated patient. A clinician should attempt to determine a patient's usual daily dose of barbiturates and then verify the dosage clinically. For example, a clinician can give a test dose of 200 mg of pentobarbital every hour until a mild intoxication occurs but withdrawal symptoms are absent (Table 20.8-4). The clinician can then taper the total daily dose at a rate of about 10 percent of the total daily dose. Once the correct dosage is determined, a long-acting barbiturate can be used for the detoxification period. During this process, the patient may begin to experience withdrawal symptoms, in which case the clinician should halve the daily decrement.

Table 20.8-4
Pentobarbital Test Dose Procedure for Barbiturate Withdrawal

Symptoms after Test Dose of 200 mg Oral Pentobarbital	Estimated 24-Hour Oral Pentobarbital Dose (mg)	Estimated 24-Hour Oral Phenobarbital Dose (mg)
Level I: Asleep but arousable; withdrawal symptoms not likely	0	0
Level II: Mild sedation; patient may have slurred speech, ataxia, nystagmus	500–600	150–200
Level III: Patient is comfortable; no evidence of sedation; may have nystagmus	800	250
Level IV: No drug effect	1,000–1,200	300–600

In the withdrawal procedure, phenobarbital can be substituted for the more commonly abused short-acting barbiturates. The effects of phenobarbital last longer, and because barbiturate blood levels fluctuate less, phenobarbital does not cause observable toxic signs or a serious overdose. An adequate dose is 30 mg of phenobarbital for every 100 mg of the short-acting substance. The user should be maintained for at least 2 days at that level before the dose is reduced further. The regimen is analogous to the substitution of methadone for heroin.

After withdrawal is complete, the patient must overcome the desire to start taking the substance again. Although substitution of nonbarbiturate sedatives or hypnotics for barbiturates has been suggested as a preventive therapeutic measure, this often results in replacing one substance dependence with another. If a user is to remain substance free, follow-up treatment, usually with psychiatric help and community support, is vital. Otherwise, a patient will almost certainly return to barbiturates or a substance with similar hazards.

Overdose

The treatment of overdose of this class of substances involves gastric lavage, activated charcoal, and careful monitoring of vital signs and central nervous system (CNS) activity. Patients who overdose and come to medical attention while awake should be kept from slipping into unconsciousness. Vomiting should be induced, and activated charcoal should be administered to delay gastric absorption. If a patient is comatose, the clinician must establish an intravenous fluid line, monitor the patient's vital signs, insert an endotracheal tube to maintain a patent airway, and provide mechanical ventilation, if necessary. Hospitalization of a comatose patient in an intensive care unit is usually required during the early stages of recovery from such overdoses.

EXPERT OPINION

The International Study of Expert Judgment on Therapeutic Use of Benzodiazepines and Other Psychotherapeutic Medications was designed to gather systematic data on the opinions of leading clinicians concerning the benefits and risks of benzodiazepines and alternative treatments of anxiety. This survey study addressed the relative risks of benzodiazepines compared with other agents and comparative risks within the class. The expert panel assessed risk based on a drug's potential to produce tolerance, rebound symptoms, a withdrawal syndrome, and ease of discontinuation.

Two thirds of the expert panel reported that long-term use of benzodiazepines for the treatment of anxiety disorders does not pose a high risk of dependence and abuse. Although agreement was that the pharmacological properties of the medication may be the most important contributor to development of withdrawal symptoms, no consensus existed on whether benzodiazepines with shorter and longer half-lives have similar dependence potential. A clear consensus was that the differences in withdrawal symptoms are clinically negligible with gradual dose tapering. Because differences in abuse liability among the various benzodiazepines have not been demonstrated in humans, and because the benefits of benzodiazepine treatment clearly outweigh the risks, most physicians on the expert panel opposed increased restrictions on benzodiazepine prescribing.

Despite the expert opinion stated earlier, state and federal agencies have attempted to restrict the distribution of benzodiazepines by requiring special reporting forms. For example, in New York State, through the use of a newly enacted prescription monitoring program (PMP) called I-STOP, effective since August 27, 2013, doctors cannot write a prescription for a benzodiazepine unless they first search a computerized database that contains the names of all persons in the state who were ever prescribed benzodiazepines and other controlled substances. Governments have taken these and other such measures in an attempt to stem the tide of abuse. However most abuse results from the illicit manufacture, sale, and diversion of substances, particularly to cocaine and opioid addicts, not from physicians' prescriptions or legitimate pharmaceutical companies. These programs do not stem the tide of illegal use of valuable medications and interfere in the practice of medicine and in the confidential relationship between doctor and patient.

20.9 Stimulant-Related Disorders

AMPHETAMINES

Amphetamines and amphetamine-like drugs are among the most widely used illicit substances, second only to cannabis, in the United States, Asia, Great Britain, Australia, and several other Western European countries. Methamphetamine, a congener of amphetamine, has become even more popular in recent years.

The racemic amphetamine sulfate (Benzedrine) was first synthesized in 1887, and it was introduced to clinical practice in 1932 as an over-the-counter inhaler for the treatment of nasal congestion and asthma. In 1937, amphetamine sulfate tablets were introduced for the treatment of narcolepsy, postencephalitic parkinsonism, depression, and lethargy. In the 1970s, a variety of social and regulatory factors began to curb widespread amphetamine distribution. The current U.S. Food and Drug Administration (FDA)-approved indications for amphetamine are limited to attention-deficit/hyperactivity disorder (ADHD) and narcolepsy; however, amphetamines are also used in the treatment of obesity, depression, dysthymia, chronic fatigue syndrome, acquired immunodeficiency syndrome (AIDS), dementia, multiple sclerosis, fibromyalgia, and neurasthenia.

Preparations

The major amphetamines currently available and used in the United States are dextroamphetamine (Dexedrine), methamphetamine (Desoxyn), a mixed dextroamphetamine-amphetamine salt (Adderall), and the amphetamine-like compound methylphenidate (Ritalin). These drugs go by such street names as ice, crystal, crystal meth, and speed. As a general class, the amphetamines are referred to as analeptics, sympathomimetics, stimulants, and psychostimulants. The typical amphetamines are used to increase performance and to induce a euphoric feeling, for example, by students studying for examinations, by long-distance truck drivers on trips, by business people with important deadlines, by athletes in competition, and by soldiers during wartime. Although not as addictive as cocaine, amphetamines are nonetheless addictive drugs.

Other amphetamine-like substances are ephedrine, pseudoephedrine, and phenylpropanolamine (PPA). These drugs, PPA in particular, can dangerously exacerbate hypertension, precipitate a toxic psychosis, cause intestinal infarction, or result in death. The safety margin for PPA is particularly narrow, and three to four times the normal dose can result in life-threatening hypertension. In 2005, medications containing PPA were recalled by the FDA, and in 2006, the FDA prohibited the sale of over-the-counter medications containing pseudoephedrine, which was being used illegally to make methamphetamine.

Amphetamine-type drugs with abuse potential also include phendimetrazine (Preludin), which is included in Schedule II of the Controlled Substance Act (CSA), and diethylpropion (Tenuate), benzphetamine (Didrex), and phentermine (Ionamin), which are included in Schedules III or IV of the CSA. It is presumed that all of these drugs are capable of producing all of the listed amphetamine-induced disorders. Modafinil (Provigil), used in the treatment of narcolepsy, also has stimulant and euphorogenic effects in humans, but its toxicity and likelihood of producing amphetamine-induced disorders are unknown.

Methamphetamine is a potent form of amphetamine that abusers of the substance inhale, smoke, or inject intravenously. Its psychological effects last for hours and are described as particularly powerful. Unlike cocaine (see discussion later in this section), which must be imported, methamphetamine is a synthetic drug that can be manufactured domestically in illicit laboratories.

Other agents called *substituted* or *designer amphetamines* are discussed separately later in this section.

Epidemiology

Amphetamine-type stimulant abuse represents major public health and law enforcement problems in the United States and abroad, primarily due to the consumption of methamphetamine. According to the Community Epidemiology Work Group, methamphetamine abuse occurs at epidemic levels in Hawaii, on the West Coast, and in some Southern states, and continues to spread eastward. Nationally, treatment admission rates for methamphetamine dependence more than doubled between 1995 and 2012, and in the western United States, treatment admission rates for methamphetamine dependence are higher than those of either cocaine or heroin. According to the National Association of Counties, nearly half (48 percent) of 500 county law enforcement agencies in the United States name methamphetamine as the primary drug problem, more than cocaine (22 percent), marijuana (22 percent), and heroin (2 percent) combined. Similarly, almost 40 percent of state and local law enforcement agencies identify methamphetamine as their greatest drug threat, second only to cocaine, a higher percentage than any other drug.

On a global basis, use of amphetamine-type stimulants, including methamphetamine, is also a major concern, ranking as the second most widely used substance, following marijuana, according to a report from the United Nations Office on Drugs and Crime. According to the 2010 National Survey on Drug Use and Health (NSDUH), 353,000 persons 12 years or older were current users of methamphetamine (0.1 percent).

Neuropharmacology

All the amphetamines are rapidly absorbed orally and have a rapid onset of action, usually within 1 hour when taken orally. The classic amphetamines are also taken intravenously and have an almost immediate effect by this route. Nonprescribed amphetamines and designer amphetamines are also inhaled (“snorting”). Tolerance develops with both classic and designer amphetamines, although amphetamine users often overcome the tolerance by taking more of the drug. Amphetamine is less addictive than cocaine, as evidenced by experiments on rats in which not all animals spontaneously self-administered low doses of amphetamine.

The classic amphetamines (i.e., dextroamphetamine, methamphetamine, and methylphenidate) produce their primary effects by causing the release of catecholamines, particularly dopamine, from presynaptic terminals. The effects are particularly potent for the dopaminergic neurons projecting from the ventral tegmental area to the cerebral cortex and the limbic areas. This pathway has been termed the *reward circuit pathway*, and its activation is probably the major addicting mechanism for the amphetamines. The designer amphetamines cause the release of catecholamines (dopamine and norepinephrine) and of serotonin, the neurotransmitter implicated as the major neurochemical pathway for hallucinogens. Therefore, the clinical effects of designer amphetamines are a blend of the effects of classic amphetamines and those of hallucinogens.

COCAINE

Cocaine has been used in its raw form for more than 15 centuries. In the United States, cycles of widespread stimulant misuse and associated problems have occurred for more than 100 years. Cocaine and cocaine use disorders became a major public health issue in the 1980s when an epidemic of use spread throughout the country. Due to education and intervention, cocaine use has since declined. However, high rates of legal, psychiatric, medical, and social problems related to cocaine use still exist, thus cocaine related disorders remain an important public health issue.

Cocaine is an alkaloid derived from the shrub *Erythroxylum coca*, which is indigenous to South America, where the leaves of the shrub are chewed by local inhabitants to obtain the stimulating effects (Fig. 20.9-1). The cocaine alkaloid was first isolated in 1855 and first used as a local anesthetic in 1880. It is still used as a local anesthetic, especially for eye, nose, and throat surgery, for which its vasoconstrictive and analgesic effects are helpful. In 1884, Sigmund Freud made a study of cocaine's general pharmacological effects and, for a period of time, according to his biographers, was addicted to the drug. In the 1880s and 1890s, cocaine was widely touted as a cure for many ills and was listed in the 1899 *Merck Manual*. It was the active ingredient in the beverage Coca-Cola until 1903. In 1914, however, once its addictive and adverse effects had been recognized, cocaine was classified as a narcotic, along with morphine and heroin.

FIGURE 20.9-1

Cocaine is an alkaloid obtained from coca leaves.

Epidemiology

Cocaine Use. In 2012, 1.5 million (0.6 percent) persons aged 12 years or older used cocaine in the past month. Persons aged 18 to 25 (1.5 percent) had a higher rate of past month cocaine use than persons aged 26 or older (0.5 percent) and youths aged 12 to 17 (0.9 percent). Males (0.8 percent) were twice as likely as females (0.4 percent) to have used cocaine in the past year. Asians had the lowest rate of past year cocaine use (0.5 percent) compared with other racial or ethnic groups.

Cocaine Abuse and Dependence. In 2012 more than 1.0 million (0.4 percent) persons aged 12 or older met the criteria for abuse of, or dependence on, cocaine in the past year. Persons aged 18 to 25 (0.9 percent) had the highest rate of past year cocaine abuse or dependence, followed by persons aged 26 or older (0.4 percent) and youths aged 12 to 17 (0.2 percent). Males (0.9 percent) were more than twice as likely as females (0.4 percent) to have met the criteria for cocaine abuse or dependence. Blacks (1.1 percent) and Hispanics (0.9 percent) had higher rates of cocaine abuse or dependence than whites (0.5 percent), and the rate for Asians (0.1 percent) was lower than that for blacks, Hispanics, whites, American Indians or Alaskan Natives (1.2 percent), and non-Hispanic persons who identified themselves with two or more races (0.9 percent).

Crack Cocaine. An estimated 1.1 million (0.4 percent) persons aged 12 or older used crack cocaine in the past year, and 492,000 (0.2 percent) persons used crack cocaine in the past month. Persons aged 18 to 25 (0.5 percent) had the highest rate of past year crack use, followed by persons aged 26 or older (0.4 percent) and youths aged 12 to 17 (0.1 percent). Males (0.5 percent) were twice as likely as females (0.3 percent) to have used crack cocaine in the past year. Asians had the lowest rate of past year crack cocaine use (0.1 percent) compared with other racial or ethnic groups. Blacks (0.9 percent), whites (0.4 percent), Hispanics or Latinos (0.3 percent), and persons who identified themselves with two or more non-Hispanic races (0.9 percent) had higher rates of past year crack cocaine use than American Indians or Alaska Natives (0.2 percent) and Native Hawaiians or Other Pacific Islanders (0.1 percent).

Current cocaine use is on the decline, primarily because of increased awareness of cocaine's risks, as well as a comprehensive public campaign about cocaine and its effects. The societal effects of the decrease in cocaine use, however, have been somewhat offset by the frequent use over the past years of crack.

Comorbidity

As with other substance-related disorders, cocaine-related disorders are often accompanied by additional psychiatric disorders. The development of mood disorders and alcohol-related disorders usually follows the onset of cocaine-related disorders, whereas anxiety disorders, antisocial personality disorder, and ADHD are thought to precede the development of cocaine-related disorders. Most studies of comorbidity in patients with cocaine-related disorders have shown that major depressive disorder, bipolar II disorder, cyclothymic disorder, anxiety disorders, and antisocial personality disorder are the most commonly associated psychiatric diagnoses. The percentages of

comorbidity in cocaine users are presented in [Table 20.9-1](#).

Table 20.9-1
Additional Psychiatric Diagnoses among Cocaine Users Seeking Treatment (New Haven Cocaine Diagnostic Study Results, Percentages)

Psychiatric Diagnosis	Current Disorder	Lifetime Disorder
Major depression	4.7	30.5
Cyclothymia/hyperthymia	19.9	19.9
Mania	0.0	3.7
Hypomania	2.0	7.4
Panic disorder	0.3	1.7
Generalized anxiety disorder	3.7	7.0
Phobia	11.7	13.4
Schizophrenia	0.0	0.3
Schizoaffective disorder	0.3	1.0
Alcoholism	28.9	61.7
Antisocial personality disorder	32.9	32.9
Attention-deficit disorder		34.9

(Adapted from Rounsaville BJ, Anton SI, Carroll K, et al. Psychiatric diagnoses of treatment-seeking cocaine abusers. *Arch Gen Psychiatry*. 1991;48:43.)

Etiology

Genetic Factors. The most convincing evidence to date of a genetic influence on cocaine dependence comes from studies of twins. Monozygotic twins have higher concordance rates for stimulant dependence (cocaine, amphetamines, and amphetamine-like drugs) than dizygotic twins. The analyses indicate that genetic factors and unique (unshared) environmental factors contribute about equally to the development of stimulant dependence.

Sociocultural Factors. Social, cultural, and economic factors are powerful determinants of initial use, continuing use, and relapse. Excessive use is far more likely in countries where cocaine is readily available. Different economic opportunities may influence certain groups more than others to engage in selling illicit drugs, and selling is more likely to be carried out in familiar communities than in communities where the seller runs a high risk of arrest.

Learning and Conditioning. Learning and conditioning are also considered important in perpetuating cocaine use. Each inhalation or injection of cocaine yields a “rush” and a euphoric experience that reinforces the antecedent drug-taking behavior. In addition, the environmental cues associated with substance use become associated with the euphoric state so that long after a period of cessation, such cues (e.g., white powder and paraphernalia) can elicit memories of the euphoric state and reawaken craving for cocaine.

In cocaine abusers (but not in normal controls), cocaine-related stimuli activate brain regions subserving episodic and working memory and produce electroencephalography (EEG) arousal (desynchronization). Increased metabolic activity in the limbic-related regions, such as the amygdala, parahippocampal gyrus, and dorsolateral prefrontal cortex, reportedly correlates with reports of craving for cocaine, but the degree of EEG arousal does not.

Pharmacological Factors. As a result of actions in the central nervous system (CNS), cocaine can produce a sense of alertness, euphoria, and well-being. Users may experience decreased hunger and less need for sleep. Performance impaired by fatigue is usually improved. Some users believe that cocaine enhances sexual performance.

Neuropharmacology

Cocaine's primary pharmacodynamic action related to its behavioral effects is competitive blockade of dopamine reuptake by the dopamine transporter. This blockade increases the concentration of dopamine in the synaptic cleft and results in increased activation of both dopamine type 1 (D₁) and type 2 (D₂) receptors. The effects of cocaine on the activity mediated by D₃, D₄, and D₅ receptors are not yet well understood, but at least one preclinical study has implicated the D₃ receptor. Although the behavioral effects are attributed primarily to the blockade of dopamine reuptake, cocaine also blocks the reuptake of norepinephrine and serotonin. The behavioral effects related to these activities are receiving increased attention in the scientific literature. The effects of cocaine on cerebral blood flow and cerebral glucose use have also been studied. Results in most studies generally showed that cocaine is associated with decreased cerebral blood flow and possibly with the development of patchy areas of decreased glucose use.

The behavioral effects of cocaine are felt almost immediately and last for a relatively brief time (30 to 60 minutes); thus users require repeated doses of the drug to maintain the feelings of intoxication. Despite the short-lived behavioral effects, metabolites of cocaine can be present in the blood and urine for up to 10 days.

Cocaine has powerful addictive qualities. Because of its potency as a positive reinforcer of behavior, psychological dependence on cocaine can develop after a single use. With repeated administration, both tolerance and sensitivity to various effects of cocaine can arise, although the development of tolerance or sensitivity is apparently caused by many factors and is not easily predicted. Physiological dependence on cocaine does occur, although cocaine withdrawal is mild compared with withdrawal from opiates and opioids.

Researchers recently reported that positron emission tomography (PET) scans of the brains of patients being treated for cocaine addiction show high activation in the mesolimbic dopamine system when addicts profoundly crave a drug. Researchers exposed patients to cues that had previously caused them to crave cocaine, and patients described feelings of intense cravings for the drug while PET scans showed activation in areas from the amygdala and the anterior cingulate to the tip of both temporal lobes. Some researchers claim that the mesolimbic dopamine system is also active in patients with nicotine addiction, and the same system has been linked to cravings for heroin, morphine, amphetamines, marijuana, and alcohol.

The D₂ receptors in the mesolimbic dopamine system have been held responsible for the heightened activity during periods of craving. PET scans of patients recovering from cocaine addiction are reported to show a drop in neuronal activity consistent with a lessened ability to receive dopamine, and the reduction in this ability, although it decreases over time, is apparent as long as a year and a half after withdrawal. The pattern of reduced brain activity reflects the course of the craving; between the third and fourth weeks of withdrawal, the activity is at its lowest level, and the risk of patient relapse is highest. After about 1 year, the brains of former addicts are almost back to normal, although whether the dopamine cells ever return to a completely normal state is debatable.

Methods of Use

Because drug dealers often dilute cocaine powder with sugar or procaine, street cocaine varies greatly in purity. Cocaine is sometimes cut with amphetamine. The most common method of using cocaine is inhaling the finely chopped powder into the nose, a practice referred to as “snorting” or “tooting.” Other methods of ingesting cocaine are subcutaneous or intravenous injection and smoking (freebasing). Freebasing involves mixing street cocaine with chemically extracted pure cocaine alkaloid (the freebase) to get an increased effect. Smoking is also the method used to ingest crack cocaine. Inhaling is the least dangerous method of cocaine use; intravenous injection and smoking are the most dangerous. The most direct methods of ingestion are often associated with cerebrovascular diseases, cardiac abnormalities, and

death. Although cocaine can be taken orally, it is rarely ingested via this, the least effective, route.

Crack. Crack, a freebase form of cocaine, is extremely potent. It is sold in small, ready-to-smoke amounts, often called “rocks.” Crack cocaine is highly addictive; even one or two experiences with the drug can cause intense craving for more. Users have been known to resort to extremes of behavior to obtain the money to buy more crack. Reports from urban emergency rooms have also associated extremes of violence with crack abuse.

DIAGNOSIS AND CLINICAL FEATURES

Stimulant Use Disorder

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) diagnostic criteria for stimulant use disorder are similar to the criteria used for other substance use disorders (see page 621).

Amphetamine dependence can result in a rapid downward spiral of a person’s abilities to cope with work- and family-related obligations and stresses. A person who abuses amphetamines requires increasingly high doses of amphetamine to obtain the usual high, and physical signs of amphetamine abuse (e.g., decreased weight and paranoid ideas) almost always develop with continued abuse.

Mr. H, a 35-year-old married man, was admitted to a psychiatric hospital because he felt persecuted by gang members who were out to kill him. He could not explain why they wished to kill him, but he heard voices from people whom he suspected to be mob drug dealers and they were discussing that they should kill him. He used methamphetamine for several years, so he had dealt with drug dealers before. He began using at age 27 at the persuasion of a friend to try it. After an injection of 20 mg, he felt good and powerful and his sleepiness and fatigue disappeared. After a few tries Mr. H found that he could not stop using it. He constantly thought about how he would obtain the drug and started increasing the dosage he used. During times that he could not get methamphetamine, he felt lethargic and sleepy and became irritable and dysphoric. Mr. H’s wife learned of his drug use and attempted to persuade him to stop using it. He lost his job 2 months prior to his admission because he was repeatedly abusive to work colleagues because he felt that they were trying to harm him. With no income, Mr. H had to cut down his use of methamphetamine to only occasional usage. He finally decided to quit when his wife threatened to divorce him. Once he stopped using, he felt very tired, seemed gloomy, and often sat in his favorite chair and did nothing. After a few weeks, Mr. H told his wife that he did not wish to leave the house because he had heard dealers on the street talking about him. He wanted all doors and windows locked, and he refused to eat in fear that the food may be poisoned.

On examination, Mr. H seemed withdrawn, only giving short answers to questions. He was in clear consciousness and fully oriented and showed no marked impairment of cognitive functions. Physical and neurological testing showed no abnormalities except needle scars on his arms from methamphetamine injections. An EEG was normal.

Clinically and practically, cocaine use disorder can be suspected in patients who evidence unexplained changes in personality. Common changes associated with cocaine use are irritability, impaired ability to concentrate, compulsive behavior, severe insomnia, and weight loss. Colleagues at work and family members may notice a person’s general and increasing inability to perform the expected tasks associated with work and family life. The patient may show new evidence of increased debt or inability to pay bills on time because of the large sums used to buy cocaine. Cocaine abusers often excuse themselves from work or social situations every 30 to 60 minutes to find a secluded place to inhale more cocaine. Because of the vasoconstricting effects of cocaine, users almost always develop nasal congestion, which they may attempt to self-medicate with decongestant sprays.

Mr. D, a 45-year-old married man, was referred by his therapist to a private outpatient substance abuse treatment program for evaluation and treatment of a possible cocaine problem. According to the therapist, Mr. D’s wife expressed concern for a possible substance abuse problem on several occasions. A few days prior, Mr. D admitted to the therapist and his wife that he “occasionally” used cocaine for the past year. His wife insisted that he obtain treatment for his drug problem or else she would file for divorce. Mr. D reluctantly conceded to treatment, but insisted that his cocaine use was not a problem and that he felt capable of stopping without entering a treatment program.

During the initial evaluation interview, Mr. D reported that he currently used cocaine, intranasally, 3 to 5 days a week, and that this pattern has been continuing for a year and a half. On average, he consumes a total of 1 to 2 grams of cocaine weekly. He mostly uses cocaine at work, in his office or in the bathroom. He usually started thinking about cocaine during his drive to work in the morning and once at work was unable avoid thinking about the cocaine in his desk drawer. Despite his attempts at distraction and postponing use, he usually takes his first line of cocaine within an hour of arriving at work. On some days he will take another two to three lines over the course of the day, but, on days where he is frustrated and stressed, he may take a line or two every hour from morning until late afternoon. He rarely uses cocaine at home and never uses in front of his wife or his three daughters. He occasionally takes a line or two during a weekday evening or weekends at home when everyone else is out of the house. He denies current use of alcohol or any other illicit drug. He denies any history of alcohol or drug abuse and any history of emotional or marital problems.

Stimulant Intoxication

The diagnostic criteria for stimulant intoxication emphasize behavioral and physical signs and symptoms of stimulant use (Table 20.9-2). Persons use stimulants for their characteristic effects of elation, euphoria, heightened self-esteem, and perceived improvement on mental and physical tasks. With high doses, symptoms of intoxication include agitation, irritability, impaired judgment, impulsive and potentially dangerous sexual behavior, aggression, a generalized increase in psychomotor activity, and potentially, symptoms of mania. The major associated physical symptoms are tachycardia, hypertension, and mydriasis.

 **Table 20.9-2**
Signs and Symptoms of Stimulant Intoxication

- ▶ Mydriasis
- ▶ Psychomotor agitation or retardation
- ▶ Tachycardia or bradycardia
- ▶ Perspiration or chills
- ▶ Cardiac arrhythmias or chest pain
- ▶ Elevated or lowered blood pressure
- ▶ Dyskinesias
- ▶ Dystonias
- ▶ Weight loss
- ▶ Nausea or vomiting
- ▶ Muscular weakness
- ▶ Respiratory depression
- ▶ Confusion, seizures, or coma

Mrs. T, a 45-year-old married business woman, was admitted to psychiatric service after a 3-month period in which she became increasingly mistrustful of others and suspicious of business associates. She took statements from others out of context, twisting their words, and making inappropriately hostile and accusatory comments. On one occasion, Mrs. T physically attacked a coworker in a bar accusing her of having an affair with her husband and plotting with other coworkers to kill her.

One year previously, Mrs. T was prescribed methylphenidate for narcolepsy due to daily irresistible sleep attacks and episodes of sudden loss of muscle tone when she became emotionally excited. After taking the medication, Mrs. T became asymptomatic and was able to work effectively and have an active social life with family and friends.

In the 5 months before admission, Mrs. T had been using increasingly large doses of methylphenidate to maintain alertness late at night because of an increased amount of work that could not be handled during the day. She reported that during this time she often could feel her heart race and that she had trouble sitting still.

Mr. P, an 18-year-old man, was brought to a hospital emergency room via ambulance in the middle of the night. He was accompanied by a friend who decided to call an ambulance because he felt Mr. P was going to die. Mr. P was agitated and argumentative, his breathing was irregular and rapid, his pulse was rapid, and his pupils were dilated. His friend eventually admitted that they used a lot of cocaine that evening.

When his mother arrived at the hospital, Mr. P's condition had somewhat improved, although his loud singing created a commotion in the emergency room. His mother states Mr. P has some disciplinary problems; he is disobedient, resentful, and violently argumentative. He had been arrested on a few occasions for shoplifting and for driving while intoxicated. His mother suspected that Mr. P was using drugs due to his behavior and because she heard him talk to his friends about drugs, however, she has no direct proof of his use.

Within 24 hours, Mr. P was well and willing to talk. He boastfully stated that he had been using alcohol and various drugs regularly since he was 13. It started with just alcohol and marijuana, but once he entered high school and became acquainted with older youths, he experimented with other drugs such as speed and cocaine. By the time he was 16, he was using combinations of alcohol, speed, marijuana, and cocaine. He settled on just cocaine after a year of mixing drugs.

Mr. P frequently skipped school and when he attended school he was usually intoxicated. To support his habit, he acquired money in various schemes, such as borrowing money from friends that he had no intention of paying back or stealing car radios or stealing from his mother.

Despite his blatant admission of drug use, Mr. P denies having a problem. When asked about his ability to control his drug use, he defensively replies "Of course I can. No problem. I just don't see any damn reason to stop."

Stimulant Withdrawal

After stimulant intoxication, a "crash" occurs with symptoms of anxiety, tremulousness, dysphoric mood, lethargy, fatigue, nightmares (accompanied by rebound rapid eye movement [REM] sleep), headache, profuse sweating, muscle cramps, stomach cramps, and insatiable hunger. The withdrawal symptoms generally peak in 2 to 4 days and are resolved in 1 week. The most serious withdrawal symptom is depression, which can be particularly severe after the sustained use of high doses of stimulants and which can be associated with suicidal ideation or behavior. A person in the state of withdrawal can experience powerful and intense cravings for cocaine, especially because taking cocaine can eliminate the unpleasant withdrawal symptoms. Persons experiencing cocaine withdrawal often attempt to self-medicate with alcohol, sedatives, hypnotics, or anti-anxiety agents such as diazepam (Valium).

Stimulant Intoxication Delirium

Delirium associated with stimulant use generally results from high doses of a stimulant or from sustained use, and so sleep deprivation affects the clinical presentation. The combination of stimulants with other substances and the use of stimulants by a person with preexisting brain damage can also cause development of delirium. It is not uncommon for university students who are using amphetamines to cram for examinations to exhibit this type of delirium.

Stimulant-Induced Psychotic Disorder

The hallmark of stimulant-induced psychotic disorder is the presence of paranoid delusions and hallucinations, which occurs in up to 50 percent of stimulant users. Auditory hallucinations are also common, but visual and tactile hallucinations are less common than paranoid delusions. The sensation of bugs crawling beneath the skin (formication) has been reported to be associated with cocaine use. The presence of these symptoms depends on the dose, duration of use, and the user's sensitivity to the substance. Cocaine-induced psychotic disorders are most common with intravenous use and crack users, and the psychotic symptoms are more common in men than in women. The treatment of choice for amphetamine-induced psychotic disorder is the short-term use of an antipsychotic medication such as haloperidol (Haldol).

Mr. H is a 20-year-old college student who was functioning well until the weeks of his finals, when he began taking large amounts of cocaine because he felt he was unprepared for his tests. He began having delusional beliefs that he was being followed by the police and a detective at the request of his parents in order to spy on him. He also believed that his roommate would give reports to the detective about his study habits and social life. He was brought to the emergency room after he threatened to harm his roommate if he continued to report on him.

During evaluation, Mr. P reported sleeplessness and auditory hallucinations that told him that his roommate was conspiring against him. He was very agitated and paced continuously. After admission to the hospital, Mr. P was given antipsychotics and sleeping medications and recovered in 3 days.

Stimulant-Induced Mood Disorder

The DSM-5 allows for the diagnoses of stimulant-induced bipolar disorder and stimulant-induced depressive disorder, either of which can begin during either intoxication or withdrawal. In general, intoxication is associated with manic or mixed mood features, whereas withdrawal is associated with depressive mood features.

Stimulant-Induced Anxiety Disorder

The DSM-5 allows for the diagnosis of stimulant-induced anxiety disorder. The onset of stimulant-induced anxiety disorder can also occur during intoxication or withdrawal. Stimulants can induce symptoms similar to those seen in panic disorder, and phobic disorders, in particular.

Stimulant-Induced Obsessive-Compulsive Disorder

The DSM-5 allows for the diagnosis of stimulant-induced obsessive-compulsive disorder. The onset can occur during intoxication or withdrawal. After high doses of stimulants, some individuals develop time-limited stereotyped behaviors or rituals (i.e., picking at clothing, and arranging and rearranging items purposelessly) that share some features with the type of compulsions seen in obsessive-compulsive disorder.

Stimulant-Induced Sexual Dysfunction

The DSM-5 allows for the diagnosis of stimulant-induced sexual dysfunction. Amphetamines may be prescribed as an antidote to the sexual side effects of serotonergic agents such as fluoxetine (Prozac), but stimulants are often misused by persons to enhance sexual experiences. High doses and long-term use are associated with erectile disorder and other sexual dysfunctions.

Stimulant-Induced Sleep Disorder

Stimulant-induced sleep disorder can begin during either intoxication or withdrawal, and sleep dysfunction can vary depending on the onset. Stimulant intoxication can produce insomnia and sleep deprivation, whereas persons undergoing stimulant withdrawal can experience hypersomnolence and nightmares.

ADVERSE EFFECTS

Amphetamines

Physical. Amphetamine abuse can produce adverse effects, the most serious of which include cerebrovascular, cardiac, and gastrointestinal effects. Among the specific life-threatening conditions are myocardial infarction, severe hypertension, cerebrovascular disease, and ischemic colitis. A continuum of neurological symptoms, from twitching to tetany to seizures to coma and death, is associated with increasingly high amphetamine doses. Intravenous use of amphetamines can transmit human immunodeficiency virus (HIV) and hepatitis and further the development of lung abscesses, endocarditis, and necrotizing angitis. Several studies have shown that abusers of amphetamines knew little—or did not care—about safe-sex practices and the use of condoms. The non-life-threatening adverse effects of amphetamine abuse include flushing, pallor, cyanosis, fever, headache, tachycardia, palpitations, nausea, vomiting, bruxism (teeth grinding), shortness of breath, tremor, and ataxia. Pregnant women who use amphetamines often have babies with low birthweight, small head circumference, early gestational age, and growth retardation.

Psychological. The adverse psychological effects associated with amphetamine use include restlessness, dysphoria, insomnia, irritability, hostility, and confusion. Amphetamine use can also induce symptoms of anxiety disorders, such as generalized anxiety disorder and panic disorder, as well as ideas of reference, paranoid delusions, and hallucinations.

Cocaine

A common adverse effect associated with cocaine use is nasal congestion; serious inflammation, swelling, bleeding, and ulceration of the nasal mucosa can also occur. Long-term use of cocaine can also lead to perforation of the nasal septa. Freebasing and smoking crack can damage the bronchial passages and the lungs. The intravenous use of cocaine can result in infection, embolisms, and the transmission of human immunodeficiency virus (HIV). Minor neurological complications with cocaine use include the development of acute dystonia, tics, and migraine-like headaches. The major complications of cocaine use, however, are cerebrovascular, epileptic, and cardiac. About two thirds of these acute toxic effects occur within 1 hour of intoxication, about one fifth occur in 1 to 3 hours, and the remainder occurs up to several days later.

Cerebrovascular Effects. The most common cerebrovascular diseases associated with cocaine use are nonhemorrhagic cerebral infarctions. When hemorrhagic infarctions do occur, they can include subarachnoid, intraparenchymal, and intraventricular hemorrhages. Transient ischemic attacks have also been associated with cocaine use. Although these vascular disorders usually affect the brain, spinal cord hemorrhages have also been reported. The obvious pathophysiological mechanism for these vascular disorders is vasoconstriction, but other pathophysiological mechanisms have also been proposed.

Seizures. Seizures have been reported to account for 3 to 8 percent of cocaine-related emergency room visits. Cocaine is the substance of abuse most commonly associated with seizures; the second most common substance is amphetamine. Cocaine-induced seizures are usually single events, although multiple seizures and status epilepticus are also possible. A rare and easily misdiagnosed complication of cocaine use is partial complex status epilepticus, which should be considered as a diagnosis in a patient who seems to have cocaine-induced psychotic disorder with an unusually fluctuating course. The risk of having cocaine-induced seizures is highest in patients with a history of epilepsy who use high doses of cocaine as well as crack.

Cardiac Effects. Myocardial infarctions and arrhythmias are perhaps the most common cocaine-induced cardiac abnormalities. Cardiomyopathies can develop with long-term use of cocaine, and cardioembolic cerebral infarctions can be a further complication of cocaine-induced myocardial dysfunction.

Death. High doses of cocaine are associated with seizures, respiratory depression, cerebrovascular diseases, and myocardial infarctions—all of which can lead to death in persons who use cocaine. Users may experience warning signs of syncope or chest pain but may ignore these signs because of the irrepensible desire to take more cocaine. Deaths have also been reported with the ingestion of “speedballs,” which are combinations of opioids and cocaine.

Other Agents

Substituted Amphetamines. MDMA (3,4-methylene-dioxymethamphetamine) is one of a series of substituted amphetamines that also includes MDEA, MDA (3,4-methylene-dioxyamphetamine), DOB (2,5-dimethoxy-4-bromoamphetamine), PMA (paramethoxyamphetamine), and others. These drugs produce subjective effects resembling those of amphetamine and LSD (lysergic acid diethylamide), and in that sense, MDMA and similar analogues may represent a distinct category of drugs.

A methamphetamine derivative that came into use in the 1980s, MDMA was not technically subject to legal regulation at the time. Although it has been labeled a “designer drug” in the belief that it was deliberately synthesized to evade legal regulation, it was actually synthesized and patented in 1914. Several psychiatrists used it as an adjunct to psychotherapy and concluded that it had value. At one time, it was advertised as legal and was used in psychotherapy for its subjective effects. It was never approved by the FDA, however. Its use raised questions of both safety and legality, because the related amphetamine derivatives MDA, DOB, and PMA had caused a number of overdose deaths, and MDA was known to cause extensive destruction of serotonergic nerve terminals in the CNS. Using emergency scheduling authority, the Drug Enforcement Agency made MDMA a Schedule I drug under the CSA, along with LSD, heroin, and marijuana. Despite its illegal status, MDMA continues to be manufactured, distributed, and used in the United States, Europe, and Australia. Its use is common in Australia and Great Britain at extended dances (“raves”) popular with adolescents and young adults.

MECHANISMS OF ACTION. The unusual properties of the drugs may be a consequence of the different actions of the optical isomers: the *R*(-) isomers produce LSD-like effects and the amphetamine-like properties are linked to *S*(+) isomers. The LSD-like actions, in turn, may be linked to the capacity to release serotonin. The various derivatives may exhibit significant differences in subjective effects and toxicity. Animals in laboratory experiments will self-administer the drugs, suggesting prominent amphetamine-like effects.

SUBJECTIVE EFFECTS. After taking usual doses (100 to 150 mg), MDMA users experience elevated mood and, according to various reports, increased self-confidence and sensory sensitivity; peaceful feelings coupled with insight, empathy, and closeness to persons; and decreased appetite. Difficulty concentrating and an increased capacity to focus have both been reported. Dysphoric reactions, psychotomimetic effects, and psychosis have also been reported. Higher doses seem more likely to produce psychotomimetic effects. Sympathomimetic effects of tachycardia, palpitation, increased blood pressure, sweating, and bruxism are common. The subjective effects are reported to be prominent for about 4 to 8 hours, but they may not last as long or may last longer, depending on the dose and route of administration. The drug is usually taken orally but is also snorted and injected. Both tachyphylaxis and some tolerance are reported by users.

TOXICITY. Although it is not as toxic as MDA, various somatic toxicities have been attributed to MDMA use as well as fatal overdoses. It does not appear to be neurotoxic when injected into the brains of animals, but it is metabolized to MDA in both animals and humans. In animals, MDMA produces selective, long-lasting damage to serotonergic nerve terminals. It is not certain if the levels of the MDA metabolite reached in humans after the usual doses of MDMA suffice to produce lasting damage. Users of MDMA show differences in neuroendocrine responses to serotonergic probes, and studies of former MDMA users show global and regional decreases in serotonin transporter binding, as measured by PET (Fig. 20.9-2).

FIGURE 20.9-2

Positron emission tomography (PET) images obtained 75 to 95 minutes postinjection of [¹¹C]McN5652 and [¹¹C]DASB in a representative control subject and a representative 3,4-methylenedioxymethamphetamine (MDMA) subject, demonstrating the reductions in serotonin transporter (SERT) binding in the MDMA subject with both radioligands. PET images are normalized to a common maximum. (Reprinted from McCann UD, Szabo Z, Seckin E, Rosenblatt P, Mathews WB. Quantitative PET studies of serotonin transporter MDMA users and controls using [¹¹C]McN5652 and [¹¹C]DASB. *Neuropsychopharmacology*. 2005;30[9]:1741, with permission.)

Currently, no established clinical uses exist for MDMA, although before its regulation, there were several reports of its beneficial effects as an adjunct to psychotherapy.

Khat. The fresh leaves of *Catha edulis*, a bush native to East Africa, have been used as a stimulant in the Middle East, Africa, and the Arabian Peninsula for at least 1,000 years. Khat is still widely used in Ethiopia, Kenya, Somalia, and Yemen. The amphetamine-like effects of khat have long been recognized, and although efforts to isolate the active ingredient were first undertaken in the 19th century, only since the 1970s has cathinone (*S*(-)- α -aminopropiophenone or *S*(-)-2-amino-1-phenyl-1-propanone) been identified as the substance responsible. Cathinone is a precursor moiety that is normally enzymatically converted in the plant to the less-active entities norephedrine and cathine (norpseudoephedrine), which explains why only the fresh leaves of the plant are valued for their stimulant effects. Cathinone has most of the CNS and peripheral actions of amphetamine and appears to have the same mechanism of action. In humans, it elevates mood, decreases hunger, and alleviates fatigue. At high doses, it can induce an amphetamine-like psychosis in humans. Because it is typically absorbed buccally after chewing the leaf and because the alkaloid is metabolized relatively rapidly, high toxic blood levels are rarely reached. Concern about khat use is linked to its dependence-producing properties rather than to its acute toxicity. It is estimated that five million doses are consumed each day, despite prohibition of its use in a number of African and Arab countries.

In the 1990s, several clandestine laboratories began synthesizing methcathinone, a drug with actions similar to those of cathinone. Known by a number of street names (e.g., bath salts, “CAT,” “goob,” and “crank”), its popularity is primarily owing to its ease of synthesis from ephedrine or pseudoephedrine, which were readily available until placed under special controls. Methcathinone has been moved to Schedule I of the CSA. The patterns of use, adverse effects, and complications closely resemble those reported for amphetamine.

“Club Drugs”. The use of a certain group of substances popularly called *club drugs* is often associated with dance clubs, bars, and all-night dance parties (raves). The group includes LSD, γ -hydroxybutyrate (GHB), ketamine, methamphetamine, MDMA (ecstasy), and Rohypnol or “roofies” (flunitrazepam). These substances are not all in the same drug class, and they do not produce the same physical or subjective effects. GHB, ketamine, and Rohypnol have been called *date rape drugs* because they produce disorienting and sedating effects, and often users cannot recall what occurred during all or part of an episode under the influence of the drug. Hence, it is alleged that these drugs might be surreptitiously placed in a beverage, or a person might be convinced to take the drug and then not recall clearly what occurred after ingestion.

Emergency department mentions of GHB, ketamine, and Rohypnol are relatively few. Of the club drugs, methamphetamine is the substance that accounts for the largest share of treatment admissions.

TREATMENT AND REHABILITATION

Amphetamines

The treatment of amphetamine-related (or amphetamine-like) disorders shares with cocaine-related disorders the difficulty of helping patients remain abstinent from the drug, which is powerfully reinforcing and induces craving. An inpatient setting and the use of multiple therapeutic methods (individual, family, and group psychotherapy) are usually necessary to achieve lasting abstinence. The treatment of specific amphetamine-induced disorders (e.g., amphetamine-induced psychotic disorder and amphetamine-induced anxiety disorder) with

specific drugs (e.g., antipsychotic and anxiolytics) may be necessary on a short-term basis. Antipsychotics may be prescribed for the first few days. In the absence of psychosis, diazepam (Valium) is useful to treat patients' agitation and hyperactivity.

Physicians should establish a therapeutic alliance with patients to deal with the underlying depression, personality disorder, or both. Because many patients are heavily dependent on the drug, however, psychotherapy may be especially difficult.

Comorbid conditions, such as depression, may respond to antidepressant medication. Bupropion (Wellbutrin) may be of use after patients have withdrawn from amphetamine. It has the effect of producing feelings of well-being as these patients cope with the dysphoria that may accompany abstinence.

Cocaine

Detoxification. The cocaine withdrawal syndrome is distinct from that of opioids, alcohol, or sedative-hypnotic agents, because no physiological disturbances necessitate inpatient or residential drug withdrawal. Thus, it is generally possible to engage in a therapeutic trial of outpatient withdrawal before deciding whether a more intensive or controlled setting is required for patients unable to stop without help in limiting their access to cocaine. Patients withdrawing from cocaine typically experience fatigue, dysphoria, disturbed sleep, and some craving; some may experience depression. No pharmacological agents reliably reduce the intensity of withdrawal, but recovery over a week or two is generally uneventful. It may take longer, however, for sleep, mood, and cognitive function to recover fully.

Most cocaine users do not come to treatment voluntarily. Their experience with the substance is too positive, and the negative effects are perceived as too minimal, to warrant seeking treatment. Those who do not seek treatment often have polysubstance-related disorder, fewer negative consequences associated with cocaine use, fewer work- or family-related obligations, and increased contact with the legal system and with illegal activities.

The major hurdle to overcome in the treatment of cocaine-related disorders is the user's intense craving for the drug. Although animal studies have shown that cocaine is a powerful inducer of self-administration, these studies have also shown that animals limit their use of cocaine when negative reinforcers are experimentally linked to the cocaine intake. In humans, negative reinforcers may take the form of work and family-related problems brought on by cocaine use. Therefore, clinicians must take a broad treatment approach and include social, psychological, and perhaps biological strategies in the treatment program.

Attaining abstinence from cocaine in patients may require complete or partial hospitalization to remove them from the usual social settings in which they had obtained or used cocaine. Frequent, unscheduled urine testing is almost always necessary to monitor patients' continued abstinence, especially in the first weeks and months of treatment. Relapse prevention therapy (RPT) relies on cognitive and behavioral techniques in addition to hospitalization and outpatient therapy to achieve the goal of abstinence.

Psychosocial Therapies. Psychological intervention usually involves individual, group, and family modalities. In individual therapy, therapists should focus on the dynamics leading to cocaine use, the perceived positive effects of the cocaine, and other ways to achieve these effects. Group therapy and support groups, such as Narcotics Anonymous, often focus on discussions with other persons who use cocaine and on sharing experiences and effective coping methods. Family therapy is often an essential component of the treatment strategy. Common issues discussed in family therapy are the ways the patient's past behavior has harmed the family and the responses of family members to these behaviors. Therapy should also focus, however, on the future and on changes in the family's activities that may help the patient stay off the drug and direct energies in different directions. This approach can be used on an outpatient basis.

NETWORK THERAPY. Network therapy was developed as a specialized type of combined individual and group therapy to ensure greater success in the office-based treatment of addicted patients. Network therapy uses both psychodynamic and cognitive-behavioral approaches to individual therapy while engaging the patient in a group support network. The group, composed of the patient's family and peers, is used as a therapeutic network joining the patient and therapist at intervals in therapy sessions. The approach promotes group cohesiveness as a vehicle for engaging patients in this treatment. This network is managed by the therapist to provide cohesiveness and support and to promote compliance with treatment. Although network therapy has not received systematic controlled evaluation, it is frequently applied in the psychiatric practice because it is one of the few manualized approaches that has been designed for use by individual practitioners in an office setting.

Pharmacological Adjuncts. Presently, no pharmacological treatments produce decreases in cocaine use comparable to the decreases in opioid use seen when heroin users are treated with methadone, levomethadyl acetate (ORLAAM) (commonly called L-a-acetylmethadol [LAAM]), or buprenorphine (Buprenex). A variety of pharmacological agents, most of which are approved for other uses, have been, and are being, tested clinically for the treatment of cocaine dependence and relapse.

Cocaine users presumed to have preexisting ADHD or mood disorders have been treated with methylphenidate (Ritalin) and lithium (Eskalith), respectively. Those drugs are of little or no benefit in patients without the disorders, and clinicians should adhere strictly to maximal diagnostic criteria before using either of them in the treatment of cocaine dependence. In patients with ADHD, slow-release forms of methylphenidate may be less likely to trigger cocaine craving, but the impact of such pharmacotherapy on cocaine use remains to be demonstrated.

Many pharmacological agents have been explored on the premise that chronic cocaine use alters the function of multiple neurotransmitter systems, especially the dopaminergic and serotonergic transmitters regulating hedonic tone, and that cocaine induces a state of relative dopaminergic deficiency. Although the evidence for such alterations in dopaminergic function has been growing, it has been difficult to demonstrate that agents theoretically capable of modifying dopamine function can alter the course of treatment.

Tricyclic antidepressant drugs yielded some positive results when used early in treatment with minimally drug-dependent patients; however, they are of little or no use inducing abstinence in moderate or severe cases.

Also tried but not confirmed effective in controlled studies are other antidepressants, such as bupropion, monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors (SSRIs), antipsychotics, lithium, several different calcium channel inhibitors, and anticonvulsants. One study found that 300 mg a day of phenytoin (Dilantin) reduced cocaine use; this study requires further replication.

Several agents are being developed that have not been tried in human studies. These include agents that would selectively block or stimulate dopamine receptor subtypes (e.g., selective D₁ agonists) and drugs that can selectively block the access of cocaine to the dopamine transporters but still permit the transporters to remove cocaine from the synapse. Another approach is aimed at preventing cocaine from reaching the brain by using antibodies to bind cocaine in the bloodstream (a so-called "cocaine vaccine"). Such cocaine-binding antibodies do reduce the reinforcing effects of cocaine in animal models. Also under study are catalytic antibodies that accelerate the hydrolysis of cocaine, and butyrylcholinesterase (pseudocholinesterase), which appears to hydrolyze cocaine selectively and is normally present in the body.

Vigabatrin is a drug that has been used as a treatment for refractory pediatric epilepsy, which appears to function by significantly elevating brain γ -aminobutyric acid (GABA) levels. In animals, vigabatrin was also noted to attenuate cocaine, nicotine, heroin, alcohol, and methamphetamine-induced increases in extracellular nucleus accumbens dopamine as well as drug-seeking behaviors associated with these biochemical changes. Preliminary clinical studies suggest efficacy for the treatment of cocaine and methamphetamine dependence. Large scale clinical trials for this indication are needed, however.

▲ 20.10 Tobacco-Related Disorders

Tobacco use disorder is among the most prevalent, deadly, and costly of substance dependencies. It is also one of the most ignored, particularly by psychiatrists, because despite recent research that shows commonalities between tobacco dependence and other substance use disorders, tobacco dependence differs from other substance dependencies in unique ways. Tobacco does not cause behavioral problems; therefore, few tobacco-dependent persons seek or are referred for psychiatric treatment. Tobacco is a legal drug and most persons who stop tobacco use have done so without treatment. Thus a common, but erroneous, view is that, unlike alcohol and other illicit drugs, most smokers do not need treatment.

Several recent events may reverse the reluctance of psychiatrists to play a role in treating tobacco dependence: (1) the growing recognition that most psychiatric patients smoke and many die from tobacco dependence; (2) remaining smokers will be more and more likely to have psychiatric problems, which suggests that many need more intensive treatments; and (3) the development of multiple pharmacological agents to aid smokers in quitting.

EPIDEMIOLOGY

The *2004 Monitoring the Future Survey* concluded that, despite the demonstrated health risk associated with cigarette smoking, young Americans continue to smoke. However, 30-day smoking rates among high school students declined from peaks reached in 1996 for eighth-graders (21.0 percent) and tenth-graders (30.4 percent) and in 1997 for seniors (36.5 percent). In 2011, 30-day rates reached the lowest levels ever reported by *Monitoring the Future* surveys for eighth-graders (6.1 percent), tenth-graders (11.8 percent), and twelfth-graders (18.7 percent), with tenth-graders showing the most significant decline. Of high school seniors, 19 percent reported smoking during the month preceding their responses to the survey.

The decrease in smoking rates among young Americans corresponds to several years in which increased proportions of teens said they believe a “great” health risk is associated with cigarette smoking and expressed disapproval of smoking one or more packs of cigarettes a day. Students’ personal disapproval of smoking had risen for some years. In 2011, 88 percent of eighth-graders, 85.8 percent of tenth-graders, and 83 percent of twelfth-graders stated that they “disapprove” or “strongly disapprove” of people smoking one or more packs of cigarettes per day. In addition, eighth-graders and tenth-graders reported significant increases in the perceived harmfulness of smoking one or more packs of cigarettes per day.

The World Health Organization (WHO) estimates that there are 1 billion smokers worldwide, and they smoke 6 trillion cigarettes a year. The WHO also estimates that tobacco kills more than 3 million persons each year. Although the number of persons in the United States who smoke is decreasing, the number of persons smoking in developing countries is increasing. The rate of quitting smoking has been highest among well-educated white men and lowest among women, blacks, teenagers, and those with low levels of education.

Tobacco is smoked most commonly in cigarettes, and then, in descending order, cigars, snuff, chewing tobacco, and in pipes. About 3 percent of all persons in the United States currently use snuff or chewing tobacco, and about 6 percent of young adults ages 18 to 25 use those forms of tobacco.

Currently, about 19.3 percent of Americans smoke. The mean age of onset of smoking is 16 years, and few persons start smoking after 20. Dependence features appear to develop quickly. Classroom and other programs to prevent initiation are only mildly effective, but increased taxation does decrease initiation.

More than 75 percent of smokers have tried to quit, and about 40 percent try to quit each year. On a given attempt, only 30 percent remain abstinent for even 2 days, and only 5 to 10 percent stop permanently. Most smokers make 5 to 10 attempts, however, so eventually 50 percent of “ever smokers” quit. In the past, 90 percent of successful attempts to quit involved no treatment. With the advent of over-the-counter (OTC) and non-nicotine medications in 1998, about one third of all attempts involved the use of medication.

In terms of the diagnosis of tobacco use disorder per se, about 20 percent of the population develops tobacco dependence at some point, making it one of the most prevalent psychiatric disorders. Approximately 85 percent of current daily smokers are tobacco dependent. Tobacco withdrawal occurs in about 50 percent of smokers who try to quit.

According to the Centers of Disease Control and Prevention (CDC), regional differences exist in smoking throughout the United States. The 13 states with the highest prevalence of current smoking are Kentucky, West Virginia, Oklahoma, Mississippi, Indiana, Missouri, Alabama, Louisiana, Nevada, Tennessee, Alaska, North Carolina, and Ohio. Those states with lowest prevalence are Utah, California, Washington, Massachusetts, Rhode Island, District of Columbia, Hawaii, Maryland, Connecticut, New Hampshire, New Jersey, and Arizona. Utah had the lowest prevalence for men (10.6 percent) and for women (7.9 percent).

Education

Level of education attainment correlated with tobacco use. Of adults who had not completed high school, 37 percent smoked cigarettes, whereas only 17 percent of college graduates smoked.

Psychiatric Patients

Psychiatrists must be particularly concerned and knowledgeable about tobacco dependence because of the high proportion of psychiatric patients who smoke. Approximately 50 percent of all psychiatric outpatients, 70 percent of outpatients with bipolar I disorder, almost 90 percent of outpatients with schizophrenia, and 70 percent of patients with substance use disorder smoke. Moreover, data indicate that patients with depressive disorders or anxiety disorders are less successful in their attempts to quit smoking than other persons; thus, a holistic health approach for these patients probably includes helping them address their smoking habits in addition to the primary mental disorder. The high percentage of patients with schizophrenia who smoke has been attributed to tobacco's ability to reduce their extraordinary sensitivity to outside sensory stimuli and to increase their concentration. In that sense, such patients are self-monitoring to relieve distress.

Death

Death is the primary adverse effect of cigarette smoking. Tobacco use is associated with approximately 400,000 premature deaths each year in the United States—25 percent of all deaths. The causes of death include chronic bronchitis and emphysema (51,000 deaths), bronchogenic cancer (106,000 deaths), 35 percent of fatal myocardial infarctions (115,000 deaths), cerebrovascular disease, cardiovascular disease, and almost all cases of chronic obstructive pulmonary disease and lung cancer. The increased use of chewing tobacco and snuff (smokeless tobacco) has been associated with the development of oropharyngeal cancer, and the resurgence of cigar smoking is likely to lead to an increase in the occurrence of this type of cancer.

Researchers have found that 30 percent of cancer deaths in the United States are caused by tobacco smoke, the single most lethal carcinogen in the United States. Smoking (mainly cigarette smoking) causes cancer of the lung, upper respiratory tract, esophagus, bladder, and pancreas and probably of the stomach, liver, and kidney. Smokers are eight times more likely than nonsmokers to develop lung cancer, and lung cancer has surpassed breast cancer as the leading cause of cancer-related deaths in women. Even secondhand smoke (discussed below) causes a few thousand cancer deaths each year in the United States, about the same number as are caused by radon exposure. Despite these staggering statistics, smokers can dramatically lower their chances of developing smoke-related cancers simply by quitting.

NEUROPHARMACOLOGY

The psychoactive component of tobacco is nicotine, which affects the central nervous system (CNS) by acting as an agonist at the nicotinic subtype of acetylcholine receptors. About 25 percent of the nicotine inhaled during smoking reaches the bloodstream, through which nicotine reaches the brain within 15 seconds. The half-life of nicotine is about 2 hours. Nicotine is believed to produce its positive reinforcing and addictive properties by activating the dopaminergic pathway projecting from the ventral tegmental area to the cerebral cortex and the limbic system. In addition to activating this dopamine reward system, nicotine causes an increase in the concentrations of circulating norepinephrine and epinephrine and an increase in the release of vasopressin, β -endorphin, adrenocorticotrophic hormone (ACTH), and cortisol. These hormones are thought to contribute to the basic stimulatory effects of nicotine on the CNS.

DIAGNOSIS

Tobacco Use Disorder

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorder* (DSM-5) includes a diagnosis for tobacco use disorder characterized by craving, persistent and recurrent use, tolerance, and withdrawal if tobacco is stopped. Dependence on tobacco develops quickly, probably because nicotine activates the ventral tegmental area dopaminergic system, the same system affected by cocaine and amphetamine. The development of dependence is enhanced by strong social factors that encourage smoking in some settings and by the powerful effects of tobacco company advertising. Persons are likely to smoke if their parents or siblings smoke and serve as role models. Several recent studies have also suggested a genetic diathesis toward tobacco dependence. Most persons who smoke want to quit and have tried many times to quit but have been unsuccessful.

Tobacco Withdrawal

The DSM-5 does not have a diagnostic category for tobacco intoxication, but it does have a diagnostic category for nicotine withdrawal. Withdrawal symptoms can develop within 2 hours of smoking the last cigarette; they generally peak in the first 24 to 48 hours and can last for weeks or months. The common symptoms include an intense craving for tobacco, tension, irritability, difficulty concentrating, drowsiness and paradoxical trouble sleeping, decreased heart rate and blood pressure, increased appetite and weight gain, decreased motor performance, and increased muscle tension. A mild syndrome of tobacco withdrawal can appear when a smoker switches from regular to low-nicotine cigarettes.

CLINICAL FEATURES

Behaviorally, the stimulatory effects of nicotine produce improved attention, learning, reaction time, and problem-solving ability. Tobacco users also report that cigarette smoking lifts their mood, decreases tension, and lessens depressive feelings. Results of studies of the effects of nicotine on cerebral blood flow (CBF) suggest that short-term nicotine exposure increases CBF without changing cerebral oxygen metabolism, but long-term nicotine exposure decreases CBF. In contrast to its stimulatory CNS effects, nicotine acts as a skeletal muscle relaxant.

Adverse Effects

Nicotine is a highly toxic alkaloid. Doses of 60 mg in an adult are fatal secondary to respiratory paralysis; doses of 0.5 mg are delivered by smoking an average cigarette. In low doses the signs and symptoms of nicotine toxicity include nausea, vomiting, salivation, pallor (caused by peripheral vasoconstriction), weakness, abdominal pain (caused by increased peristalsis), diarrhea, dizziness, headache, increased blood pressure, tachycardia, tremor, and cold sweats. Toxicity is also associated with an inability to concentrate, confusion, and sensory disturbances. Nicotine is further associated with a decrease in the user's amount of rapid eye movement (REM) sleep. Tobacco use during pregnancy has been associated with an increased incidence of low birth weight babies and an increased incidence of newborns with persistent pulmonary hypertension.

Health Benefits of Smoking Cessation

Smoking cessation has major and immediate health benefits for persons of all ages and provides benefits for persons with and without

smoking-related diseases. Former smokers live longer than those who continue to smoke. Smoking cessation decreases the risk for lung cancer and other cancers, myocardial infarction, cerebrovascular diseases, and chronic lung diseases. Women who stop smoking before pregnancy or during the first 3 to 4 months of pregnancy reduce their risk for having low birth weight infants to that of women who never smoked. The health benefits of smoking cessation substantially exceed any risks from the average 5-pound (2.3 kg) weight gain or any adverse psychological effects after quitting.

TREATMENT

Strategies to prevent tobacco use in children and adolescents are listed in Table 20.10-1. For those who already smoke, psychiatrists should advise them to quit smoking. For patients who are ready to stop smoking, it is best to set a “quit date.” Most clinicians and smokers prefer abrupt cessation, but because no good data indicate that abrupt cessation is better than gradual cessation, patient preference for gradual cessation should be respected. Brief advice should focus on the need for medication or group therapy, weight gain concerns, high-risk situations, making cigarettes unavailable, and so forth. Because relapse is often rapid, the first follow-up phone call or visit should be 2 to 3 days after the quit date. These strategies have been shown to double self-initiated quit rates (Table 20.10-2).

Table 20.10-1
Primary Care Interventions to Prevent Tobacco Use in Children and Adolescents

Population	School-aged children and adolescents
Recommendation	Provide interventions to prevent initiation of tobacco use.
Risk assessment	The strongest factors associated with smoking initiation in children and adolescents are parental smoking and parental nicotine dependence. Other factors include low levels of parental monitoring, easy access to cigarettes, perception that peers smoke, and exposure to tobacco promotions.
Behavioral counseling interventions	Behavioral counseling interventions, such as face-to-face or phone interaction with a health care provider, print materials, and computer applications, can reduce the risk for smoking initiation in school-aged children and adolescents. The type and intensity of effective behavioral interventions substantially varies.
Balance of benefits and harms	There is a moderate net benefit to providing primary care interventions to prevent tobacco use in school-aged children and adolescents.
Other relevant USPSTF recommendations	The USPSTF has made recommendations on counseling and interventions to prevent tobacco use and tobacco-caused disease in adults and pregnant women. These recommendations are available at www.uspreventiveservicestaskforce.org .

For a summary of the evidence systematically reviewed in making this recommendation, the full recommendation statement, and supporting documents, please go to www.uspreventiveservicestaskforce.org. U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/uspstf/uspstbac.htm>)

Table 20.10-2
Typical Quit Rates of Common Therapies

Therapy	Rate (%)
Self-quit	5
Self-help books	10
Physician advice	10
Over-the-counter patch or gum	15
Medication plus advice	20
Behavior therapy alone	20
Medication plus group therapy	30

Ms. H was a 45-year-old patient with schizophrenia who smoked 35 cigarettes per day. She began her cigarette use at approximately 20 years of age during the prodromal stages of her first psychotic break. During the first 20 years of treatment, no psychiatrist or physician advised her to stop smoking.

When the patient was 43 years of age, her primary physician recommended smoking cessation. Ms. H attempted to stop on her own but lasted only 48 hours, partly because her housemates and friends smoked. During a routine medication check, her psychiatrist recommended that she stop smoking, and Ms. H described her prior attempts. The psychiatrist and Ms. H discussed ways to avoid smokers and had the patient announce her intent to quit and request that her friends try not to smoke around her and to offer encouragement for her attempt to quit. The psychiatrist also noted that Ms. H became irritable, slightly depressed, and restless, and that she had insomnia during prior cessation attempts, and thus recommended medications. Ms. H chose to use a nicotine patch plus nicotine gum as needed.

The psychiatrist had Ms. H call 2 days after her attempt to quit smoking. At this point, Ms. H stated that the patch and gum were helping. One week later, the patient returned after having relapsed back to smoking. The psychiatrist praised Ms. H for not smoking for 4 days. He suggested that Ms. H contact him again if she wished to try to stop again. Seven months later, during another medication check, the psychiatrist again asked Ms. H to consider cessation, but she was reluctant.

Two months later, Ms. H called and said she wished to try again. This time, the psychiatrist and Ms. H listed several activities that she could do to avoid being around friends who smoked, phoned Ms. H's boyfriend to ask him to assist her in stopping, asked the nurses on the inpatient ward to call Ms. H to encourage her, plus enrolled Ms. H in a support group for the next 4 weeks. This time the psychiatrist prescribed the non-nicotine medication varenicline (Chantix). Ms. H was followed with 15-minute visits for each of the first 3 weeks. She had two “slips” but did not go back to smoking and remained an ex-smoker. (Adapted from John R. Hughes, M.D.)

Psychosocial Therapies

Behavior therapy is the most widely accepted and well-proved psychological therapy for smoking. Skills training and relapse prevention identify high-risk situations and plan and practice behavioral or cognitive coping skills for those situations in which smoking occurs. Stimulus control involves eliminating cues for smoking in the environment. Aversive therapy has smokers smoke repeatedly and rapidly to the point of nausea, which associates smoking with unpleasant, rather than pleasant, sensations. Aversive therapy appears to be effective but requires a good therapeutic alliance and patient compliance.

Hypnosis. Some patients benefit from a series of hypnotic sessions. Suggestions about the benefits of not smoking are offered and assimilated into the patient's cognitive framework as a result. Posthypnotic suggestions that cause cigarettes to taste bad or to produce nausea when smoked are also used.

Psychopharmacological Therapies

Nicotine Replacement Therapies. All nicotine replacement therapies double cessation rates, presumably because they reduce nicotine withdrawal. These therapies can also be used to reduce withdrawal in patients on smoke-free wards. Replacement therapies use a short period of maintenance of 6 to 12 weeks, often followed by a gradual reduction period of another 6 to 12 weeks.

Nicotine polacrilex gum (Nicorette) is an OTC product that releases nicotine via chewing and buccal absorption. A 2 mg variety for those who smoke fewer than 25 cigarettes a day and a 4 mg variety for those who smoke more than 25 cigarettes a day are available. Smokers are to use one to two pieces of gum per hour up to a maximum of 24 pieces per day after abrupt cessation. Venous blood concentrations from the gum are one third to one half the between-cigarette levels. Acidic beverages (coffee, tea, soda, and juice) should not be used before, during, or after gum use because they decrease absorption. Compliance with the gum has often been a problem. Adverse effects are minor and include bad taste and sore jaws. About 20 percent of those who quit use the gum for long periods, but 2 percent use gum for longer than a year; long-term use does not appear to be harmful. The major advantage of nicotine gum is its ability to provide relief in high-risk situations.

Nicotine lozenges (Commit) deliver nicotine and are also available in 2 mg and 4 mg forms; they are useful especially for patients who smoke a cigarette immediately on awakening. Generally, 9 to 20 lozenges a day are used during the first 6 weeks, with decrease in dosage thereafter. Lozenges offer the highest level of nicotine of all nicotine replacement products. Users must suck the lozenge until dissolved and not swallow it. Side effects include insomnia, nausea, heartburn, headache, and hiccups.

Nicotine patches, also sold OTC, are available in a 16-hour, no-taper preparation (Nicotrol) and a 24- or 16-hour tapering preparation (Nicoderm CQ). Patches are administered each morning and produce blood concentrations about half those of smoking. Compliance is high, and the only major adverse effects are rashes and, with 24-hour wear, insomnia. Using gum and patches in high-risk situations increases quit rates by another 5 to 10 percent. No studies have been done to determine the relative efficacies of 24- or 16-hour patches or of taper and no-taper patches. After 6 to 12 weeks, the patch is discontinued because it is not for long-term use.

Nicotine nasal spray (Nicotrol), available only by prescription, produces nicotine concentrations in the blood that are more similar to those from smoking a cigarette, and it appears to be especially helpful for heavily dependent smokers. The spray, however, causes rhinitis, watering eyes, and coughing in more than 70 percent of patients. Although initial data suggested abuse liability, further trials have not found this.

The nicotine inhaler, a prescription product, was designed to deliver nicotine to the lungs, but the nicotine is actually absorbed in the upper throat. It delivers 4 mg per cartridge and resultant nicotine levels are low. The major asset of the inhaler is that it provides a behavioral substitute for smoking. The inhaler doubles quit rates. These devices require frequent puffing—about 20 minutes to extract 4 mg of nicotine—and have minor adverse effects.

Non-nicotine Medications. Non-nicotine therapy may help smokers who object philosophically to the notion of replacement therapy and smokers who fail replacement therapy. Bupropion (Zyban) (marketed as Wellbutrin for depression) is an antidepressant medication that has both dopaminergic and adrenergic actions. Bupropion is started at 150 mg per day for 3 days and increased to 150 mg twice a day for 6 to 12 weeks. Daily dosages of 300 mg double quit rates in smokers with and without a history of depression. In one study, combined bupropion and nicotine patch had higher quit rates than either alone. Adverse effects include insomnia and nausea, but these are rarely significant. Seizures have not occurred in smoking trials. Of interest, nortriptyline (Pamelor) appears to be effective for smoking cessation and is recommended as a second-line drug.

Clonidine (Catapres) decreases sympathetic activity from the locus ceruleus and, thus, is thought to abate withdrawal symptoms. Whether given as a patch or orally, 0.2 to 0.4 mg a day of clonidine appears to double quit rates; however, the scientific database for the efficacy of clonidine is neither as extensive nor as reliable as that for nicotine replacement; also, clonidine can cause drowsiness and hypotension. Some patients benefit from benzodiazepine therapy (10 to 30 mg per day) for the first 2 to 3 weeks of abstinence.

A nicotine vaccine that produces nicotine-specific antibodies in the brain is under investigation at the National Institute on Drug Abuse (NIDA).

Combined Psychosocial and Pharmacological Therapy

Several studies have shown that combining nicotine replacement and behavior therapy increases quit rates over either therapy alone.

Smoke-Free Environment

Secondhand smoke can contribute to lung cancer death and coronary heart disease in adult nonsmokers. Each year, an estimated 3,000 lung cancer deaths and 62,000 deaths from coronary artery disease in adult nonsmokers are attributed to secondhand smoke. Among children, secondhand smoke is implicated in sudden infant death syndrome, low birth weight, chronic middle ear infections, and respiratory illnesses (e.g., asthma, bronchitis, and pneumonia). Two national health objectives for 2010 are to reduce cigarette smoking among adults to 12 percent and the proportion of nonsmokers exposed to environment tobacco smoke to 45 percent.

Involuntary exposure to secondhand smoke remains a common public health hazard that is preventable by appropriate regulatory policies. Bans on smoking in public places reduce exposure to secondhand smoke and the number of cigarettes smoked by smokers. Support is nearly universal for bans in schools and day-care centers and strong support for bans in indoor work areas and restaurants. Clean indoor air policies are one way to change social norms about smoking and reduce tobacco consumption. Bans on outdoor smoking in areas, such as public parks, are increasing and in 2006 one municipality in California banned smoking entirely within city limits except in one's own home or car and windows had to remain closed. Currently over 600 municipalities have smoke-free park laws, including New York City, which banned smoking in all its public parks, including famed Central Park, in 2011.

20.11 Anabolic-Androgenic Steroid Abuse

The anabolic-androgenic steroids (AAS) are a family of hormones that includes testosterone, the natural male hormone, which together with numerous synthetic analogs of testosterone have been developed over the last 70 years (Table 20.11-1). These drugs exhibit various degrees of anabolic (muscle building) and androgenic (masculinizing) effects; none of these drugs display purely anabolic effects in the absence of androgenic effects. It is important not to confuse the anabolic-androgenic steroids (AAS) (testosterone-like hormones) with corticosteroids (cortisol-like hormones such as hydrocortisone and prednisone). Corticosteroids are hormones secreted by the adrenal gland, rather than by the testes. Corticosteroids have no muscle-building properties and, hence, little abuse potential; they are widely prescribed to treat numerous inflammatory conditions such as poison ivy or asthma. AAS, by contrast, have only limited legitimate medical applications, such as in the treatment of hypogonadal men, the wasting syndrome associated with human immunodeficiency virus (HIV) infection, and a few specific diseases such as hereditary angioedema and Fanconi's anemia. AAS, however, are widely used illicitly, especially by boys and young men seeking to gain increased muscle mass and strength, either for athletic purposes or simply to improve personal appearance.

Table 20.11-1
Examples of Commonly Used Anabolic Steroids

Compounds usually administered orally
Fluoxymesterone (Halotestin, Android-F, Ultadren)
Methandienone (formerly called methandrostenolone; Dianabol)
Methyltestosterone (Android, Testred, Virilon)
Mibolerone (Cheque Drops ^a)
Oxandrolone (Anavar)
Oxymetholone (Anadrol, Hemogenin)
Mesterolone (Mestoranum, Proviron)
Stanozolol (Winstrol)
Compounds usually administered intramuscularly
Nandrolone decanoate (Deca-Durabolin)
Nandrolone phenpropionate (Durabolin)
Methenolone enanthate (Primobolan Depot)
Boldenone undecylenate (Equipose ^a)
Stanozolol (Winstrol-V ^a)
Testosterone esters blends (Sustanon, Sten)
Testosterone cypionate
Testosterone enanthate (Delatestryl)
Testosterone propionate (Testoviron, Androlan)
Testosterone undecanoate (Andriol, Restandol)
Trenbolone acetate (Finajet, Finaplix ^a)
Trenbolone hexahydrobencylcarbonate (Parabolan)

^aVeterinary compound.

Note: Many of the brand names listed in this table foreign, but they are included because of the widespread illicit use of foreign steroid preparations in the United States.

AAS does not have its own diagnostic category in the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5); rather it is coded as one of the other or unknown substance related disorders.

EPIDEMIOLOGY

Use of AAS is widespread among men in the United States, but are much less frequently used by women. Approximately 890,000 American men and approximately 190,000 American women reported having used AAS at some time during their lives. Approximately 286,000 men and 26,000 women are estimated to use steroids each year. Among this number, nearly one third, or 98,000, were between 12 and 17 years of age. Various studies of high school students in the United States have produced even higher estimates of the prevalence of anabolic steroid use among adolescents. Across studies of high school students, it is estimated that 3 to 12 percent of males and 0.5 to 2.0 percent of females have used AAS during their lifetimes.

The current high rates of steroid use among younger individuals appear to represent an important shift in the epidemiology of steroid use. In the 1970s, use of these drugs was largely confined to competition bodybuilders, other elite weight-training athletes, and elite athletes in other sports. Since then, however, it appears that an increasing number of young men, and occasionally even young women, may be using these drugs purely to enhance personal appearance rather than for any athletic purpose.

PHARMACOLOGY

All steroid drugs—including AAS, estrogens, and corticosteroids—are synthesized in vivo from cholesterol and resemble cholesterol in their chemical structure. Testosterone has a four-ring chemical structure containing 19 carbon atoms (Fig. 20.11-1).

FIGURE 20.11-1
Molecular structure of testosterone.

Normal testosterone plasma concentrations for men range from 300 to 1,000 ng/dL. Generally, 200 mg of testosterone cypionate taken every 2 weeks restores physiological testosterone concentrations in a hypogonadal male. A eugonadal male who initiates physiological dosages of testosterone has no net gain in testosterone concentrations because exogenously administered AAS shut down endogenous testosterone production via feedback inhibition of the hypothalamic-pituitary-gonadal axis. Consequently, illicit users take higher than therapeutic dosages to achieve supraphysiological effects. The dose–response curve for anabolic effects may be logarithmic, which could explain why illicit users generally take 10 to 100 times the therapeutic dosages. Doses in this range are most easily achieved by taking combinations of oral and injected AAS, which illicit AAS users often do. Transdermal testosterone, available by prescription for testosterone replacement therapy, may also be used.

Therapeutic Indications

The AAS are indicated primarily for testosterone deficiency (male hypogonadism), hereditary angioedema (a congenital skin disorder), and some uncommon forms of anemia caused by bone marrow or renal failure. In women, AAS are given, although not as first-choice agents, for metastatic breast cancer, osteoporosis, endometriosis, and adjunctive treatment of menopausal symptoms. In men, they have been used experimentally as a male contraceptive and for treating major depressive disorder and sexual disorders in eugonadal men. Recently, they have been used to treat wasting syndromes associated with acquired immunodeficiency syndrome (AIDS). Controlled studies have also suggested that testosterone has antidepressant effects in some men infected with HIV with major depressive disorder, and is also a supplementary (augmentation) treatment in some depressed men with low endogenous testosterone levels who are refractory to conventional antidepressants.

Adverse Reactions

The most common adverse medical effects of AAS involve the cardiovascular, hepatic, reproductive, and dermatological systems.

The AAS produce an adverse cholesterol profile by increasing levels of low-density lipoprotein cholesterol and decreasing levels of high-density lipoprotein cholesterol. High-dose use of AAS can also activate hemostasis and increase blood pressure. Isolated case reports of myocardial infarction, cardiomyopathy, left ventricular hypertrophy, and stroke among users of AAS, including fatalities, have appeared.

Among the AAS-induced endocrine effects in men are testicular atrophy and sterility, both usually reversible after discontinuing AAS, and gynecomastia, which may persist until surgical removal. In women, shrinkage of breast tissue, irregular menses (diminution or cessation), and masculinization (clitoral hypertrophy, hirsutism, and deepened voice) can occur. Masculinizing effects in women may be irreversible. Androgens taken during pregnancy could cause masculinization of a female fetus. Dermatological effects include acne and male pattern baldness. Abuse of AAS by children has led to concerns that AAS-induced premature closure of bony epiphyses could cause shortened stature. Other uncommon adverse effects include edema of the extremities caused by water retention, exacerbation of tic disorders, sleep apnea, and polycythemia.

ETIOLOGY

The major reason for taking illicit AAS is to enhance either athletic performance or physical appearance. Taking AAS is reinforced because they can produce the athletic and physical effects that users desire, especially when combined with proper diet and training. Further reinforcement derives from winning competitions and from social admiration for physical appearance. AAS users also perceive that they can train more intensively for longer durations with less fatigue and with decreased recovery times between workouts.

The dramatic effects of AAS on muscle growth are illustrated in [Figure 20.11-2](#), which compares a “natural” bodybuilder who has never used these drugs with a bodybuilder of identical height and body fat who has used AAS extensively.

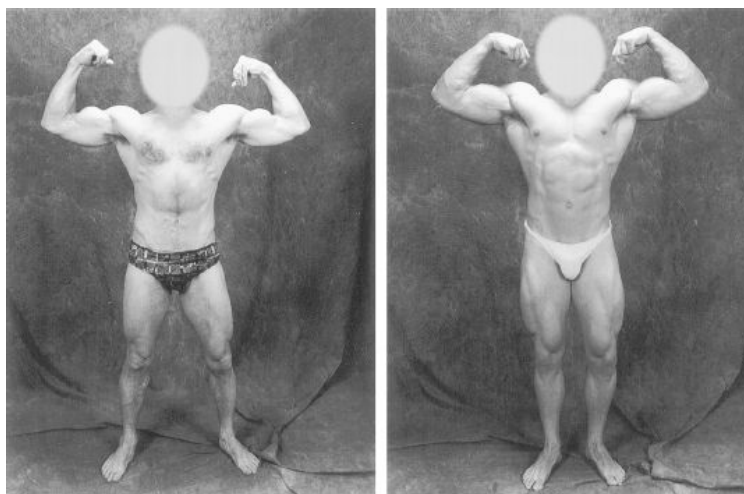

FIGURE 20.11-2
Physical effects of anabolic steroid use. The photographs compare a “natural” bodybuilder who has never used anabolic steroids (left) with a man who has used large doses of anabolic steroids over several years (right). Both men are 67 inches tall and have 7 percent body fat. The

man on the left weighs 170 lbs and represents approximately the maximum degree of muscularity obtainable without drugs. His fat-free mass index is 25.4 kg/m² by the formula of Elana Kouri, et al. The man on the right weighs 213 lbs and has a fat-free mass index of 31.7 kg/m². Note the muscle hypertrophy from steroid use is particularly marked in the upper body in the pectoralis, deltoid, trapezius, and biceps muscles. Any man significantly more muscular than the man on the left has almost certainly abused anabolic steroids. (Courtesy of H.G. Pope M.D.)

Although the anabolic or muscle-building properties of AAS are clearly important to those seeking to enhance athletic performance and physical appearance, psychoactive effects may also be important in the persistent and dependent use of AAS. Anecdotally, some AAS users report feelings of power, aggressiveness, and euphoria, which become associated with, and can reinforce, AAS taking.

In general, males are more likely to take AAS than females, and athletes are more likely to take AAS than nonathletes. Some male and female weight lifters may have muscle dysmorphia, a form of body dysmorphic disorder in which the individual feels that he or she is not sufficiently muscular and lean.

DIAGNOSIS AND CLINICAL FEATURES

Steroids may initially induce euphoria and hyperactivity. After relatively short periods, however, their use can become associated with increased anger, arousal, irritability, hostility, anxiety, somatization, and depression (especially during times when steroids are not used). Several studies have demonstrated that 2 to 15 percent of anabolic steroid abusers experience hypomanic or manic episodes, and a smaller percentage may have clearly psychotic symptoms. Also disturbing is a correlation between steroid abuse and violence ("roid rage" in the parlance of users). Steroid abusers with no record of antisocial behavior or violence have committed murders and other violent crimes.

Steroids are addictive substances. When abusers stop taking steroids, they can become depressed, anxious, and concerned about the physical state of their bodies. Some similarities have been noted between athletes' views of their muscles and the views of patients with anorexia nervosa about their bodies; to an observer, both groups seem to distort realistic assessment of the body.

Iatrogenic addiction is a consideration in view of the increasing number of geriatric patients who are receiving testosterone from their physicians in an attempt to increase libido and reverse some aspects of aging.

Mr. A is a 26-year-old single man. He is 69 inches tall and presently weighs 204 pounds, with a body fat of 11 percent. He reports that he began lifting weights at age 17, at which time he weighed 155 pounds. About 2 years after beginning his weight lifting, he began taking AAS, which he obtained through a friend at his gymnasium. His first "cycle" (course) of AAS, lasting for 9 weeks, involved methandienone (Methanabol), 30 mg a day, orally, and testosterone cypionate, 600 mg a week, intramuscularly. During these 9 weeks he gained 20 pounds of muscle mass. He was so pleased with these results that he took five further cycles of AAS over the course of the next 6 years. During his most ambitious cycle, approximately 1 year ago, he used testosterone cypionate, 600 mg per week; nandrolone decanoate, 400 mg a week; stanozolol (Winstrol), 12 mg a day; and oxandrolone (Anavar), 10 mg a day.

During each of the cycles Mr. A has noted euphoria, irritability, and grandiose feelings. These symptoms were most prominent during his most recent cycle, when he felt "invincible." During this cycle he also noted a decreased need for sleep, racing thoughts, and a tendency to spend excessive amounts of money. For example, he impulsively purchased a \$2,700 stereo system when he realistically could not afford to spend more than \$500. He also became uncharacteristically irritable with his girlfriend, and on one occasion put his fist through the side window of her car during an argument, an act inconsistent with his normally mild-mannered personality. After this cycle of AAS ended, he became mildly depressed for about 2 months.

Mr. A has used a number of drugs to lose weight in preparation for bodybuilding contests. These include ephedrine, amphetamine, triiodothyronine, and thyroxin. Recently, he has also begun to use the opioid agonist-antagonist nalbuphine intravenously (IV) to treat muscle aches from weight lifting. He also used oral opioids, such as controlled-release oxycodone (OxyContin), at least once a week. He uses oral opioids sometimes to treat muscle aches, but often simply to get high. He reports that use of nalbuphine and other opioids is widespread among other AAS users of his acquaintance.

Mr. A exhibits characteristic features of muscle dysmorphia. He checks his appearance dozens of times a day in mirrors, or when he sees his reflection in a store window or even in the back of a spoon. He becomes anxious if he misses even one day of working out at the gym, and acknowledges that his preoccupation with weight lifting has cost him both social and occupational opportunities. Although he has a 48-inch chest and 19-inch biceps, he has frequently declined invitations to go to the beach or a swimming pool for fear that he would look too small when seen in a bathing suit. He is anxious because he has lost some weight since the end of his previous cycle of AAS and is eager to resume another cycle of AAS in the near future. (Adapted from Harrison G. Pope, Jr., M.D., and Kirk J. Brower, M.D.)

TREATMENT

Abstinence is the treatment goal of choice for patients manifesting AAS abuse or dependence. To the extent that users of AAS abuse other addictive substances (including alcohol), traditional treatment approaches for substance-related disorders may be used. Nevertheless, AAS users may differ from other addicted patients in several ways that have implications for treatment. First, the euphorogenic and reinforcing effects of AAS may only become apparent after weeks or months of use in conjunction with intensive exercising. When compared with immediately and passively reinforcing drugs, such as cocaine, heroin, and alcohol, AAS use may entail more delayed gratification. Second, AAS users may manifest greater commitment to culturally endorsed values of physical fitness, success, victory, and goal directness than users of other illicit drugs. Finally, AAS users are often preoccupied with their physical attributes and may rely excessively on these attributes for self-esteem. Treatment therefore depends on a therapeutic alliance that is based on a thorough and nonjudgmental understanding of the patient's values and motivations for using AAS.

AAS Withdrawal

Supportive therapy and monitoring are essential for treating AAS withdrawal because suicidal depressions can occur. Hospitalization may be required when suicidal ideation is severe. Patients should be educated about the possible course of withdrawal and reassured that symptoms are time-limited and manageable. Antidepressant agents are best reserved for patients whose depressive symptomatology persists for several weeks after AAS discontinuation and who meet criteria for major depressive disorder. Selective serotonin reuptake inhibitors (SSRIs) are the preferred agents because of their favorable adverse effect profile and their effectiveness in the only reported case series of treated AAS users with major depressive disorder. Physical withdrawal symptoms are not life-threatening and do not ordinarily require pharmacotherapy. Nonsteroidal antiinflammatory drugs (NSAIDs) may be useful to treat musculoskeletal pain and headaches.

ANABOLIC STEROID-INDUCED MOOD DISORDERS

Irritability, aggressiveness, hypomania, and frank mania associated with anabolic steroid use probably represent one of the most important public health issues associated with these drugs. Although athletes using these drugs have long recognized that syndromes of anger and irritability could be associated with AAS use, these syndromes were little recognized in the scientific literature until the late 1980s and

1990s. Since then, a series of observational field studies of athletes has suggested that some AAS users develop prominent hypomanic or even manic symptoms during AAS use.

A possible serious consequence of AAS-induced mood disorders may be violent or even homicidal behavior. Several published reports have anecdotally described individuals with no apparent history of psychiatric disorder, no criminal record, and no history of violence, who committed violent crimes, including murder, while under the influence of AAS. In a number of cases, AAS use has been cited in criminal trials as a possible mitigating factor in the defense of such individuals. Although a causal link is difficult to establish in these cases, evidence of AAS use has frequently been presented in forensic settings as a possible mitigating factor in criminal behavior.

Depressive syndromes induced by AAS have occurred and suicide is a risk. A brief and self-limited syndrome of depression occurs on AAS withdrawal, probably as a result of the depression of the hypothalamic-pituitary-gonadal axis after exogenous AAS administration.

ANABOLIC STEROID-INDUCED PSYCHOTIC DISORDER

Psychotic symptoms are rare in association with anabolic steroid use, but they have been described in a few cases, primarily in individuals who were using the equivalent of more than 1,000 mg of testosterone a week. Usually, these symptoms have consisted of grandiose or paranoid delusions, generally occurring in the context of a manic episode, although occasionally occurring in the absence of a frank manic syndrome. In most cases reported, psychotic symptoms have disappeared promptly (within a few weeks) after the discontinuation of the offending agent, although temporary treatment with antipsychotic agents was sometimes required.

OTHER ANABOLIC STEROID-RELATED DISORDERS

Symptoms of anxiety disorders, such as panic disorder and social phobia can occur during AAS use. AAS use may serve as a “gateway to the use of opioid agonist or antagonists, such as nalbuphine, or to use of frank opioid agonists, such as heroin.” A study of men admitted for substance dependence treatment in Massachusetts produced similar findings.

DEHYDROEPIANDROSTERONE AND ANDROSTENEDIONE

Dehydroepiandrosterone (DHEA), a precursor hormone for both estrogens and androgens, is available over the counter. Recent years have seen an interest in DHEA for improving cognition, depression, sex drive, and general well-being in elderly adults. Some reports suggest that DHEA in dosages of 50 to 100 mg per day increases the sense of physical and social well-being in women aged 40 to 70 years. Reports also exist of androgenic effects, including irreversible hirsutism, hair loss, voice deepening, and other undesirable sequelae. In addition, DHEA has at least a theoretical potential of enhancing tumor growth in persons with latent, hormone-sensitive malignancies, such as prostate, cervical, and breast cancer. Despite its significant popularity, few controlled data exist on the safety or efficacy of DHEA.

20.12 Other Substance Use and Addictive Disorders

This section considers a diverse set of drugs not covered in the previous sections that are not easily categorized and grouped with other substances. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes a diagnostic category for these substances called unknown or unspecified substance-related disorders. Some of these are discussed in the following.

γ-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB) is a naturally occurring neurotransmitter in the brain that is related to sleep regulation. GHB increases dopamine levels in the brain. In general, GHB is a central nervous system (CNS) depressant with effects through the endogenous opioid system. It is used to induce anesthesia and long-term sedation, but its unpredictable duration of action limits its use. GHB has been evaluated recently for the treatment of alcohol and opioid withdrawal and narcolepsy.

Until 1990, GHB was sold in U.S. health food stores, and body builders used it as a steroid alternative. Reports indicate, however, that GHB is abused for its intoxicating effects and consciousness-altering properties. It is variously referred to as “GBH” and “liquid ecstasy,” and

it is sold illicitly in various forms (e.g., powder and liquid). Similar chemicals, which the body converts to GBH, include γ -butyrolactone (GBL) and 1,4-butanediol. Adverse effects include nausea, vomiting, respiratory problems, seizures, coma, and death. In some reports, GHB abuse has been linked to a syndrome similar to Wernicke-Korsakoff syndrome.

NITRITE INHALANTS

The nitrite inhalants include amyl, butyl, and isobutyl nitrites, all of which are called “poppers” in popular jargon. The intoxication syndromes seen with nitrites can differ markedly from the syndromes seen with the standard inhalant substances, such as lighter fluid and airplane glue. Nitrite inhalants are used by persons seeking the associated mild euphoria, altered sense of time, feeling of fullness in the head, and, possibly, increased sexual feelings. The nitrite compounds are used by some gay men and users of other drugs to heighten sexual stimulation during orgasm and, in some cases, to relax the anal sphincter for penile penetration. Under such circumstances, a person may use the substance for a few or a dozen times within several hours.

Adverse reactions include a toxic syndrome characterized by nausea, vomiting, headache, hypotension, drowsiness, and irritation of the respiratory tract. Some evidence indicates that nitrite inhalants can adversely affect immune function. Because sildenafil (Viagra) and its congeners are lethal when combined with nitrite compounds, persons at risk should be cautioned never to use the two together.

NITROUS OXIDE

Nitrous oxide, commonly known as “laughing gas,” is a widely available anesthetic agent that is subject to abuse because of its ability to produce feelings of lightheadedness and of floating, sometimes experienced as pleasurable or specifically as sexual. With long-term abuse patterns, nitrous oxide use has been associated with delirium and paranoia. Female dental assistants exposed to high levels of nitrous oxide have reportedly experienced reduced fertility.

A 35-year-old male dentist with no history of other substance problems complained of problems with nitrous oxide abuse for 10 years. This had begun as experimentation with what he had considered a harmless substance. His rate of use increased over several years, however, eventually becoming almost daily for months at a time. He felt a craving before sessions of use. Then, using the gas while alone in his office, he immediately felt numbness, a change in his temperature and heart rate, and alleviation of depressed feelings. “Things would go through my mind. Time was erased.” He sometimes fell asleep. Sessions might last a few minutes or up to 8 hours. They ended when the craving and euphoria ended. He had often tried to stop or cut down, sometimes consulting a professional about the problem.

OTHER SUBSTANCES

Nutmeg

Nutmeg can be ingested in a number of preparations. When nutmeg is taken in sufficiently high doses, it can induce depersonalization, derealization, and a feeling of heaviness in the limbs. In sufficiently high doses, morning glory seeds can produce a syndrome resembling that seen with lysergic acid diethylamide (LSD), characterized by altered sensory perceptions and mild visual hallucinations.

Catnip

Catnip can produce cannabis-like intoxication in low doses and LSD-like intoxication in high doses.

Betel Nuts

Betel nuts, when chewed, can produce a mild euphoria and a feeling of floating in space.

Kava

Kava, derived from a pepper plant native to the South Pacific, produces sedation and incoordination and is associated with hepatitis, lung abnormalities, and weight loss.

Over-the-Counter Drugs

Some persons abuse over-the-counter and prescription medications, such as cortisol, antiparkinsonian agents, and antihistamines.

Ephedra

Ephedra, a natural substance found in herbal tea, acts like epinephrine and, when abused, produces cardiac arrhythmia and fatalities.

Chocolate

A controversial possible substance of abuse is chocolate derived from the cacao bean. Anandamide, an ingredient in chocolate, stimulates the same receptors as marijuana. Other compounds in chocolate include tryptophan, the precursor of serotonin, and phenylalanine, an amphetamine-like substance, both of which improve mood. So-called chocoholics may be self-medicating because of a depressive diathesis.

POLYSUBSTANCE-RELATED DISORDER

Substance users often abuse more than one substance. A diagnosis of polysubstance dependence is appropriate if, for a period of at least 12 months, a person has repeatedly used substances from at least three categories (not including nicotine and caffeine), even if the diagnostic criteria for a substance-related disorder are not met for any single substance, as long as, during this period, the criteria for substance dependence have been met for the substances considered as a group.

TREATMENT AND REHABILITATION

Treatment approaches for the substances covered in this section vary according to substances, patterns of abuse, availability of psychosocial support systems, and patients' individual features. Two major treatment goals for substance abuse have been determined: the first is abstinence from the substance; and the second is the physical, psychiatric, and psychosocial well-being of the patient. Significant damage has often been done to a patient's support systems during prolonged periods of substance abuse. For a patient to stop a pattern of substance abuse successfully, adequate psychosocial supports must be in place to foster the difficult change in behavior.

In some rare cases, it may be necessary to initiate treatment on an inpatient unit. Although an outpatient setting is more desirable than an inpatient setting, the temptations available to an outpatient for repeated use may present too high a hurdle for the initiation of treatment. Inpatient treatment is also indicated in the case of severe medical or psychiatric symptoms, a history of failed outpatient treatments, a lack

of psychosocial supports, or a particularly severe or long-term history of substance abuse. After an initial period of detoxification, patients need a sustained period of rehabilitation. Throughout treatment, individual, family, and group therapies can be effective. Education about substance abuse and support for patients' efforts are essential factors in treatment.

20.13 Gambling Disorder

Gambling disorder is characterized by persistent and recurrent maladaptive gambling that causes economic problems and significant disturbances in personal, social, or occupational functioning. Aspects of the maladaptive behavior include (1) a preoccupation with gambling; (2) the need to gamble with increasing amounts of money to achieve the desired excitement; (3) repeated unsuccessful efforts to control, cut back, or stop gambling; (4) gambling as a way to escape from problems; (5) gambling to recoup losses; (6) lying to conceal the extent of the involvement with gambling; (7) the commission of illegal acts to finance gambling; (8) jeopardizing or losing personal and vocational relationships because of gambling; and (9) a reliance on others for money to pay off debts.

Previous editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) include pathological gambling disorder in the impulse-control disorder category because of patient's preoccupation or compulsion to gamble. However, the criteria for the disorder are structured more like a substance-related or addiction disorder than an impulse-control disorder, with the need to gamble with increased amounts of money to achieve desired excitement (tolerance) and feelings of irritability and restlessness when attempting to reduce or stop gambling (withdrawal). Substance use is often a common comorbidity with gambling. Thus, in the fifth edition of the DSM (DSM-5), gambling disorder is included in the section on substance use and addictive disorders and is diagnosed as a non-substance-related disorder.

EPIDEMIOLOGY

Although comprehensive worldwide statistics have yet to be compiled, excellent local studies all point to a 3 to 5 percent rate of problem gamblers in the general population and an approximate 1 percent rate of individuals meeting the requirements for gambling disorder. Problem gambling is more common in men and young adults than in women and older adults; however, escalation has been noted in the poor, notably poor minorities; adolescents; elderly retirees; and women. One of three pathological gamblers is now female: it has been suggested that women are gambling more because of an increased presence in the workplace that provides them with more cash. These groups are still underserved with regard to research and treatment. The prevalence of gambling disorder in individuals who have a substance use disorder is higher, with various surveys showing rates of 10 to 18 percent of patients with substance abuse being pathological gamblers.

As every type of gambling has become increasingly accessible over the last few decades, the rate of normal and pathological gambling has risen spectacularly, especially in locales with legalized gambling. The most popular types of gambling are numbers/lotto (62.2 percent), slot machines or bingo (48.9 percent), gambling at a casino (44.7 percent), and office sports pools (44.3 percent) (Table 20.13-1). The least popular are betting on sports with a bookie or parlay card, internet gambling, and speculating on high-risk investments.

Table 20.13-1
Lifetime Prevalence of Gambling Types

Type of Gambling	Prevalence (%)
A. Sports Betting	
Office Sports Pool	44.3
Sports with Bookie or Parlay Cards	5.8
Betting on Horse/Dog races/Dog or Cock Fights	25.0
Gambling at a Casino	44.7
B. Other types of gambling that involve some aspect of mental or physical skill	
Games involving mental skill (e.g., cards)	35.8
Games involving physical skill (e.g., pool)	22.7
Speculating on high-risk investments	8.4
Internet gambling	1.0
C. Types of gambling that largely involve chance	
Playing Lotto/Numbers	62.2
Gambling Machines (e.g. video poker)	26.1
Slot Machines/Bingo/Pull Tabs	48.9

(Adapted from Kessler RC, Hwang I, LaBrie R, Petuhova M, Sampson NA, Winters KC, Shaffer HJ. DSM-IV pathological gambling in the National Comorbidity Survey Replication. *Psychological Med*. 2008;38:1355, with permission.)

Family histories of pathological gamblers show an increased rate of substance abuse (particularly alcoholism) and depressive disorders. A parent or influential relative of the patient often has been a problem or pathological gambler. The family circle is likely to be competitively and materialistically oriented, evincing intense admiration for money and associated symbols of success. In this respect, compulsive gambling has been called the dark side of the American dream.

COMORBIDITY

Significant comorbidity occurs between pathological gambling and mood disorders (especially, major depression and bipolarity) and other substance use and addictive disorders (notably, alcohol and stimulant abuse and caffeine and tobacco dependence). Comorbidity also exists with attention-deficit/hyperactivity disorder (ADHD) (particularly in childhood), various personality disorders (notably, narcissistic, antisocial, and borderline personality disorders), and disruptive, impulse control, and conduct disorders. Although many pathological

gamblers have obsessive personality traits, full-blown obsessive-compulsive disorder (OCD) is uncommon in this group.

ETIOLOGY

Psychosocial Factors

Several factors may predispose persons to develop the disorder: loss of a parent by death, separation, divorce, or desertion before a child is 15 years of age; inappropriate parental discipline (absence, inconsistency, or harshness); exposure to, and availability of, gambling activities for adolescents; a family emphasis on material and financial symbols; and a lack of family emphasis on saving, planning, and budgeting.

Psychoanalytic theory has focused on a number of core character difficulties. Sigmund Freud suggested that compulsive gamblers have an unconscious desire to lose, and gamble to relieve unconscious feelings of guilt. Another suggestion is that the gamblers are narcissists, whose grandiose and omnipotent fantasies lead them to believe they can control events and even predict their outcome. Learning theorists view uncontrolled gambling as resulting from erroneous perceptions about control of impulses.

Biological Factors

Several studies have suggested that gamblers' risk-taking behavior may have an underlying neurobiological cause. These theories have centered on both serotonergic and noradrenergic receptor systems. Male pathological gamblers may have subnormal 3-methoxy-4-hydroxyphenyl glycol (MHPG) concentrations in plasma, increased MHPG concentrations in the cerebrospinal fluid (CSF), and increased urinary output of norepinephrine. Evidence also implicates serotonergic regulatory dysfunction in the pathological gambler. Chronic gamblers have low platelet monoamine oxidase (MAO) activity, a marker of serotonin activity, also linked to difficulties with inhibition. Further studies are needed to confirm these findings.

DIAGNOSIS AND CLINICAL FEATURES

In addition to the features already described, pathological gamblers often appear overconfident, somewhat abrasive, energetic, and free spending. They often show obvious signs of personal stress, anxiety, and depression. They commonly have the attitude that money is both the cause of, and the solution to all their problems. As their gambling increases, they are usually forced to lie to obtain money and to continue gambling while hiding the extent of their gambling. They make no serious attempt to budget or save money. When their borrowing resources are strained, they are likely to engage in antisocial behavior to obtain money for gambling. Their criminal behavior is typically nonviolent, such as forgery, embezzlement, or fraud, and they consciously intend to return or repay the money. Complications include alienation from family members and acquaintances, the loss of life accomplishments, suicide attempts, and association with fringe and illegal groups. Arrest for nonviolent crimes may lead to imprisonment.

Gerry was a 35-year-old former auto dealership owner. Two of his uncles were compulsive gamblers, and his paternal grandfather was hospitalized with major depressive illness. He played poker and had been a racecourse habitué since the age of 15 years. He had dropped out of college after a few months and become a car sales representative. Soon he was promoted to showroom manager and then went out on his own. By age 32 years, he was a multimillionaire owner of a dealership chain, happily married with two children.

Gerry continued to gamble frequently. He was a successful weekend sports bettor, as well as a consistent winner at weekly gin rummy and poker games and occasional jaunts to Las Vegas and Atlantic City.

In the context of his wife giving birth to a stillborn child, Gerry started going to casinos more often, gradually increasing the size of bets at blackjack and craps. His sport wagers also escalated. His games at home gradually became boring—"there was zilch action." He began frequenting an illegal local poker parlor that featured high-stake action.

Over several years, Gerry slipped into a typical gambling spiral. He accumulated several million dollars in debts and lied to family and colleagues about his whereabouts. He raided business and personal accounts, including his children's college funds, maxed out credit cards, and borrowed from loan sharks at exorbitant rates. He grew profoundly depressed and seriously thought of killing himself in a car crash so that his insurance would "take care of my family after I am gone."

Gerry's dire situation was unmasked when his Porsche was repossessed one Sunday morning. Initially his wife threatened to divorce him. However, a wealthy relative intervened and bailed him out. He swore never to gamble again, entered Gamblers Anonymous, and within 2 months resumed his frantic chasing.

Over the next decade, Gerry underwent four more episodes of recovery and relapse. His wife divorced him, he lost his dealerships, and he had to declare bankruptcy. Gerry finally enrolled in a pilot dual-diagnostic recovery program, where he was diagnosed with atypical bipolar disorder. His treatment included Gamblers Anonymous meetings, individual and family counseling, and pharmacotherapy with bupropion (Wellbutrin) and lamotrigine (Lamictal).

Gerry eventually reconciled with his wife and family. He returned to selling cars, started living modestly, and continued to attend Gamblers Anonymous meetings regularly. However, he declared emphatically that he always considers himself always one step away from becoming a "degenerate gambler" again. (Courtesy of Harvey Roy Greenberg, M.D.)

PSYCHOLOGICAL TESTING AND LABORATORY EXAMINATION

Male patients with gambling disorders have shown abnormalities in platelet MAO activity. Patients with pathological gambling often display high levels of impulsivity on neuropsychological tests. German studies have demonstrated increased cortisol levels in the saliva of gamblers while they gamble, which can account for the euphoria that occurs during the experience and its addictive potential.

DIFFERENTIAL DIAGNOSIS

Social gambling is distinguished from pathological gambling in that the former occurs with friends, on special occasions, and with predetermined acceptable and tolerable losses. Gambling that is symptomatic of a manic episode can usually be distinguished from pathological gambling by the history of a marked mood change and the loss of judgment preceding the gambling.

Manic-like mood changes are common in pathological gambling, but they always follow winning and are usually succeeded by depressive episodes because of subsequent losses. Persons with antisocial personality disorder may have problems with gambling. When both disorders are present, both should be diagnosed.

COURSE AND PROGNOSIS

Pathological gambling usually begins in adolescence for men and late in life for women. The disorder waxes and wanes and tends to be chronic. Four phases are seen in pathological gambling:

1. The winning phase, ending with a big win, equal to about a year's salary, which hooks patients. Women usually do not have a big win, but use gambling as an escape from problems.

2. The progressive-loss phase, in which patients structure their lives around gambling and then move from being excellent gamblers to being stupid ones who take considerable risks, cash in securities, borrow money, miss work, and lose jobs.
3. The desperate phase, with patients frenziedly gambling with large amounts of money, not paying debts, becoming involved with loan sharks, writing bad checks, and possibly embezzling.
4. The hopeless stage of accepting that losses can never be made up, but the gambling continues because of the associated arousal or excitement. The disorder may take up to 15 years to reach the last phase, but then, within a year or two, patients have totally deteriorated.

TREATMENT

Gamblers seldom come forward voluntarily to be treated. Legal difficulties, family pressures, or other psychiatric complaints bring gamblers to treatment. Gamblers Anonymous (GA) was founded in Los Angeles in 1957 and modeled on Alcoholics Anonymous (AA) (Table 20.13-2). It is accessible, at least in large cities, and is an effective treatment for gambling in some patients. GA is a method of inspirational group therapy that involves public confession, peer pressure, and the presence of reformed gamblers (as with sponsors in AA) available to help members resist the impulse to gamble. The dropout rate from GA is high, however. In some cases, hospitalization may help by removing patients from their environments. Insight-oriented psychotherapy should not be sought until patients have been away from gambling for 3 months. At this point, patients who are pathological gamblers may become excellent candidates for this form of psychotherapy. Family therapy is often valuable. Cognitive-behavioral therapy (e.g., relaxation techniques combined with visualization of gambling avoidance) has had some success.

Table 20.13-2

Twelve Steps of Gambler's Anonymous

1. We admitted we were powerless over gambling—that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to a normal way of thinking and living.
3. Made a decision to turn our will and our lives over to the care of this Power of our own understanding.
4. Made a searching and fearless moral and financial inventory of ourselves.
5. Admitted to ourselves and to another human being the exact nature of our wrongs.
6. Were entirely ready to have these defects of character removed.
7. Humbly asked God (of our understanding) to remove our shortcomings.
8. Made a list of all persons we had harmed and became willing to make amends to them all.
9. Make direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and when we were wrong, promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having made an effort to practice these principles in all our affairs, we tried to carry this message to other compulsive gamblers.

From Gamblers Anonymous. Available at <http://www.gamblersanonymous.org/ga/content/recovery-program>.

Psychopharmacological treatment, once largely unsuccessful, now plays a significant role in the management of pathological gamblers. Effective agents include antidepressants, notably selective serotonin reuptake inhibitors (SSRIs) and bupropion (Wellbutrin, Zyban); mood stabilizers, including sustained-release lithium (Eskalith) and antiepileptics such as topiramate (Topamax); atypical antipsychotics; and opioid agents such as naltrexone (ReVia). In many patients it is difficult to determine whether an antidepressant or mood stabilizer alleviates gambling cravings directly or via treatment of a comorbid condition, particularly depressive or bipolar disorders.

21.1 Introduction and Overview

Advances in molecular biology diagnostic techniques and medication management have significantly improved the ability to recognize and treat cognitive disorders. Cognition includes memory, language, orientation, judgment, conducting interpersonal relationships, performing actions (praxis), and problem solving. Cognitive disorders reflect disruption in one or more of these domains and are frequently complicated by behavioral symptoms. Cognitive disorders exemplify the complex interface among neurology, medicine, and psychiatry in that medical or neurological conditions often lead to cognitive disorders that, in turn, are associated with behavioral symptoms. It can be argued that of all psychiatric conditions, cognitive disorders best demonstrate how biological insults result in behavioral symptomatology. The clinician must carefully assess the history and context of the presentation of these disorders before arriving at a diagnosis and treatment plan.

This century-old distinction between organic and functional disorders is outdated and has been deleted from the nomenclature. Every psychiatric disorder has an organic (i.e., biological or chemical) component. Because of this reassessment, the concept of functional disorders has been determined to be misleading, and the term *functional* and its historical opposite, *organic*, are no longer used in the current *Diagnostic and Statistical Manual of Mental Disorders* (DSM) nomenclature. A further indication that the dichotomy is no longer valid is the revival of the term *neuropsychiatry*, which emphasizes the somatic substructure on which mental operations and emotions are based; it is concerned with the psychopathological accompaniments of brain dysfunction as observed in seizure disorders, for example. Neuropsychiatry focuses on the psychiatric aspects of neurological disorders and the role of brain dysfunction in psychiatric disorders.

Cognitive disorders tend to defy Occam's razor, challenging clinicians and nosologists with multiplicity, comorbidity, and unclear boundaries. These concerns are most true in elderly adults, the demographic group most at risk for cognitive disorders. Dementias of late life are particularly problematic in this regard. Existing, although often unrecognized, dementia is a major risk factor for superimposed delirium. Moreover, certain dementias, such as dementia with Lewy bodies or late stages of Alzheimer's disease, may have chronic clinical presentations virtually indistinguishable from delirium except for temporal onset and the lack of an identifiable acute source. Similarly, the course of nearly all subjects developing a progressive dementia is complicated by the onset of one or more distinct behavioral syndromes, including anxiety, depression, sleep problems, psychosis, and aggression. These symptoms can be as distressing and disabling as the primary cognitive disorder. Some of these behavioral syndromes, such as psychosis, may themselves result from independent underlying biologies and may be additive with the primary neurodegenerative process.

The boundaries between types of dementia and between dementia and normal aging can be similarly diffuse. Neuropathologic studies of both clinical and population samples have revealed a surprising truth. The most common neuropathologic presentation associated with dementia reveal mixtures of Alzheimer's disease, vascular, and Lewy body pathologies. Pure syndromes are relatively less common, although often the dementia is ascribed to one of the coexisting pathologies. Strategies regarding how to understand or reconcile multiple pathologies in the clinic are needed, although they lag behind.

DEFINITION

Delirium

Delirium is marked by short-term confusion and changes in cognition. There are four subcategories based on several causes: (1) general medical condition (e.g., infection), (2) substance induced (e.g., cocaine, opioids, phencyclidine [PCP]), (3) multiple causes (e.g., head trauma and kidney disease), and (4) other or multiple etiologies (e.g., sleep deprivation, medication). Delirium is discussed in Section 21.2.

Dementia (Major Neurocognitive Disorder)

Dementia, also referred to as major neurocognitive disorder in the fifth edition of DSM (DSM-5), is marked by severe impairment in memory, judgment, orientation, and cognition. The subcategories are (1) dementia of the Alzheimer's type, which usually occurs in persons older than 65 years of age and is manifested by progressive intellectual disorientation and dementia, delusions, or depression; (2) vascular dementia, caused by vessel thrombosis or hemorrhage; (3) human immunodeficiency virus (HIV) disease; (4) head trauma; (5) Pick's disease or frontotemporal lobar degeneration; (6) Prion disease such as Creutzfeldt-Jakob disease, which is caused by a slow-growing transmissible virus; (7) substance induced, caused by toxin or medication (e.g., gasoline fumes, atropine); (8) multiple etiologies; and (9) not specified (if cause is unknown).

In DSM-5, a less severe form of dementia called mild neurocognitive disorder is listed. Dementia is discussed in Section 21.3.

Amnestic Disorder

Amnestic disorders are classified in DSM-5 as *major neurocognitive disorders caused by other medical conditions*. They are marked primarily by memory impairment in addition to other cognitive symptoms. They may be caused by (1) medical conditions (hypoxia), (2) toxins or medications (e.g., marijuana, diazepam), and (3) unknown causes. These disorders are discussed in Section 21.4.

CLINICAL EVALUATION

During the history taking, the clinician seeks to elicit the development of the illness. Subtle cognitive disorders, fluctuating symptoms, and progressing disease processes may be tracked effectively. The clinician should obtain a detailed rendition of changes in the patient's daily routine involving such factors as self-care, job responsibilities, and work habits; meal preparation; shopping and personal support; interactions with friends; hobbies and sports; reading interests; religious, social, and recreational activities; and ability to maintain personal finances. Understanding the past life of each patient provides an invaluable source of baseline data regarding changes in function, such as attention and concentration, intellectual abilities, personality, motor skills, and mood and perception. The examiner seeks to find the particular pursuits that the patient considers most important, or central, to his or her lifestyle and attempts to discern how those pursuits have been affected by the emerging clinical condition. Such a method provides the opportunity to appraise both the impact of the illness and the patient-specific baseline for monitoring the effects of future therapies.

Mental Status Examination

After taking a thorough history, the clinician's primary tool is the assessment of the patient's mental status. As with the physical examination, the mental status examination is a means of surveying functions and abilities to allow a definition of personal strengths and weakness. It is a repeatable, structured assessment of symptoms and signs that promotes effective communication among clinicians. It also establishes the basis for future comparison, essential for documenting therapeutic effectiveness, and it allows comparisons between different patients, with a generalization of findings from one patient to another. [Table 21.1-1](#) lists the components of a comprehensive

neuropsychiatric mental status examination.

 **Table 21.1-1**
Neuropsychiatric Mental Status Examination

A. General Description	D. Mood and Affect
1. General appearance, dress, sensory aids (glasses, hearing aid)	1. Internal mood state (spontaneous and elicited; sense of humor)
2. Level of consciousness and arousal	2. Future outlook
3. Attention to environment	3. Suicidal ideas and plans
4. Posture (standing and seated)	4. Demonstrated emotional status (congruence with mood)
5. Gait	E. Insight and Judgment
6. Movements of limbs, trunk, and face (spontaneous, resting, and after instruction)	1. Insight
7. General demeanor (including evidence of responses to internal stimuli)	a. Self-appraisal and self-esteem
8. Response to examiner (eye contact, cooperation, ability to focus on interview process)	b. Understanding of current circumstances
9. Native or primary language	c. Ability to describe personal psychological and physical status
B. Language and Speech	2. Judgment
1. Comprehension (words, sentences, simple and complex commands, and concepts)	a. Appraisal of major social relationships
2. Output (spontaneity, rate, fluency, melody or prosody, volume, coherence, vocabulary, paraphasic errors, complexity of usage)	b. Understanding of personal roles and responsibilities
3. Repetition	F. Cognition
4. Other aspects	1. Memory
a. Object naming	a. Spontaneous (as evidenced during interview)
b. Color naming	b. Tested (incidental, immediate repetition, delayed recall, cued recall, recognition; verbal, nonverbal; explicit, implicit)
c. Body part identification	2. Visuospatial skills
d. Ideomotor praxis to command	3. Constructional ability
C. Thought	4. Mathematics
1. Form (coherence and connectedness)	5. Reading
2. Content	6. Writing
a. Ideational (preoccupations, overvalued ideas, delusions)	7. Fine sensory function (stereognosis, graphesthesia, two-point discrimination)
b. Perceptual (hallucinations)	8. Finger gnosis
	9. Right-left orientation
	10. "Executive functions"
	11. Abstraction

(Courtesy of Eric D. Caine, M.D., and Jeffrey M. Lyness, M.D.)

Cognition

When testing cognitive functions, the clinician should evaluate memory; visuospatial and constructional abilities; and reading, writing, and mathematical abilities. Assessment of abstraction ability is also valuable, although a patient's performance on tasks such as proverb interpretation may be a useful bedside projective test in some patients, the specific interpretation may result from a variety of factors, such as poor education, low intelligence, and failure to understand the concept of proverbs, as well as from a broad array of primary and secondary psychopathological disturbances.

PATHOLOGY AND LABORATORY EXAMINATION

As with all medical tests, psychiatric evaluations such as the mental status examination must be interpreted in the overall context of thorough clinical and laboratory assessment. Psychiatric and neuropsychiatric patients require careful physical examination, especially when issues exist that involve etiologically related or comorbid medical conditions. When consulting internists and other medical specialists, the clinician must ask specific questions to focus the differential diagnostic process and use the consultation most effectively. In particular, most systemic medical or primary cerebral diseases that lead to psychopathological disturbances also manifest with a variety of peripheral or central abnormalities.

A screening laboratory evaluation is sought initially and may be followed by a variety of ancillary tests to increase the diagnostic specificity. Table 21.1-2 lists such procedures, some of which are described below.

 **Table 21.1-2**
Screening Laboratory Tests

General Tests

- Complete blood cell count
- Erythrocyte sedimentation rate
- Electrolytes
- Glucose
- Blood urea nitrogen and serum creatinine
- Liver function tests
- Serum calcium and phosphorus
- Thyroid function tests
- Serum protein
- Levels of all drugs
- Urinalysis
- Pregnancy test for women of childbearing age
- Electrocardiography

Ancillary Laboratory Tests

Blood

- Blood cultures
- Rapid plasma reagin test
- Human immunodeficiency virus (HIV) testing (enzyme-linked immunosorbent assay [ELISA] and Western blot)
- Serum heavy metals
- Serum copper
- Ceruloplasmin
- Serum B₁₂, red blood cell (RBC) folate levels

Urine

- Culture
- Toxicology
- Heavy metal screen

Electrography

- Electroencephalography
- Evoked potentials
- Polysomnography
- Nocturnal penile tumescence

Cerebrospinal fluid

- Glucose, protein
- Cell count
- Cultures (bacterial, viral, fungal)
- Cryptococcal antigen
- Venereal Disease Research Laboratory test

Radiography

- Computed tomography
- Magnetic resonance imaging
- Positron emission tomography
- Single photon emission computed tomography

(Courtesy of Eric D. Caine, M.D., and Jeffrey M. Lyness, M.D.)

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG) is an easily accessible, noninvasive test of brain dysfunction that has high sensitivity for many disorders but relatively low specificity. Beyond its recognized uses in epilepsy, EEG's greatest utility is in detecting altered electrical rhythms associated with mild delirium, space-occupying lesions, and continuing complex partial seizures (in which the patient remains conscious, although behaviorally impaired). EEG is also sensitive to metabolic and toxic states, often showing a diffuse slowing of brain activity. The EEG is discussed in Section 3.4, Electrophysiology.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Computed tomography (CT) and magnetic resonance imaging (MRI) have proved to be powerful neuropsychiatric research tools. Recent developments in MRI allow the direct measurement of structures such as the thalamus, basal ganglia, hippocampus, and amygdala, as well as temporal and apical areas of the brain and the structures of the posterior fossa. MRI has largely replaced CT as the most utilitarian and cost-effective method of imaging in neuropsychiatry. Patients with acute cerebral hemorrhages or hematomas must continue to be assessed using CT, but these patients present infrequently in psychiatric settings. MRI better discriminates the interface between gray and white matter and is useful in detecting a variety of white matter lesions in the periventricular and subcortical regions. The pathophysiological significance of such findings remains to be defined. White matter abnormalities are detected in younger patients with multiple sclerosis or human immunodeficiency virus (HIV) infection and in older patients with hypertension, vascular dementia, or dementia of the Alzheimer's type. The prevalence of these abnormalities is also increased in healthy, aging individuals who have no defined disease process. As with CT, the greatest utility of MRI in the evaluation of patients with dementia arises from what it may exclude (tumors, vascular disease) rather than what it can demonstrate specifically.

BRAIN BIOPSY

Brain needle biopsy is used to diagnose a variety of disorders: Alzheimers disease, autoimmune encephalopathies, and tumors. It is conducted stereotactically and indicated when no other investigative techniques such as MRI or lumbar puncture have been sufficient to make a diagnosis. The procedure is not without risk in that seizures may occur if scar tissue forms at the biopsy site.

NEUROPSYCHOLOGICAL TESTING

Neuropsychological testing provides a standardized, quantitative, reproducible evaluation of a patient's cognitive abilities. Such procedures may be useful for initial evaluation and periodic assessment. Tests are available that assess abilities across the broad array of cognitive domains, and many offer comparative normative groups or adjusted scores based on normative samples. The clinician seeking neuropsychological consultation should understand enough about the strengths and weaknesses of selected procedures to benefit fully from the results obtained.

21.2 Delirium

Delirium is characterized by an acute decline in both the level of consciousness and cognition with particular impairment in attention. A life threatening, yet potentially reversible disorder of the central nervous system (CNS), delirium often involves perceptual disturbances, abnormal psychomotor activity, and sleep cycle impairment. Delirium is often underrecognized by health care workers. Part of the problem is that the syndrome has a variety of other names (Table 21.2-1).

Table 21.2-1
Delirium by Other Names

Intensive care unit psychosis
Acute confusional state
Acute brain failure
Encephalitis
Encephalopathy
Toxic metabolic state
Central nervous system toxicity
Paraneoplastic limbic encephalitis
Sundowning
Cerebral insufficiency
Organic brain syndrome

The hallmark symptom of delirium is an impairment of consciousness, usually occurring in association with global impairments of cognitive functions. Abnormalities of mood, perception, and behavior are common psychiatric symptoms. Tremor, asterixis, nystagmus, incoordination, and urinary incontinence are common neurological symptoms. Classically, delirium has a sudden onset (hours or days), a brief and fluctuating course, and rapid improvement when the causative factor is identified and eliminated, but each of these characteristic features can vary in individual patients. Physicians must recognize delirium to identify and treat the underlying cause and to avert the development of delirium-related complications such as accidental injury because of the patient's clouded consciousness.

EPIDEMIOLOGY

Delirium is a common disorder, with most incidence and prevalence rates reported in elderly adults. In community studies, 1 percent of elderly persons age 55 years or older have delirium (13 percent in the age 85 years and older group in the community). Among elderly emergency department patients, 5 to 10 percent have been reported to have delirium. At the time of admission to medical wards, between 15 and 21 percent of older patients meet criteria for delirium-prevalent cases. Of patients free of delirium at time of hospital admission, 5 to 30 percent reported subsequent incidences of delirium during hospitalization. Delirium has been reported in 10 to 15 percent of general surgical patients, 30 percent of open heart surgery patients, and more than 50 percent of patients treated for hip fractures. Delirium occurs in 70 to 87 percent of those in intensive care units and in up to 83 percent of all patients at the end of life care. Sixty percent of patients in nursing homes or postacute care settings have delirium. An estimated 21 percent of patients with severe burns and 30 to 40 percent of patients with acquired immune deficiency syndrome (AIDS) have episodes of delirium while they are hospitalized. Delirium develops in 80 percent of terminally ill patients. The causes of postoperative delirium include the stress of surgery, postoperative pain, insomnia, pain medication, electrolyte imbalances, infection, fever, and blood loss. The incidence and prevalence rates for delirium across settings are shown in Table 21.2-2.

Table 21.2-2
Delirium Incidence and Prevalence in Multiple Settings

Population	Prevalence Range (%)	Incidence Range (%)
General medical inpatients	10–30	3–16
Medical and surgical inpatients	5–15	10–55
General surgical inpatients	N/A	9–15 postoperatively
Critical care unit patients	16	16–83
Cardiac surgery inpatients	16–34	7–34
Orthopedic surgery patients	33	18–50
Emergency department	7–10	N/A
Terminally ill cancer patients	23–28	83
Institutionalized elderly	44	33

N/A, not available.

Risk for delirium could be conceptualized into two categories, predisposing and precipitating factors (Tables 21.2-3 and 21.2-4). Current

approaches to delirium focus primarily on the precipitation factors and do little to address the predisposing factors. Managing predisposing factors for delirium becomes essential in decreasing future episodes of delirium and the morbidity and mortality associated with it.

 **Table 21.2-4**
Precipitating Factors for Delirium

Drugs
Sedative-hypnotics
Narcotics
Anticholinergic drugs
Treatment with multiple drugs
Alcohol or drug withdrawal
Primary neurologic diseases
Stroke, nondominant hemispheric
Intracranial bleeding
Meningitis or encephalitis
Intercurrent illnesses
Infections
Iatrogenic complications
Severe acute illness
Hypoxia
Shock
Anemia
Fever or hypothermia
Dehydration
Poor nutritional status
Low serum albumin levels
Metabolic derangements
Surgery
Orthopedic surgery
Cardiac surgery
Prolonged cardiopulmonary bypass
Noncardiac surgery
Environmental
Admission to intensive care unit
Use of physical restraints
Use of bladder catheter
Use of multiple procedures
Pain
Emotional stress
Prolonged sleep deprivation

(Adapted from Inouye SK: Delirium in older persons. *N Engl J Med.* 2106;354(11):1157.)

 **Table 21.2-3**
Predisposing Factors for Delirium

Demographic characteristics
Age 65 years and older
Male sex
Cognitive status
Dementia
Cognitive impairment
History of delirium
Depression
Functional status
Functional dependence
Immobility
History of falls
Low level of activity
Sensory impairment
Hearing
Visual
Decreased oral intake
Dehydration
Malnutrition
Drugs
Treatment with psychoactive drugs
Treatment with drugs with anticholinergic properties
Alcohol abuse
Coexisting medical conditions
Severe medical diseases
Chronic renal or hepatic disease
Stroke
Neurological disease
Metabolic derangements
Infection with human immunodeficiency virus
Fractures or trauma
Terminal diseases

(Adapted from Inouye SK: Delirium in older persons. *N Engl J Med.* 2106;354(11):1157.)

Advanced age is a major risk factor for the development of delirium. Approximately 30 to 40 percent of hospitalized patients older than age 65 years have an episode of delirium, and another 10 to 15 percent of elderly persons exhibit delirium on admission to the hospital. Of nursing home residents older than age 75 years, 60 percent have repeated episodes of delirium. Male gender is also an independent risk factor for delirium.

Delirium is a poor prognostic sign. Rates of institutionalization are increased threefold for patients 65 years and older who exhibit delirium while in the hospital. The 3-month mortality rate of patients who have an episode of delirium is estimated to be 23 to 33 percent.

The 1-year mortality rate for patients who have an episode of delirium may be as high as 50 percent. Elderly patients who experience delirium while hospitalized have a 21 to 75 percent mortality rate during that hospitalization. After discharge, up to 15 percent of these persons die within a 1-month period, and 25 percent die within 6 months.

ETIOLOGY

The major causes of delirium are CNS disease (e.g., epilepsy), systemic disease (e.g., cardiac failure), and either intoxication or withdrawal from pharmacological or toxic agents (Table 21.2-5). When evaluating patients with delirium, clinicians should assume that any drug that a patient has taken may be etiologically relevant to the delirium.

Table 21.2-5
Common Causes of Delirium

Central nervous system disorder	Seizure (postictal, nonconvulsive status, status) Migraine Head trauma, brain tumor, subarachnoid hemorrhage, subdural, epidural hematoma, abscess, intracerebral hemorrhage, cerebellar hemorrhage, nonhemorrhagic stroke, transient ischemia
Metabolic disorder	Electrolyte abnormalities Diabetes, hypoglycemia, hyperglycemia, or insulin resistance
Systemic illness	Infection (e.g., sepsis, malaria, erysipelas, viral, plague, Lyme disease, syphilis, or abscess) Trauma Change in fluid status (dehydration or volume overload) Nutritional deficiency Burns Uncontrolled pain Heat stroke High altitude (usually >5,000 m)
Medications	Pain medications (e.g., postoperative meperidine [Demerol] or morphine [Duramorph]) Antibiotics, antivirals, and antifungals Steroids Anesthesia Cardiac medications Antihypertensives Antineoplastic agents Anticholinergic agents Neuroleptic malignant syndrome
Serotonin syndrome	
Over-the-counter preparations	Herbals, teas, and nutritional supplements
Botanicals	Jimsonweed, oleander, foxglove, hemlock, dieffenbachia, and <i>Amanita phalloides</i>
Cardiac	Cardiac failure, arrhythmia, myocardial infarction, cardiac assist device, cardiac surgery
Pulmonary	Chronic obstructive pulmonary disease, hypoxia, SIADH, acid–base disturbance
Endocrine	Adrenal crisis or adrenal failure, thyroid abnormality, parathyroid abnormality
Hematological	Anemia, leukemia, blood dyscrasia, stem cell transplant
Renal	Renal failure, uremia, SIADH
Hepatic	Hepatitis, cirrhosis, hepatic failure
Neoplasm	Neoplasm (primary brain, metastases, paraneoplastic syndrome)
Drugs of abuse	Intoxication and withdrawal
Toxins	Intoxication and withdrawal Heavy metals and aluminum

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-5 diagnostic criteria for delirium are listed in Table 21.2-6. The syndrome of delirium is almost always caused by one or more systemic or cerebral derangements that affect brain function.

Table 21.2-6
DSM-5 Diagnostic Criteria for Delirium

- A. A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).
- B. The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of the day.
- C. An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception).
- D. The disturbances in Criteria A and C are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma.
- E. There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies.

Specify whether:

Substance intoxication delirium: This diagnosis should be made instead of substance intoxication when the symptoms in Criteria A and C predominate in the clinical picture and when they are sufficiently severe to warrant clinical attention.

Coding note: The ICD-9-CM and ICD-10-CM codes for the [specific substance] intoxication delirium are indicated in the table below. Note that the ICD-10-CM code depends on whether or not there is a comorbid substance use disorder present for the same class of substance. If a mild substance use disorder is comorbid with the substance intoxication delirium, the 4th position character is "1," and the clinician should record "mild [substance] use disorder" before the substance intoxication delirium (e.g., "mild cocaine use disorder with cocaine intoxication delirium"). If a moderate or severe substance use disorder is comorbid with the substance intoxication delirium, the 4th position character is "2," and the clinician should record "moderate [substance] use disorder" or "severe [substance] use disorder," depending on the severity of the comorbid substance use disorder. If there is no comorbid substance use disorder (e.g., after a one-time heavy use of the substance), then the 4th position character is "9," and the clinician should record only the substance intoxication delirium.

	ICD-9-CM	ICD-10-CM		
		With Use Disorder, Mild	With Use Disorder, Moderate or Severe	Without Use Disorder
Alcohol	291.0	F10.121	F10.221	F10.921
Cannabis	292.81	F12.121	F12.221	F12.921
Phencyclidine	292.81	F16.212	F16.221	F16.921
Other hallucinogen	292.81	F16.121	F16.221	F16.921
Inhalant	292.81	F18.121	F18.221	F18.921
Opioid	292.81	F11.121	F11.221	F11.921
Sedative, hypnotic, or anxiolytic	292.81	F13.121	F13.221	F13.921
Amphetamine (or other stimulant)	292.81	F15.121	F15.221	F15.921
Cocaine	292.81	F14.121	F14.221	F14.921
Other (or unknown) substance	292.81	F19.121	F19.221	F19.921

Substance withdrawal delirium: This diagnosis should be made instead of substance withdrawal when the symptoms in Criteria A and C predominate in the clinical picture and when they are sufficiently severe to warrant clinical attention.

Code [specific substance] withdrawal delirium: **291.0 (F10.231)** alcohol; **292.0 (F11.23)** opioid; **292.0 (F13.231)** sedative, hypnotic, or anxiolytic; **292.0 (F19.231)** other (or unknown) substance/medication.

Medication-induced delirium: This diagnosis applies when the symptoms in Criteria A and C arise as a side effect of a medication taken as prescribed.

Coding note: The ICD-9-CM code for [specific medication]-induced delirium is **292.81**. The ICD-10-CM code depends on the type of medication. If the medication is an opioid taken as prescribed, the code is **F11.921**. If the medication is a sedative, hypnotic, or anxiolytic taken as prescribed, the code is **F13.921**. If the medication is an amphetamine-type or other stimulant taken as prescribed, the code is **F15.921**. For medications that do not fit into any of the classes (e.g., dexamethasone) and in cases in which a substance is judged to be an etiological factor but the specific class of substance is unknown, the code is **F19.921**.

293.0 (F05) Delirium due to another medical condition: There is evidence from the history, physical examination, or laboratory findings that the disturbance is attributable to the physiological consequences of another medical condition.

Coding note: Include the name of the other medical condition in the name of the delirium (e.g., 293.0 [F05] delirium due to hepatic encephalopathy). The other medical condition should also be coded and listed separately immediately before the delirium due to another medical condition (e.g., 572.3 [K72.90] hepatic encephalopathy; 293.0 [F05] delirium due to hepatic encephalopathy).

293.0 (F05) Delirium due to multiple etiologies: There is evidence from the history, physical examination, or laboratory findings that the delirium has more than one etiology (e.g., more than one etiological medical condition; another medical condition plus substance intoxication or medication side effect).

Coding note: Use multiple separate codes reflecting specific delirium etiologies (e.g., 572.2 [K72.90] hepatic encephalopathy, 293.0 [F05] delirium due to hepatic failure; 291.0 [F10.231] alcohol withdrawal delirium). Note that the etiological medical condition both appears as a separate code that precedes the delirium code and is substituted into the delirium due to another medical condition rubric.

Specify if:

Acute: Lasting a few hours or days.

Persistent: Lasting weeks or months.

Specify if:

Hyperactive: The individual has a hyperactive level of psychomotor activity that may be accompanied by mood lability, agitation, and/or refusal to cooperate with medical care.

Hypoactive: The individual has a hypoactive level of psychomotor activity that may be accompanied by sluggishness and lethargy that approaches stupor.

Mixed level of activity: The individual has a normal level of psychomotor activity even though attention and awareness are disturbed. Also includes individuals whose activity level rapidly fluctuates.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

A 70-year old woman, Mrs. K, was brought to the emergency department by the police. The police had responded to complaints from neighbors that Mrs. K was wandering the neighborhood and was not taking care of herself. When the police found Mrs. K in her apartment, she was dirty, foul smelling, and wearing nothing but a bra. Her apartment was also filthy with garbage and rotting food everywhere.

When interviewed, Mrs. K would not look at the interviewer and was confused and unresponsive to most of the questions asked. She knew her name and address but not the date. She was unable to describe the events that led to her admission.

The next day, the supervising psychiatrist attempted to interview Mrs. K. Her facial expression was still unresponsive, and she still did not know the month or the name of the hospital she was in. She explained that the neighbors called the police because she was "sick" and that she did indeed feel sick and weak, with pains in her shoulder. She also reported not eating for 3 days. She denied ever being in a psychiatric hospital or hearing voices but acknowledged seeing a psychiatrist at one point because she had trouble sleeping. She said the doctor had prescribed medication, but she could not remember the name.

The core features of delirium include altered consciousness, such as decreased level of consciousness; altered attention, which can include diminished ability to focus, sustain, or shift attention; impairment in other realms of cognitive function, which can manifest as disorientation (especially to time and space) and decreased memory; relatively rapid onset (usually hours to days); brief duration (usually days to weeks); and often marked, unpredictable fluctuations in severity and other clinical manifestations during the course of the day, sometimes worse at night (sundowning), which may range from periods of lucidity to severe cognitive impairment and disorganization.

Associated clinical features are often present and may be prominent. They can include disorganization of thought processes (ranging from mild tangentiality to frank incoherence), perceptual disturbances such as illusions and hallucinations, psychomotor hyperactivity and hypoactivity, disruption of the sleep-wake cycle (often manifested as fragmented sleep at night, with or without daytime drowsiness), mood alterations (from subtle irritability to obvious dysphoria, anxiety, or even euphoria), and other manifestations of altered neurological

function (e.g., autonomic hyperactivity or instability, myoclonic jerking, and dysarthria). The EEG usually shows diffuse slowing of background activity, although patients with delirium caused by alcohol or sedative-hypnotic withdrawal have low-voltage fast activity.

The major neurotransmitter hypothesized to be involved in delirium is acetylcholine, and the major neuroanatomical area is the reticular formation. The reticular formation of the brainstem is the principal area regulating attention and arousal; the major pathway implicated in delirium is the dorsal tegmental pathway, which projects from the mesencephalic reticular formation to the tectum and thalamus. Several studies have reported that a variety of delirium-inducing factors result in decreased acetylcholine activity in the brain. One of the most common causes of delirium is toxicity from too many prescribed medications with anticholinergic activity. Researchers have suggested other pathophysiological mechanisms for delirium. In particular, the delirium associated with alcohol withdrawal has been associated with hyperactivity of the locus ceruleus and its noradrenergic neurons. Other neurotransmitters that have been implicated are serotonin and glutamate.

PHYSICAL AND LABORATORY EXAMINATIONS

Delirium is usually diagnosed at the bedside and is characterized by the sudden onset of symptoms. A bedside mental status examination—such as the Mini-Mental State Examination, the mental status examination, or neurological signs—can be used to document the cognitive impairment and to provide a baseline from which to measure the patient's clinical course. The physical examination often reveals clues to the cause of the delirium (Table 21.2-7). The presence of a known physical illness or a history of head trauma or alcohol or other substance dependence increases the likelihood of the diagnosis.

Table 21.2-7
Physical Examination of the Delirious Patient

Parameter	Finding	Clinical Implication	
1. Pulse	Bradycardia	Hypothyroidism Stokes-Adams syndrome Increased intracranial pressure	
	Tachycardia	Hyperthyroidism Infection Heart failure	
2. Temperature	Fever	Sepsis Thyroid storm Vasculitis	
3. Blood pressure	Hypotension	Shock Hypothyroidism Addison's disease	
	Hypertension	Encephalopathy Intracranial mass	
4. Respiration	Tachypnea	Diabetes Pneumonia Cardiac failure Fever Acidosis (metabolic)	
5. Carotid vessels	Shallow Bruit or decreased pulse	Alcohol or other substance intoxication Transient cerebral ischemia	
6. Scalp and face	Evidence of trauma		
7. Neck	Evidence of nuchal rigidity	Meningitis Subarachnoid hemorrhage	
8. Eyes	Papilledema	Tumor Hypertensive encephalopathy	
	Pupillary dilatation	Anxiety Autonomic overactivity (e.g., delirium tremens)	
9. Mouth	Tongue or cheek lacerations	Evidence of generalized tonic-clonic seizures	
10. Thyroid	Enlarged	Hyperthyroidism	
11. Heart	Arrhythmia	Inadequate cardiac output, possibility of emboli	
	Cardiomegaly	Heart failure Hypertensive disease	
12. Lungs	Congestion	Primary pulmonary failure Pulmonary edema Pneumonia	
13. Breath	Alcohol Ketones	Diabetes	
14. Liver	Enlargement	Cirrhosis Liver failure	
15. Nervous system	a. Reflexes—muscle stretch	Asymmetry with Babinski's signs	Mass lesion Cerebrovascular disease Preexisting dementia
		Snout	Frontal mass Bilateral posterior cerebral artery occlusion
	b. Abducent nerve (sixth cranial nerve)	Weakness in lateral gaze	Increased intracranial pressure
	c. Limb strength	Asymmetrical	Mass lesion Cerebrovascular disease
	d. Autonomic	Hyperactivity	Anxiety Delirium

(From Strub RL, Black FW. *Neurobehavioral Disorders: A Clinical Approach*. Philadelphia: FA Davis; 1981:121, with permission.)

The laboratory workup of a patient with delirium should include standard tests and additional studies indicated by the clinical situation (Table 21.2-8). In delirium, the EEG characteristically shows a generalized slowing of activity and may be useful in differentiating delirium from depression or psychosis. The EEG of a delirious patient sometimes shows focal areas of hyperactivity. In rare cases, it may be difficult to differentiate delirium related to epilepsy from delirium related to other causes.

Table 21.2-8
Laboratory Workup of the Patient with Delirium

Standard studies

- Blood chemistries (including electrolytes, renal and hepatic indexes, and glucose)
- Complete blood count with white cell differential
- Thyroid function tests
- Serologic tests for syphilis
- Human immunodeficiency virus (HIV) antibody test
- Urinalysis
- Electrocardiogram
- Electroencephalogram
- Chest radiograph
- Blood and urine drug screens

Additional tests when indicated

- Blood, urine, and cerebrospinal fluid cultures
- B₁₂, folic acid concentrations
- Computed tomography or magnetic resonance imaging brain scan
- Lumbar puncture and CSF examination

DIFFERENTIAL DIAGNOSIS

Delirium versus Dementia

A number of clinical features help distinguish delirium from dementia (Table 21.2-9). The major differential points between dementia and delirium are the time to development of the condition and the fluctuation in level of attention in delirium compared with relatively consistent attention in dementia. The time to development of symptoms is usually short in delirium, and except for vascular dementia caused by stroke, it is usually gradual and insidious in dementia. Although both conditions include cognitive impairment, the changes in dementia are more stable over time and, for example, usually do not fluctuate over the course of a day. A patient with dementia is usually alert; a patient with delirium has episodes of decreased consciousness. Occasionally, delirium occurs in a patient with dementia, a condition known as *beclouded dementia*. A dual diagnosis of delirium can be made when there is a definite history of preexisting dementia.

 **Table 21.2-9**
Frequency of Clinical Features of Delirium Contrasted with Dementia

Feature	Dementia	Delirium
Onset	Slow	Rapid
Duration	Months to years	Hours to weeks
Attention	Preserved	Fluctuates
Memory	Impaired remote memory	Impaired recent and immediate memory
Speech	Word-finding difficulty	Incoherent (slow or rapid)
Sleep-wake cycle	Fragmented sleep	Frequent disruption (e.g., day-night reversal)
Thoughts	Impoverished	Disorganized
Awareness	Unchanged	Reduced
Alertness	Usually normal	Hypervigilant or reduced vigilance

(Adapted from Lipowski ZJ. *Delirium: Acute Confusional States*. Oxford: Oxford University Press; 1990.)

Delirium versus Schizophrenia or Depression

Delirium must also be differentiated from schizophrenia and depressive disorder. Some patients with psychotic disorders, usually schizophrenia or manic episodes, can have periods of extremely disorganized behavior difficult to distinguish from delirium. In general, however, the hallucinations and delusions of patients with schizophrenia are more constant and better organized than those of patients with delirium. Patients with schizophrenia usually experience no change in their level of consciousness or in their orientation. Patients with hypoactive symptoms of delirium may appear somewhat similar to severely depressed patients, but they can be distinguished on the basis of an EEG. Other psychiatric diagnoses to consider in the differential diagnosis of delirium are brief psychotic disorder, schizophreniform disorder, and dissociative disorders. Patients with factitious disorders may attempt to simulate the symptoms of delirium but usually reveal the factitious nature of their symptoms by inconsistencies on their mental status examinations, and an EEG can easily separate the two diagnoses.

COURSE AND PROGNOSIS

Although the onset of delirium is usually sudden, prodromal symptoms (e.g., restlessness and fearfulness) can occur in the days preceding the onset of florid symptoms. The symptoms of delirium usually persist as long as the causally relevant factors are present, although delirium generally lasts less than 1 week. After identification and removal of the causative factors, the symptoms of delirium usually recede over a 3- to 7-day period, although some symptoms may take up to 2 weeks to resolve completely. The older the patient and the longer the patient has been delirious, the longer the delirium takes to resolve. Recall of what transpired during a delirium, once it is over, is characteristically spotty; a patient may refer to the episode as a bad dream or a nightmare only vaguely remembered. As stated in the discussion on epidemiology, the occurrence of delirium is associated with a high mortality rate in the ensuing year, primarily because of the serious nature of the associated medical conditions that lead to delirium.

Whether delirium progresses to dementia has not been demonstrated in carefully controlled studies, although many clinicians believe that they have seen such a progression. A clinical observation that has been validated by some studies, however, is that periods of delirium are sometimes followed by depression or posttraumatic stress disorder.

TREATMENT

In treating delirium, the primary goal is to treat the underlying cause. When the underlying condition is anticholinergic toxicity, the use of physostigmine salicylate (Antilirium), 1 to 2 mg intravenously or intramuscularly, with repeated doses in 15 to 30 minutes may be indicated. The other important goal of treatment is to provide physical, sensory, and environmental support. Physical support is necessary so that delirious patients do not get into situations in which they may have accidents. Patients with delirium should be neither sensory deprived nor overly stimulated by the environment. They are usually helped by having a friend or relative in the room or by the presence of a regular sitter. Familiar pictures and decorations; the presence of a clock or a calendar; and regular orientations to person, place, and time help make patients with delirium comfortable. Delirium can sometimes occur in older patients wearing eye patches after cataract surgery ("black-

patch delirium”). Such patients can be helped by placing pinholes in the patches to let in some stimuli or by occasionally removing one patch at a time during recovery.

Pharmacotherapy

The two major symptoms of delirium that may require pharmacological treatment are psychosis and insomnia. A commonly used drug for psychosis is haloperidol (Haldol), a butyrophenone antipsychotic drug. Depending on a patient’s age, weight, and physical condition, the initial dose may range from 2 to 6 mg intramuscularly, repeated in an hour if the patient remains agitated. As soon as the patient is calm, oral medication in liquid concentrate or tablet form should begin. Two daily oral doses should suffice, with two-thirds of the dose being given at bedtime. To achieve the same therapeutic effect, the oral dose should be approximately 1.5 times the parenteral dose. The effective total daily dose of haloperidol may range from 5 to 40 mg for most patients with delirium. Haloperidol has been associated with prolongation of QT interval. Clinicians should evaluate baseline and periodic electrocardiograms as well as monitor cardiac status of the patient. Droperidol (Inapsine) is a butyrophenone available as an alternative intravenous (IV) formulation, although careful monitoring of the electrocardiogram may be prudent with this treatment. The U.S. Food and Drug Administration (FDA) has issued a Black Box Warning because cases of QT prolongation and torsades de pointes have been reported in patients receiving droperidol. Because of its potential for serious proarrhythmic effects and death, it should be used only in patients who do not respond well to other treatments. Phenothiazines should be avoided in delirious patients because these drugs are associated with significant anticholinergic activity.

Use of second-generation antipsychotics, such as risperidone (Risperdal), clozapine, olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), and aripiprazole (Abilify), may be considered for delirium management, but clinical trial experience with these agents for delirium is limited. Ziprasidone appears to have an activating effect and may not be appropriate in delirium management. Olanzapine is available for intramuscular (IM) use and as a rapidly disintegrating oral preparation. These routes of administration may be preferable for some patients with delirium who are poorly compliant with medications or who are too sedated to safely swallow medications.

Insomnia is best treated with benzodiazepines with short or intermediate half-lives (e.g., lorazepam [Ativan] 1 to 2 mg at bedtime). Benzodiazepines with long half-lives and barbiturates should be avoided unless they are being used as part of the treatment for the underlying disorder (e.g., alcohol withdrawal). Clinicians should be aware that there is no conclusive evidence to support the use of benzodiazepines in non-alcohol-related delirium. There have been case reports of improvement in or remission of delirious states caused by intractable medical illnesses with electroconvulsive therapy (ECT); however, routine consideration of ECT for delirium is not advised. If delirium is caused by severe pain or dyspnea, a physician should not hesitate to prescribe opioids for both their analgesic and sedative effects (Table 21.2-10).

Table 21.2-10
Pharmacological Treatment

Pharmacological Agent	Dosage	Side Effects	Comments
Typical Antipsychotics			
Haloperidol (Haldol)	0.5–1 mg p.o. twice a day (may be given every 4–6 hr as needed, too)	Extrapyramidal side (EPS) effects Prolonged QTc	Most commonly used Can be given intramuscularly
Atypical Antipsychotics			
Risperidone (Risperdal)	0.5–1 mg a day	All can prolong QTc duration EPS concerns	Limited data in delirium
Olanzapine (Zyprexa)	5–10 mg a day	Metabolic syndrome	Higher mortality in dementia patients
Quetiapine (Seroquel)	25–150 mg a day	More sedating	
Benzodiazepine			
Lorazepam (Ativan)	0.5–3 mg a day and as needed every 4 hr	Respiratory depression, paradoxical agitation	Best use in delirium secondary to alcohol or benzodiazepine withdrawal Can worsen delirium

Current trials are ongoing to see if dexmedetomidine (Precedex) is a more effective medication than haloperidol in the treatment of agitation and delirium in patients receiving mechanical ventilation in an intensive care unit.

Treatment in Special Populations

Parkinson’s Disease. In Parkinson’s disease, the antiparkinsonian agents are frequently implicated in causing delirium. If a coexistent dementia is present, delirium is twice as likely to develop in patients with Parkinson’s disease with dementia receiving antiparkinsonian agents than in those without dementia. Decreasing the dosage of the antiparkinsonian agent has to be weighed against a worsening of motor symptoms. If the antiparkinsonian agents cannot be further reduced, or if the delirium persists after attenuation of the antiparkinsonian agents, clozapine is recommended. If a patient is not able to tolerate clozapine or the required blood monitoring, alternative antipsychotic agents should be considered. Quetiapine has not been as rigorously studied as clozapine and may have parkinsonian side effects, but it is used in clinical practice to treat psychosis in Parkinson’s disease.

Terminally Ill Patients. When delirium occurs in the context of a terminal illness, issues about advanced directives and the existence of a health care proxy become more significant. This scenario emphasizes the importance of early development of advance directives for health care decision making while a person has the capacity to communicate the wishes regarding the extent of aggressive diagnostic tests at life’s end. The focus may change from an aggressive search for the etiology of the delirium to one of palliation, comfort, and assistance with dying.

21.3 Dementia (Major Neurocognitive Disorder)

Dementia refers to a disease process marked by progressive cognitive impairment in clear consciousness. Dementia does not refer to low intellectual functioning or mental retardation because these are developmental and static conditions, and the cognitive deficits in dementia represent a decline from a previous level of functioning. Dementia involves multiple cognitive domains and cognitive deficits cause significant impairment in social and occupational functioning. There are four types of dementias based on etiology: Alzheimer's disease, dementia of Lewy bodies, vascular dementia, frontotemporal dementia, traumatic brain injury (TBI), HIV, prion disease, Parkinson's disease, and Huntington's disease. Dementia can also be caused by other medical and neurological conditions or can be caused by various substances. (See Section 21.4: Amnesic Disorders.)

The critical clinical points of dementia are the identification of the syndrome and the clinical workup of its cause. The disorder can be progressive or static; permanent or reversible. An underlying cause is always assumed, although, in rare cases, it is impossible to determine a specific cause. The potential reversibility of dementia is related to the underlying pathological condition and to the availability and application of effective treatment. Approximately 15 percent of people with dementia have reversible illnesses if treatment is initiated before irreversible damage takes place.

EPIDEMIOLOGY

With the aging population, the prevalence of dementia is rising. The prevalence of moderate to severe dementia in different population groups is approximately 5 percent in the general population older than 65 years of age, 20 to 40 percent in the general population older than 85 years of age, 15 to 20 percent in outpatient general medical practices, and 50 percent in chronic care facilities.

Of all patients with dementia, 50 to 60 percent have the most common type of dementia, dementia of the Alzheimer's type (Alzheimer's disease). Dementia of the Alzheimer's type increases in prevalence with increasing age. For persons age 65 years, men have a prevalence rate of 0.6 percent and women of 0.8 percent. At age 90, rates are 21 percent. For all of these figures, 40 to 60 percent of cases are moderate to severe. The rates of prevalence (men to women) are 11 and 14 percent at age 85, 21 and 25 percent at age 90 years and 36 and 41 percent at age 95 years. Patients with dementia of the Alzheimer's type occupy more than 50 percent of nursing home beds. More than 2 million persons with dementia are cared for in these homes. By 2050, current predictions suggest that there will be 14 million Americans with Alzheimer's disease and therefore more than 18 million people with dementia.

The second most common type of dementia is vascular dementia, which is causally related to cerebrovascular diseases. Hypertension predisposes a person to the disease. Vascular dementias account for 15 to 30 percent of all dementia cases. Vascular dementia is most common in persons between the ages of 60 and 70 and is more common in men than in women. Approximately 10 to 15 percent of patients have coexisting vascular dementia and dementia of the Alzheimer's type.

Other common causes of dementia, each representing 1 to 5 percent of all cases, include head trauma; alcohol-related dementias; and various movement disorder-related dementias, such as Huntington's disease and Parkinson's disease. Because dementia is a fairly general syndrome, it has many causes, and clinicians must embark on a careful clinical workup of a patient with dementia to establish its cause.

ETIOLOGY

The most common causes of dementia in individuals older than 65 years of age are (1) Alzheimer's disease, (2) vascular dementia, and (3) mixed vascular and Alzheimer's dementia. Other illnesses that account for approximately 10 percent include Lewy body dementia; Pick's disease; frontotemporal dementias; normal-pressure hydrocephalus (NPH); alcoholic dementia; infectious dementia, such as HIV or syphilis; and Parkinson's disease. Many types of dementias evaluated in clinical settings can be attributable to reversible causes, such as metabolic abnormalities (e.g., hypothyroidism), nutritional deficiencies (e.g., vitamin B₁₂ or folate deficiencies), or dementia syndrome caused by depression. See Table 21.3-1 for a review of possible etiologies of dementia.

Table 21.3-1
Possible Etiologies of Dementia

Degenerative dementias

- Alzheimer's disease
- Frontotemporal dementias (e.g., Pick's disease)
- Parkinson's disease
- Lewy body dementia
- Idiopathic cerebral ferrocacinosis (Fahr's disease)
- Progressive supranuclear palsy

Miscellaneous

- Huntington's disease
- Wilson's disease
- Metachromatic leukodystrophy
- Neuroacanthocytosis

Psychiatric

- Pseudodementia of depression
- Cognitive decline in late-life schizophrenia

Physiologic

- Normal-pressure hydrocephalus

Metabolic

- Vitamin deficiencies (e.g., vitamin B₁₂, folate)
- Endocrinopathies (e.g., hypothyroidism)
- Chronic metabolic disturbances (e.g., uremia)

Tumor

- Primary or metastatic (e.g., meningioma or metastatic breast or lung cancer)

Traumatic

- Dementia pugilistica, posttraumatic dementia
- Subdural hematoma

Infection

- Prion diseases (e.g., Creutzfeldt-Jakob disease, bovine spongiform encephalitis, Gerstmann-Sträussler syndrome)
- Acquired immune deficiency syndrome (AIDS)
- Syphilis

Cardiac, vascular, and anoxia

- Infarction (single or multiple or strategic lacunar)
- Binswanger's disease (subcortical arteriosclerotic encephalopathy)
- Hemodynamic insufficiency (e.g., hypoperfusion or hypoxia)

Demyelinating diseases

- Multiple sclerosis

Drugs and toxins

- Alcohol
- Heavy metals
- Irradiation
- Pseudodementia due to medications (e.g., anticholinergics)
- Carbon monoxide

Dementia of the Alzheimer's Type

In 1907, Alois Alzheimer (Fig. 21.3-1) first described the condition that later assumed his name. He described a 51-year-old woman with a 4½-year course of progressive dementia. The final diagnosis of Alzheimer's disease requires a neuropathological examination of the brain; nevertheless, dementia of the Alzheimer's type is commonly diagnosed in the clinical setting after other causes of dementia have been excluded from diagnostic consideration.

FIGURE 21.3-1

Alois Alzheimer (1864–1915), a German psychiatrist, described a type of senile dementia that bears his name

Genetic Factors. Although the cause of dementia of the Alzheimer's type remains unknown, progress has been made in understanding the molecular basis of the amyloid deposits that are a hallmark of the disorder's neuropathology. Some studies have indicated that as many as 40 percent of patients have a family history of dementia of the Alzheimer's type; thus, genetic factors are presumed to play a part in the development of the disorder, at least in some cases. Additional support for a genetic influence is the concordance rate for monozygotic twins, which is higher than the rate for dizygotic twins (43 percent vs. 8 percent, respectively). In several well-documented cases, the disorder has been transmitted in families through an autosomal dominant gene, although such transmission is rare. Alzheimer's type dementia has shown linkage to chromosomes 1, 14, and 21.

AMYLOID PRECURSOR PROTEIN. The gene for amyloid precursor protein is on the long arm of chromosome 21. The process of differential splicing yields four forms of amyloid precursor protein. The β /A4 protein, the major constituent of senile plaques, is a 42-amino acid

peptide that is a breakdown product of amyloid precursor protein. In Down syndrome (trisomy 21) are found three copies of the amyloid precursor protein gene, and in a disease in which a mutation is found at codon 717 in the amyloid precursor protein gene, a pathological process results in the excessive deposition of $\beta/A4$ protein. Whether the processing of abnormal amyloid precursor protein is of primary causative significance in Alzheimer's disease is unknown, but many research groups are studying both the normal metabolic processing of amyloid precursor protein and its processing in patients with dementia of the Alzheimer's type in an attempt to answer this question.

MULTIPLE E4 GENES. One study implicated gene E4 in the origin of Alzheimer's disease. People with one copy of the gene have Alzheimer's disease three times more frequently than do those with no E4 gene, and people with two E4 genes have the disease eight times more frequently than do those with no E4 gene. Diagnostic testing for this gene is not currently recommended because it is found in persons without dementia and not found in all cases of dementia.

Neuropathology. The classic gross neuroanatomical observation of a brain from a patient with Alzheimer's disease is diffuse atrophy with flattened cortical sulci and enlarged cerebral ventricles. The classic and pathognomonic microscopic findings are senile plaques, neurofibrillary tangles, neuronal loss (particularly in the cortex and the hippocampus), synaptic loss (perhaps as much as 50 percent in the cortex), and granulo-vascular degeneration of the neurons. Neurofibrillary tangles (Fig. 21.3-2) are composed of cytoskeletal elements, primarily phosphorylated tau protein, although other cytoskeletal proteins are also present. Neurofibrillary tangles are not unique to Alzheimer's disease; they also occur in Down syndrome, dementia pugilistica (punch-drunken syndrome), Parkinson-dementia complex of Guam, Hallervorden-Spatz disease, and the brains of normal people as they age. Neurofibrillary tangles are commonly found in the cortex, the hippocampus, the substantia nigra, and the locus ceruleus.

FIGURE 21.3-2

Photomicrographs of Alzheimer's disease neuropathology. (A) Deposition of insoluble fibrillar $A\beta$ into plaques begins in the neocortex, labeled here using an antibody against $A\beta$ and appearing as reddish-brown deposits (arrows). (B) Bielchowsky stain of neocortex from an individual who died in advanced stages of Alzheimer's disease (Braak stage VI). The $A\beta$ plaques appear as dark brown in this preparation (arrows) and can be seen to be associated with dystrophic neuronal processes (arrowheads) in which insoluble microtubule-associate protein τ (MAPT) aggregates appear as black deposits. This neurofibrillary pathology also appears extensively throughout the neuropil, and several neurofibrillary tangles can be seen (open arrowheads). (C) Bielchowsky stain of neocortex from an individual who died in a less advanced disease stage (Braak stage IV). Although some neurofibrillary tangles are still evident (open arrowheads), the degree of neurofibrillary pathology in the neuropil is substantially diminished. (D) Isolated neurofibrillary tangles (open arrowheads) in entorhinal cortex that can be seen in normal aging (Bielchowsky stain). Notice the lack of $A\beta$ plaques and limited neuropil involvement. (All images obtained at $200\times$ magnification and provided courtesy of Dr. Ronald L. Hamilton, Department of Pathology, Division of Neuropathology, University of Pittsburgh School of Medicine.)

Senile plaques, also referred to as *amyloid plaques*, more strongly indicate Alzheimer's disease, although they are also seen in Down syndrome and, to some extent, in normal aging. Senile plaques are composed of a particular protein, $\beta/A4$, and astrocytes, dystrophic neuronal processes, and microglia. The number and the density of senile plaques present in postmortem brains have been correlated with the severity of the disease that affected the persons.

Neurotransmitters. The neurotransmitters that are most often implicated in the pathophysiological condition of Alzheimer's disease are acetylcholine and norepinephrine, both of which are hypothesized to be hypoactive in Alzheimer's disease. Several studies have reported data consistent with the hypothesis that specific degeneration of cholinergic neurons is present in the nucleus basalis of Meynert in persons with Alzheimer's disease. Other data supporting a cholinergic deficit in Alzheimer's disease demonstrate decreased acetylcholine and choline acetyltransferase concentrations in the brain. Choline acetyltransferase is the key enzyme for the synthesis of acetylcholine, and a reduction in choline acetyltransferase concentration suggests a decrease in the number of cholinergic neurons present. Additional support for the cholinergic deficit hypothesis comes from the observation that cholinergic antagonists, such as scopolamine and atropine, impair cognitive abilities, whereas cholinergic agonists, such as physostigmine and arecoline, enhance cognitive abilities. Decreased norepinephrine activity in Alzheimer's disease is suggested by the decrease in norepinephrine-containing neurons in the locus ceruleus found in some pathological examinations of brains from persons with Alzheimer's disease. Two other neurotransmitters implicated in the pathophysiological condition of Alzheimer's disease are the neuroactive peptides somatostatin and corticotropin; decreased concentrations of both have been reported in persons with Alzheimer's disease.

Other Causes. Another theory to explain the development of Alzheimer's disease is that an abnormality in the regulation of membrane phospholipid metabolism results in membranes that are less fluid—that is, more rigid—than normal. Several investigators are using molecular resonance spectroscopic imaging to assess this hypothesis directly in patients with dementia of the Alzheimer's type. Aluminum toxicity has also been hypothesized to be a causative factor because high levels of aluminum have been found in the brains of some patients with Alzheimer's disease, but this is no longer considered a significant etiological factor. Excessive stimulation by the transmitter glutamate that may damage neurons is another theory of causation.

Familial Multiple System Tauopathy with Presenile Dementia. A recently discovered type of dementia, familial multiple system tauopathy, shares some brain abnormalities found in people with Alzheimer's disease. The gene that causes the disorder is thought to be carried on chromosome 17. The symptoms of the disorder include short-term memory problems and difficulty maintaining balance and walking. The onset of disease occurs in the 40s and 50s, and persons with the disease live an average of 11 years after the onset of symptoms.

As in patients with Alzheimer's disease, tau protein builds up in neurons and glial cells of persons with familial multiple system tauopathy. Eventually, the protein buildup kills brain cells. The disorder is not associated with the senile plaques seen with Alzheimer's disease.

Mr. J, a 70-year-old retired businessman, was brought to psychiatric services on referral by the family physician. His wife claimed that Mr. J had become so forgetful that she was afraid to leave him alone, even at home. Mr. J retired at age 62 years after experiencing a decline in work performance during the previous 5 years. He also slowly gave up hobbies he once enjoyed (photography, reading, golf) and became increasingly quiet. However, his growing forgetfulness went basically unnoticed at home. Then one day while walking in an area he knew well, he could not find his way home. From then on his memory failure began to increase. He would forget appointments, misplace things, and lose his way around the neighborhood he resided in for 40 years. He failed to recognize people, even those he knew for many years. His wife had to start bathing and dressing him because he forgot how to do so himself.

On examination, Mr. J was disoriented in time and place. He was only able to recall his name and place of birth. Mr. J seemed lost during the interview, only responding to questions with an occasional shrug of his shoulders. When asked to name objects or to recall words or numbers, Mr. J appeared tense and distressed. Mr. J had difficulty following instructions and was unable to dress or undress himself. His general medical condition was good. Laboratory examinations showed abnormalities on Mr. J's EEG and CT scans.

Vascular Dementia

The primary cause of vascular dementia, formerly referred to as *multi-infarct dementia*, is presumed to be multiple areas of cerebral vascular disease, resulting in a symptom pattern of dementia. Vascular dementia most commonly is seen in men, especially those with preexisting hypertension or other cardiovascular risk factors. The disorder affects primarily small- and medium-sized cerebral vessels, which undergo infarction and produce multiple parenchymal lesions spread over wide areas of the brain (Fig. 21.3-3). The causes of the infarctions can include occlusion of the vessels by arteriosclerotic plaques or thrombemboli from distant origins (e.g., heart valves). An examination of a patient may reveal carotid bruits, funduscopic abnormalities, or enlarged cardiac chambers (Fig. 21.3-4).

FIGURE 21.3-4

Patients with chronic dementia usually requires custodial care in their declining years. Regressive behavior, such as finger sucking, is typical in this state. (Courtesy of Bill Stanton for Magnum Photos, Inc.)

FIGURE 21.3-3

Gross appearance of the cerebral cortex on coronal section from a patient with vascular dementia. The multiple bilateral lacunar infarcts involve the thalamus, the internal capsule, and the globus pallidus. (Courtesy of Daniel P. Perl, M.D.)

Binswanger’s Disease. Binswanger’s disease (Fig. 21.3-5), also known as *subcortical arteriosclerotic encephalopathy*, is characterized by the presence of many small infarctions of the white matter that spare the cortical regions (Fig. 21.3-6). Although Binswanger’s disease was previously considered a rare condition, the advent of sophisticated and powerful imaging techniques, such as MRI, has revealed that the condition is more common than previously thought.

Otto Binswanger

FIGURE 21.3-5

Otto Binswanger (1852–1929), a Swiss psychiatrist who described a condition he call “encephalitis subcorticalis chronica progressive,” now known as Binswanger’s disease.

FIGURE 21.3-6

Binswanger’s disease. Cross-section demonstrating extensive subcortical white matter infarction, with sparing of the overlying gray matter. (Courtesy of Dushyant Purohit, M.D., Neuropathology Division, Mount Sinai School of Medicine, New York, NY.)

Frontotemporal Dementia (Pick’s Disease)

In contrast to the parietal-temporal distribution of pathological findings in Alzheimer’s disease, Pick’s disease (Fig. 21.3-7) is characterized by a preponderance of atrophy in the frontotemporal regions. These regions also have neuronal loss; gliosis; and neuronal Pick’s bodies,

which are masses of cytoskeletal elements. Pick's bodies are seen in some postmortem specimens but are not necessary for the diagnosis. The cause of Pick's disease is unknown, but the disease constitutes approximately 5 percent of all irreversible dementias. It is most common in men, especially those who have a first-degree relative with the condition. Pick's disease is difficult to distinguish from dementia of the Alzheimer's type, although the early stages of Pick's disease are more often characterized by personality and behavioral changes, with relative preservation of other cognitive functions, and it typically begins before 75 years of age. Familial cases may have an earlier onset, and some studies have shown that approximately half of the cases of Pick's disease are familial (Fig. 21.3-8). Features of Klüver-Bucy syndrome (e.g., hypersexuality, placidity, and hyperorality) are much more common in Pick's disease than in Alzheimer's disease.

FIGURE 21.3-7

Arnold Pick (1851–1924), a Czech neurologist and psychiatrist who described frontotemporal dementia and the Pick bodies that are characteristic of the disorder.

FIGURE 21.3-8

Pick's disease gross pathology. This demonstrates the marked frontal and temporal atrophy seen in frontotemporal dementias, such as Pick's disease. (Courtesy of Dushyant Purohit, M.D., Neuropathology Division, Mount Sinai School of Medicine, New York, NY.)

Lewy Body Disease

Lewy body disease is a dementia clinically similar to Alzheimer's disease and often characterized by hallucinations, parkinsonian features, and extrapyramidal signs (Table 21.3-2). Lewy inclusion bodies are found in the cerebral cortex (Fig. 21.3-9). The exact incidence is unknown. These patients often have Capgras syndrome (reduplicative paramnesia) as part of the clinical picture.

FIGURE 21.3-9

Photomicrographs of Lewy body pathology. (A) Abnormal accumulation of α -synuclein aggregates demonstrated by immunocytochemistry in the amygdala of a subject with dementia. Lewy bodies appear as dense intracellular inclusions (arrows), but staining of neuronal processes can be seen throughout the neuropil (arrowheads). In individuals in whom Lewy body pathology occurs concurrently with Alzheimer's disease, the amygdala is often the only region affected. (B) Classic appearance of a Lewy body (arrow) in a large pigmented neuron of the substantia nigra. (C) Lewy body pathology in the neocortex. Both Lewy bodies (arrows) and substantial labeling of neuronal processes in the neuropil (arrowheads) are evident. (Magnification for [A] and [B] 200 \times , for [C] 400 \times . All images provided courtesy of Dr. Ronald L. Hamilton, Department of Pathology, Division of Neuropathology, University of Pittsburgh School of Medicine.)

Table 21.3-2
Clinical Criteria for Dementia with Lewy Bodies (DLB)

The patient must have sufficient cognitive decline to interfere with social or occupational functioning. Of note early in the illness, memory symptoms may not be as prominent as attention, frontosubcortical skills, and visuospatial ability. Probable DLB requires two or more core symptoms, whereas possible DLB only requires one core symptom.

Core features

- Fluctuating levels of attention and alertness
- Recurrent visual hallucinations
- Parkinsonian features (cogwheeling, bradykinesia, and resting tremor)

Supporting features

- Repeated falls
- Syncope
- Sensitivity to neuroleptics
- Systematized delusions
- Hallucinations in other modalities (e.g. auditory, tactile)

(Adapted from McKeith LG, Galasko D, Kosaka K. Consensus guidelines for the clinical and pathologic diagnosis of dementia with Lewy bodies (DLB): Report of the consortium on DLB international workshop. *Neurology*. 1996;47:1113–1124, with permission.)

Huntington’s Disease

Huntington’s disease (Fig. 21.3-10) is classically associated with the development of dementia. The dementia seen in this disease is the subcortical type of dementia, characterized by more motor abnormalities and fewer language abnormalities than in the cortical type of dementia (Table 21.3-3). The dementia of Huntington’s disease exhibits psychomotor slowing and difficulty with complex tasks, but memory, language, and insight remain relatively intact in the early and middle stages of the illness. As the disease progresses, however, the dementia becomes complete; the features distinguishing it from dementia of the Alzheimer’s type are the high incidence of depression and psychosis in addition to the classic choreoathetoid movement disorder.

FIGURE 21.3-10
George Huntington (1850–1916), an American physician who first described the disease that bears his name, Huntington’s disease.

Table 21.3-3
Distinguishing Features of Subcortical and Cortical Dementias

Characteristic	Subcortical Dementia	Cortical Dementia	Recommended Tests
Language	No aphasia (anomia, if severe)	Aphasia early	FAS test
Memory	Impaired recall (retrieval) > recognition (encoding)	Recall and recognition impaired	Boston Naming test WAIS-R vocabulary test Wechsler memory scale; Symbol Digit Paired Associate Learning (Brandt)
Attention and immediate recall	Impaired	Impaired	WAIS-R digit span
Visuospatial skills	Impaired	Impaired	Picture arrangement, object assembly and block design; WAIS subtests
Calculation	Preserved until late	Involved early	Mini-Mental State
Frontal system abilities (executive function)	Disproportionately affected	Degree of impairment consistent with other involvement	Wisconsin Card Sorting Test; Odd Man Out test; Picture Absurdities
Speed of cognitive processing	Slowed early	Normal until late in disease	Trail making A and B; Paced Auditory Serial Addition Test (PASAT)
Personality	Apathetic, inert	Unconcerned	MMPI
Mood	Depressed	Euthymic	Beck and Hamilton depression scales
Speech	Dysarthric	Articulate until late	Verbal fluency (Rosen, 1980)
Posture	Bowed or extended	Upright	
Coordination	Impaired	Normal until late	
Motor speed and control	Slowed	Normal	Finger-tap; grooved pegboard
Adventitious movements	Chorea, tremor tics, dystonia	Absent (Alzheimer's dementia—some myoclonus)	
Abstraction	Impaired	Impaired	Category test (Halstead Battery)

(From Pajean AK, Román GC. HIV encephalopathy and dementia. In: J Biller, RG Kathol, eds. *The Psychiatric Clinics of North America: The Interface of Psychiatry and Neurology*. Vol. 15. Philadelphia: WB Saunders; 1992:457.)

Parkinson's Disease

As with Huntington's disease, parkinsonism is a disease of the basal ganglia, commonly associated with dementia and depression. An estimated 20 to 30 percent of patients with Parkinson's disease have dementia, and an additional 30 to 40 percent have measurable impairment in cognitive abilities. The slow movements of persons with Parkinson's disease are paralleled in the slow thinking of some affected patients, a feature that clinicians may refer to as *bradyphrenia*.

Mr. M, 77 years of age, came for a neurological examination because he noticed his memory was slipping and he was having difficulty concentrating, which interfered with his work. He complained of slowness and losing his train of thought. His wife stated that he was becoming withdrawn and was more reluctant to participate in activities he usually enjoyed. He denied symptoms of depression other than feeling mildly depressed about his disabilities. Two years prior, Mr. M developed an intermittent resting tremor in his right hand and a shuffling gait. Although a psychiatrist considered a diagnosis of Parkinson's disease, it was not confirmed by a neurologist and therefore was never treated.

During an initial neurological examination, Mr. M's spontaneous speech was hesitant and unclear (dysarthric). Cranial nerve examination was normal. Motor tone was increased slightly in the neck and all limbs. He performed alternating movements in his hands slowly. He had a slight intermittent tremor of his right arm at rest. Reflexes were symmetrical. A neuropsychological examination was performed three weeks later. It was found that Mr. M showed impairment of memory, naming, and constructional abilities.

HIV-Related Dementia

Encephalopathy in HIV infection is associated with dementia and is termed *acquired immune deficiency syndrome (AIDS) dementia complex*, or *HIV dementia*. Patients infected with HIV experience dementia at an annual rate of approximately 14 percent. An estimated 75 percent of patients with AIDS have involvement of the CNS at the time of autopsy. The development of dementia in people infected with HIV is often paralleled by the appearance of parenchymal abnormalities in MRI scans. Other infectious dementias are caused by *Cryptococcus* or *Treponema pallidum*.

The diagnosis of AIDS dementia complex is made by confirmation of HIV infection and exclusion of alternative pathology to explain cognitive impairment. The American Academy of Neurology AIDS Task Force developed research criteria for the clinical diagnosis of CNS disorders in adults and adolescents (Table 21.3-4). The AIDS Task Force criteria for AIDS dementia complex require laboratory evidence for systemic HIV, at least two cognitive deficits, and the presence of motor abnormalities or personality changes. Personality changes may be manifested by apathy, emotional lability, or behavioral disinhibition. The AIDS Task Force criteria also require the absence of clouding of consciousness or evidence of another etiology that could produce the cognitive impairment. Cognitive, motor, and behavioral changes are assessed using physical, neurological, and psychiatric examinations, in addition to neuropsychological testing.

Table 21.3-4
Criteria for Clinical Diagnosis of HIV Type 1-Associated Dementia Complex

Laboratory evidence for systemic human immunodeficiency virus (HIV) type 1 infection with confirmation by Western blot, polymerase chain reaction, or culture.

Acquired abnormality in at least two cognitive abilities for a period of at least 1 month: attention and concentration, speed of processing information, abstraction and reasoning, visuospatial skills, memory and learning, and speech and language. The decline should be verified by reliable history and mental status examination. History should be obtained from an informant, and examination should be supplemented by neuropsychological testing.

Cognitive dysfunction causes impairment in social or occupational functioning. Impairment should not be attributable solely to severe systemic illness.

At least one of the following:

Acquired abnormality in motor function verified by clinical examination (e.g., slowed rapid movements, abnormal gait, incoordination, hyperreflexia, hypertonia, or weakness), neuropsychological tests (e.g., fine motor speed, manual dexterity, or perceptual motor skills), or both.

Decline in motivation or emotional control or a change in social behavior. This may be characterized by a change in personality with apathy, inertia, irritability, emotional lability, or a new onset of impaired judgment or disinhibition.

This does not exclusively occur in the context of a delirium.

Evidence of another etiology, including active central nervous system opportunistic infection, malignancy, psychiatric disorders (e.g., major depression), or substance abuse, if present, is *not* the cause of the previously mentioned symptoms and signs.

(Adapted from Working Group of the American Academy of Neurology AIDS Task Force: Nomenclature and research case definitions for neurologic manifestations of human immunodeficiency virus-type 1 (HIV-1) infection. *Neurology*. 1991;41:778-785, with permission.)

Head Trauma-Related Dementia

Dementia can be a sequela of head trauma. The so-called punch-drunk syndrome (dementia pugilistica) occurs in boxers after repeated head trauma over many years. It is characterized by emotional lability, dysarthria, and impulsivity. It has also been observed in professional football players who developed dementia after repeated concussions over many years.

Mrs. S, 75 years of age, was brought to the emergency department after being found wandering her neighborhood in a confused and disoriented state. She was in good health until a few months prior when her husband was hospitalized for 10 days for minor surgery. About a month after her husband returned home, he and their two adult children, who do not reside with them, reported a noticeable change in Mrs. S's mental status. Mrs. S became hyperactive and appeared to have excessive energy, was agitated and irritable, and had difficulty sleeping at night.

At examination, Mrs. S was disoriented to time and place, agitated, and confused. Her husband revealed upon interview that Mrs. S has for many years suffered from dizziness and lightheadedness upon standing and occasionally suffered from falls, none of which caused any major damage. Not long before her confused symptoms began, Mrs. S had apparently suffered a fall one night, and her husband found her the next morning lying next to the bed in a confused state. Because of her history of falls, neither Mr. S nor Mrs. S thought much of the incident. A CT scan revealed the presence of a subdural hematoma, which was then evacuated. Afterward, Mrs. S's confusion and disorientation cleared and she returned to her normal state of functioning.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-5 diagnostic criteria are listed in [Tables 21.3-5](#) and [21.3-6](#). DSM-5 makes a distinction between major and minor cognitive disorder based upon levels of functioning, but the underlying etiology is similar.

Table 21.3-5
DSM-5 Diagnostic Criteria for Major Neurocognitive Disorder (Dementia)

- A. Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
 - 1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a significant decline in cognitive function; and
 - 2. A substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment.
- B. The cognitive deficits interfere with independence in everyday activities (i.e., at a minimum, requiring assistance with complex instrumental activities of daily living such as paying bills or managing medications).
- C. The cognitive deficits do not occur exclusively in the context of a delirium.
- D. The cognitive deficits are not better explained by another mental disorder (e.g., major depressive disorder, schizophrenia).

Specify whether due to:

- Alzheimer's disease
- Frontotemporal lobar degeneration
- Lewy body disease
- Vascular disease
- Traumatic brain injury
- Substance/medication use
- HIV infection
- Prion disease
- Parkinson's disease
- Huntington's disease
- Another medical condition
- Multiple etiologies
- Unspecified

Coding note: Code based on medical or substance etiology. In some cases, there is a need for an additional code for the etiological medical condition, which must immediately precede the diagnostic code for major neurocognitive disorder.

Specify:

Without behavioral disturbance: If the cognitive disturbance is not accompanied by any clinically significant behavioral disturbance.

With behavioral disturbance (specify disturbance): If the cognitive disturbance is accompanied by a clinically significant behavioral disturbance (e.g., psychotic symptoms, mood disturbance, agitation, apathy, or other behavioral symptoms).

Specify current severity:

Mild: Difficulties with instrumental activities of daily living (e.g., housework, managing money).

Moderate: Difficulties with basic activities of daily living (e.g., feeding, dressing).

Severe: Fully dependent.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Table 21.3-6
DSM-5 Diagnostic Criteria for Major or Mild Neurocognitive Disorder Due to Alzheimer's Disease

- A. The criteria are met for major or mild neurocognitive disorder.
- B. There is insidious onset and gradual progression of impairment in one or more cognitive domains (for major neurocognitive disorder, at least two domains must be impaired).
- C. Criteria are met for either probable or possible Alzheimer's disease as follows:
For major neurocognitive disorder:
Probable Alzheimer's disease is diagnosed if either of the following is present; otherwise, **possible Alzheimer's disease** should be diagnosed.
 - 1. Evidence of a causative Alzheimer's disease genetic mutation from family history or genetic testing.
 - 2. All three of the following are present:
 - a. Clear evidence of a decline in memory and learning and at least one other cognitive domain (based on detailed history or serial neuropsychological testing).
 - b. Steadily progressive, gradual decline in cognition, without extended plateaus.
 - c. No evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease, or another neurological, mental, or systemic disease or condition likely contributing to cognitive decline).
- For mild neurocognitive disorder:**
Probable Alzheimer's disease is diagnosed if there is evidence of a causative Alzheimer's disease genetic mutation from either genetic testing or family history.
Possible Alzheimer's disease is diagnosed if there is no evidence of a causative Alzheimer's disease genetic mutation from either genetic testing or family history, and all three of the following are present:
 - 1. Clear evidence of decline in memory and learning.
 - 2. Steadily progressive, gradual decline in cognition, without extended plateaus.
 - 3. No evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease, or another neurological, mental, or systemic disease or condition likely contributing to cognitive decline).
- D. The disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systemic disorder.
Coding note: For probable major neurocognitive disorder due to Alzheimer's disease, with behavioral disturbance, code first **331.0 (G30.9)** Alzheimer's disease, followed by **294.11 (F02.81)** major neurocognitive disorder due to Alzheimer's disease. For probable neurocognitive disorder due to Alzheimer's disease, without behavioral disturbance, code first **331.0 (G30.9)** Alzheimer's disease, followed by **294.10 (F02.80)** major neurocognitive disorder due to Alzheimer's disease, without behavioral disturbance.
For possible major neurocognitive disorder due to Alzheimer's disease, code **331.9 (G31.9)** possible major neurocognitive disorder due to Alzheimer's disease. (**Note:** Do not use the additional code for Alzheimer's disease. Behavioral disturbance cannot be coded but should be indicated in writing.)
For mild neurocognitive disorder due to Alzheimer's disease, code **331.83 (G31.84)**. (**Note:** Do not use the additional code for Alzheimer's disease. Behavioral disturbance cannot be coded but should be indicated in writing.)

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

The diagnosis of dementia is based on the clinical examination, including a mental status examination, and on information from the patient's family, friends, and employers. Complaints of a personality change in a patient older than age 40 years suggest that a diagnosis of dementia should be carefully considered.

Clinicians should note patients' complaints about intellectual impairment and forgetfulness as well as evidence of patients' evasion, denial, or rationalization aimed at concealing cognitive deficits. Excessive orderliness, social withdrawal, or a tendency to relate events in minute detail can be characteristic, and sudden outbursts of anger or sarcasm can occur. Patients' appearance and behavior should be observed. Lability of emotions; sloppy grooming; uninhibited remarks; silly jokes; or a dull, apathetic, or vacuous facial expression and manner suggest the presence of dementia, especially when coupled with memory impairment.

Memory impairment is typically an early and prominent feature in dementia, especially in dementias involving the cortex, such as dementia of the Alzheimer's type. Early in the course of dementia, memory impairment is mild and usually most marked for recent events; people forget telephone numbers, conversations, and events of the day. As the course of dementia progresses, memory impairment becomes severe, and only the earliest learned information (e.g., a person's place of birth) is retained.

Inasmuch as memory is important for orientation to person, place, and time, orientation can be progressively affected during the course of a dementing illness. For example, patients with dementia may forget how to get back to their rooms after going to the bathroom. No matter how severe the disorientation seems, however, patients show no impairment in their level of consciousness.

Dementing processes that affect the cortex, primarily dementia of the Alzheimer's type and vascular dementia, can affect patients' language abilities.

Psychiatric and Neurological Changes

Personality. Changes in the personality of a person with dementia are especially disturbing for their families. Preexisting personality traits may be accentuated during the development of a dementia. Patients with dementia may also become introverted and seem to be less concerned than they previously were about the effects of their behavior on others. Persons with dementia who have paranoid delusions are generally hostile to family members and caretakers. Patients with frontal and temporal involvement are likely to have marked personality changes and may be irritable and explosive.

Hallucinations and Delusions. An estimated 20 to 30 percent of patients with dementia (primarily patients with dementia of the Alzheimer's type) have hallucinations, and 30 to 40 percent have delusions, primarily of a paranoid or persecutory and unsystematized nature, although complex, sustained, and well-systematized delusions are also reported by these patients. Physical aggression and other forms of violence are common in demented patients who also have psychotic symptoms.

Mood. In addition to psychosis and personality changes, depression and anxiety are major symptoms in an estimated 40 to 50 percent of patients with dementia, although the full syndrome of depressive disorder may be present in only 10 to 20 percent. Patients with dementia also may exhibit pathological laughter or crying—that is, extremes of emotions—with no apparent provocation.

Cognitive Change. In addition to the aphasias in patients with dementia, apraxias and agnosias are common. Other neurological signs that can be associated with dementia are seizures, seen in approximately 10 percent of patients with dementia of the Alzheimer's type and in 20 percent of patients with vascular dementia, and atypical neurological presentations, such as nondominant parietal lobe syndromes. Primitive reflexes, such as the grasp, snout, suck, tonic-foot, and palmomentar reflexes, may be present on neurological examination, and myoclonic jerks are present in 5 to 10 percent of patients.

Patients with vascular dementia may have additional neurological symptoms, such as headaches, dizziness, faintness, weakness, focal neurological signs, and sleep disturbances, possibly attributable to the location of the cerebrovascular disease. Pseudobulbar palsy, dysarthria, and dysphagia are also more common in vascular dementia than in other dementing conditions.

Catastrophic Reaction. Patients with dementia also exhibit a reduced ability to apply what Kurt Goldstein called the “abstract attitude.” Patients have difficulty generalizing from a single instance, forming concepts, and grasping similarities and differences among concepts. Furthermore, the ability to solve problems, to reason logically, and to make sound judgments is compromised. Goldstein also described a catastrophic reaction marked by agitation secondary to the subjective awareness of intellectual deficits under stressful circumstances. Persons usually attempt to compensate for defects by using strategies to avoid demonstrating failures in intellectual performance; they may change the subject, make jokes, or otherwise divert the interviewer. Lack of judgment and poor impulse control appear commonly, particularly in dementias that primarily affect the frontal lobes. Examples of these impairments include coarse language, inappropriate jokes, neglect of personal appearance and hygiene, and a general disregard for the conventional rules of social conduct.

Sundowner Syndrome. Sundowner syndrome is characterized by drowsiness, confusion, ataxia, and accidental falls. It occurs in older people who are overly sedated and in patients with dementia who react adversely to even a small dose of a psychoactive drug. The syndrome also occurs in demented patients when external stimuli, such as light and interpersonal orienting cues, are diminished.

Vascular Dementia

The general symptoms of vascular dementia are the same as those for dementia of the Alzheimer's type, but the diagnosis of vascular dementia requires either clinical or laboratory evidence in support of a vascular cause of the dementia. Vascular dementia is more likely to show a decremental, stepwise deterioration than is Alzheimer's disease.

Substance-Induced Persisting Dementia

To facilitate the clinician's thinking about differential diagnosis, substance-induced persisting dementia is listed in two places, with the dementias and with the substance-related disorders. The specific substances that cross references are alcohol, inhalants, sedatives, hypnotics, or anxiolytics, and other or unknown substances.

Alcohol-Induced Persisting Dementia. To make the diagnosis of alcohol-induced persisting dementia, the criteria for dementia must be met. Because amnesia can also occur in the context of Korsakoff's psychosis, it is important to distinguish between memory impairment accompanied by other cognitive deficits (i.e., dementia) and amnesia caused by thiamine deficiency. To complicate matters, however, evidence also suggests that other cognitive functions, such as attention and concentration, may also be impaired in Wernicke-Korsakoff syndrome. In addition, alcohol abuse is frequently associated with mood changes, so poor concentration and other cognitive symptoms often observed in the context of a major depression must also be ruled out. Prevalence rates differ considerably according to the population studied and the diagnostic criteria used, although alcohol-related dementia has been estimated to account for approximately 4 percent of dementias.

PATHOLOGY, PHYSICAL FINDINGS, AND LABORATORY EXAMINATION

A comprehensive laboratory workup must be performed when evaluating a patient with dementia. The purposes of the workup are to detect reversible causes of dementia and to provide the patient and family with a definitive diagnosis. The range of possible causes of dementia mandates selective use of laboratory tests. The evaluation should follow informed clinical suspicion based on the history and physical and mental status examination results. The continued improvements in brain imaging techniques, particularly MRI, have made differentiation between dementia of the Alzheimer's type and vascular dementia, in some cases, somewhat more straightforward than in the past. An active area of research is the use of single-photon emission computed tomography (SPECT) to detect patterns of brain metabolism in various types of dementias; the use of SPECT images may soon help in the clinical differential diagnosis of dementing illnesses.

A general physical examination is a routine component of the workup for dementia. It may reveal evidence of systemic disease causing brain dysfunction, such as an enlarged liver and hepatic encephalopathy, or it may demonstrate systemic disease related to particular CNS processes. The detection of Kaposi's sarcoma, for example, should alert the clinician to the probable presence of AIDS and the associated possibility of AIDS dementia complex. Focal neurological findings, such as asymmetrical hyperreflexia or weakness, are seen more often in vascular than in degenerative disease. Frontal lobe signs and primitive reflexes occur in many disorders and often point to greater progression.

DIFFERENTIAL DIAGNOSIS

Dementia of the Alzheimer's Type versus Vascular Dementia

Classically, vascular dementia has been distinguished from dementia of the Alzheimer's type by the decremental deterioration that can

accompany cerebrovascular disease over time. Although the discrete, stepwise deterioration may not be apparent in all cases, focal neurological symptoms are more common in vascular dementia than in dementia of the Alzheimer's type, as are the standard risk factors for cerebrovascular disease.

Vascular Dementia versus Transient Ischemic Attacks

Transient ischemic attacks (TIAs) are brief episodes of focal neurological dysfunction lasting less than 24 hours (usually 5 to 15 minutes). Although a variety of mechanisms may be responsible, the episodes are frequently the result of microembolization from a proximal intracranial arterial lesion that produces transient brain ischemia, and the episodes usually resolve without significant pathological alteration of the parenchymal tissue. Approximately one-third of persons with untreated TIAs experience a brain infarction later; therefore, recognition of TIAs is an important clinical strategy to prevent brain infarction.

Clinicians should distinguish episodes involving the vertebrobasilar system from those involving the carotid arterial system. In general, symptoms of vertebrobasilar disease reflect a transient functional disturbance in either the brainstem or the occipital lobe; carotid distribution symptoms reflect unilateral retinal or hemispheric abnormality. Anticoagulant therapy, antiplatelet agglutinating drugs such as aspirin, and extracranial and intracranial reconstructive vascular surgery are effective in reducing the risk of infarction in patients with TIAs.

Delirium

In general, delirium is distinguished by rapid onset, brief duration, cognitive impairment fluctuation during the course of the day; nocturnal exacerbation of symptoms; marked disturbance of the sleep-wake cycle; and prominent disturbances in attention and perception.

Depression

Some patients with depression have symptoms of cognitive impairment difficult to distinguish from symptoms of dementia. The clinical picture is sometimes referred to as *pseudodementia*, although the term *depression-related cognitive dysfunction* is preferable and more descriptive (Table 21.3-7). Patients with depression-related cognitive dysfunction generally have prominent depressive symptoms, more insight into their symptoms than do demented patients, and often a history of depressive episodes.

Table 21.3-7
Major Clinical Features Differentiating Pseudodementia from Dementia

Pseudodementia	Dementia
Clinical Course and History	
Family always aware of dysfunction and its severity	Family often unaware of dysfunction and its severity
Onset can be dated with some precision	Onset can be dated only within broad limits
Symptoms of short duration before medical help is sought	Symptoms usually of long duration before medical help is sought
Rapid progression of symptoms after onset	Slow progression of symptoms throughout course
History of previous psychiatric dysfunction common	History of previous psychiatric dysfunction unusual
Complaints and Clinical Behavior	
Patients usually complain much of cognitive loss	Patients usually complain little of cognitive loss
Patients' complaints of cognitive dysfunction usually detailed	Patients' complaints of cognitive dysfunction usually vague
Patients emphasize disability	Patients conceal disability
Patients highlight failures	Patients delight in accomplishments, however trivial
Patients make little effort to perform even simple tasks	Patients struggle to perform tasks
	Patients rely on notes, calendars, and so on to keep up
Patients usually communicate strong sense of distress	Patients often appear unconcerned
Affective change often pervasive	Affect labile and shallow
Loss of social skills often early and prominent	Social skills often retained
Behavior often incongruent with severity of cognitive dysfunction	Behavior usually compatible with severity of cognitive dysfunction
Nocturnal accentuation of dysfunction uncommon	Nocturnal accentuation of dysfunction common
Clinical Features Related to Memory, Cognitive, and Intellectual Dysfunctions	
Attention and concentration often well preserved	Attention and concentration usually faulty
"Don't know" answers typical	Near-miss answers frequent
On tests of orientation, patients often give "don't know" answers	On tests of orientation, patients often mistake unusual for usual
Memory loss for recent and remote events usually severe	Memory loss for recent events usually more severe than for remote events
Memory gaps for specific periods or events common	Memory gaps for specific periods unusual ^a
Marked variability in performance on tasks of similar difficulty	Consistently poor performance on tasks of similar difficulty

^aExcept when caused by delirium, trauma, seizures, and so on.
(Reprinted with permission from Wells CE. Pseudodementia. *Am J Psychiatry*. 1979;136:898.)

Factitious Disorder

Persons who attempt to simulate memory loss, as in factitious disorder, do so in an erratic and inconsistent manner. In true dementia, memory for time and place is lost before memory for person, and recent memory is lost before remote memory.

Schizophrenia

Although schizophrenia can be associated with some acquired intellectual impairment, its symptoms are much less severe than are the related symptoms of psychosis and thought disorder seen in dementia.

Normal Aging

Aging is not necessarily associated with any significant cognitive decline, but minor memory problems can occur as a normal part of aging. These normal occurrences are sometimes referred to as *benign senescent forgetfulness*, *age-associated memory impairment*, or *normal benign age-related senescence*. They are distinguished from dementia by their minor severity and because they do not interfere significantly with a person's social or occupational behavior. See Section 21.6 for a discussion of mild cognitive impairment.

Other Disorders

Intellectual disability, which does not include memory impairment, occurs in childhood. Amnestic disorder is characterized by circumscribed loss of memory and no deterioration. Major depression in which memory is impaired responds to antidepressant medication. Malingering and pituitary disorder must be ruled out, but they are unlikely.

COURSE AND PROGNOSIS

The classic course of dementia is an onset in the patient's 50s or 60s, with gradual deterioration over 5 to 10 years, leading eventually to death. The age of onset and the rapidity of deterioration vary among different types of dementia and within individual diagnostic categories. The average survival expectation for patients with dementia of the Alzheimer's type is approximately 8 years, with a range of 1 to 20 years. Data suggest that in persons with an early onset of dementia or with a family history of dementia, the disease is likely to have a rapid course. In a recent study of 821 persons with Alzheimer's disease, the median survival time was 3.5 years. After dementia is diagnosed, patients must have a complete medical and neurological workup because 10 to 15 percent of all patients with dementia have a potentially reversible condition if treatment is initiated before permanent brain damage occurs.

The most common course of dementia begins with a number of subtle signs that may, at first, be ignored by both the patient and the people closest to the patient. A gradual onset of symptoms is most commonly associated with dementia of the Alzheimer's type, vascular dementia, endocrinopathies, brain tumors, and metabolic disorders. Conversely, the onset of dementia resulting from head trauma, cardiac arrest with cerebral hypoxia, or encephalitis can be sudden. Although the symptoms of the early phase of dementia are subtle, they become conspicuous as the dementia progresses, and family members may then bring a patient to a physician's attention. People with dementia may be sensitive to the use of benzodiazepines or alcohol, which can precipitate agitated, aggressive, or psychotic behavior. In the terminal stages of dementia, patients become empty shells of their former selves—profoundly disoriented, incoherent, amnesic, and incontinent of urine and feces.

With psychosocial and pharmacological treatment and possibly because of the self-healing properties of the brain, the symptoms of dementia may progress slowly for a time or may even recede somewhat. Symptom regression is certainly a possibility in reversible dementias (dementias caused by hypothyroidism, NPH, and brain tumors) after treatment is initiated. The course of the dementia varies from a steady progression (commonly seen with dementia of the Alzheimer's type) to an incrementally worsening dementia (commonly seen with vascular dementia) to a stable dementia (as may be seen in dementia related to head trauma).

Psychosocial Determinants

The severity and course of dementia can be affected by psychosocial factors. The greater a person's premorbid intelligence and education, the better the ability to compensate for intellectual deficits. People who have a rapid onset of dementia use fewer defenses than do those who experience an insidious onset. Anxiety and depression can intensify and aggravate the symptoms. Pseudodementia occurs in depressed people who complain of impaired memory but, in fact, have a depressive disorder. When the depression is treated, the cognitive defects disappear.

TREATMENT

The first step in the treatment of dementia is verification of the diagnosis. Accurate diagnosis is imperative because the progression may be halted or even reversed if appropriate therapy is provided. Preventive measures are important, particularly in vascular dementia. Such measures might include changes in diet, exercise, and control of diabetes and hypertension. Pharmacological agents might include antihypertensive, anticoagulant, or antiplatelet agents. Blood pressure control should aim for the higher end of the normal range because that has been demonstrated to improve cognitive function in patients with vascular dementia. Blood pressure below the normal range has been demonstrated to further impair cognitive function in patients with dementia. The choice of antihypertensive agent can be significant in that β -adrenergic receptor antagonists have been associated with exaggeration of cognitive impairment. Angiotensin-converting enzyme (ACE) inhibitors and diuretics have not been linked to exaggeration of cognitive impairment and are thought to lower blood pressure without affecting cerebral blood flow, which is presumed to be correlated with cognitive function. Surgical removal of carotid plaques may prevent subsequent vascular events in carefully selected patients. The general treatment approach to patients with dementia is to provide supportive medical care; emotional support for the patients and their families; and pharmacological treatment for specific symptoms, including disruptive behavior.

Psychosocial Therapies

The deterioration of mental faculties has significant psychological meaning for patients with dementia. The experience of a sense of continuity over time depends on memory. Recent memory is lost before remote memory in most cases of dementia, and many patients are highly distressed by clearly recalling how they used to function while observing their obvious deterioration. At the most fundamental level, the self is a product of brain functioning. Patients' identities begin to fade as the illness progresses, and they can recall less and less of their past. Emotional reactions ranging from depression to severe anxiety to catastrophic terror can stem from the realization that the sense of self is disappearing.

Patients often benefit from a supportive and educational psychotherapy in which the nature and course of their illness are clearly explained. They may also benefit from assistance in grieving and accepting the extent of their disability and from attention to self-esteem issues. Any areas of intact functioning should be maximized by helping patients identify activities in which successful functioning is possible. A psychodynamic assessment of defective ego functions and cognitive limitations can also be useful. Clinicians can help patients find ways to deal with the defective ego functions, such as keeping calendars for orientation problems, making schedules to help structure activities, and taking notes for memory problems.

Psychodynamic interventions with family members of patients with dementia may be of great assistance. Those who take care of a patient struggle with feelings of guilt, grief, anger, and exhaustion as they watch a family member gradually deteriorate. A common problem that develops among caregivers involves their self-sacrifice in caring for a patient. The gradually developing resentment from this self-sacrifice is often suppressed because of the guilt feelings it produces. Clinicians can help caregivers understand the complex mixture of feelings associated with seeing a loved one decline and can provide understanding as well as permission to express these feelings. Clinicians must also be aware of the caregivers' tendencies to blame themselves or others for patients' illnesses and must appreciate the role that patients with dementia play in the lives of family members.

Pharmacotherapy

Clinicians may prescribe benzodiazepines for insomnia and anxiety, antidepressants for depression, and antipsychotic drugs for delusions and hallucinations, but they should be aware of possible idiosyncratic drug effects in older people (e.g., paradoxical excitement, confusion, and increased sedation). In general, drugs with high anticholinergic activity should be avoided.

Donepezil (Aricept), rivastigmine (Exelon), galantamine (Remiryl), and tacrine (Cognex) are cholinesterase inhibitors used to treat mild to moderate cognitive impairment in Alzheimer's disease. They reduce the inactivation of the neurotransmitter acetylcholine and thus potentiate the cholinergic neurotransmitter, which in turn produces a modest improvement in memory and goal-directed thought. These drugs are most useful for persons with mild to moderate memory loss who have sufficient preservation of their basal forebrain cholinergic neurons to benefit from augmentation of cholinergic neurotransmission.

Donepezil is well tolerated and widely used. Tacrine is rarely used because of its potential for hepatotoxicity. Fewer clinical data are available for rivastigmine and galantamine, which appear more likely to cause gastrointestinal (GI) and neuropsychiatric adverse effects than does donepezil. None of these medications prevents the progressive neuronal degeneration of the disorder. Prescribing information for anticholinesterase inhibitors can be found in Section 36.14.

Memantine (Namenda) protects neurons from excessive amounts of glutamate, which may be neurotoxic. The drug is sometimes combined with donepezil. It has been known to improve dementia.

Other Treatment Approaches. Other drugs being tested for cognitive-enhancing activity include general cerebral metabolic enhancers, calcium channel inhibitors, and serotonergic agents. Some studies have shown that selegiline (Eldepryl), a selective type B monoamine oxidase (MAO_B) inhibitor, may slow the advance of this disease. Ondansetron (Zofran), a 5-HT₃ receptor antagonist, is under investigation.

Estrogen replacement therapy may reduce the risk of cognitive decline in postmenopausal women; however, more studies are needed to confirm this effect. Complementary and alternative medicine studies of ginkgo biloba and other phytomedicinals are required to see if they have a positive effect on cognition. Reports have appeared of patients using nonsteroidal antiinflammatory agents having a lower risk of developing Alzheimer's disease. Vitamin E has not been shown to be of value in preventing the disease.

21.4 Major or Minor Neurocognitive Disorder Due to Another Medical Condition (Amnesic Disorders)

The amnesic disorders are coded in the DSM-5 as “major or minor neurocognitive disorders due to another medical condition.” All of these disorders cause impairment in memory as the major sign and symptom, although other signs of cognitive decline may coexist. The authors of *Synopsis* believe amnesic disorder to be a clinically useful descriptive category of illness, but they are coded in DSM-5 as a neurocognitive disorder due to another medical condition with the specific medical condition noted.

The amnesic disorders are a broad category that results from a variety of diseases and conditions that have amnesia as the major complaint. The syndrome is defined primarily by impairment in the ability to create new memories. Three different etiologies exist: amnesic disorder caused by a general medical condition (e.g., head trauma), substance-induced persisting amnesic disorder (e.g., caused by carbon monoxide poisoning or chronic alcohol consumption), and amnesic disorder not otherwise specified for cases in which the etiology is unclear.

EPIDEMIOLOGY

No adequate studies have reported on the incidence or prevalence of amnesic disorders. Amnesia is most commonly found in alcohol use disorders and in head injury. In general practice and hospital settings, the frequency of amnesia related to chronic alcohol abuse has decreased, and the frequency of amnesia related to head trauma has increased.

ETIOLOGY

The major neuroanatomical structures involved in memory and in the development of an amnesic disorder are particular diencephalic structures such as the dorsomedial and midline nuclei of the thalamus and midtemporal lobe structures such as the hippocampus, the mamillary bodies, and the amygdala. Although amnesia is usually the result of bilateral damage to these structures, some cases of unilateral damage result in an amnesic disorder, and evidence indicates that the left hemisphere may be more critical than the right hemisphere in the development of memory disorders. Many studies of memory and amnesia in animals have suggested that other brain areas may also be involved in the symptoms accompanying amnesia. Frontal lobe involvement can result in such symptoms as confabulation and apathy, which can be seen in patients with amnesic disorders.

Amnesic disorders have many potential causes (Table 21.4-1). Thiamine deficiency, hypoglycemia, hypoxia (including carbon monoxide poisoning), and herpes simplex encephalitis all have a predilection to damage the temporal lobes, particularly the hippocampi, and thus can be associated with the development of amnesic disorders. Similarly, when tumors, cerebrovascular diseases, surgical procedures, or multiple sclerosis plaques involve the diencephalic or temporal regions of the brain, the symptoms of an amnesic disorder may develop. General insults to the brain, such as seizures, ECT, and head trauma, can also result in memory impairment. Transient global amnesia is presumed to be a cerebrovascular disorder involving transient impairment in blood flow through the vertebrobasilar arteries.

Table 21.4-1
Major Causes of Amnestic Disorders

Thiamine deficiency (Korsakoff's syndrome)
Hypoglycemia
Primary brain conditions
Seizures
Head trauma (closed and penetrating)
Cerebral tumors (especially thalamic and temporal lobe)
Cerebrovascular diseases (especially thalamic and temporal lobe)
Surgical procedures on the brain
Encephalitis due to herpes simplex
Hypoxia (including nonfatal hanging attempts and carbon monoxide poisoning)
Transient global amnesia
Electroconvulsive therapy
Multiple sclerosis
Substance-related causes
Alcohol use disorders
Neurotoxins
Benzodiazepines (and other sedative-hypnotics)
Many over-the-counter preparations

Many drugs have been associated with the development of amnesia, and clinicians should review all drugs taken, including nonprescription drugs, in the diagnostic workup of a patient with amnesia. The benzodiazepines are the most commonly used prescription drugs associated with amnesia. All benzodiazepines can be associated with amnesia, especially if combined with alcohol. When triazolam (Halcion) is used in doses of 0.25 mg or less, which are generally equivalent to standard doses of other benzodiazepines, amnesia is no more often associated with triazolam than with other benzodiazepines. With alcohol and higher doses, anterograde amnesia has been reported.

DIAGNOSIS

The recognition of amnestic disorder occurs when impairment in the ability to learn new information or the inability to recall previously learned information, as a result of which there is significant impairment in social or occupational functioning and which is caused by a general medical condition (including physical trauma). Amnestic disorder may be transient, lasting for hours or days or chronic lasting weeks or months. A diagnosis of substance-induced persisting amnestic disorder is made when evidence suggests that the symptoms are causatively related to the use of a substance. The DSM-5 refers clinicians to specific diagnoses within substance-related disorders: alcohol-induced disorder; sedative, hypnotic, or anxiolytic-induced disorder; and other (or unknown) substance-induced disorder.

CLINICAL FEATURES AND SUBTYPES

The central symptom of amnestic disorders is the development of a memory disorder characterized by an impairment in the ability to learn new information (anterograde amnesia) and an inability to recall previously remembered knowledge (retrograde amnesia). The symptom must result in significant problems for patients in their social or occupational functioning. The time in which a patient is amnestic can begin directly at the point of trauma or include a period before the trauma. Memory for the time during the physical insult (e.g., during a cerebrovascular event) may also be lost.

Short-term and recent memory are usually impaired. Patients cannot remember what they had for breakfast or lunch, the name of the hospital, or their doctors. In some patients, the amnesia is so profound that the patient cannot orient himself or herself to city and time, although orientation to person is seldom lost in amnestic disorders. Memory for overlearned information or events from the remote past, such as childhood experiences, is good, but memory for events from the less remote past (over the past decade) is impaired. Immediate memory (tested, for example, by asking a patient to repeat six numbers) remains intact. With improvement, patients may experience a gradual shrinking of the time for which memory has been lost, although some patients experience a gradual improvement in memory for the entire period.

The onset of symptoms can be sudden, as in trauma, cerebrovascular events, and neurotoxic chemical assaults, or gradual, as in nutritional deficiency and cerebral tumors. The amnesia can be of short duration.

A variety of other symptoms can be associated with amnestic disorders. For patients with other cognitive impairments, a diagnosis of dementia or delirium is more appropriate than a diagnosis of an amnestic disorder. Both subtle and gross changes in personality can accompany the symptoms of memory impairment in amnestic disorders. Patients may be apathetic, lack initiative, have unprovoked episodes of agitation, or appear to be overly friendly or agreeable. Patients with amnestic disorders can also appear bewildered and confused and may attempt to cover their confusion with confabulatory answers to questions. Characteristically, patients with amnestic disorders do not have good insight into their neuropsychiatric conditions.

A 73-year-old survivor of the Holocaust was admitted to the psychiatric unit from a local nursing home. She was born in Germany to a middle-class family. Her education was truncated because of internment in a concentration camp. She immigrated to Israel after liberation from the concentration camp and later to the United States, where she married and raised a family. Premorbidly, she was described as a quiet, intelligent, and loving woman who spoke several languages. At 55 years of age, she had a significant carbon monoxide exposure when a gas line leaked while she and her husband slept. Her husband died of carbon monoxide poisoning, but the patient survived after a period of coma. After being stabilized, she displayed significant cognitive and behavioral problems. She had difficulty with learning new information and making appropriate plans. She retained the ability to perform activities of daily living but could not be relied on to pay bills, buy food, cook, or clean, despite appearing to have retained the intellectual ability to do these tasks. She was admitted to a nursing home after several difficult years at home and in the homes of relatives. In the nursing home, she was able to learn her way about the facility. She displayed little interest in scheduled group activities, hobbies, reading, or television. She had frequent behavioral problems. She repeatedly pressed staff to get her sweets and snacks and cursed them vociferously with racial epithets and disparaging comments on their weight and dress. On one occasion, she scratched the cars of several staff with a key. Neuropsychological testing demonstrated severe deficits in delayed recall; intact performance on language and general knowledge measures; and moderate deficits on domains of executive function, such as concept formation and cognitive flexibility. She was noted to respond immediately to firmly set limits and rewards, but deficits in memory prevented long-term incorporation of these boundaries. Management involved development of a behavioral plan that could be implemented at the nursing home and empirical trials of medications aimed at amelioration of irritability.

Cerebrovascular Diseases

Cerebrovascular diseases affecting the hippocampus involve the posterior cerebral and basilar arteries and their branches. Infarctions are rarely limited to the hippocampus; they often involve the occipital or parietal lobes. Thus, common accompanying symptoms of cerebrovascular diseases in this region are focal neurological signs involving vision or sensory modalities. Cerebrovascular diseases affecting the bilateral medial thalamus, particularly the anterior portions, are often associated with symptoms of amnesic disorders. A few case studies report amnesic disorders from rupture of an aneurysm of the anterior communicating artery, resulting in infarction of the basal forebrain region.

Multiple Sclerosis

The pathophysiological process of multiple sclerosis involves the seemingly random formation of plaques within the brain parenchyma. When the plaques occur in the temporal lobe and the diencephalic regions, symptoms of memory impairment can occur. In fact, the most common cognitive complaints in patients with multiple sclerosis involve impaired memory, which occurs in 40 to 60 percent of patients. Characteristically, digit span memory is normal, but immediate recall and delayed recall of information are impaired. The memory impairment can affect both verbal and nonverbal material.

Korsakoff's Syndrome

Korsakoff's syndrome is an amnesic syndrome caused by thiamine deficiency, most commonly associated with the poor nutritional habits of people with chronic alcohol abuse. Other causes of poor nutrition (e.g., starvation), gastric carcinoma, hemodialysis, hyperemesis gravidarum, prolonged IV hyperalimentation, and gastric plication can also result in thiamine deficiency. Korsakoff's syndrome is often associated with Wernicke's encephalopathy, which is the associated syndrome of confusion, ataxia, and ophthalmoplegia. In patients with these thiamine deficiency-related symptoms, the neuropathological findings include hyperplasia of the small blood vessels with occasional hemorrhages, hypertrophy of astrocytes, and subtle changes in neuronal axons. Although the delirium clears up within a month or so, the amnesic syndrome either accompanies or follows untreated Wernicke's encephalopathy in approximately 85 percent of all cases.

Patients with Korsakoff's syndrome typically demonstrate a change in personality as well, such that they display a lack of initiative, diminished spontaneity, and a lack of interest or concern. These changes appear frontal lobe-like, similar to the personality change ascribed to patients with frontal lobe lesions or degeneration. Indeed, such patients often demonstrate *executive function* deficits on neuropsychological tasks involving attention, planning, set shifting, and inferential reasoning consistent with frontal pattern injuries. For this reason, Korsakoff's syndrome is not a pure memory disorder, although it certainly is a good paradigm of the more common clinical presentations for the amnesic syndrome.

The onset of Korsakoff's syndrome can be gradual. Recent memory tends to be affected more than is remote memory, but this feature is variable. Confabulation, apathy, and passivity are often prominent symptoms in the syndrome. With treatment, patients may remain amnesic for up to 3 months and then gradually improve over the ensuing year. Administration of thiamine may prevent the development of additional amnesic symptoms, but the treatment seldom reverses severe amnesic symptoms when they are present. Approximately one-third to one-fourth of all patients recover completely, and approximately one-fourth of all patients have no improvement of their symptoms.

Alcoholic Blackouts

Some persons with severe alcohol abuse may exhibit the syndrome commonly referred to as an alcoholic blackout. Characteristically, these persons awake in the morning with a conscious awareness of being unable to remember a period the night before during which they were intoxicated. Sometimes specific behaviors (hiding money in a secret place and provoking fights) are associated with the blackouts.

Electroconvulsive Therapy

Electroconvulsive therapy treatments are usually associated with retrograde amnesia for a period of several minutes before the treatment and anterograde amnesia after the treatment. The anterograde amnesia usually resolves within 5 hours. Mild memory deficits may remain for 1 to 2 months after a course of ECT treatments, but the symptoms are completely resolved 6 to 9 months after treatment.

Head Injury

Head injuries (both closed and penetrating) can result in a wide range of neuropsychiatric symptoms, including dementia, depression, personality changes, and amnesic disorders. Amnesic disorders caused by head injuries are commonly associated with a period of retrograde amnesia leading up to the traumatic incident and amnesia for the traumatic incident itself. The severity of the brain injury correlates somewhat with the duration and severity of the amnesic syndrome, but the best correlate of eventual improvement is the degree of clinical improvement in the amnesia during the first week after the patient regains consciousness.

Transient Global Amnesia

Transient global amnesia is characterized by the abrupt loss of the ability to recall recent events or to remember new information. The syndrome is often characterized by mild confusion and a lack of insight into the problem; a clear sensorium; and, occasionally, the inability to perform some well-learned complex tasks. Episodes last from 6 to 24 hours. Studies suggest that transient global amnesia occurs in 5 to 10 cases per 100,000 persons per year, although, for patients older than age 50 years, the rate may be as high as 30 cases per 100,000 persons per year. The pathophysiology is unknown, but it likely involves ischemia of the temporal lobe and the diencephalic brain regions. Several studies of patients with SPECT have shown decreased blood flow in the temporal and parietotemporal regions, particularly in the left hemisphere. Patients with transient global amnesia almost universally experience complete improvement, although one study found that approximately 20 percent of patients may have recurrence of the episode, and another study found that approximately 7 percent of patients may have epilepsy. Patients with transient global amnesia have been differentiated from patients with transient ischemic attacks in that fewer patients have diabetes, hypercholesterolemia, and hypertriglyceridemia, but more have hypertension and migrainous episodes.

PATHOLOGY AND LABORATORY EXAMINATION

Laboratory findings diagnostic of amnesic disorder may be obtained using quantitative neuropsychological testing. Standardized tests also are available to assess recall of well-known historical events or public figures to characterize an individual's inability to remember previously learned information. Performance on such tests varies among individuals with amnesic disorder. Subtle deficits in other cognitive functions may be noted in individuals with amnesic disorder. Memory deficits, however, constitute the predominant feature of the mental status examination and account largely for any functional deficits. No specific or diagnostic features are detectable on imaging studies such as MRI or CT. Damage of midtemporal lobe structures is common, however, and may be reflected in enlargement of third ventricle or temporal horns or in structural atrophy detected by MRI.

DIFFERENTIAL DIAGNOSIS

Table 21.4-1 lists the major causes of amnesic disorders. To make the diagnosis, clinicians must obtain a patient's history, conduct a complete physical examination, and order all appropriate laboratory tests. Other diagnoses, however, can be confused with the amnesic disorders.

Dementia and Delirium

Amnesic disorders can be distinguished from delirium because they occur in the absence of a disturbance of consciousness and are striking for the relative preservation of other cognitive domains.

Table 21.4-2 outlines the key distinctions between Alzheimer's dementia and the amnesic disorders. Both disorders can have an insidious onset with slow progression, as in a Korsakoff's psychosis in a chronic drinker. Amnesic disorders, however, can also develop precipitously, as in Wernicke's encephalopathy, transient global amnesia, or anoxic insults. Although Alzheimer's dementia progresses relentlessly, amnesic disorders tend to remain static or even improve after the offending cause has been removed. In terms of the actual memory deficits, the amnesic disorder and Alzheimer's disease still differ. Alzheimer's disease has an impact on retrieval in addition to encoding and consolidation. The deficits in Alzheimer's disease extend beyond memory to general knowledge (semantic memory), language, praxis, and general function. These are spared in amnesic disorders. The dementias associated with Parkinson's disease, AIDS, and other subcortical disorders demonstrate disproportionate impairment of retrieval, but relatively intact encoding and consolidation and thus can be distinguished from amnesic disorders. The subcortical pattern dementias are also likely to display motor symptoms, such as bradykinesia, chorea, or tremor, that are not components of the amnesic disorders.

Table 21.4-2
Comparison of Syndrome Characteristics in Alzheimer's Disease and Amnesic Disorder

Characteristic	Alzheimer's Dementia	Amnesic Disorder
Onset	Insidious	Can be abrupt
Course	Progressive deterioration	Static or improvement
Anterograde memory	Impaired	Impaired
Retrograde memory	Impaired	Temporal gradient
Episodic memory	Impaired	Impaired
Semantic memory	Impaired	Intact
Language	Impaired	Intact
Praxis or function	Impaired	Intact

Normal Aging

Some minor impairment in memory may accompany normal aging, but the requirement that the memory impairment cause significant impairment in social or occupational functioning should exclude normal aging from the diagnosis.

Dissociative Disorders

The dissociative disorders can sometimes be difficult to differentiate from the amnesic disorders. Patients with dissociative disorders, however, are more likely to have lost their orientation to self and may have more selective memory deficits than do patients with amnesic disorders. For example, patients with dissociative disorders may not know their names or home addresses, but they are still able to learn new information and remember selected past memories. Dissociative disorders are also often associated with emotionally stressful life events involving money, the legal system, or troubled relationships.

Factitious Disorders

Patients with factitious disorders who are mimicking an amnesic disorder often have inconsistent results on memory tests and have no evidence of an identifiable cause. These findings, coupled with evidence of primary or secondary gain for a patient, should suggest a factitious disorder.

COURSE AND PROGNOSIS

The course of an amnesic disorder depends on its etiology and treatment, particularly acute treatment. Generally, the amnesic disorder has a static course. Little improvement is seen over time, but also no progression of the disorder occurs. The exceptions are the acute amnesias, such as transient global amnesia, which resolves entirely over hours to days, and the amnesic disorder associated with head trauma, which improves steadily in the months subsequent to the trauma. Amnesia secondary to processes that destroy brain tissue, such as stroke, tumor, and infection, are irreversible, although, again, static, after the acute infection or ischemia has been staunched.

TREATMENT

The primary approach to treating amnesic disorders is to treat the underlying cause. Although a patient is amnesic, supportive prompts about the date, the time, and the patient's location can be helpful and can reduce the patient's anxiety. After resolution of the amnesic episode, psychotherapy of some type (cognitive, psychodynamic, or supportive) may help patients incorporate the amnesic experience into their lives.

Psychotherapy

Psychodynamic interventions may be of considerable value for patients who have amnesic disorders that result from insults to the brain. Understanding the course of recovery in such patients helps clinicians to be sensitive to the narcissistic injury inherent in damage to the CNS.

The first phase of recovery, in which patients are incapable of processing what happened because the ego defenses are overwhelmed, requires clinicians to serve as a supportive auxiliary ego who explains to a patient what is happening and provides missing ego functions. In the second phase of recovery, as the realization of the injury sets in, patients may become angry and feel victimized by the malevolent hand of fate. They may view others, including the clinician, as bad or destructive, and clinicians must contain these projections without becoming punitive or retaliatory. Clinicians can build a therapeutic alliance with patients by explaining slowly and clearly what happened and by offering an explanation for a patient's internal experience. The third phase of recovery is integrative. As a patient accepts what has happened, a clinician can help the patient form a new identity by connecting current experiences of the self with past experiences. Grieving over the lost faculties may be an important feature of the third phase.

Most patients who are amnesic because of brain injury engage in denial. Clinicians must respect and empathize with the patient's need to deny the reality of what has happened. Insensitive and blunt confrontations destroy any developing therapeutic alliance and can cause patients to feel attacked. In a sensitive approach, clinicians help patients accept their cognitive limitations by exposing them to these deficits

bit by bit over time. When patients fully accept what has happened, they may need assistance in forgiving themselves and any others involved, so that they can get on with their lives. Clinicians must also be wary of being seduced into thinking that all of the patient's symptoms are directly related to the brain insult. An evaluation of preexisting personality disorders, such as borderline, antisocial, and narcissistic personality disorders, must be part of the overall assessment; many patients with personality disorders place themselves in situations that predispose them to injuries. These personality features may become a crucial part of the psychodynamic psychotherapy.

Recently, centers for cognitive rehabilitation have been established whose rehabilitation-oriented therapeutic milieu is intended to promote recovery from brain injury, especially that from traumatic causes. Despite the high cost of extended care at these sites, which provide both long-term institutional and daytime services, no data have been developed to define therapeutic effectiveness for the heterogeneous groups of patients who participate in such tasks as memory retaining.

21.5 Neurocognitive and Other Disorders Due to a General Medical Condition

Increasingly, scientific views of mental illness recognize that, whether caused by an identifiable anomaly (e.g., brain tumor), a neurotransmitter disturbance of unclear origin (e.g., schizophrenia), or a consequence of deranged upbringing or environment (e.g., personality disorder), all mental disorders ultimately share one common underlying theme: aberration in brain function. Treatments for those conditions, whether psychological or biological, attempt to restore normal brain chemistry.

The differential diagnosis for a mental syndrome in a patient should always include consideration of (1) any general medical condition that a patient may have and (2) any prescription, nonprescription, or illegal substances that a patient may be taking. Although some specific medical conditions have classically been associated with mental syndromes, a much larger number of general medical conditions have been associated with mental syndromes in case reports and small studies.

The mental disorders caused by a general medical condition span the entire spectrum of diagnostic categories. Thus, one can have a cognitive disorder, mood disorder, sleep disorder, anxiety disorder, and psychotic disorder to mention but a few that are caused or aggravated by a medical condition. In this section, neurocognitive disorders due to a general medical condition are described, including epilepsy, autoimmune disorders and AIDS, of which psychiatrists should be aware.

SPECIFIC DISORDERS

Epilepsy

Epilepsy is the most common chronic neurological disease in the general population and affects approximately 1 percent of the population in the United States. For psychiatrists, the major concerns about epilepsy are consideration of an epileptic diagnosis in psychiatric patients, the psychosocial ramifications of a diagnosis of epilepsy for a patient, and the psychological and cognitive effects of commonly used anticonvulsant drugs. With regard to the first of these concerns, 30 to 50 percent of all persons with epilepsy have psychiatric difficulties sometime during the course of their illness. The most common behavioral symptom of epilepsy is a change in personality. Psychosis and violence occur much less commonly than was previously believed.

Definitions. A seizure is a transient paroxysmal pathophysiological disturbance of cerebral function caused by a spontaneous, excessive discharge of neurons. Patients are said to have epilepsy if they have a chronic condition characterized by recurrent seizure. The ictus, or ictal event, is the seizure itself. The nonictal periods are categorized as preictal, postictal, and interictal. The symptoms during the ictal event are determined primarily by the site of origin in the brain for the seizure and by the pattern of the spread of seizure activity through the brain. Interictal symptoms are influenced by the ictal event and other neuropsychiatric and psychosocial factors, such as coexisting psychiatric or neurological disorders, the presence of psychosocial stressors, and premorbid personality traits.

Classification. The two major categories of seizures are partial and generalized. Partial seizures involve epileptiform activity in localized brain regions. Generalized seizures involve the entire brain (Fig. 21.5-1). A classification system for seizures is outlined in Table 21.5-1.

FIGURE 21.5-1

Electroencephalographic recording during generalized tonic-clonic seizure showing rhythmic sharp waves and muscle artifact during tonic phase, spike and wave discharges during clonic phase, and attenuation of activity during postictal state. (Courtesy of Barbara F. Westmoreland, M.D.)

Table 21.5-1
International Classification of Epileptic Seizures

- I. Partial seizures (seizures beginning locally)
 - A. Partial seizures with elementary symptoms (generally without impairment of consciousness)
 - 1. With motor symptoms
 - 2. With sensory symptoms
 - 3. With autonomic symptoms
 - 4. Compound forms
 - B. Partial seizures with complex symptoms (generally with impairment of consciousness; temporal lobe or psychomotor seizures)
 - 1. With impairment of consciousness only
 - 2. With cognitive symptoms
 - 3. With affective symptoms
 - 4. With psychosensory symptoms
 - 5. With psychosensory symptoms (automatisms)
 - 6. Compound forms
 - C. Partial seizures secondarily generalized
- II. Generalized seizures (bilaterally symmetrical and without local onset)
 - A. Absences (petit mal)
 - B. Myoclonus
 - C. Infantile spasms
 - D. Clonic seizures
 - E. Tonic seizures
 - F. Tonic-clonic seizures (grand mal)
 - G. Atonic seizures
 - H. Akinetic seizures
- III. Unilateral seizures
- IV. Unclassified seizures (because of incomplete data)

(Adapted from Gastaut H. Clinical and electroencephalographical classification of epileptic seizures. *Epilepsia*. 1970;11:102, with permission.)

GENERALIZED SEIZURES. Generalized tonic-clonic seizures exhibit the classic symptoms of loss of consciousness, generalized tonic-clonic movements of the limbs, tongue biting, and incontinence. Although the diagnosis of the ictal events of the seizure is relatively straightforward, the postictal state, characterized by a slow, gradual recovery of consciousness and cognition, occasionally presents a diagnostic dilemma for a psychiatrist in an emergency department. The recovery period from a generalized tonic-clonic seizure ranges from a few minutes to many hours, and the clinical picture is that of a gradually clearing delirium. The most common psychiatric problems associated with generalized seizures involve helping patients adjust to a chronic neurological disorder and assessing the cognitive or behavioral effects of anticonvulsant drugs.

Absence Seizure (Petit Mal). A difficult type of generalized seizure for a psychiatrist to diagnose is an absence, or petit mal, seizure. The epileptic nature of the episodes may go unrecognized because the characteristic motor or sensory manifestations of epilepsy may be absent or so slight that they do not arouse suspicion. Petit mal epilepsy usually begins in childhood between the ages of 5 and 7 years and ceases by puberty. Brief disruptions of consciousness, during which the patient suddenly loses contact with the environment, are characteristic of petit mal epilepsy, but the patient has no true loss of consciousness and no convulsive movements during the episodes. The EEG produces a characteristic pattern of three-per-second spike-and-wave activity (Fig. 21.5-2). In rare instances, petit mal epilepsy begins in adulthood. Adult-onset petit mal epilepsy can be characterized by sudden, recurrent psychotic episodes or deliriums that appear and disappear abruptly. The symptoms may be accompanied by a history of falling or fainting spells.

FIGURE 21.5-2

Petit mal epilepsy characterized by bilaterally synchronous, 3-Hz spike and slow-wave activity.

PARTIAL SEIZURES. Partial seizures are classified as either simple (without alterations in consciousness) or complex (with an alteration in consciousness). Somewhat more than half of all patients with partial seizures have complex partial seizures. Other terms used for complex partial seizures are temporal lobe epilepsy, psychomotor seizures, and limbic epilepsy; these terms, however, are not accurate descriptions of the clinical situation. Complex partial epilepsy, the most common form of epilepsy in adults, affects approximately three of 1,000 persons. About 30 percent of patients with complex partial seizures have major mental illness such as depression.

SYMPTOMS

PREICTAL SYMPTOMS. Preictal events (auras) in complex partial epilepsy include autonomic sensations (e.g., fullness in the stomach, blushing, and changes in respiration); cognitive sensations (e.g., *déjà vu*, *jamais vu*, forced thinking, dreamy states); affective states (e.g., fear, panic, depression, elation); and, classically, automatisms (e.g., lip smacking, rubbing, chewing).

ICTAL SYMPTOMS. Brief, disorganized, and uninhibited behavior characterizes the ictal event. Although some defense attorneys may claim otherwise, rarely does a person exhibit organized, directed violent behavior during an epileptic episode. The cognitive symptoms include amnesia for the time during the seizure and a period of resolving delirium after the seizure. A seizure focus can be found on an EEG in 25 to 50 percent of all patients with complex partial epilepsy (Fig. 21.5-3). The use of sphenoidal or anterior temporal electrodes and sleep-deprived EEGs may increase the likelihood of finding an EEG abnormality. Multiple normal EEGs are often obtained for a patient with complex partial epilepsy; therefore, normal EEGs cannot be used to exclude a diagnosis of complex partial epilepsy. The use of long-term EEG recordings (usually 24 to 72 hours) can help clinicians detect a seizure focus in some patients. Most studies show that the use of nasopharyngeal leads does not add much to the sensitivity of an EEG, but they do add to the discomfort of the procedure for the patient.

FIGURE 21.5-3

An interictal encephalograph in a patient with complex partial seizures reveals frequent left temporal spike discharges and rare, independent right temporal sharp-wave activity. (From Cascino GD. Complex partial seizures: clinical features and differential diagnosis. *Psychiatr Clin North Am.* 1992;15:377, with permission.)

INTERICTAL SYMPTOMS

Personality Disturbances. The most frequent psychiatric abnormalities reported in patients with epilepsy are personality disorders, and they are especially likely to occur in patients with epilepsy of temporal lobe origin. The most common features are religiosity, a heightened experience of emotions—a quality usually called *viscosity of personality*—and changes in sexual behavior. The syndrome in its complete form is relatively rare even in those with complex partial seizures of temporal lobe origin. Many patients are not affected by personality disturbances; others have a variety of disturbances that differ strikingly from the classic syndrome.

A striking religiosity may be manifested not only by increased participation in overtly religious activities but also by unusual concern for moral and ethical issues, preoccupation with right and wrong, and heightened interest in global and philosophical concerns. The hyperreligious features can sometimes seem like the prodromal symptoms of schizophrenia and can result in a diagnostic problem in an adolescent or a young adult.

The symptom of viscosity of personality is usually most noticeable in a patient's conversation, which is likely to be slow, serious, ponderous, pedantic, overly replete with

nonessential details, and often circumstantial. The listener may grow bored but be unable to find a courteous and successful way to disengage from the conversation. The speech tendencies, often mirrored in the patient's writing, result in a symptom known as *hypergraphia*, which some clinicians consider virtually pathognomonic for complex partial epilepsy.

Changes in sexual behavior may be manifested by hypersexuality; deviations in sexual interest, such as fetishism and transvestism; and, most commonly, hyposexuality. The hyposexuality is characterized both by a lack of interest in sexual matters and by reduced sexual arousal. Some patients with the onset of complex partial epilepsy before puberty may fail to reach a normal level of sexual interest after puberty, although this characteristic may not disturb the patient. For patients with the onset of complex partial epilepsy after puberty, the change in sexual interest may be bothersome and worrisome.

Psychotic Symptoms. Interictal psychotic states are more common than ictal psychoses. Schizophrenia-like interictal episodes can occur in patients with epilepsy, particularly those with temporal lobe origins. An estimated 10 percent of all patients with complex partial epilepsy have psychotic symptoms. Risk factors for the symptoms include female gender, left-handedness, the onset of seizures during puberty, and a left-sided lesion.

The onset of psychotic symptoms in epilepsy is variable. Classically, psychotic symptoms appear in patients who have had epilepsy for a long time, and the onset of psychotic symptoms is preceded by the development of personality changes related to the epileptic brain activity. The most characteristic symptoms of the psychoses are hallucinations and paranoid delusions. Patients usually remain warm and appropriate in affect, in contrast to the abnormalities of affect commonly seen in patients with schizophrenia. The thought disorder symptoms in patients with psychotic epilepsy are most commonly those involving conceptualization and circumstantiality rather than the classic schizophrenic symptoms of blocking and looseness.

Violence. Episodic violence has been a problem in some patients with epilepsy, especially epilepsy of temporal and frontal lobe origin. Whether the violence is a manifestation of the seizure itself or is of interictal psychopathological origin is uncertain. Most evidence points to the extreme rarity of violence as an ictal phenomenon. Only in rare cases should violence in the patient with epilepsy be attributed to the seizure itself.

Mood Disorder Symptoms. Mood disorder symptoms, such as depression and mania, are seen less often in epilepsy than are schizophrenia-like symptoms. The mood disorder symptoms that do occur tend to be episodic and appear most often when the epileptic foci affect the temporal lobe of the nondominant cerebral hemisphere. The importance of mood disorder symptoms may be attested to by the increased incidence of attempted suicide in people with epilepsy.

Diagnosis. A correct diagnosis of epilepsy can be particularly difficult when the ictal and interictal symptoms of epilepsy are severe manifestations of psychiatric symptoms in the absence of significant changes in consciousness and cognitive abilities. Psychiatrists, therefore, must maintain a high level of suspicion during the evaluation of a new patient and must consider the possibility of an epileptic disorder even in the absence of the classic signs and symptoms. Another differential diagnosis to consider is pseudoseizure, in which a patient has some conscious control over mimicking the symptoms of a seizure (Table 21.5-2).

Table 21.5-2
Differentiating Features of Pseudoseizures and Epileptic Seizures

Feature	Epileptic Seizures	Pseudoseizure
Clinical features		
Nocturnal seizure	Common	Uncommon
Stereotyped aura	Usually	None
Cyanotic skin changes during seizures	Common	None
Self-injury	Common	Rare
Incontinence	Common	Rare
Postictal confusion	Present	None
Body movements	Tonic or clonic or both	Nonstereotyped and asynchronous
Affected by suggestion	No	Yes
EEG features		
Spike and waveforms	Present	Absent
Postictal slowing	Present	Absent
Interictal abnormalities	Variable	Variable

EEG, electroencephalogram.
(From Stevenson JM, King JH. Neuropsychiatric aspects of epilepsy and epileptic seizures. In: Hales RE, Yudofsky SC, eds. *American Psychiatric Press Textbook of Neuropsychiatry*. Washington, DC: American Psychiatric Press; 1987:220.)

For patients who have previously received a diagnosis of epilepsy, the appearance of new psychiatric symptoms should be considered as possibly representing an evolution in their epileptic symptoms. The appearance of psychotic symptoms, mood disorder symptoms, personality changes, or symptoms of anxiety (e.g., panic attacks) should cause a clinician to evaluate the control of the patient's epilepsy and to assess the patient for the presence of an independent mental disorder. In such circumstances, the clinician should evaluate the patient's compliance with the anticonvulsant drug regimen and should consider whether the psychiatric symptoms could be adverse effects from the antiepileptic drugs themselves. When psychiatric symptoms appear in a patient who has had epilepsy diagnosed or considered as a diagnosis in the past, the clinician should obtain results of one or more EEG examinations.

In patients who have not previously received a diagnosis of epilepsy, four characteristics should cause a clinician to be suspicious of the possibility: the abrupt onset of psychosis in a person previously regarded as psychologically healthy, the abrupt onset of delirium without a recognized cause, a history of similar episodes with abrupt onset and spontaneous recovery, and a history of previous unexplained falling or fainting spells.

Treatment. First-line drugs for generalized tonic-clonic seizures are valproate and phenytoin (Dilantin). First-line drugs for partial seizures include carbamazepine, oxcarbazepine (Trileptal), and phenytoin. Ethosuximide (Zarontin) and valproate are first-line drugs for absence (petit mal) seizures. The drugs used for various types of seizures are listed in Table 21.5-3. Carbamazepine and valproic acid may be helpful in controlling the symptoms of irritability and outbursts of aggression, as are the typical antipsychotic drugs. Psychotherapy, family counseling, and group therapy may be useful in addressing the psychosocial issues associated with epilepsy. In addition, clinicians should be aware that many antiepileptic drugs cause mild to moderate cognitive impairment, and an adjustment of the dosage or a change in medications should be considered if symptoms of cognitive impairment are a problem in a patient.

Table 21.5-3
Commonly Used Anticonvulsant Drugs

Drug	Use	Maintenance Dosage (mg/day)
Carbamazepine (Tegretol, Carbatrol)	Generalized tonic-clonic, partial	600–1,200
Clonazepam (Klonopin)	Absence, atypical myoclonic	2–12
Ethosuximide (Zarontin)	Absence	1,000–2,000
Gabapentin (Neurontin)	Complex partial seizures (augmentation)	900–3,600
Lamotrigine (Lamictal)	Complex partial seizures, generalized (augmentation)	300–500
Oxcarbazepine (Trileptal)	Partial	600–2,400
Phenobarbital	Generalized tonic-clonic	100–200
Phenytoin (Dilantin)	Generalized tonic-clonic, partial, status epilepticus	300–500
Primidone (Mysoline)	Partial	750–1,000
Tiagabine (Gabitril)	Generalized	32–56
Topiramate (Topamax)	Complex partial seizures (augmentation)	200–400
Valproate	Absence, myoclonic generalized tonic-clonic akinetic, partial seizures	750–1,000
Zonisamide (Zonegran)	Generalized	400–600

Brain Tumors

Brain tumors and cerebrovascular diseases can cause virtually any psychiatric symptom or syndrome, but cerebrovascular diseases, by the nature of their onset and symptom pattern, are rarely misdiagnosed as mental disorders. In general, tumors are associated with fewer psychopathological signs and symptoms than are cerebrovascular diseases affecting a similar volume of brain tissue. The two key approaches to the diagnosis of either condition are a comprehensive clinical history and a complete neurological examination. Performance of the appropriate brain imaging technique is usually the final diagnostic procedure; the imaging should confirm the clinical diagnosis.

Clinical Features, Course, and Prognosis. Mental symptoms are experienced at some time during the course of illness in approximately 50 percent of patients with brain tumors. In approximately 80 percent of these patients with mental symptoms, the tumors are located in frontal or limbic brain regions rather than in parietal or temporal regions. Whereas meningiomas are likely to cause focal symptoms by compressing a limited region of the cortex, gliomas are likely to cause diffuse symptoms. Delirium is most often a component of rapidly growing, large, or metastatic tumors. If a patient's history and a physical examination reveal bowel or bladder incontinence, a frontal lobe tumor should be suspected; if the history and examination reveal abnormalities in memory and speech, a temporal lobe tumor should be suspected.

COGNITION. Impaired intellectual functioning often accompanies the presence of a brain tumor, regardless of its type or location.

LANGUAGE SKILLS. Disorders of language function may be severe, particularly if tumor growth is rapid. In fact, defects of language function often obscure all other mental symptoms.

MEMORY. Loss of memory is a frequent symptom of brain tumors. Patients with brain tumors exhibit Korsakoff's syndrome and retain no memory of events that occurred since the illness began. Events of the immediate past, even painful ones, are lost. Patients, however, retain old memories and are unaware of their loss of recent memory.

PERCEPTION. Prominent perceptual defects are often associated with behavioral disorders, especially because patients must integrate tactile, auditory, and visual perceptions to function normally.

AWARENESS. Alterations of consciousness are common late symptoms of increased intracranial pressure caused by a brain tumor. Tumors arising in the upper part of the brainstem can produce a unique symptom called *akinetic mutism*, or *vigilant coma*. The patient is immobile and mute yet alert.

Colloid Cysts. Although they are not brain tumors, colloid cysts located in the third ventricle can exert physical pressure on structures within the diencephalon and produce such mental symptoms as depression, emotional lability, psychotic symptoms, and personality changes. The classic associated neurological symptoms are position-dependent intermittent headaches.

Head Trauma

Head trauma can result in an array of mental symptoms and lead to a diagnosis of dementia due to head trauma or to mental disorder not otherwise specified due to a general medical condition (e.g., postconcussional disorder). The postconcussive syndrome remains controversial because it focuses on the wide range of psychiatric symptoms, some serious, that can follow what seems to be minor head trauma.

Pathophysiology. Head trauma is a common clinical situation; an estimated 2 million incidents involve head trauma each year. Head trauma most commonly occurs in people 15 to 25 years of age and has a male-to-female predominance of approximately 3 to 1. Gross estimates based on the severity of the head trauma suggest that virtually all patients with serious head trauma, more than half of patients with moderate head trauma, and about 10 percent of patients with mild head trauma have ongoing neuropsychiatric sequelae resulting from the head trauma. Head trauma can be divided grossly into penetrating head trauma (e.g., trauma produced by a bullet) and blunt trauma, in which there is no physical penetration of the skull. Blunt trauma is far more common than penetrating head trauma. Motor vehicle accidents account for more than half of all the incidents of blunt CNS trauma; falls, violence, and sports-related head trauma account for most of the remaining cases (Fig. 21.5-4).

FIGURE 21.5-4

Severe contusion of the frontal poles has resulted in their atrophy and distortion. (Courtesy of Dr. H. M. Zimmerman.)

Whereas brain injury from penetrating wounds is usually localized to the areas directly affected by the missile, brain injury from blunt trauma involves several mechanisms. During the actual head trauma, the head usually moves back and forth violently, so that the brain hits repeatedly against the skull as it and the skull are mismatched in their rapid deceleration and acceleration. This crashing results in focal contusions, and the stretching of the brain parenchyma produces diffuse axonal injury. Later developing processes, such as edema and hemorrhaging, can result in further damage to the brain.

Symptoms. The two major clusters of symptoms related to head trauma are those of cognitive impairment and of behavioral sequelae. After a period of posttraumatic amnesia, there is usually a 6- to 12-month period of recovery, after which the remaining symptoms are likely to be permanent. The most common cognitive problems are decreased speed in information processing, decreased attention, increased distractibility, deficits in problem-solving and in the ability to sustain effort, and problems with memory and learning new information. A variety of language disabilities can also occur.

Behaviorally, the major symptoms involve depression, increased impulsivity, increased aggression, and changes in personality. These symptoms can be further exacerbated by the use of alcohol, which is often involved in the head trauma event itself. A debate has ensued about how preexisting character and personality traits affect the development of behavioral symptoms after head trauma. The critical studies needed to answer the question definitively have not yet been done, but the weight of opinion is leaning toward a biologically and neuroanatomically based association between the head trauma and the behavioral sequelae.

Treatment. The treatment of the cognitive and behavioral disorders in patients with head trauma is basically similar to the treatment approaches used in other patients with these symptoms. One difference is that patients with head trauma may be particularly susceptible to the side effects associated with psychotropic drugs; therefore, treatment with these agents should be initiated in lower dosages than usual, and they should be titrated upward more slowly than usual. Standard antidepressants can be used to treat depression, and either anticonvulsants or antipsychotics can be used to treat aggression and impulsivity. Other approaches to the symptoms include lithium, calcium channel blockers, and β -adrenergic receptor antagonists.

Clinicians must support patients through individual or group psychotherapy and should support the major caretakers through couples and family therapy. Patients with minor and moderate head trauma often rejoin their families and restart their jobs; therefore, all involved parties need help to adjust to any changes in the patient's personality and mental abilities.

Demyelinating Disorders

Multiple sclerosis (MS) is the major demyelinating disorder. Other demyelinating disorders include amyotrophic lateral sclerosis (ALS), metachromatic leukodystrophy, adrenoleukodystrophy, gangliosidoses, subacute sclerosing panencephalitis, and Kufs' disease. All of these disorders can be associated with neurological, cognitive, and behavioral symptoms.

Multiple Sclerosis. MS is characterized by multiple episodes of symptoms, pathophysiologically related to multifocal lesions in the white matter of the CNS (Fig. 21.5-5). The cause remains unknown, but studies have focused on slow viral infections and disturbances in the immune system. The estimated prevalence of MS in the Western Hemisphere is 50 per 100,000 people. The disease is much more frequent in cold and temperate climates than in the tropics and subtropics and more common in women than in men; it is predominantly a disease of young adults. In most patients, the onset occurs between the ages of 20 and 40 years.

FIGURE 21.5-5

Multiple sclerosis. Irregular, seemingly punched out zones of demyelination are evident in this section through the level of the fourth ventricle. Myelin stain. $2.6\times$. (Courtesy of Dr. H. M. Zimmerman.)

The neuropsychiatric symptoms of MS can be divided into cognitive and behavioral types. Research reports have found that 30 to 50 percent of patients with MS have mild cognitive impairment and that 20 to 30 percent of them have serious cognitive impairments. Although evidence indicates that patients with MS experience a decline in their general intelligence, memory is the most commonly affected cognitive function. The severity of the memory impairment does not seem to be correlated with the severity of the neurological symptoms or the duration of the illness.

The behavioral symptoms associated with MS are varied and can include euphoria, depression, and personality changes. Psychosis is a rare complication. Approximately 25 percent of persons with MS exhibit a euphoric mood that is not hypomanic but somewhat more cheerful than their situation warrants and not necessarily in character with their disposition before the onset of MS. Only 10 percent of patients with MS have a sustained and elevated mood, although it is still not truly hypomanic. Depression, however, is common; it affects 25 to 50 percent of patients with MS and results in a higher rate of suicide than is seen in the general population. Risk factors for suicide in patients with MS are male sex, onset of MS before age 30 years, and a relatively recent diagnosis of the disorder. Personality changes are also common in patients with MS; they affect 20 to 40 percent of patients and are often characterized by increased irritability or apathy.

Amyotrophic Lateral Sclerosis. ALS is a progressive, noninherited disease of asymmetrical muscle atrophy. It begins in adult life and progresses over months or years to involve all the striated muscles except the cardiac and ocular muscles. In addition to muscle atrophy, patients have signs of pyramidal tract involvement. The illness is rare and occurs in approximately 1.6 persons per 100,000 annually. A few patients have concomitant dementia. The disease progresses rapidly, and death generally occurs within 4 years of onset.

Infectious Diseases

Herpes Simplex Encephalitis. Herpes simplex encephalitis, the most common type of focal encephalitis, most commonly affects the frontal and temporal lobes. The symptoms often include anosmia, olfactory and gustatory hallucinations, and personality changes and can also involve bizarre or psychotic behaviors. Complex partial epilepsy may also develop in patients with herpes simplex encephalitis. Although the mortality rate for the infection has decreased, many patients exhibit personality changes, symptoms of memory loss, and psychotic symptoms.

Rabies Encephalitis. The incubation period for rabies ranges from 10 days to 1 year, after which symptoms of restlessness, overactivity, and agitation can develop. Hydrophobia, present in up to 50 percent of patients, is characterized by an intense fear of drinking water. The fear develops from the severe laryngeal and diaphragmatic spasms that the patients experience when they drink water. When rabies encephalitis develops, the disease is fatal within days or weeks.

Neurosyphilis. Neurosyphilis (also known as general paresis) appears 10 to 15 years after the primary *Treponema* infection. Since the advent of penicillin, neurosyphilis has become a rare disorder, although AIDS is associated with reintroducing neurosyphilis into medical practice in some urban settings. Neurosyphilis generally affects the frontal lobes and results in personality changes, development of poor judgment, irritability, and decreased care for self. Delusions of grandeur develop in 10 to 20 percent of affected patients. The disease progresses with the development of dementia and tremor until patients are parietic. The neurological symptoms include Argyll-Robertson pupils, which are small, irregular, and unequal and have light-near reflex dissociation, tremor, dysarthria, and hyperreflexia. Cerebrospinal fluid (CSF) examination shows lymphocytosis, increased protein, and a positive result on a Venereal Disease Research Laboratory (VDRL) test.

Chronic Meningitis. Chronic meningitis is now seen more often than in the recent past because of the immunocompromised condition of people with AIDS. The usual causative agents are *Mycobacterium tuberculosis*, *Cryptococcus* spp., and *Coccidioides* spp. The usual symptoms are headache, memory impairment, confusion, and fever.

Subacute Sclerosing Panencephalitis. Subacute sclerosing panencephalitis is a disease of childhood and early adolescence, with a 3-to-1 male-to-female ratio. The onset usually follows either an infection with measles or a vaccination for measles. The initial symptoms may be behavioral change, temper tantrums, sleepiness, and hallucinations, but the classic symptoms of myoclonus, ataxia, seizures, and intellectual deterioration eventually develop. The disease progresses relentlessly to coma and death in 1 to 2 years.

Lyme Disease. Lyme disease is caused by infection with the spirochete *Borrelia burgdorferi* transmitted through the bite of the deer tick (*Ixodes scapularis*), which feeds on infected deer and mice. About 16,000 cases are reported annually in the United States.

A characteristic bull's-eye rash (Fig. 21.5-6) is found at the site of the tick bite followed shortly thereafter by flulike symptoms. Impaired cognitive functioning and mood changes are associated with the illness and may be the presenting complaint. These include memory lapses, difficulty concentrating, irritability, and depression.

FIGURE 21.5-6

Erythema migrans (“bull’s-eye” rash) on the thigh. (From Barbour R. Lyme disease. In: Hoeprich PD, Jordan MC, Ronald AR, eds. *Infectious Diseases: A Treatise of Infectious Processes*. Philadelphia: JB Lippincott; 1994:1329, with permission.)

No clear-cut diagnostic test is available. About 50 percent of patients become seropositive to *B. burgdorferi*. Prophylaxis vaccine is not always effective and is controversial. Treatment consists of a 14- to 21-day course of doxycycline (Vibramycin), which results in a 90 percent cure rate. Specific psychotropic drugs can be targeted to treat the psychiatric sign or symptom (e.g., diazepam [Valium] for anxiety). Left untreated, about 60 percent of persons develop a chronic condition. Such patients may be given an erroneous diagnosis of a primary depression rather than one secondary to the medical condition. Support groups for patients with chronic Lyme disease are important. Group members provide each other with emotional support that helps improve their quality of life.

Prion Disease. Prion disease is a group of related disorders caused by a transmissible infectious protein known as a *prion*. Included in this group are Creutzfeldt-Jakob disease (CJD), Gerstmann-Straussler-Scheinker disorder (GSS), fatal familial insomnia (FFI), and kuru. A variant of CJD (vCJD), also called “mad cow disease,” appeared in 1995 in the United Kingdom and is attributed to the transmission of bovine spongiform encephalopathy (BSE) from cattle to humans. Collectively, these disorders are also known as *subacute spongiform encephalopathy* because of shared neuropathological changes that consist of (1) spongiform vacuolization, (2) neuronal loss, and (3) astrocyte proliferation in the cerebral cortex. Amyloid plaques may or may not be present.

ETIOLOGY. Prions are transmissible agents but differ from viruses in that they lack nucleic acid. Prions are mutated proteins generated from the human prion protein gene (PrP), which is located on the short arm of chromosome 20. No direct link exists between prion disease and Alzheimer’s disease, which has been traced to chromosome 21.

The PrP mutates into a disease-related isoform PrP-Super-C (PrP^{Sc}), which can replicate and is infectious. The neuropathological changes that occur in prion disease are presumed to be caused by direct neurotoxic effects of PrP^{Sc}.

The specific prion disease that develops depends on the mutation of PrP that occurs. Mutations at PrP 178N/129V cause CJD, mutations at 178N/129M cause FFI, and mutations at 102L/129M cause GSS and kuru. Other mutations of PrP have been described, and research continues in this important area of genomic identification. Some mutations are both fully penetrant and autosomal dominant and account for inherited forms of prion disease. For example, both GSS and FFI are inherited disorders, and about 10 percent of cases of CJD are also inherited. Prenatal testing for the abnormal PrP gene is available; whether or not such testing should be routinely done is open to question at this time.

CREUTZFELDT-JAKOB DISEASE. First described in 1920, CJD is an invariably fatal, rapidly progressive disorder that occurs mainly in middle-aged or older adults. It manifests initially with fatigue, flulike symptoms, and cognitive impairment. As the disease progresses, focal neurological findings such as aphasia and apraxia occur. Psychiatric manifestations are protean and include emotional lability, anxiety, euphoria, depression, delusions, hallucinations, or marked personality changes. The disease progresses over months, leading to dementia, akinetic mutism, coma, and death.

The rates of CJD range from one to two cases per 1 million persons a year worldwide. The infectious agent self-replicates and can be transmitted to humans by inoculation with infected tissue and sometimes by ingestion of contaminated food. Iatrogenic transmission has been reported via transplantation of contaminated cornea or dura mater or to children via contaminated supplies of human growth hormone derived from infected persons. Neurosurgical transmission has also been reported. Household contacts are not at greater risk for developing the disease than the general population unless there is direct inoculation.

Diagnosis requires pathological examination of the cortex, which reveals the classic triad of spongiform vacuolation, loss of neurons, and astrocyte cell proliferation. The cortex and basal ganglia are most affected. An immunoassay test for CJD in the CSF shows promise in supporting the diagnosis; however, this needs to be tested more extensively. Although not specific for CJD, EEG abnormalities are present in nearly all patients, consisting of a slow and irregular background rhythm with periodic complex discharges. CT and MRI studies may reveal cortical atrophy later in the course of disease. SPECT and positron emission tomography (PET) reveal heterogeneously decreased uptake throughout the cortex.

No known treatment exists for CJD. Death usually occurs within 6 months after diagnosis.

VARIANT CJD. In 1995, a variant of CJD (vCJD) appeared in the United Kingdom. The patients affected all died; they were young (younger than age 40 years), and none had risk factors of CJD. At autopsy, prion disease was found. The disease was attributed to the transmission in the United Kingdom of BSE between cattle and from cattle to humans in the 1980s. BSE appears to have originated from sheep scrapie-contaminated feed given to cattle. Scrapie is a spongiform encephalopathy found in sheep and goats that has not been shown to cause human disease; however, it is transmissible to other animal species.

The mean age of onset is 29 years, and about 150 people worldwide had been infected as of 2006. Clinicians must be alert to the

diagnosis in young people with behavioral and psychiatric abnormalities in association with cerebellar signs such as ataxia or myoclonus. The psychiatric presentation of vCJD is not specific. Most patients have reported depression, withdrawal, anxiety, and sleep disturbance. Paranoid delusions have occurred. Neuropathological changes are similar to those in vCJD, with the addition of amyloid plaques.

Epidemiological data are still being gathered. The incubation period for vCJD and the amount of infected meat product required to cause infection are unknown. One patient was reported to have been a vegetarian for 5 years before his disease was diagnosed. vCJD can be diagnosed antemortem by examining the tonsils with Western blot immunostains to detect PrP^{Sc} in lymphoid tissue. Diagnosis relies on the development of progressive neurodegenerative features in persons who have ingested contaminated meat or brains. No cure exists, and death usually occurs within 2 to 3 years after diagnosis. Prevention is dependent on careful monitoring of cattle for disease and feeding them grain instead of meat byproducts.

KURU. Kuru is an epidemic prion disease found in New Guinea that is caused by cannibalistic funeral rituals in which the brains of the deceased are eaten. Women are more affected by the disorder than men, presumably because they participate in the ceremony to a greater extent. Death usually occurs within 2 years after symptoms develop. Neuropsychiatric signs and symptoms consist of ataxia, chorea, strabismus, delirium, and dementia. Pathological changes are similar to those with other prion disease: neuronal loss, spongiform lesions, and astrocytic proliferation. The cerebellum is most affected. Iatrogenic transmission of kuru has occurred when cadaveric material such as dura mater and corneas were transplanted into normal recipients. Since the cessation of cannibalism in New Guinea, the incidence of the disease has decreased drastically.

GERSTMANN-STRAUSSLER-SCHINKER DISEASE. First described in 1928, GSS is a neurodegenerative syndrome characterized by ataxia, chorea, and cognitive decline leading to dementia. It is caused by a mutation in the PrP gene that is fully penetrant and autosomal dominant; thus, the disease is inherited, and affected families have been identified over several generations. Genetic testing can confirm the presence of the abnormal genes before onset. Pathological changes characteristic of prion disease are present: spongiform lesions, neuronal loss, and astrocyte proliferation. Amyloid plaques have been found in the cerebellum. Onset of the disease occurs between 30 and 40 years of age. The disease is fatal within 5 years of onset.

FATAL FAMILIAL INSOMNIA. FFI is an inherited prion disease that primarily affects the thalamus. A syndrome of insomnia and autonomic nervous system dysfunction consisting of fever, sweating, labile blood pressure, and tachycardia occurs that is debilitating. Onset is in middle adulthood, and death usually occurs in 1 year. No treatment currently exists.

FUTURE DIRECTIONS. Determining how prions mutate to produce disease phenotypes and determining how they are transmitted between different mammalian species are major areas of research. Public health measures to prevent transmission of animal disease to humans are ongoing and must be relentless, especially because these disorders are invariably fatal within a few years of onset. Developing genetic interventions that prevent or repair damage to the normal prion gene offers the best hope of cure. Psychiatrists are faced with having to manage cases of persons who actually have the disease and those with hypochondriacal fears of having contracted the disease. In some patients, such fears can reach delusional proportions. Treatment is symptomatic and involves anxiolytics, antidepressants, and psychostimulants, depending on symptoms. Supportive psychotherapy may be of use in early stages to help patients and family cope with the illness.

Preventing unintentional human-to-human or animal-to-human transmission of prions remains the best way to limit the scope of these diseases. Sporadic cases of CJD will still appear, however, because of the rare spontaneous mutation of the normal prion protein into the abnormal form. At present, little exists to offer patients with prion disease other than supportive treatment and emotional support.

Immune Disorders

The major immune disorders in contemporary society is HIV and AIDS, but other immune disorders such as lupus erythematosus and autoimmune disorders that affect brain neurotransmitters (discussed below) can also present diagnostic and treatment challenges to mental health clinicians.

HIV Infection and AIDS

HIV is a retrovirus related to the human T-cell leukemia viruses (HTLV) and to retroviruses that infect animals, including nonhuman primates. At least two types of HIV have been identified, HIV-1 and HIV-2. HIV-1 is the causative agent for most HIV-related diseases; HIV-2, however seems to be causing an increasing number of infections in Africa. Other types of HIV may exist, which are now classified as HIV-O. HIV is present in blood; semen; cervical and vaginal secretions; and, to a lesser extent, in saliva, tears, breast milk, and the CSF of those who are infected. HIV is most often transmitted through sexual intercourse or the transfer of contaminated blood from one person to another. Health providers should be aware of the guidelines for safe sexual practices and should advise their patients to practice safe sex (Table 21.5-4). The Centers for Disease Control and Prevention guidelines for the prevention of HIV from infected to uninfected persons is listed in Table 21.5-5.

Table 21.5-5

Centers for Disease Control and Prevention Guidelines for the Prevention of HIV Transmission from Infected to Uninfected Persons

Infected persons should be counseled to prevent the further transmission of HIV by:

1. Informing prospective sex partners of their infection with HIV so they can take appropriate precautions. Abstinence from sexual activity with another person is one option that would eliminate any risk of sexually transmitted HIV infection.
2. Protecting a partner during any sexual activity by taking appropriate precautions to prevent that person's coming into contact with the infected person's blood, semen, urine, feces, saliva, cervical secretions, or vaginal secretions. Although the efficacy of using condoms to prevent infections with HIV is still under study, the consistent use of condoms should reduce the transmission of HIV by preventing exposure to semen and infected lymphocytes.
3. Informing previous sex partners and any persons with whom needles were shared of their potential exposure to HIV and encouraging them to seek counseling and testing.
4. For IV drug abusers, enrolling or continuing in programs to eliminate the abuse of IV substances. Needles, other apparatus, and drugs must never be shared.
5. Never sharing toothbrushes, razors, or other items that could become contaminated with blood.
6. Refraining from donating blood, plasma, body organs, other tissue, or semen.
7. Avoiding pregnancy until more is known about the risks of transmitting HIV from the mother to the fetus or newborn.
8. Cleaning and disinfecting surfaces on which blood or other body fluids have spilled in accordance with previous recommendations.
9. Informing physicians, dentists, and other appropriate health professionals of antibody status when seeking medical care, so that the patient can be appropriately evaluated.

HIV, human immunodeficiency virus; IV, intravenous.
(From Centers for Disease Control (CDC). Additional recommendations to reduce sexual and drug abuse-related transmission of human T-lymphotropic virus type III/lymphadenopathy-associated virus. *MMWR Morb Mortal Wkly Rep.* 1986;35:152.)

Table 21.5-4 AIDS Safe-Sex Guidelines

Remember: Any activity that allows for the exchange of body fluids of one person through the mouth, anus, vagina, bloodstream, cuts, or sores of another person is considered unsafe at this time.

Safe-sex practices

- Massage, hugging, body-to-body rubbing
- Dry social kissing
- Masturbation
- Acting out sexual fantasies (that do not include any unsafe-sex practices)
- Using vibrators or other instruments (provided they are not shared)

Low-risk sex practices

These activities are not considered completely safe:

- French (wet) kissing (without mouth sores)
- Mutual masturbation
- Vaginal and anal intercourse while using a condom
- Oral sex, male (fellatio), while using a condom
- Oral sex, female (cunnilingus), while using a barrier
- External contact with semen or urine, provided there are no breaks in the skin

Unsafe-sex practices

- Vaginal or anal intercourse without a condom
- Semen, urine, or feces in the mouth or the vagina
- Unprotected oral sex (fellatio or cunnilingus)
- Blood contact of any kind
- Sharing sex instruments or needles

AIDS, acquired immunodeficiency syndrome.
(From Moffatt B, Spiegel J, Parrish S, Helquist M. *AIDS: A Self-Care Manual.* Santa Monica, CA: IBS Press; 1987:125, with permission.)

After infection with HIV, AIDS is estimated to develop in 8 to 11 years, although this time is gradually increasing because of early treatment. When a person is infected with HIV, the virus primarily targets T4 (helper) lymphocytes, so-called CD4+ lymphocytes, to which the virus binds because of a glycoprotein (gp120) on the viral surface has a high affinity for the CD4 receptor on T4 lymphocytes. After binding, the virus can inject its ribonucleic acid (RNA) into the infected lymphocyte, where the RNA is transcribed into deoxyribonucleic acid (DNA) by the action of reverse transcriptase. The resultant DNA can then be incorporated into the host cell's genome and translated and eventually transcribed when the lymphocyte is stimulated to divide. After viral proteins have been produced by lymphocytes, the various components of the virus assemble, and new mature viruses bud off from the host cell.

Diagnosis

SERUM TESTING. Techniques are now widely available to detect the presence of anti-HIV antibodies in human. The conventional test uses blood (time to result, 3 to 10 days) and the rapid test uses an oral swab (time to result, 20 minutes). Both tests are 99.9 percent sensitive and specific. Health care workers and their patients must understand that the presence of HIV antibodies indicate infection, not immunity to infection. Those who test positive have been exposed to the virus, have the virus within their bodies, have the potential to transmit the virus to another person, and will almost certainly eventually develop AIDS. Those who test negative have either not been exposed to the HIV virus and are not infected or were exposed to the HIV virus but have not yet developed the antibodies, which is a possibility if the exposure occurred less than 1 year before testing. Seroconversion most commonly occurs 6 to 12 weeks after infection, although in rare cases seroconversion can take 6 to 12 months.

COUNSELING. Although specific groups of persons are at high risk for contracting HIV and should be tested, any person who wants to be tested should probably be tested. The reason for requesting a test should be ascertained to detect unspoken concerns and motivations that may merit psychotherapeutic intervention.

Past practices that may have put the testee at risk for HIV infection and safe sexual practices should be discussed. During posttest counseling, counselors should explain that a negative test finding implies that safe sexual behavior and the avoidance of shared hypodermic

needles are recommended for the person to remain free of HIV infection. Those with positive results must receive counseling about safe practices and potential treatment options. They may need additional psychotherapeutic interventions if anxiety or depressive disorders develop after they discover that they are infected. A person may react to a positive HIV test finding with a syndrome similar to posttraumatic stress disorder. Adjustment disorder with anxiety or depressed mood may develop in as many as 25 percent of those informed of a positive HIV test result.

CONFIDENTIALITY. No one should be given an HIV test without previous knowledge and consent, although various jurisdictions and organizations, such as the military, now require HIV testing for all inhabitants or members. The results of an HIV test can be shared with other members of a medical team, although the information should be provided to no one else except for special circumstances. The patient should be advised against disclosing the result of HIV testing too readily to employers, friends, and family members; the information could result in discrimination in employment, housing, and insurance.

The major exception to restriction of disclosure is the need to notify potential and past sexual or IV substance use partners. If a treating physician knows that a patient who is HIV infected is putting another person at risk of becoming infected, the physician may try either to hospitalize the infected person involuntarily (to prevent danger to others) or to notify the potential victim. Clinicians should be aware of the laws about such issues, which vary among the states. These guidelines also apply to inpatient psychiatric wards when a patient with HIV infection is believed to be sexually active with other patients.

Clinical Features

NON-NEUROLOGICAL FACTORS. About 30 percent of persons infected with HIV experience a flulike syndrome 3 to 6 weeks after becoming infected; most never notice any symptoms immediately or shortly after their infection. The flulike syndrome includes fever, myalgia, headaches, fatigue, GI symptoms, and sometimes a rash. The syndrome may be accompanied by splenomegaly and lymphadenopathy.

The most common infection in persons affected with HIV who have AIDS is *Pneumocystis carinii* pneumonia, which is characterized by a chronic, nonproductive cough, and dyspnea, sometimes sufficiently severe to result in hypoxemia and its resultant cognitive effects. For psychiatrists, the importance of these non-neurological, nonpsychiatric complications lies in their biological effects on patients' brain function (e.g., hypoxia in *P. carinii* pneumonia) and their psychological effects on patients' moods and anxiety states.

NEUROLOGICAL FACTORS. An extensive array of disease processes can affect the brain of a patient infected with HIV (Table 21.5-6). The most important diseases for mental health workers to be aware of are *HIV mild neurocognitive disorder* and *HIV-associated dementia*.

 **Table 21.5-6**
Conditions Associated with Human Immunodeficiency Virus (HIV) Infection

Bacterial infections, multiple or recurrent ^a
Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive ^b
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex, chronic ulcers (>1 month's duration); or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi's sarcoma
Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia ^a
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
<i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i> , disseminated or extrapulmonary
<i>Mycobacterium tuberculosis</i> , any site (pulmonary ^b or extrapulmonary)
<i>Mycobacterium</i> , other species or unidentified species, disseminated or extrapulmonary
<i>Pneumocystis carinii</i> pneumonia
Pneumonia, recurrent ^b
Progressive multifocal leukoencephalopathy
<i>Salmonella</i> septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to HIV

^aChildren younger than 13 years old.

^bAdded in the 1993 expansion of the AIDS surveillance case definition for adolescents and adults.

(Adapted from 1993 revised classification system for HIV infection and expanded surveillance, case definition for AIDS among adolescents and adults. *MMWR Recomm Rep.* 1992;41.)

PSYCHIATRIC SYNDROMES. HIV-associated dementia presents with the typical triad of symptoms seen in other subcortical dementias—memory and psychomotor speed impairments, depressive symptoms, and movement disorders. Patients may initially notice slight problems with reading, comprehension, memory, and mathematical skills, but these symptoms are subtle and may be overlooked or discounted as fatigue and illness. The Modified HIV Dementia Scale is a useful bedside screen and can be administered serially to document disease progression. The development of dementia in HIV-infected patients is generally a poor prognostic sign, and 50 to 75 percent of patients with dementia die within 6 months.

HIV-associated neurocognitive disorder (also known as HIV encephalopathy) is characterized by impaired cognitive functioning and reduced mental activity that interferes with work, domestic, and social functioning. No laboratory findings are specific to the disorder, and it occurs independently of depression and anxiety. Progression to HIV-associated dementia usually occurs but may be prevented by early treatment.

Delirium can result from the same causes that lead to dementia in patients with HIV. Clinicians have classified delirious states characterized by both increased and decreased activity. Delirium in patients infected with HIV is probably underdiagnosed, but it should always precipitate a medical workup of a patient infected with HIV to determine whether a new CNS-related process has begun.

Patients with HIV infection may have any of the anxiety disorders, but generalized anxiety disorder, posttraumatic stress disorder, and

obsessive-compulsive disorder (OCD) are particularly common.

Adjustment disorder with anxiety or depressed mood has been reported in 5 to 20 percent of HIV-infected patients. The incidence of adjustment disorder in HIV-infected patients is higher than usual in some special populations, such as military recruits and prison inmates.

Depression is a significant problem in HIV and AIDS. Approximately 4 to 40 percent of HIV-infected patients meet the criteria for depressive disorders. Major depression is a risk factor for HIV infection by virtue of its impact on behavior, intensification of substance abuse, exacerbation of self-destructive behaviors, and promotion for poor partner choice in relationships. The pre-HIV infection prevalence of depressive disorders may be higher than usual in some groups who are at risk for contracting HIV. Depression has been shown to hinder effective treatment in infected persons. Patients with major depression are at increased risk for disease progression and death. HIV increases the risk of developing major depression through a variety of mechanisms, including direct injury to subcortical areas of the brain, chronic stress, worsening social isolation, and intense demoralization. Depression is higher in women than in men.

Mania can occur at any stage of HIV infection for individuals with preexisting bipolar disorder. AIDS mania is a type of mania that most commonly occurs in late-stage HIV infections and is associated with cognitive impairment. AIDS mania has a somewhat different clinical profile than bipolar mania. Patients tend to have cognitive slowing or dementia, and irritability is more characteristic than euphoria. AIDS mania is usually quite severe in its presentation and malignant in its course. It seems to be more chronic than episodic, has infrequent spontaneous remissions, and usually relapses with cessation of treatment. One clinically significant presentation is the delusional belief that one has discovered the cure for HIV or has been cured, which may result in high-risk behaviors and the spread of the HIV infection.

Substance abuse is a primary vector for the spread of HIV. This impact is directed not only at those who use IV drugs and their sexual partners but also at those who are disinhibited or cognitively impaired by intoxication and are driven by addiction to impulsive behaviors and unsafe sexual practices. Ongoing substance abuse has grave medical implications for HIV-infected patients. The accumulation of medical sequelae from chronic substance abuse can accelerate the process of immunocompromise and amplify the progressive burdens of the HIV infection itself. In addition to the direct physical effects cause by drugs, active substance use is highly associated with both nonadherence and reduced access to antiretroviral medication. Suicidal ideation and suicide attempts may increase in patients with HIV infection and AIDS. The risk factors for suicide among persons infected with HIV are having friends who died from AIDS, recent notification of HIV seropositivity, relapses, difficult social issues relating to homosexuality, inadequate social and financial support, and the presence of dementia or delirium.

Psychotic symptoms are usually later-stage complications of HIV infection. They require immediate medical and neurological evaluation and often require management with antipsychotic medications.

The worried well are persons in high-risk groups who, although they tested negative and are disease free, are anxious about contracting the virus. Some are reassured by repeated negative test results, but others cannot be reassured. Their worry well status can progress quickly to generalized anxiety disorder, panic attacks, OCD, and hypochondriasis.

Treatment. Prevention is the primary approach to HIV infection. Primary prevention involves protecting persons from getting the disease; secondary prevention involves modification of the disease's course. All persons with any risk of HIV infection should be informed about safe-sex practices and about the necessity to avoid sharing contaminated hypodermic needles. The assessment of patients infected with HIV should include a complete sexual and substance-abuse history, a psychiatric history, and an evaluation of the support systems available to them.

PHARMACOTHERAPY. A growing list of agents that act at different points in viral replication has raised the hope that HIV might be permanently suppressed or actually eradicated from the body. These agents are divided into five major drug classes. Reverse transcriptase inhibitors (RTIs) interfere with the critical step during the HIV life cycle known as reverse transcription. There are two types of RTIs: nucleoside/nucleotide RTIs (NRTIs), which are faulty DNA building blocks, and non-nucleoside RTIs (NNRTIs), which bind to RT, interfering with its ability to convert the HIV RNA into HIV DNA. Protease inhibitors interfere with the protease enzyme that HIV uses to produce infectious viral particles. Fusion or entry inhibitors interfere with the virus' ability to fuse with the cellular membrane, thereby blocking entry into the host cell. Integrase inhibitors block integrase, the enzyme HIV uses to integrate genetic material of the virus into its target host cell. Multidrug combination products combine drugs from more than one class into a single product. The most common of this class of drugs is the highly active antiretroviral therapy (HAART). [Table 21.5-7](#) lists the available agents in each of these categories.

Table 21.5-7
Antiretroviral Agents

Generic Names	Trade Name	Usual Abbreviation
Reverse Transcriptase Inhibitors		
Nucleoside/nucleotide reverse transcriptase inhibitors		
Lamivudine and zidovudine	Combivir	
Emtricitabine	Emtriva	FTC
Lamivudine	Epivir	3TC
Abacavir and lamivudine	Epzicom	
Zidovudine, azidothymidine	Retrovir	ZDV or AZT
Abacavir, zidovudine, and lamivudine	Trizivir	
Tenofovir disoproxil fumarate and emtricitabine	Truvada	
Didanosine, dideoxyinosine	Videx	ddl
Enteric-coated didanosine	Videx EC	ddl EC
Tenofovir disoproxil fumarate	Viread	TDF
Stavudine	Zerit	d4t
Abacavir sulfate	Ziagen	ABC
Nonnucleoside Reverse Transcriptase Inhibitors		
Rilpivirine	Edurant	
Etravirine	Intelence	
Delavirdine	Rescriptor	DLV
Efavirenz	Sustiva	EFV
Nevirapine	Viramune	NVP
Protease Inhibitors		
Amprenavir	Agenerase	APV
Tipranavir	Aptivus	TPV
Indinavir	Crixivan	IDV
Saquinavir mesylate	Invirase	SQV
Lopinavir and ritonavir	Kaletra	LPV/RTV
Fosamprenavir calcium	Lexiva	FOS-APV
Ritonavir	Norvir	RTV
Darunavir	Prezista	
Atazanavir sulfate	Reyataz	ATV
Delfinavir mesylate	Viracept	NFV
Fusion/Entry Inhibitors		
Enfuvirtide	Fuzeon	T-20
Maraviroc	Selzentry	
Multi-class Combination Products		
Efavirenz, emtricitabine, and tenofovir disoproxil fumarate	Atripla	
Emtricitabine, rilpivirine, and tenofovir disoproxil fumarate	Complera	

The antiretroviral agents have many adverse effects. Of importance to psychiatrists is that protease inhibitors can increase levels of certain psychotropic drugs such as bupropion (Wellbutrin), meperidine (Demerol), various benzodiazepines, and selective serotonin reuptake inhibitors (SSRIs). Caution must be taken in prescribing psychotropic drugs to persons taking protease inhibitors.

PSYCHOTHERAPY. Major psychodynamic themes for patients infected with HIV involved self-blame, self-esteem, and issues regarding death. The entire range of psychotherapeutic approaches may be appropriate for patients with HIV-related disorders. Both individual and group therapy can be effective. Individual therapy may be either short term or long term and may be supportive, cognitive, behavioral, or psychodynamic. Group therapy techniques can range from psychodynamic to completely supportive in nature. Direct counseling regarding substance use and its potential adverse effects on health of the patient who is HIV infected is indicated. Specific treatments for particular substance-related disorders should be initiated if necessary for the total well-being of the patient.

Systemic Lupus Erythematosus. Systemic lupus erythematosus (SLE) is an autoimmune disease that involves inflammation of multiple organ systems. The officially accepted diagnosis of SLE requires a patient to have four of 11 criteria that have been defined by the American Rheumatism Association. Between 5 and 50 percent of patients with SLE have mental symptoms at the initial presentation, and approximately 50 percent eventually show neuropsychiatric manifestations. The major symptoms are depression, insomnia, emotional lability, nervousness, and confusion. Treatment with steroids commonly induces further psychiatric complications, including mania and psychosis.

Autoimmune Disorders Affecting Brain Neurotransmitters

A group of autoimmune receptor-seeking disorders have been identified that cause an encephalitis that mimics schizophrenia. Among those is anti-NMDA(N-methyl D-aspartate)-receptor encephalitis that causes dissociative symptoms, amnesia and vivid hallucinations. The disorder occurs mostly in women and was described in a memoir entitled *Brain on Fire*. There is no treatment although intravenous immunoglobulins have proved useful. Recovery does occur but some patients might require prolonged intensive care.

Endocrine Disorders

Thyroid Disorders. Hyperthyroidism is characterized by confusion; anxiety; and an agitated, depressive syndrome. Patients may also complain of being easily fatigued and of feeling generally weak. Insomnia, weight loss despite increased appetite, tremulousness, palpitations, and increased perspiration are also common symptoms. Serious psychiatric symptoms include impairments in memory, orientation, and judgment; manic excitement; delusions; and hallucinations.

In 1949, Irvin Asher named hypothyroidism “myxedema madness.” In its most severe form, hypothyroidism is characterized by paranoia, depression, hypomania, and hallucinations. Slowed thinking and delirium can also be symptoms. The physical symptoms include weight gain, a deep voice, thin and dry hair, loss of the lateral eyebrow, facial puffiness, cold intolerance, and impaired hearing. Approximately 10 percent of all patients have residual neuropsychiatric symptoms after hormone replacement therapy.

Parathyroid Disorders. Dysfunction of the parathyroid gland results in the abnormal regulation of calcium metabolism. Excessive secretion of parathyroid hormone causes hypercalcemia, which can result in delirium, personality changes, and apathy in 50 to 60 percent of patients and cognitive impairments in approximately 25 percent of patients. Neuromuscular excitability, which depends on proper calcium ion concentration, is reduced, and muscle weakness may appear.

Hypocalcemia can occur with hypoparathyroid disorders and can result in neuropsychiatric symptoms of delirium and personality changes. If the calcium level decreases gradually, clinicians may see the psychiatric symptoms without the characteristic tetany of hypocalcemia. Other symptoms of hypocalcemia are cataract formation, seizures, extrapyramidal symptoms, and increased intracranial pressure.

Adrenal Disorders. Adrenal disorders disturb the normal secretion of hormones from the adrenal cortex and produce significant neurological and psychological changes. Patients with chronic adrenocortical insufficiency (Addison's disease), which is most frequently the result of adrenocortical atrophy or granulomatous invasion caused by tuberculous or fungal infection, exhibit mild mental symptoms, such as apathy, easy fatigability, irritability, and depression. Occasionally, confusion or psychotic reactions develop. Cortisone or one of its synthetic derivatives is effective in correcting such abnormalities.

Excessive quantities of cortisol produced endogenously by an adrenocortical tumor or hyperplasia (Cushing's syndrome) lead to a secondary mood disorder, a syndrome of agitated depression, and often suicide. Decreased concentration and memory deficits may also be present. Psychotic reactions, with schizophrenia-like symptoms, are seen in a few patients. The administration of high doses of exogenous corticosteroids typically leads to a secondary mood disorder similar to mania. Severe depression can follow the termination of steroid therapy.

Pituitary Disorders. Patients with total pituitary failure can exhibit psychiatric symptoms, particularly postpartum women who have hemorrhaged into the pituitary, a condition known as *Sheehan's syndrome*. Patients have a combination of symptoms, especially of thyroid and adrenal disorders, and can show virtually any psychiatric symptom.

Metabolic Disorders

A common cause of organic brain dysfunction, metabolic encephalopathy can produce alterations in mental processes, behavior, and neurological functions. The diagnosis should be considered whenever recent and rapid changes in behavior, thinking, and consciousness have occurred. The earliest signals are likely to be impairment of memory, particularly recent memory, and impairment of orientation. Some patients become agitated, anxious, and hyperactive; others become quiet, withdrawn, and inactive. As metabolic encephalopathies progress, confusion or delirium gives way to decreased responsiveness; stupor; and, eventually, death.

Hepatic Encephalopathy. Severe hepatic failure can result in hepatic encephalopathy, characterized by asterixis, hyperventilation, EEG abnormalities, and alterations in consciousness. The alterations in consciousness can range from apathy to drowsiness to coma. Associated psychiatric symptoms are changes in memory, general intellectual skills, and personality.

Uremic Encephalopathy. Renal failure is associated with alterations in memory, orientation, and consciousness. Restlessness, crawling sensations on the limbs, muscle twitching, and persistent hiccups are associated symptoms. In young people with brief episodes of uremia, the neuropsychiatric symptoms tend to be reversible; in elderly people with long episodes of uremia, the neuropsychiatric symptoms can be irreversible.

Hypoglycemic Encephalopathy. Hypoglycemic encephalopathy can be caused either by excessive endogenous production of insulin or by excessive exogenous insulin administration. The premonitory symptoms, which do not occur in every patient, include nausea, sweating, tachycardia, and feelings of hunger, apprehension, and restlessness. As the disorder progresses, disorientation, confusion, and hallucinations, as well as other neurological and medical symptoms, can develop. Stupor and coma can occur, and a residual and persistent dementia can sometimes be a serious neuropsychiatric sequela of the disorder.

Diabetic Ketoacidosis. Diabetic ketoacidosis begins with feelings of weakness, easy fatigability, and listlessness and increasing polyuria and polydipsia. Headache and sometimes nausea and vomiting appear. Patients with diabetes mellitus have an increased likelihood of chronic dementia with general arteriosclerosis.

Acute Intermittent Porphyria. The porphyrias are disorders of heme biosynthesis that result in excessive accumulation of porphyrins. The triad of symptoms is acute, colicky abdominal pain; motor polyneuropathy; and psychosis. Acute intermittent porphyria is an autosomal dominant disorder that affects more women than men and has its onset between ages 20 and 50 years. The psychiatric symptoms include anxiety, insomnia, lability of mood, depression, and psychosis. Some studies have found that between 0.2 and 0.5 percent of chronic psychiatric patients may have undiagnosed porphyrias. Barbiturates precipitate or aggravate the attacks of acute porphyria, and the use of barbiturates for any reason is absolutely contraindicated in a person with acute intermittent porphyria and in anyone who has a relative with the disease.

Nutritional Disorders

Niacin Deficiency. Dietary insufficiency of niacin (nicotinic acid) and its precursor tryptophan is associated with pellagra, a globally occurring nutritional deficiency disease seen in association with alcohol abuse, vegetarian diets, and extreme poverty and starvation. The neuropsychiatric symptoms of pellagra include apathy, irritability, insomnia, depression, and delirium; the medical symptoms include dermatitis, peripheral neuropathies, and diarrhea. The course of pellagra has traditionally been described as "five Ds": dermatitis, diarrhea, delirium, dementia, and death. The response to treatment with nicotinic acid is rapid, but dementia from prolonged illness may improve only slowly and incompletely.

Thiamine Deficiency. Thiamine (vitamin B₁) deficiency leads to beriberi, characterized chiefly by cardiovascular and neurological changes, and to Wernicke-Korsakoff syndrome, which is most often associated with chronic alcohol abuse. Beriberi occurs primarily in Asia and in areas of famine and poverty. The psychiatric symptoms include apathy, depression, irritability, nervousness, and poor concentration; severe memory disorders can develop with prolonged deficiencies.

Cobalamin Deficiency. Deficiencies in cobalamin (vitamin B₁₂) arise because of the failure of the gastric mucosal cells to secrete a specific substance, intrinsic factor, required for the normal absorption of vitamin B₁₂ in the ileum. The deficiency state is characterized by the development of a chronic macrocytic megaloblastic anemia (pernicious anemia) and by neurological manifestations resulting from degenerative changes in the peripheral nerves, the spinal cord, and the brain. Neurological changes are seen in approximately 80 percent of all patients. These changes are commonly associated with megaloblastic anemia, but they occasionally precede the onset of hematological abnormalities.

Mental changes, such as apathy, depression, irritability, and moodiness, are common. In a few patients, encephalopathy and its associated delirium, delusions, hallucinations, dementia, and sometimes paranoid features are prominent and are sometimes called *megaloblastic madness*. The neurological manifestations of vitamin B₁₂ deficiency can be rapidly and completely arrested by early and continued administration of parenteral vitamin therapy.

Toxins

Environmental toxins are becoming an increasingly serious threat to physical and mental health in contemporary society.

Mercury. Mercury poisoning can be caused by either inorganic or organic mercury. Inorganic mercury poisoning results in the “mad hatter” syndrome (previously seen in workers in the hat industry who softened felt by putting it in their mouths), with depression, irritability, and psychosis. Associated neurological symptoms are headache, tremor, and weakness. Organic mercury poisoning can be caused by contaminated fish or grain and can result in depression, irritability, and cognitive impairment. Associated symptoms are sensory neuropathies, cerebellar ataxia, dysarthria, paresthesias, and visual field defects. Mercury poisoning in pregnant women causes abnormal fetal development. No specific therapy is available, although chelation therapy with dimercaprol has been used in acute poisoning.

Lead. Lead poisoning occurs when the amount of lead ingested exceeds the body’s ability to eliminate it. It takes several months for toxic symptoms to appear.

The signs and symptoms of lead poisoning depend on the level of lead in the blood. When lead reaches levels above 200 mg/L, symptoms of severe lead encephalopathy occur, with dizziness, clumsiness, ataxia, irritability, restlessness, headache, and insomnia. Later, an excited delirium occurs, with associated vomiting and visual disturbances, and progresses to convulsions, lethargy, and coma.

Treatment of lead encephalopathy should be instituted as rapidly as possible, even without laboratory confirmation, because of the high mortality rate. The treatment of choice to facilitate lead excretion is intravenous administration of calcium disodium edetate (calcium disodium versenate) daily for 5 days.

Manganese. Early manganese poisoning (sometimes called *manganese madness*) causes symptoms of headache, irritability, joint pains, and somnolence. An eventual picture appears of emotional lability, pathological laughter, nightmares, hallucinations, and compulsive and impulsive acts associated with periods of confusion and aggressiveness. Lesions involving the basal ganglia and pyramidal system result in gait impairment, rigidity, monotonous or whispering speech, tremors of the extremities and tongue, masked facies (manganese mask), micrographia, dystonia, dysarthria, and loss of equilibrium. The psychological effects tend to clear 3 or 4 months after the patient’s removal from the site of exposure, but neurological symptoms tend to remain stationary or to progress. No specific treatment exists for manganese poisoning, other than removal from the source of poisoning. The disorder is found in persons working in refining ore, brick workers, and those making steel casings.

Arsenic. Chronic arsenic poisoning most commonly results from prolonged exposure to herbicides containing arsenic or from drinking water contaminated with arsenic. Arsenic is also used in the manufacture of silicon-based computer chips. Early signs of toxicity are skin pigmentation, GI complaints, renal and hepatic dysfunction, hair loss, and a characteristic garlic odor to the breath. Encephalopathy eventually occurs, with generalized sensory and motor loss. Chelation therapy with dimercaprol has been used successfully to treat arsenic poisoning.

21.6 Mild Cognitive Impairment

The past decade has seen the emergence of a new concept, *mild cognitive impairment* (MCI), which is defined as the presence of mild cognitive decline not warranting the diagnosis of dementia but with preserved basic activities of daily living.

In the DSM-5, MCI is classified as *mild neurocognitive disorder due to multiple etiologies* or *unspecified neurocognitive disorder*. It will most likely receive more attention in future revisions of the DSM.

DEFINITION

Although the term *mild cognitive impairment* has been in use for more than 25 years, it was suggested as a diagnostic category designed to fill the gap between cognitive changes associated with aging and cognitive impairment suggestive of dementia. The criteria proposed by the Mayo Clinic Alzheimer’s Disease Research Center (MCADRC) are (1) memory complaint, preferably qualified by an informant; (2) objective memory impairment for age and education; (3) preserved general cognitive function; (4) intact activities of daily living; and (5) not demented (Table 21.6-1). However, at this time there are no international diagnostic criteria for MCI.

Table 21.6-1
Mild Cognitive Impairment Original Criteria

1. Memory complaint, preferably qualified by an informant
2. Memory impairment for age and education
3. Preserved general cognitive function
4. Intact activities of daily living
5. Not demented

Historical Perspective

The imprecise border between normal aging-related cognitive decline and dementia-related cognitive impairment has been described for several decades. Thus, in 1962, Kral introduced the terms *benign senescent forgetfulness* (forgetfulness for less important facts and awareness of problems) and *malignant senescent forgetfulness* (memory problems for recent events and lack of awareness). In 1986, the National Institutes of Mental Health (NIMH) recommended the term *age associated memory impairment* for age-related normal memory changes. In 1994, the International Psychogeriatrics Association presented the concept of *age-associated cognitive decline*, which described cognitive deficits including but not limited to memory impairment in the absence of dementia or other affecting cognitive conditions. *Cognitive impairment no dementia* was introduced in 1997 by the Canadian Study of Health and Aging to describe the presence of nondemented cognitive impairment regardless of the underlying process (neurological, psychiatric, medical). Several other classifications, including age-consistent memory impairment and late life forgetfulness, are defined on the bases of performance on various cognitive tests.

The exact place of MCI in the psychiatric nosology will be challenging. Based on the current definition of MCI, functional impairment is an exclusion criterion for MCI, but the same “functional impairment” is one of the standard criteria for defining psychiatric disorders. Further developments in finding biological markers for MCI will probably contribute to a more solid conceptualization and, hopefully, treatment of patients with prodromal dementia (Table 21.6-2).

Table 21.6-2
Terms Related to Mild Cognitive Impairment

Term	Author(s)	Year	Inclusion Criteria	Observations
Malignant senescent forgetfulness (MSF)	VA Kral	1962	Memory difficulties for recent events Lack of awareness regarding the memory deficit	Two-year follow-up showed a faster evolution of patients with MSF toward dementia
Age associated memory impairment (AAMI)	NIMH (Crook, Bartus, and Ferris)	1986	Age-related memory disturbances leading to (1) subjective concern; (2) functional problem No underlying neurological illness	Memory tests were validated on young populations, leading to high rates of AAMI in elderly adults
Age associated cognitive decline (AACD)	International Psychogeriatric Association and World Health Organization (Levy)	1994	Cognitive deficits not meeting the criteria for dementia	Does not include prognosis regarding evolution to dementia Includes several kinds of cognitive decline (not exclusive memory decline)
Cognitively impaired no dementia (CIND)	Canadian Study of Health and Aging	1997	Age 65 years and older	Includes static encephalopathies

EPIDEMIOLOGY AND ETIOLOGY OF MCI

The recognition that Alzheimer’s disease pathology may exist in the brain long before the presence of clinical symptoms led to the focus on preclinical stages, with the purpose of characterizing initial impairments that are associated with an increased risk of progression to Alzheimer’s disease.

The clinical expression of MCI can be viewed as a result of the interaction among several risk factors and several protective factors. The most significant risk factors are related to the different types of neurodegeneration witnessed in dementias. These are clinically expressed in different subtypes of MCI, especially those associated with amnesia. Other risk factors include the APOE4 allele status and cerebrovascular events in the form of either cerebrovascular accident or lacunar disease. The role of chronic exposure to high levels of cortisol, as seen in late life depression, is also hypothesized to increase the risk for cognitive impairment through hippocampal volume reduction. The notion of “brain reserve” suggests that effects of brain size and neuron density may be protective against dementia despite the presence of neurodegeneration (a larger number of neurons and a bigger brain volume would protect against clinical manifestations of Alzheimer’s disease despite the presence of neurodegeneration) (Fig. 21.6-1).

		MCI Subtypes				
		Degen-erative	Vascular	Psychiatric	Medical conditions	
Clinical classification	Amnesic MCI	Single domain	AD		Depr	
		Multiple domain	AD	VaD	Depr	
	Non-amnesic MCI	Single domain	FTD			
		Multiple domain	DLB	VaD		

FIGURE 21.6-1

Outcome of clinical phenotypes of mild cognitive impairment (MCI) according to presumed etiology. AD, Alzheimer’s disease; Depr, depression; DLB, dementia with Lewy bodies; FRD, frontotemporal dementia; VaD, vascular dementia. (Adapted with permission from Petersen RC, ed. *Mild Cognitive Impairment: Aging to Alzheimer’s Disease*. New York: Oxford University Press; 2003.)

CLINICAL PRESENTATION

The clinical picture of MCI is a function of the criteria used to define it. Memory impairment is necessary but has been difficult to quantify.

One measure has been objective loss of memory or other cognitive domain that is more than 1.5 standard deviations below the mean for individuals of similar age and education. Some have suggested subjective complaints of memory loss be used as a marker, but this runs the risk of many false-positive diagnoses.

Assessment

Neuropsychological Assessment. Most experts agree that earlier deficits are noted in episodic (vs. semantic) memory. There is no consensus among experts with regard to which memory tests and which cutoffs to use. There is a lack of norms, test scores do not have normal distributions, and test performance is influenced by multiple demographic characteristics. Several experts have proposed that a scale such as the delayed recall task from the Consortium to Establish a Registry for Alzheimer's Disease might be useful in detecting Alzheimer's disease in the earliest stages. Brief mental status instruments (e.g., the Mini-Mental State Examination) are relatively insensitive for the detection of memory problems in MCI.

Biomarkers. Several markers of progression from MCI to Alzheimer's disease have been studied in the past decade. Among these, apolipoprotein E4 (ApoE4) allele carrier status has been one of the most prominent variables. For the amnesic MCI, ApoE4 has been shown to be a risk factor for a more rapid progression to Alzheimer's disease. Several CSF markers have also been identified as possible predictors of disease progression: Pathological low concentrations of A β ₄₂ (the 42 amino acid form of β -amyloid) as well as pathological high concentrations of total tau (t-tau) and phospho tau (p-tau) may differentiate early Alzheimer's disease from normal aging. Locating alterations in the expression of proteins involved in the pathogenetic pathways of Alzheimer's disease (proteomic approach) is another approach used to help early detection of Alzheimer's disease. Several proteins (cystatin C, β -2 microglobulin, and BEGF polypeptides) have been detected through new techniques, and currently there are a number of proteins from both CSF and blood that are implicated in Alzheimer's disease pathology.

Genetics. Because MCI is regarded as the prodromal stage for several disorders (Alzheimer's disease, frontotemporal or vascular dementia), different genes are probably related to MCI. Four genes have been described in relationship with Alzheimer's disease: the amyloid precursor protein (APP) gene, presenilin-1 (PSEN1), presenilin-2 (PSEN2), and the apolipoprotein E (APOE) gene. Because the first three genes are involved in rare autosomal dominant forms of Alzheimer's disease, screening for each of these mutations will have very limited value for the diagnosis of MCI in the general population. The APOE gene, a common genetic risk factor for early as well as for late-onset Alzheimer's disease, has been studied more thoroughly in relationship to MCI, but the results have been inconsistent. Because the etiology of MCI is heterogeneous, it is likely that a very large number of different genes underlie the pathology of MCI. Most of these genes are yet to be discovered.

Neuroimaging. Advances in neuroimaging studies aim to develop measures allowing the differentiation between MCI and healthy aging as well as within MCI among subjects who will convert to Alzheimer's disease or will remain stable over time.

Structural studies of volumetric MCI showed early changes in the medial temporal structures, including neuronal atrophy, decreased synaptic density, and overall neuronal loss. Atrophy of the hippocampal volume and entorhinal cortex has been described in MCI. Atrophy of the hippocampal formation was also reported to predict the rate of progression from MCI to Alzheimer's disease. Three-dimensional modeling techniques have localized shape alteration and specific regions of atrophy within the hippocampus. Other methods such as tensor-based morphometry allow tracking brain changes in detail, quantifying tissue growth or atrophy throughout the brain and indicating the local rate at which tissue is being lost. Other innovations in neuroimaging include MR relaxometry, imaging of iron deposition, diffusion tensor imaging, and high-field MRI scanning.

Perhaps the most promising development has been the advent of PET tracer compounds that visualize amyloid plaques and neurofibrillary tangles. These new compounds—Pittsburgh Compound B (carbon-11-PIB) and fluorine-18-FDDNP—track pathology changes in the preclinical stages of Alzheimer's disease. These specific tracers allow investigators to visualize the pathological process and are also used to monitor progression from MCI to Alzheimer's disease. However, the burden of β -amyloid plaques does not always correlate with the clinical stages because some MCI subjects can present with minimal burden similar to healthy control participants, but others have amyloid burden comparable to Alzheimer's disease participants. A single biomarker will probably be insufficient to identify incipient Alzheimer's disease. Thus, the combination of several markers further increases the accuracy of the prediction and will probably become the norm as described by recent studies (combination of decreased parietal rCBF and CSF biomarkers as A β ₄₂, t-tau, and p-tau) (Fig. 21.6-2).

FIGURE 21.6-2

Positron emission tomography images obtained with the amyloid-imaging agent Pittsburgh Compound-B ([carbon-11]-PIB) in a normal individual with mild cognitive impairment (MCI; *center images*) and a patient with mild Alzheimer's disease (AD) (*far right*). Some MCI patients have control-like levels of amyloid, some have Alzheimer's disease-like levels of amyloid, and some have intermediate levels. (Courtesy of William E. Klunk, M.D., University of Pittsburgh, Department of Psychiatry, Pittsburgh, PA. All rights retained.)

Diagnostic Differential

The Cognitive Continuum. The cognitive continuum describes the subtle pathway from age-related cognitive decline to MCI to dementia. Per this model, there is an overlap at both ends of MCI, which indicates that it can be quite challenging to identify the transition points (Figure 21.6-3). In practice, differentiating MCI from age-related cognitive decline resides mainly on neuropsychological testing, showing a cognitive decline more severe for age and less education. The main differentiation between MCI and Alzheimer's disease resides in the lack of functional impairment in MCI.

FIGURE 21.6-3

Cognitive continuum showing the overlap in the boundary between normal aging and the mild cognitive impairment and Alzheimer's disease. (Reprinted with permission from Petersen RC, ed. *Mild Cognitive Impairment: Aging to Alzheimer's Disease*. New York: Oxford University Press, 2003.)

COURSE AND PROGNOSIS

The typical rate at which MCI patients progress to Alzheimer's disease is 10 to 15 percent per year and is associated with progressive loss of function. However, several studies have indicated that the diagnosis is not stable in both directions; patients can either convert to Alzheimer's disease or revert back to normal. This variability in course is related to the heterogeneous source of the subjects (clinical vs. community) as well as to the heterogeneous definition criteria used by different studies. Amnesic MCI has been associated with increased morbidity compared with reference subjects.

TREATMENT

There are no FDA-approved treatments for MCI at this time. MCI treatment involves adequate screening and diagnosis. Ideally, MCI treatment would also include improvement of memory loss together with prevention of further cognitive decline to dementia. Cognitive training programs have been reported as mildly beneficial for compensating memory difficulties in MCI. Controlling for vascular risk factors (high blood pressure, hypercholesterolemia, diabetes mellitus) may be a benefit preventive method for those MCI cases underlying vascular pathology. Currently, sensitive tools (imaging techniques or biomarkers) are not available for MCI screening in the general population.

In primary care setting, clinicians should maintain a high suspicion for subjective cognitive complaints and should corroborate these complaints with collateral information whenever possible. Also, identifying reversible causes of cognitive impairment (hypothyroidism, vitamin B₁₂ deficiency, medication-induced cognitive impairment, depression) can further benefit some of the prodromal dementia MCI cases.

Currently, there is no evidence for long-term efficacy of pharmacotherapies in reversing MCI. Several epidemiological studies indicated a reduced risk of dementia in persons taking antihypertensive medications, cholesterol-lowering drugs, antioxidants, and anti-inflammatory and estrogen therapy, but no randomized controlled trials verify these data. With regard to cognitive enhancers, as of 2007, there have been seven trials designed for amnesic MCI, with ambiguous results (Table 21.6-3). Most of these studies were confronted with several problems, including (1) obtaining homogeneous samples and identifying potential beneficiaries of treatment; (2) treating a wider population, which led to large percentages of negative responses and problematic side effects; and (3) translation of the MCI construct into multiple cultures and languages and using Alzheimer's disease diagnosis as the primary outcome, given the variability of this diagnosis in different countries.

Table 21.6-3
Treatment Trials for Mild Cognitive Impairment

Study	Patients (n)	Duration	Primary Outcome	Results	OBS	Sponsor
Donepezil + vitamin E (Thall et al., 1999)	769	3 years	Conversion to AD	Partially positive (reduced risk of developing AD in the active arm group for the first 12 months)	Amnesic MCI status and the presence of APOE4 allele—predictive of rate of progression to AD	ADCS
Donepezil (Salloway et al., 2004)	269	24 weeks	ADAS-Cog total score; NYU PTIR	Negative	Positive results in secondary outcome measures (ADAS-Cog13)	Pfizer (The Donepezil "401" Study Group)
Rivastigmine (Feldman et al., 2007)	1,018	48 months	Conversion to AD	Negative		Novartis
Galantamine (Johnson and Johnson, 2004)	2,048	2 years	Progression of CDR score (from .5 to 1)	Negative	Attention assessed by DSST favored galantamine in both studies	Johnson & Johnson
Rofecoxib (Thall et al., 2005)	1,457	3–4 years	Conversion to AD	Negative	Primary outcome favored placebo while secondary outcomes (ADS-cog, CDR) did not differentiate between rofecoxib and placebo	Merck
Piracetam	675	12 months	Composite score extracted from eight tests	Negative		UCB Pharma

AD, Alzheimer's disease; ADCS, Alzheimer Disease Cooperative Study; CDR, Clinical Dementia Rating; DSST, Digit Symbol Substitution test; MCI, mild cognitive impairment; MCI, mild cognitive impairment; NYU PTIR, New York University Paragraph Test Immediate Recall.

Advances in MCI detection will be paramount for early detection and treatment of patients with Alzheimer's disease; experts agree that disease-modifying treatments for Alzheimer's disease will focus on cognitively intact individuals at increased risk. The field of identifying sensitive and specific biomarkers (biological and neuroimaging markers) will probably witness exponential development in the coming years.

Personality Disorders

The understanding of personality and its disorders distinguishes psychiatry fundamentally from all other branches of medicine. A person is a self-aware human being, as C. Robert Cloninger said, not “a machine-like object that lacks self-awareness.” Personality refers to all of the characteristics that adapt in unique ways to ever-changing internal and external environments.

Personality disorders are common and chronic. They occur in 10 to 20 percent of the general population, and their duration is expressed in decades. Approximately 50 percent of all psychiatric patients have a personality disorder, which is frequently comorbid with other clinical syndromes. Personality disorder is also a predisposing factor for other psychiatric disorders (e.g., substance use, suicide, affective disorders, impulse-control disorders, eating disorders, and anxiety disorders) in which it interferes with treatment outcomes of many clinical syndromes and increases personal incapacitation, morbidity, and mortality of these patients.

Persons with personality disorders are far more likely to refuse psychiatric help and to deny their problems than persons with anxiety disorders, depressive disorders, or obsessive-compulsive disorder. In general, personality disorder symptoms are ego syntonic (i.e., acceptable to the ego, as opposed to ego dystonic) and alloplastic (i.e., adapt by trying to alter the external environment rather than themselves). Persons with personality disorders do not feel anxiety about their maladaptive behavior. Because they do not routinely acknowledge pain from what others perceive as their symptoms, they often seem disinterested in treatment and impervious to recovery.

CLASSIFICATION

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) defines a general personality disorder as an enduring pattern of behavior and inner experiences that deviates significantly from the individual’s cultural standards; is rigidly pervasive; has an onset in adolescence or early adulthood; is stable through time; leads to unhappiness and impairment; and manifests in at least two of the following four areas: cognition, affectivity, interpersonal function, or impulse control. When personality traits are rigid and maladaptive and produce functional impairment or subjective distress, a personality disorder may be diagnosed.

Personality disorder subtypes classified in DSM-5 are *schizotypal*, *schizoid*, and *paranoid* (Cluster A); *narcissistic*, *borderline*, *antisocial*, and *histrionic* (Cluster B); and *obsessive-compulsive*, *dependent*, and *avoidant* (Cluster C). The three clusters are based on descriptive similarities. Cluster A includes three personality disorders with odd, aloof features (paranoid, schizoid, and schizotypal). Cluster B includes four personality disorders with dramatic, impulsive, and erratic features (borderline, antisocial, narcissistic, and histrionic). Cluster C includes three personality disorders sharing anxious and fearful features (avoidant, dependent, and obsessive-compulsive). Individuals frequently exhibit traits that are not limited to a single personality disorder. When a patient meets the criteria for more than one personality disorder, clinicians should diagnose each.

ETIOLOGY

Genetic Factors

The best evidence that genetic factors contribute to personality disorders comes from investigations of more than 15,000 pairs of twins in the United States. The concordance for personality disorders among monozygotic twins was several times that among dizygotic twins. Moreover, according to one study, monozygotic twins reared apart are about as similar as monozygotic twins reared together. Similarities include multiple measures of personality and temperament, occupational and leisure-time interests, and social attitudes.

Cluster A personality disorders are more common in the biological relatives of patients with schizophrenia than in control groups. More relatives with schizotypal personality disorder occur in the family histories of persons with schizophrenia than in control groups. Less correlation exists between paranoid or schizoid personality disorder and schizophrenia.

Cluster B personality disorders apparently have a genetic base. Antisocial personality disorder is associated with alcohol use disorders. Depression is common in the family backgrounds of patients with borderline personality disorder. These patients have more relatives with mood disorders than do control groups, and persons with borderline personality disorder often have a mood disorder as well. A strong association is found between histrionic personality disorder and somatization disorder (Briquet’s syndrome); patients with each disorder show an overlap of symptoms.

Cluster C personality disorders may also have a genetic base. Patients with avoidant personality disorder often have high anxiety levels. Obsessive-compulsive traits are more common in monozygotic twins than in dizygotic twins, and patients with obsessive-compulsive personality disorder show some signs associated with depression—for example, shortened rapid eye movement (REM) latency period and abnormal dexamethasone-suppression test (DST) results.

Biological Factors

Hormones. Persons who exhibit impulsive traits also often show high levels of testosterone, 17-estradiol, and estrone. In nonhuman primates, androgens increase the likelihood of aggression and sexual behavior, but the role of testosterone in human aggression is unclear. DST results are abnormal in some patients with borderline personality disorder who also have depressive symptoms.

Platelet Monoamine Oxidase. Low platelet monoamine oxidase (MAO) levels have been associated with activity and sociability in monkeys. College students with low platelet MAO levels report spending more time in social activities than students with high platelet MAO levels. Low platelet MAO levels have also been noted in some patients with schizotypal disorders.

Smooth Pursuit Eye Movements. Smooth pursuit eye movements are saccadic (i.e., jumpy) in persons who are introverted, who have low self-esteem and tend to withdraw, and who have schizotypal personality disorder. These findings have no clinical application, but they do indicate the role of inheritance.

Neurotransmitters. Endorphins have effects similar to those of exogenous morphine, such as analgesia and the suppression of arousal. High endogenous endorphin levels may be associated with persons who are phlegmatic. Studies of personality traits and the dopaminergic and serotonergic systems indicate an arousal-activating function for these neurotransmitters. Levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, are low in persons who attempt suicide and in patients who are impulsive and aggressive.

Raising serotonin levels with serotonergic agents such as fluoxetine (Prozac) can produce dramatic changes in some character traits of personality. In many persons, serotonin reduces depression, impulsiveness, and rumination and can produce a sense of general well-being. Increased dopamine concentrations in the central nervous system produced by certain psychostimulants (e.g., amphetamines) can induce euphoria. The effects of neurotransmitters on personality traits have generated much interest and controversy about whether personality traits are inborn or acquired.

Electrophysiology. Changes in electrical conductance on the electroencephalogram (EEG) occur in some patients with personality disorders, most commonly antisocial and borderline types; these changes appear as slow-wave activity on EEGs.

Psychoanalytic Factors

Sigmund Freud suggested that personality traits are related to a fixation at one psychosexual stage of development. For example, those with an oral character are passive and dependent because they are fixated at the oral stage, when the dependence on others for food is prominent. Those with an anal character are stubborn, parsimonious, and highly conscientious because of struggles over toilet training during the anal period.

Wilhelm Reich subsequently coined the term *character armor* to describe persons' characteristic defensive styles for protecting themselves from internal impulses and from interpersonal anxiety in significant relationships. Reich's theory has had a broad influence on contemporary concepts of personality and personality disorders. For example, each human being's unique stamp of personality is considered largely determined by his or her characteristic defense mechanisms. Each personality disorder has a cluster of defenses that help psychodynamic clinicians recognize the type of character pathology present. Persons with paranoid personality disorder, for instance, use projection, whereas schizoid personality disorder is associated with withdrawal.

When defenses work effectively, persons with personality disorders master feelings of anxiety, depression, anger, shame, guilt, and other affects. Their behavior is ego syntonic; that is, it creates no distress for them even though it may adversely affect others. They may also be reluctant to engage in a treatment process; because their defenses are important in controlling unpleasant affects, they are not interested in surrendering them.

In addition to characteristic defenses in personality disorders, another central feature is internal object relations. During development, particular patterns of the self in relation to others are internalized. Through introjection, children internalize a parent or another significant person as an internal presence that continues to feel like an object rather than a self. Through identification, children internalize parents and others in such a way that the traits of the external object are incorporated into the self and the child "owns" the traits. These internal self-representations and object representations are crucial in developing the personality and, through externalization and projective identification, are played out in interpersonal scenarios in which others are coerced into playing a role in the person's internal life. Hence, persons with personality disorders are also identified by particular patterns of interpersonal relatedness that stem from these internal object relations patterns.

Defense Mechanisms. To help those with personality disorders, psychiatrists must appreciate patients' underlying defenses, the unconscious mental processes that the ego uses to resolve conflicts among the four lodestars of the inner life: instinct (wish or need), reality, important persons, and conscience. When defenses are most effective, especially in those with personality disorders, they can abolish anxiety and depression at the conscious level. Thus, abandoning a defense increases conscious awareness of anxiety and depression—a major reason that those with personality disorders are reluctant to alter their behavior.

Although patients with personality disorders may be characterized by their most dominant or rigid mechanism, each patient uses several defenses. Therefore, the management of defense mechanisms used by patients with personality disorders is discussed here as a general topic and not as an aspect of the specific disorders. Many formulations presented here in the language of psychoanalytic psychiatry can be translated into principles consistent with cognitive and behavioral approaches.

FANTASY. Many persons who are often labeled schizoid—those who are eccentric, lonely, or frightened—seek solace and satisfaction within themselves by creating imaginary lives, especially imaginary friends. In their extensive dependence on fantasy, these persons often seem to be strikingly aloof. Therapists must understand that the unsociableness of these patients rests on a fear of intimacy. Rather than criticizing them or feeling rebuffed by their rejection, therapists should maintain a quiet, reassuring, and considerate interest without insisting on reciprocal responses. Recognition of patients' fear of closeness and respect for their eccentric ways are both therapeutic and useful.

DISSOCIATION. Dissociation or denial is a Pollyanna-like replacement of unpleasant affects with pleasant ones. Persons who frequently dissociate are often seen as dramatizing and emotionally shallow; they may be labeled histrionic personalities. They behave like anxious adolescents who, to erase anxiety, carelessly expose themselves to exciting dangers. Accepting such patients as exuberant and seductive is to overlook their anxiety, but confronting them with their vulnerabilities and defects makes them still more defensive. Because these patients seek appreciation of their courage and attractiveness, therapists should not behave with inordinate reserve. While remaining calm and firm, clinicians should realize that these patients are often inadvertent liars, but they benefit from ventilating their own anxieties and may in the process "remember" what they "forgot." Often therapists deal best with dissociation and denial by using displacement. Thus, clinicians may talk with patients about an issue of denial in an unthreatening circumstance. Empathizing with the denied affect without directly confronting patients with the facts may allow them to raise the original topic themselves.

ISOLATION. Isolation is characteristic of controlled, orderly persons who are often labeled obsessive-compulsive personalities. Unlike those with histrionic personality, persons with obsessive-compulsive personality remember the truth in fine detail but without affect. In a crisis, patients may show intensified self-restraint, overly formal social behavior, and obstinacy. Patients' quests for control may annoy clinicians or make them anxious. Often, such patients respond well to precise, systematic, and rational explanations and value efficiency, cleanliness, and punctuality as much as they do clinicians' effective responsiveness. Whenever possible, therapists should allow such patients to control their own care and should not engage in a battle of wills.

PROJECTION. In projection, patients attribute their own unacknowledged feelings to others. Patients' excessive faultfinding and sensitivity to criticism may appear to therapists as prejudiced, hypervigilant injustice collecting but should not be met by defensiveness and argument. Instead, clinicians should frankly acknowledge even minor mistakes on their part and should discuss the possibility of future difficulties. Strict honesty; concern for patients' rights; and maintaining the same formal, concerned distance as used with patients who use fantasy defenses are all helpful. Confrontation guarantees a lasting enemy and early termination of the interview. Therapists need not agree with patients' injustice collecting, but they should ask whether both can agree to disagree.

The technique of counterprojection is especially helpful. Clinicians acknowledge and give paranoid patients full credit for their feelings and perceptions; they neither dispute patients' complaints nor reinforce them but agree that the world described by patients is conceivable. Interviewers can then talk about real motives and feelings, misattributed to someone else, and begin to cement an alliance with patients.

SPLITTING. In splitting, persons toward whom patients' feelings are, or have been, ambivalent are divided into good and bad. For example, in an inpatient setting, a patient may idealize some staff members and uniformly disparage others. This defense behavior can be highly disruptive on a hospital ward and can ultimately provoke the staff to turn against the patient. When staff members anticipate the process, discuss it at staff meetings, and gently confront the patient with the fact that no one is all good or all bad, the phenomenon of splitting can be dealt with effectively.

PASSIVE AGGRESSION. Persons with passive-aggressive defense turn their anger against themselves. In psychoanalytic terms, this phenomenon is called *masochism* and includes failure, procrastination, silly or provocative behavior, self-demeaning clowning, and frankly self-destructive acts. The hostility in such behavior is never entirely concealed. Indeed, in a mechanism such as wrist cutting, others feel as much anger as if they themselves had been assaulted and view the patient as a sadist, not a masochist. Therapists can best deal with passive aggression by helping patients to ventilate their anger.

ACTING OUT. In acting out, patients directly express unconscious wishes or conflicts through action to avoid being conscious of either the accompanying idea or the affect. Tantrums, apparently motiveless assaults, child abuse, and pleasureless promiscuity are common examples. Because the behavior occurs outside reflective awareness, acting out often appears to observers to be unaccompanied by guilt, but when acting out is impossible, the conflict behind the defense may be accessible. The clinician faced with acting out, either aggressive or sexual, in an interview situation must recognize that the patient has lost control, that anything the interviewer says will probably be misheard, and that getting the patient's attention is of paramount importance. Depending on the circumstances, a clinician's response may be, "How can I help you if you keep screaming?" Or, if the patient's loss of control seems to be escalating, say, "If you continue screaming, I'll leave." An interviewer who feels genuinely frightened of the patient can simply leave and, if necessary, ask for help from ward attendants or the police.

PROJECTIVE IDENTIFICATION. The defense mechanism of projective identification appears mainly in borderline personality disorder and consists of three steps. First, an aspect of the self is projected onto someone else. The projector then tries to coerce the other person into identifying with what has been projected. Finally, the recipient of the projection and the projector feel a sense of oneness or union.

PARANOID PERSONALITY DISORDER

Persons with paranoid personality disorder are characterized by long-standing suspiciousness and mistrust of persons in general. They refuse responsibility for their own feelings and assign responsibility to others. They are often hostile, irritable, and angry. Bigots, injustice collectors, pathologically jealous spouses, and litigious cranks often have paranoid personality disorder.

Epidemiology

Data suggest that the prevalence of paranoid personality disorder is 2 to 4 percent of the general population. Those with the disorder rarely seek treatment themselves; when referred to treatment by a spouse or an employer, they can often pull themselves together and appear undistressed. Relatives of patients with schizophrenia show a higher incidence of paranoid personality disorder than control participants. Some evidence suggests a more specific familial relationship with delusional disorder, persecutory type. The disorder is more commonly diagnosed in men than in women in clinical samples. The prevalence among persons who are homosexual is no higher than usual, as was once thought, but it is believed to be higher among minority groups, immigrants, and persons who are deaf than it is in the general population.

Diagnosis

On psychiatric examination, patients with paranoid personality disorder may be formal in manner and act baffled about having to seek psychiatric help. Muscular tension, an inability to relax, and a need to scan the environment for clues may be evident, and the patient's manner is often humorless and serious. Although some premises of their arguments may be false, their speech is goal directed and logical. Their thought content shows evidence of projection, prejudice, and occasional ideas of reference. The DSM-5 diagnostic criteria are listed in Table 22-1.

Table 22-1
DSM-5 Diagnostic Criteria for Paranoid Personality Disorder

- A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
1. Suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her.
 2. Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates.
 3. Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her.
 4. Reads hidden demeaning or threatening meanings into benign remarks or events.
 5. Persistently bears grudges (i.e., is unforgiving of insults, injuries, or slights).
 6. Perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack.
 7. Has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner.
- B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, or another psychotic disorder and is not attributable to the physiological effects of another medical condition.
- Note:** If criteria are met prior to the onset of schizophrenia, add "premorbid," i.e., "paranoid personality disorder (premorbid)."

Clinical Features

The hallmarks of paranoid personality disorder are excessive suspiciousness and distrust of others expressed as a pervasive tendency to interpret actions of others as deliberately demeaning, malevolent, threatening, exploiting, or deceiving. This tendency begins by early adulthood and appears in a variety of contexts. Almost invariably, those with the disorder expect to be exploited or harmed by others in some way. They frequently dispute, without any justification, friends' or associates' loyalty or trustworthiness. Such persons are often pathologically jealous and, for no reason, question the fidelity of their spouses or sexual partners. Persons with this disorder externalize their own emotions and use the defense of projection; they attribute to others the impulses and thoughts that they cannot accept in themselves. Ideas of reference and logically defended illusions are common.

Persons with paranoid personality disorder are affectively restricted and appear to be unemotional. They pride themselves on being rational and objective, but such is not the case. They lack warmth and are impressed with, and pay close attention to, power and rank. They express disdain for those they see as weak, sickly, impaired, or in some way defective. In social situations, persons with paranoid personality disorder may appear business-like and efficient, but they often generate fear or conflict in others.

Differential Diagnosis

Paranoid personality disorder can usually be differentiated from delusional disorder by the absence of fixed delusions. Unlike persons with

paranoid schizophrenia, those with personality disorders have no hallucinations or formal thought disorder. Paranoid personality disorder can be distinguished from borderline personality disorder because patients who are paranoid are rarely capable of overly involved, tumultuous relationships with others. Patients with paranoia lack the long history of antisocial behavior of persons with antisocial character. Persons with schizoid personality disorder are withdrawn and aloof and do not have paranoid ideation.

Course and Prognosis

No adequate, systematic long-term studies of paranoid personality disorder have been conducted. In some, paranoid personality disorder is lifelong; in others, it is a harbinger of schizophrenia. In still others, paranoid traits give way to reaction formation, appropriate concern with morality, and altruistic concerns as they mature or as stress diminishes. In general, however, those with paranoid personality disorder have lifelong problems working and living with others. Occupational and marital problems are common.

Treatment

Psychotherapy. Psychotherapy is the treatment of choice for those with paranoid personality disorder. Therapists should be straightforward in all their dealings with these patients. If a therapist is accused of inconsistency or a fault, such as lateness for an appointment, honesty and an apology are preferable to a defensive explanation. Therapists must remember that trust and toleration of intimacy are troubled areas for patients with this disorder. Individual psychotherapy thus requires a professional and not overly warm style from therapists. Clinicians' overzealous use of interpretation—especially interpretation about deep feelings of dependence, sexual concerns, and wishes for intimacy—increases patients' mistrust significantly. Patients who are paranoid usually do not do well in group psychotherapy, although it can be useful for improving social skills and diminishing suspiciousness through role playing. Many cannot tolerate the intrusiveness of behavior therapy, also used for social skills training.

At times, patients with paranoid personality disorder behave so threateningly that therapists must control or set limits on their actions. Delusional accusations must be dealt with realistically but gently and without humiliating patients. Patients who are paranoid are profoundly frightened when they feel that those trying to help them are weak and helpless; therefore, therapists should never offer to take control unless they are willing and able to do so.

Pharmacotherapy. Pharmacotherapy is useful in dealing with agitation and anxiety. In most cases, an antianxiety agent such as diazepam (Valium) suffices. It may be necessary, however, to use an antipsychotic such as haloperidol (Haldol) in small dosages and for brief periods to manage severe agitation or quasi-delusional thinking. The antipsychotic drug pimozide (Orap) has successfully reduced paranoid ideation in some patients.

SCHIZOID PERSONALITY DISORDER

Schizoid personality disorder is characterized by a lifelong pattern of social withdrawal. Persons with schizoid personality disorder are often seen by others as eccentric, isolated, or lonely. Their discomfort with human interaction; their introversion; and their bland, constricted affect are noteworthy.

Epidemiology

The prevalence of schizoid personality disorder is not clearly established, but the disorder may affect 5 percent of the general population. The sex ratio of the disorder is unknown; some studies report a 2-to-1 male-to-female ratio. Persons with the disorder tend to gravitate toward solitary jobs that involve little or no contact with others. Many prefer night work to day work so that they need not deal with many persons.

Diagnosis

On an initial psychiatric examination, patients with schizoid personality disorder may appear ill at ease. They rarely tolerate eye contact, and interviewers may surmise that such patients are eager for the interview to end. Their affect may be constricted, aloof, or inappropriately serious, but underneath the aloofness, sensitive clinicians can recognize fear. These patients find it difficult to be lighthearted: Their efforts at humor may seem adolescent and off the mark. Their speech is goal directed, but they are likely to give short answers to questions and to avoid spontaneous conversation. They may occasionally use unusual figures of speech, such as an odd metaphor, and may be fascinated with inanimate objects or metaphysical constructs. Their mental content may reveal an unwarranted sense of intimacy with persons they do not know well or whom they have not seen for a long time. Their sensorium is intact, their memory functions well, and their proverbial interpretations are abstract. The DSM-5 diagnostic criteria are listed in [Table 22-2](#).

Table 22-2
DSM-5 Diagnostic Criteria for Schizoid Personality Disorder

- A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
1. Neither desires nor enjoys close relationships, including being part of a family.
 2. Almost always chooses solitary activities.
 3. Has little, if any, interest in having sexual experiences with another person.
 4. Takes pleasure in few, if any, activities.
 5. Lacks close friends or confidants other than first-degree relatives.
 6. Appears indifferent to the praise or criticism of others.
 7. Shows emotional coldness, detachment, or flattened affectivity.
- B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder and is not attributable to the physiological effects of another medical condition.
- Note:** If criteria are met prior to the onset of schizophrenia, add "premorbid," i.e., "schizoid personality disorder (premorbid)."

Clinical Features

Persons with schizoid personality disorder seem to be cold and aloof; they display a remote reserve and show no involvement with everyday events and the concerns of others. They appear quiet, distant, seclusive, and unsociable. They may pursue their own lives with remarkably little need or longing for emotional ties, and they are the last to be aware of changes in popular fashion.

The life histories of such persons reflect solitary interests and success at noncompetitive, lonely jobs that others find difficult to tolerate. Their sexual lives may exist exclusively in fantasy, and they may postpone mature sexuality indefinitely. Men may not marry because they are unable to achieve intimacy; women may passively agree to marry an aggressive man who wants the marriage. Persons with schizoid personality disorder usually reveal a lifelong inability to express anger directly. They can invest enormous affective energy in nonhuman interests, such as mathematics and astronomy, and they may be very attached to animals. Dietary and health fads, philosophical movements, and social improvement schemes, especially those that require no personal involvement, often engross them.

Although persons with schizoid personality disorder appear self-absorbed and lost in daydreams, they have a normal capacity to recognize reality. Because aggressive acts are rarely included in their repertoire of usual responses, most threats, real or imagined, are dealt with by fantasized omnipotence or resignation. They are often seen as aloof, yet such persons can sometimes conceive, develop, and give to the world genuinely original, creative ideas.

Differential Diagnosis

Schizoid personality disorder is distinguished from schizophrenia, delusional disorder, and affective disorder with psychotic features based on periods with positive psychotic symptoms, such as delusions and hallucinations in the latter. Although patients with paranoid personality disorder share many traits with those with schizoid personality disorder, the former exhibit more social engagement, a history of aggressive verbal behavior, and a greater tendency to project their feelings onto others. If just as emotionally constricted, patients with obsessive-compulsive and avoidant personality disorders experience loneliness as dysphoric, possess a richer history of past object relations, and do not engage as much in autistic reverie. Theoretically, the chief distinction between a patient with schizotypal personality disorder and one with schizoid personality disorder is that the patient who is schizotypal is more similar to a patient with schizophrenia in oddities of perception, thought, behavior, and communication. Patients with avoidant personality disorder are isolated but strongly wish to participate in activities, a characteristic absent in those with schizoid personality disorder. Schizoid personality disorder is distinguished from autistic disorder and Asperger's syndrome by more severely impaired social interactions and stereotypical behaviors and interests than in those two disorders.

Course and Prognosis

The onset of schizoid personality disorder usually occurs in early childhood or adolescence. As with all personality disorders, schizoid personality disorder is long lasting but not necessarily lifelong. The proportion of patients who incur schizophrenia is unknown.

Treatment

Psychotherapy. The treatment of patients with schizoid personality disorder is similar to that of those with paranoid personality disorder. Patients who are schizoid tend toward introspection; however, these tendencies are consistent with psychotherapists' expectations, and such patients may become devoted, if distant, patients. As trust develops, patients who are schizoid may, with great trepidation, reveal a plethora of fantasies, imaginary friends, and fears of unbearable dependence—even of merging with the therapist.

In group therapy settings, patients with schizoid personality disorder may be silent for long periods; nonetheless, they do become involved. The patients should be protected against aggressive attack by group members for their proclivity to be silent. With time, the group members become important to patients who are schizoid and may provide the only social contact in their otherwise isolated existence.

Pharmacotherapy. Pharmacotherapy with small dosages of antipsychotics, antidepressants, and psychostimulants has benefitted some patients. Serotonergic agents may make patients less sensitive to rejection. Benzodiazepines may help diminish interpersonal anxiety.

SCHIZOTYPAL PERSONALITY DISORDER

Persons with schizotypal personality disorder are strikingly odd or strange, even to laypersons. Magical thinking, peculiar notions, ideas of reference, illusions, and derealization are part of a schizotypal person's everyday world.

Epidemiology

Schizotypal personality disorder occurs in about 3 percent of the population. The sex ratio is unknown; however, it is frequently diagnosed in females with fragile X syndrome. DSM-5 suggests the disorder may be slightly more common in males. A greater association of cases exists among the biological relatives of patients with schizophrenia than among control participants and a higher incidence among monozygotic twins than among dizygotic twins (33 percent vs. 4 percent in one study).

Etiology

Adoption, family, and twin studies demonstrate an increased prevalence of schizotypal features in the families of schizophrenic patients, especially when schizotypal features were not associated with comorbid affective symptoms.

Diagnosis

Schizotypal personality disorder is diagnosed on the basis of the patients' peculiarities of thinking, behavior, and appearance. Taking a history may be difficult because of the patients' unusual way of communicating. The DSM-5 diagnostic criteria for schizotypal personality disorder are given in [Table 22-3](#).

 **Table 22-3**
DSM-5 Diagnostic Criteria for Schizotypal Personality Disorder

- A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Ideas of reference (excluding delusions of reference).
 2. Odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations).
 3. Unusual perceptual experiences, including bodily illusions.
 4. Odd thinking or speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped).
 5. Suspiciousness or paranoid ideation.
 6. Inappropriate or constricted affect.
 7. Behavior or appearance that is odd, eccentric, or peculiar.
 8. Lack of close friends or confidants other than first-degree relatives.
 9. Excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self.
- B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder.
- Note:** If criteria are met prior to the onset of schizophrenia, add "premorbid," i.e., "schizotypal personality disorder (premorbid)."

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Patients with schizotypal personality disorder exhibit disturbed thinking and communicating. Although frank thought disorder is absent, their speech may be distinctive or peculiar, may have meaning only to them, and often needs interpretation. As with patients with schizophrenia, those with schizotypal personality disorder may not know their own feelings and yet are exquisitely sensitive to, and aware of, the feelings of others, especially negative affects such as anger. These patients may be superstitious or claim powers of clairvoyance and may believe that they have other special powers of thought and insight. Their inner world may be filled with vivid imaginary relationships and child-like fears and fantasies. They may admit to perceptual illusions or macropsia and confess that other persons seem wooden and all the same.

Because persons with schizotypal personality disorder have poor interpersonal relationships and may act inappropriately, they are isolated and have few, if any, friends. Patients may show features of borderline personality disorder, and indeed, both diagnoses can be made. Under stress, patients with schizotypal personality disorder may decompensate and have psychotic symptoms, but these are usually brief. Patients with severe cases of the disorder may exhibit anhedonia and severe depression.

Differential Diagnosis

Theoretically, persons with schizotypal personality disorder can be distinguished from those with schizoid and avoidant personality disorders by the presence of oddities in their behavior, thinking, perception, and communication and perhaps by a clear family history of schizophrenia. Patients with schizotypal personality disorder can be distinguished from those with schizophrenia by their absence of psychosis. If psychotic symptoms do appear, they are brief and fragmentary. Some patients meet the criteria for both schizotypal personality disorder and borderline personality disorder. Patients with paranoid personality disorder are characterized by suspiciousness but lack the odd behavior of patients with schizotypal personality disorder.

Course and Prognosis

According to current clinical thinking, the schizotype is the premorbid personality of the patient with schizophrenia. Some, however, maintain a stable schizotypal personality throughout their lives and marry and work, despite their oddities. A long-term study by Thomas McGlashan reported that 10 percent of those with schizotypal personality disorder eventually committed suicide.

Treatment

Psychotherapy. The principles of treatment of schizotypal personality disorder do not differ from those of schizoid personality disorder, but clinicians must deal sensitively with the former. These patients have peculiar patterns of thinking, and some are involved in cults, strange religious practices, and the occult. Therapists must not ridicule such activities or be judgmental about these beliefs or activities.

Pharmacotherapy. Antipsychotic medication may be useful in dealing with ideas of reference, illusions, and other symptoms of the disorder and can be used in conjunction with psychotherapy. Antidepressants are useful when a depressive component of the personality is present.

ANTISOCIAL PERSONALITY DISORDER

Antisocial personality disorder is an inability to conform to the social norms that ordinarily govern many aspects of a person's adolescent and adult behavior. Although characterized by continual antisocial or criminal acts, the disorder is not synonymous with criminality.

Epidemiology

The 12-month prevalence rates of antisocial personality disorder are between 0.2 and 3 percent according to DSM-5. It is more common in poor urban areas and among mobile residents of these areas. The highest prevalence of antisocial personality disorder is found among the most severe samples of men with alcohol use disorder (over 70 percent) and in prison populations, where the prevalence may be as high as 75 percent. It is much more common in males than in females. Boys with the disorder come from larger families than girls with the disorder. The onset of the disorder is before the age of 15 years. Girls usually have symptoms before puberty and boys even earlier. A familial pattern is present; the disorder is five times more common among first-degree relatives of men with the disorder than among control participants.

Diagnosis

Patients with antisocial personality disorder can fool even the most experienced clinicians. In an interview, patients can appear composed and credible, but beneath the veneer (or, to use Hervey Cleckley's term, *the mask of sanity*) lurks tension, hostility, irritability, and rage. A stress interview, in which patients are vigorously confronted with inconsistencies in their histories, may be necessary to reveal the pathology.

A diagnostic workup should include a thorough neurological examination. Because patients often show abnormal EEG results and soft neurological signs suggesting minimal brain damage in childhood, these findings can be used to confirm the clinical impression. The DSM-5 diagnostic criteria are listed in [Table 22-4](#).

 **Table 22-4**
DSM-5 Diagnostic Criteria for Antisocial Personality Disorder

- A. A pervasive pattern of disregard for and violation of the rights of others, occurring since age 15 years, as indicated by three (or more) of the following:
1. Failure to conform to social norms with respect to lawful behaviors, as indicated by repeatedly performing acts that are grounds for arrest.
 2. Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure.
 3. Impulsivity or failure to plan ahead.
 4. Irritability and aggressiveness, as indicated by repeated physical fights or assaults.
 5. Reckless disregard for safety of self or others.
 6. Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations.
 7. Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another.
- B. The individual is at least age 18 years.
C. There is evidence of conduct disorder with onset before age 15 years.
D. The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or bipolar disorder.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Patients with antisocial personality disorder can often seem to be normal and even charming and ingratiating. Their histories, however, reveal many areas of disordered life functioning. Lying, truancy, running away from home, thefts, fights, substance abuse, and illegal activities are typical experiences that patients report as beginning in childhood. These patients often impress opposite-sex clinicians with the colorful, seductive aspects of their personalities, but same-sex clinicians may regard them as manipulative and demanding. Patients with antisocial personality disorder exhibit no anxiety or depression, a lack that may seem grossly incongruous with their situations, although suicide threats and somatic preoccupations may be common. Their own explanations of their antisocial behavior make it seem mindless, but their mental content reveals the complete absence of delusions and other signs of irrational thinking. In fact, they frequently have a heightened sense of reality testing and often impress observers as having good verbal intelligence.

Persons with antisocial personality disorder are highly representative of so-called con men. They are extremely manipulative and can frequently talk others into participating in schemes for easy ways to make money or to achieve fame or notoriety. These schemes may eventually lead the unwary to financial ruin or social embarrassment or both. Those with this disorder do not tell the truth and cannot be trusted to carry out any task or adhere to any conventional standard of morality. Promiscuity, spousal abuse, child abuse, and drunk driving are common events in their lives. A notable finding is a lack of remorse for these actions; that is, they appear to lack a conscience.

Differential Diagnosis

Antisocial personality disorder can be distinguished from illegal behavior in that antisocial personality disorder involves many areas of a person's life. When illegal behavior is only for gain and is not accompanied by the rigid, maladaptive, and persistent personality traits characteristic of a personality disorder, it is classified as criminal behavior not associated with a personality disorder according to DSM-5.

Dorothy Lewis found that many of these persons have a neurological or mental disorder that has been either overlooked or undiagnosed. More difficult is the differentiation of antisocial personality disorder from substance abuse. When both substance abuse and antisocial behavior begin in childhood and continue into adult life, both disorders should be diagnosed. When, however, the antisocial behavior is clearly secondary to premonitory alcohol abuse or other substance abuse, the diagnosis of antisocial personality disorder is not warranted.

In diagnosing antisocial personality disorder, clinicians must adjust for the distorting effects of socioeconomic status, cultural background, and sex. Furthermore, the diagnosis of antisocial personality disorder is not warranted when intellectual disability, schizophrenia, or mania can explain the symptoms.

Course and Prognosis

When an antisocial personality disorder develops, it runs an unremitting course, with the height of antisocial behavior usually occurring in late adolescence. The prognosis varies. Some reports indicate that symptoms decrease as persons grow older. Many patients have somatization disorder and multiple physical complaints. Depressive disorders, alcohol use disorders, and other substance abuse are common.

Treatment

Psychotherapy. If patients with antisocial personality disorder are immobilized (e.g., placed in hospitals), they often become amenable to psychotherapy. When patients feel that they are among peers, their lack of motivation for change disappears. Perhaps for this reason, self-help groups have been more useful than jails in alleviating the disorder.

Before treatment can begin, firm limits are essential. Therapists must find ways of dealing with patients' self-destructive behavior. And to overcome patients' fear of intimacy, therapists must frustrate patients' desire to run from honest human encounters. In doing so, therapists face the challenge of separating control from punishment and of separating help and confrontation from social isolation and retribution.

Pharmacotherapy. Pharmacotherapy is used to deal with incapacitating symptoms such as anxiety, rage, and depression, but because patients are often substance abusers, drugs must be used judiciously. If a patient shows evidence of attention-deficit/hyperactivity disorder, psychostimulants such as methylphenidate (Ritalin) may be useful. Attempts have been made to alter catecholamine metabolism with drugs and to control impulsive behavior with antiepileptic drugs, for example, carbamazepine (Tegretol) or valproate (Depakote), especially if

abnormal waveforms are noted on an EEG. β -Adrenergic receptor antagonists have been used to reduce aggression.

BORDERLINE PERSONALITY DISORDER

Patients with borderline personality disorder stand on the border between neurosis and psychosis, and they are characterized by extraordinarily unstable affect, mood, behavior, object relations, and self-image. The disorder has also been called *ambulatory schizophrenia*, *as-if personality* (a term coined by Helene Deutsch), *pseudoneurotic schizophrenia* (described by Paul Hoch and Phillip Politan), and *psychotic character disorder* (described by John Frosch). The 10th revision of the *International Classification of Diseases 10* (ICD-10) uses the term *emotionally unstable personality disorder*.

Epidemiology

No definitive prevalence studies are available, but borderline personality disorder is thought to be present in about 1 to 2 percent of the population and is twice as common in women as in men. An increased prevalence of major depressive disorder, alcohol use disorders, and substance abuse is found in first-degree relatives of persons with borderline personality disorder.

Diagnosis

According to DSM-5, the diagnosis of borderline personality disorder can be made by early adulthood when patients show at least five of the criteria listed in Table 22-5. Biological studies may aid in the diagnosis; some patients with borderline personality disorder show shortened REM latency and sleep continuity disturbances, abnormal DST results, and abnormal thyrotropin-releasing hormone test results. Those changes, however, are also seen in some patients with depressive disorders.

Table 22-5
DSM-5 Diagnostic Criteria for Borderline Personality Disorder

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment.
(**Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5).
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). (**Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5.)
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
9. Transient, stress-related paranoid ideation or severe dissociative symptoms.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Persons with borderline personality disorder almost always appear to be in a state of crisis. Mood swings are common. Patients can be argumentative at one moment, depressed the next, and later complain of having no feelings. Patients can have short-lived psychotic episodes (so-called *micropsychotic episodes*) rather than full-blown psychotic breaks, and the psychotic symptoms of these patients are almost always circumscribed, fleeting, or doubtful. The behavior of patients with borderline personality disorder is highly unpredictable, and their achievements are rarely at the level of their abilities. The painful nature of their lives is reflected in repetitive self-destructive acts. Such patients may slash their wrists and perform other self-mutilations to elicit help from others, to express anger, or to numb themselves to overwhelming affect.

Because they feel both dependent and hostile, persons with this disorder have tumultuous interpersonal relationships. They can be dependent on those with whom they are close and, when frustrated, can express enormous anger toward their intimate friends. Patients with borderline personality disorder cannot tolerate being alone, and they prefer a frantic search for companionship, no matter how unsatisfactory, to their own company. To assuage loneliness, if only for brief periods, they accept a stranger as a friend or behave promiscuously. They often complain about chronic feelings of emptiness and boredom and the lack of a consistent sense of identity (identity diffusion); when pressed, they often complain about how depressed they usually feel, despite the flurry of other affects.

Otto Kernberg described the defense mechanism of projective identification that occurs in patients with borderline personality disorder. In this primitive defense mechanism, intolerable aspects of the self are projected onto another; the other person is induced to play the projected role, and the two persons act in unison. Therapists must be aware of this process so they can act neutrally toward such patients.

Most therapists agree that these patients show ordinary reasoning abilities on structured tests, such as the Wechsler Adult Intelligence Scale, and show deviant processes only on unstructured projective tests, such as the Rorschach test.

Functionally, patients with borderline personality disorder distort their relationships by considering each person to be either all good or all bad. They see persons as either nurturing attachment figures or as hateful, sadistic figures who deprive them of security needs and threaten them with abandonment whenever they feel dependent. As a result of this splitting, the good person is idealized and the bad person devalued. Shifts of allegiance from one person or group to another are frequent. Some clinicians use the concepts of panphobia, pananxiety, panambivalence, and chaotic sexuality to delineate these patients' characteristics.

Differential Diagnosis

The disorder is differentiated from schizophrenia on the basis that the patient with borderline personality lacks prolonged psychotic episodes, thought disorder, and other classic schizophrenic signs. Patients with schizotypal personality disorder show marked peculiarities of

thinking, strange ideation, and recurrent ideas of reference. Those with paranoid personality disorder are marked by extreme suspiciousness. Patients with borderline personality disorder generally have chronic feelings of emptiness and short-lived psychotic episodes; they act impulsively and demand extraordinary relationships; they may mutilate themselves and make manipulative suicide attempts.

Course and Prognosis

Borderline personality disorder is fairly stable; patients change little over time. Longitudinal studies show no progression toward schizophrenia, but patients have a high incidence of major depressive disorder episodes. The diagnosis is usually made before the age of 40 years, when patients are attempting to make occupational, marital, and other choices and are unable to deal with the normal stages of the life cycle.

Treatment

Psychotherapy. Psychotherapy for patients with borderline personality disorder is an area of intensive investigation and has been the treatment of choice. For best results, pharmacotherapy has been added to the treatment regimen.

Psychotherapy is difficult for the patient and therapist alike. Patients regress easily, act out their impulses, and show labile or fixed negative or positive transferences, which are difficult to analyze. Projective identification may also cause countertransference problems when therapists are unaware that patients are unconsciously trying to coerce them to act out a particular behavior. The splitting defense mechanism causes patients to alternately love and hate therapists and others in the environment. A reality-oriented approach is more effective than in-depth interpretations of the unconscious.

Therapists have used behavior therapy to control patients' impulses and angry outbursts and to reduce their sensitivity to criticism and rejection. Social skills training, especially with videotape playback, helps enable patients to see how their actions affect others and thereby improve their interpersonal behavior.

Patients with borderline personality disorder often do well in a hospital setting in which they receive intensive psychotherapy on both an individual and a group basis. In a hospital, they can also interact with trained staff members from a variety of disciplines and can be provided with occupational, recreational, and vocational therapy. Such programs are especially helpful when the home environment is detrimental to a patient's rehabilitation because of intrafamilial conflicts or other stresses, such as parental abuse. Within the protected environment of the hospital, patients who are excessively impulsive, self-destructive, or self-mutilating can be given limits, and their actions can be observed. Under ideal circumstances, patients remain in the hospital until they show marked improvement, up to 1 year in some cases. Patients can then be discharged to special support systems, such as day hospitals, night hospitals, and halfway houses.

DIALECTICAL BEHAVIOR THERAPY. A particular form of psychotherapy called dialectical behavior therapy (DBT) has been used for patients with borderline personality disorder, especially those with parasuicidal behavior, such as frequent cutting. For further discussion of DBT, see [Section 29.5](#) in [Chapter 29](#).

MENTALIZATION-BASED TREATMENT. Another type of psychotherapy for borderline personality disorder is called mentalization-based therapy (MBT). Mentalization is a social construct that allows a person to be attentive to the mental states of oneself and of others; it comes from a person's awareness of mental processes and subjective states that arise in interpersonal interactions. MBT is based on a theory that borderline personality symptoms, such as difficulty regulating emotions and managing impulsivity, are a result of patients' reduced capacities to mentalize. Thus, it is believed that recovery of mentalization helps patients build relationship skills as they learn to better regulate their thoughts and feelings. MBT was found to be effective for borderline personality disorder in several randomized, controlled research trials.

TRANSFERENCE-FOCUSED PSYCHOTHERAPY. Transference-focused psychotherapy (TFP) is a modified form of psychodynamic psychotherapy used for the treatment of borderline personality disorder that is based on Otto Kernberg's object relations theory. The therapist relies on two major processes in working with the patient: The first is clarification, in which the transference is analyzed more directly than in traditional psychotherapy so that the patient becomes quickly aware of his or her distortions about the therapist. The second is confrontation, whereby the therapist points out how these transference distortions interfere with interpersonal relations toward others (objects). The mechanism of splitting used by borderline patients is characterized by their having a good object and a bad object and is used as a defense against anxiety. If therapy is successful, then the need for splitting diminishes, object relations are improved, and a more normal level of functioning is achieved. Studies comparing TFP, DBT, psychodynamic psychotherapy, and supportive psychotherapy show that all are useful and all show varying degrees of success. As yet, no consensus has been reached as to which, if any, of these is superior to the others.

Pharmacotherapy. Pharmacotherapy is useful to deal with specific personality features that interfere with patients' overall functioning. Antipsychotics have been used to control anger, hostility, and brief psychotic episodes. Antidepressants improve the depressed mood common in patients with borderline personality disorder. The MAO inhibitors (MAOIs) have successfully modulated impulsive behavior in some patients. Benzodiazepines, particularly alprazolam (Xanax), help anxiety and depression, but some patients show a disinhibition with this class of drugs. Anticonvulsants, such as carbamazepine, may improve global functioning for some patients. Serotonergic agents such as selective serotonin reuptake inhibitors (SSRIs) have been helpful in some cases.

HISTRIONIC PERSONALITY DISORDER

Persons with histrionic personality disorder are excitable and emotional and behave in a colorful, dramatic, extroverted fashion. Accompanying their flamboyant aspects, however, is often an inability to maintain deep, long-lasting attachments.

Epidemiology

Limited data from general population studies suggest a prevalence of histrionic personality disorder of about 1 to 3 percent. Rates of about 10 to 15 percent have been reported in inpatient and outpatient mental health settings when structured assessment is used. The disorder is diagnosed more frequently in women than in men. Some studies have found an association with somatization disorder and alcohol use disorders.

Diagnosis

In interviews, patients with histrionic personality disorder are generally cooperative and eager to give a detailed history. Gestures and dramatic punctuation in their conversations are common; they may make frequent slips of the tongue, and their language is colorful. Affective display is common, but when pressed to acknowledge certain feelings (e.g., anger, sadness, and sexual wishes), they may respond with surprise, indignation, or denial. The results of the cognitive examination are usually normal, although a lack of perseverance may be shown on arithmetic or concentration tasks, and the patients' forgetfulness of affect-laden material may be astonishing. DSM-5 diagnostic criteria are listed in [Table 22-6](#).

Table 22.6

DSM-5 Diagnostic Criteria for Histrionic Personality Disorder

A pervasive pattern of excessive emotionality and attention seeking, beginning in early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Is uncomfortable in situations in which he or she is not the center of attention.
2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior.
3. Displays rapidly shifting and shallow expression of emotions.
4. Consistently uses physical appearance to draw attention to self.
5. Has a style of speech that is excessively impressionistic and lacking in detail.
6. Shows self-dramatization, theatricality, and exaggerated expression of emotion.
7. Is suggestible (i.e., easily influenced by others or circumstances).
8. Considers relationships to be more intimate than they actually are.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Persons with histrionic personality disorder show a high degree of attention-seeking behavior. They tend to exaggerate their thoughts and feelings and make everything sound more important than it really is. They display temper tantrums, tears, and accusations when they are not the center of attention or are not receiving praise or approval.

Seductive behavior is common in both sexes. Sexual fantasies about persons with whom patients are involved are common, but patients are inconsistent about verbalizing these fantasies and may be coy or flirtatious rather than sexually aggressive. In fact, histrionic patients may have a psychosexual dysfunction; women may be anorgasmic, and men may be impotent. Their need for reassurance is endless. They may act on their sexual impulses to reassure themselves that they are attractive to the other sex. Their relationships tend to be superficial, however, and they can be vain, self-absorbed, and fickle. Their strong dependence needs make them overly trusting and gullible.

The major defenses of patients with histrionic personality disorder are repression and dissociation. Accordingly, such patients are unaware of their true feelings and cannot explain their motivations. Under stress, reality testing easily becomes impaired.

Differential Diagnosis

Distinguishing between histrionic personality disorder and borderline personality disorder is difficult, but in borderline personality disorder, suicide attempts, identity diffusion, and brief psychotic episodes are more likely. Although both conditions may be diagnosed in the same patient, clinicians should separate the two. Somatization disorder (Briquet's syndrome) may occur in conjunction with histrionic personality disorder. Patients with brief psychotic disorder and dissociative disorders may warrant a coexisting diagnosis of histrionic personality disorder.

Course and Prognosis

With age, persons with histrionic personality disorder show fewer symptoms, but because they lack the energy of earlier years, the difference in number of symptoms may be more apparent than real. Persons with this disorder are sensation seekers, and they may get into trouble with the law, abuse substances, and act promiscuously.

Treatment

Psychotherapy. Patients with histrionic personality disorder are often unaware of their own real feelings; clarification of their inner feelings is an important therapeutic process. Psychoanalytically oriented psychotherapy, whether group or individual, is probably the treatment of choice for histrionic personality disorder.

Pharmacotherapy. Pharmacotherapy can be adjunctive when symptoms are targeted (e.g., the use of antidepressants for depression and somatic complaints, anti-anxiety agents for anxiety, and antipsychotics for derealization and illusions).

NARCISSISTIC PERSONALITY DISORDER

Persons with narcissistic personality disorder are characterized by a heightened sense of self-importance, lack of empathy, and grandiose feelings of uniqueness. Underneath, however, their self-esteem is fragile and vulnerable to even minor criticism.

Epidemiology

According to DSM-5, estimates of the prevalence of narcissistic personality disorder range from less than 1 to 6 percent in community samples. Persons with the disorder may impart an unrealistic sense of omnipotence, grandiosity, beauty, and talent to their children; thus, offspring of such parents may have a higher than usual risk for developing the disorder themselves.

Diagnosis

Table 22-7 gives the DSM-5 diagnostic criteria for narcissistic personality disorder.

Table 22-7
DSM-5 Diagnostic Criteria for Narcissistic Personality Disorder

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements).
2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love.
3. Believes that he or she is "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions).
4. Requires excessive admiration.
5. Has a sense of entitlement (i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations).
6. Is interpersonally exploitative (i.e., takes advantage of others to achieve his or her own ends).
7. Lacks empathy: is unwilling to recognize or identify with the feelings and needs of others.
8. Is often envious of others or believes that others are envious of him or her.
9. Shows arrogant, haughty behaviors or attitudes.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Persons with narcissistic personality disorder have a grandiose sense of self-importance; they consider themselves special and expect special treatment. Their sense of entitlement is striking. They handle criticism poorly and may become enraged when someone dares to criticize them, or they may appear completely indifferent to criticism. Persons with this disorder want their own way and are frequently ambitious to achieve fame and fortune. Their relationships are tenuous, and they can make others furious by their refusal to obey conventional rules of behavior. Interpersonal exploitiveness is commonplace. They cannot show empathy, and they feign sympathy only to achieve their own selfish ends. Because of their fragile self-esteem, they are susceptible to depression. Interpersonal difficulties, occupational problems, rejection, and loss are among the stresses that narcissists commonly produce by their behavior—stresses they are least able to handle.

Differential Diagnosis

Borderline, histrionic, and antisocial personality disorders often accompany narcissistic personality disorder, so a differential diagnosis is difficult. Patients with narcissistic personality disorder have less anxiety than those with borderline personality disorder; their lives tend to be less chaotic, and they are less likely to attempt suicide. Patients with antisocial personality disorder have a history of impulsive behavior, often associated with alcohol or other substance abuse, which frequently gets them into trouble with the law. Patients with histrionic personality disorder show features of exhibitionism and interpersonal manipulativeness that resemble those of patients with narcissistic personality disorder.

Course and Prognosis

Narcissistic personality disorder is chronic and difficult to treat. Patients with the disorder must constantly deal with blows to their narcissism resulting from their own behavior or from life experience. Aging is handled poorly; patients value beauty, strength, and youthful attributes, to which they cling inappropriately. They may be more vulnerable, therefore, to midlife crises than are other groups.

Treatment

Psychotherapy. Because patients must renounce their narcissism to make progress, the treatment of narcissistic personality disorder is difficult. Psychiatrists such as Kernberg and Heinz Kohut have advocated using psychoanalytic approaches to effect change, but much research is required to validate the diagnosis and to determine the best treatment. Some clinicians advocate group therapy for their patients so they can learn how to share with others and, under ideal circumstances, can develop an empathic response to others.

Pharmacotherapy. Lithium (Eskalith) has been used with patients whose clinical picture includes mood swings. Because patients with narcissistic personality disorder tolerate rejection poorly and are susceptible to depression, antidepressants, especially serotonergic drugs, may also be of use.

AVOIDANT PERSONALITY DISORDER

Persons with avoidant personality disorder show extreme sensitivity to rejection and may lead socially withdrawn lives. Although shy, they are not asocial and show a great desire for companionship, but they need unusually strong guarantees of uncritical acceptance. Such persons are commonly described as having an inferiority complex.

Epidemiology

The prevalence of the disorder is suggested to be about 2 to 3 percent of the general population according to DSM-5. No information is available on sex ratio or familial pattern. Infants classified as having a timid temperament may be more susceptible to the disorder than those who score high on activity-approach scales.

Diagnosis

In clinical interviews, patients' most striking aspect is anxiety about talking with an interviewer. Their nervous and tense manner appears to wax and wane with their perception of whether an interviewer likes them. They seem vulnerable to the interviewer's comments and suggestions and may regard a clarification or interpretation as criticism. The DSM-5 diagnostic criteria for avoidant personality disorder are listed in [Table 22-8](#).

Table 22-8
DSM-5 Diagnostic Criteria for Avoidant Personality Disorder

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Avoids occupational activities that involve significant interpersonal contact because of fears of criticism, disapproval, or rejection.
2. Is unwilling to get involved with people unless certain of being liked.
3. Shows restraint within intimate relationships because of the fear of being shamed or ridiculed.
4. Is preoccupied with being criticized or rejected in social situations.
5. Is inhibited in new interpersonal situations because of feelings of inadequacy.
6. Views self as socially inept, personally unappealing, or inferior to others.
7. Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Hypersensitivity to rejection by others is the central clinical feature of avoidant personality disorder, and patients' main personality trait is timidity. These persons desire the warmth and security of human companionship but justify their avoidance of relationships by their alleged fear of rejection. When talking with someone, they express uncertainty, show a lack of self-confidence, and may speak in a self-effacing manner. Because they are hypervigilant about rejection, they are afraid to speak up in public or to make requests of others. They are apt to misinterpret other persons' comments as derogatory or ridiculing. The refusal of any request leads them to withdraw from others and to feel hurt.

In the vocational sphere, patients with avoidant personality disorder often take jobs on the sidelines. They rarely attain much personal advancement or exercise much authority but seem shy and eager to please. These persons are generally unwilling to enter relationships unless they are given an unusually strong guarantee of uncritical acceptance. Consequently, they often have no close friends or confidants.

Differential Diagnosis

Patients with avoidant personality disorder desire social interaction, unlike patients with schizoid personality disorder, who want to be alone. Patients with avoidant personality disorder are not as demanding, irritable, or unpredictable as those with borderline and histrionic personality disorders. Avoidant personality disorder and dependent personality disorder are similar. Patients with dependent personality disorder are presumed to have a greater fear of being abandoned or unloved than those with avoidant personality disorder, but the clinical picture may be indistinguishable.

Course and Prognosis

Many persons with avoidant personality disorder are able to function in a protected environment. Some marry, have children, and live their lives surrounded only by family members. If their support system fails, however, they are subject to depression, anxiety, and anger. Phobic avoidance is common, and patients with the disorder may give histories of social phobia or incur social phobia in the course of their illness.

Treatment

Psychotherapy. Psychotherapeutic treatment depends on solidifying an alliance with patients. As trust develops, a therapist must convey an accepting attitude toward the patient's fears, especially the fear of rejection. The therapist eventually encourages a patient to move out into the world to take what are perceived as great risks of humiliation, rejection, and failure. But therapists should be cautious when giving assignments to exercise new social skills outside therapy; failure can reinforce a patient's already poor self-esteem. Group therapy may help patients understand how their sensitivity to rejection affects them and others. Assertiveness training is a form of behavior therapy that may teach patients to express their needs openly and to enlarge their self-esteem.

Pharmacotherapy. Pharmacotherapy has been used to manage anxiety and depression when they are associated with the disorder. Some patients are helped by β -adrenergic receptor antagonists, such as atenolol (Tenormin), to manage autonomic nervous system hyperactivity, which tends to be high in patients with avoidant personality disorder, especially when they approach feared situations. Serotonergic agents may help rejection sensitivity. Theoretically, dopaminergic drugs might engender novelty-seeking behavior in these patients; however, the patient must be psychologically prepared for any new experience that might result.

DEPENDENT PERSONALITY DISORDER

Persons with dependent personality disorder subordinate their own needs to those of others, get others to assume responsibility for major areas of their lives, lack self-confidence, and may experience intense discomfort when alone for more than a brief period. The disorder has been called *passive-dependent personality*. Freud described an oral-dependent personality dimension characterized by dependence, pessimism, fear of sexuality, self-doubt, passivity, suggestibility, and lack of perseverance; his description is similar to the DSM-5 categorization of dependent personality disorder.

Epidemiology

Dependent personality disorder is more common in women than in men. DSM-5 reports an estimated prevalence of 0.6 percent. One study diagnosed 2.5 percent of all personality disorders as falling into this category. It is more common in young children than in older ones. Persons with chronic physical illness in childhood may be most susceptible to the disorder.

Diagnosis

In interviews, patients appear compliant. They try to cooperate, welcome specific questions, and look for guidance. The DSM-5 diagnostic criteria for dependent personality disorder are listed in [Table 22-9](#).

Table 22-9

DSM-5 Diagnostic Criteria for Dependent Personality Disorder

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others.
2. Needs others to assume responsibility for most major areas of his or her life.
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval. (**Note:** Do not include realistic fears of retribution.)
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy).
5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant.
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself.
7. Urgently seeks another relationship as a source of care or support when a close relationship ends.
8. Is unrealistically preoccupied with fears of being left to take care of himself or herself.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Dependent personality disorder is characterized by a pervasive pattern of dependent and submissive behavior. Persons with the disorder cannot make decisions without an excessive amount of advice and reassurance from others. They avoid positions of responsibility and become anxious if asked to assume a leadership role. They prefer to be submissive. When on their own, they find it difficult to persevere at tasks but may find it easy to perform these tasks for someone else.

Because persons with the disorder do not like to be alone, they seek out others on whom they can depend; their relationships, thus, are distorted by their need to be attached to another person. In folie à deux (shared psychotic disorder), one member of the pair usually has dependent personality disorder; the submissive partner takes on the delusional system of the more aggressive, assertive partner on whom he or she depends.

Pessimism, self-doubt, passivity, and fears of expressing sexual and aggressive feelings all typify the behavior of persons with dependent personality disorder. An abusive, unfaithful, or alcoholic spouse may be tolerated for long periods to avoid disturbing the sense of attachment.

Differential Diagnosis

The traits of dependence are found in many psychiatric disorders, so the differential diagnosis is difficult. Dependence is a prominent factor in patients with histrionic and borderline personality disorders, but those with dependent personality disorder usually have a long-term relationship with one person rather than a series of persons on whom they are dependent, and they do not tend to be overtly manipulative. Patients with schizoid and schizotypal personality disorders may be indistinguishable from those with avoidant personality disorder. Dependent behavior can also occur in patients with agoraphobia, but these patients tend to have a high level of overt anxiety or even panic.

Course and Prognosis

Little is known about the course of dependent personality disorder. Occupational functioning tends to be impaired because persons with the disorder cannot act independently and without close supervision. Social relationships are limited to those on whom they can depend, and many suffer physical or mental abuse because they cannot assert themselves. They risk major depressive disorder if they lose the person on whom they depend, but with treatment, the prognosis is favorable.

Treatment

Psychotherapy. The treatment of dependent personality disorder is often successful. Insight-oriented therapies enable patients to understand the antecedents of their behavior, and with the support of a therapist, patients can become more independent, assertive, and self-reliant. Behavioral therapy, assertiveness training, family therapy, and group therapy have all been used, with successful outcomes in many cases.

A pitfall may arise in treatment when a therapist encourages a patient to change the dynamics of a pathological relationship (e.g., supports a physically abused wife in seeking help from the police). At this point, patients may become anxious and unable to cooperate in therapy; they may feel torn between complying with the therapist and losing a pathological external relationship. Therapists must show great respect for these patients' feelings of attachment, no matter how pathological these feelings may seem.

Pharmacotherapy. Pharmacotherapy has been used to deal with specific symptoms, such as anxiety and depression, which are common associated features of dependent personality disorder. Patients who experience panic attacks or who have high levels of separation anxiety may be helped by imipramine (Tofranil). Benzodiazepines and serotonergic agents have also been useful. If a patient's depression or withdrawal symptoms respond to psychostimulants, they may be used.

OBSESSIVE-COMPULSIVE PERSONALITY DISORDER

Obsessive-compulsive personality disorder is characterized by emotional constriction, orderliness, perseverance, stubbornness, and indecisiveness. The essential feature of the disorder is a pervasive pattern of perfectionism and inflexibility.

Epidemiology

DSM-5 reports an estimated prevalence ranging from 2 to 8 percent. It is more common in men than in women and is diagnosed most often in oldest siblings. The disorder also occurs more frequently in first-degree biological relatives of persons with the disorder than in the general population. Patients often have backgrounds characterized by harsh discipline. Freud hypothesized that the disorder is associated with difficulties in the anal stage of psychosexual development, generally around the age of 2 years, but various studies have failed to validate this theory.

Diagnosis

In interviews, patients with obsessive-compulsive personality disorder may have a stiff, formal, and rigid demeanor. Their affect is not blunted or flat but can be described as constricted. They lack spontaneity, and their mood is usually serious. Such patients may be anxious about not being in control of the interview. Their answers to questions are unusually detailed. The defense mechanisms they use are rationalization, isolation, intellectualization, reaction formation, and undoing. The DSM-5 diagnostic criteria for obsessive-compulsive personality disorder are listed in Table 22-10.

Table 22-10
DSM-5 Diagnostic Criteria for Obsessive-Compulsive Personality Disorder

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost.
2. Shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met).
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity).
4. Is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification).
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value.
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things.
7. Adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes.
8. Shows rigidity and stubbornness.

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

Clinical Features

Persons with obsessive-compulsive personality disorder are preoccupied with rules, regulations, orderliness, neatness, details, and the achievement of perfection. These traits account for the general constriction of the entire personality. They insist that rules be followed rigidly and cannot tolerate what they consider infractions. Accordingly, they lack flexibility and are intolerant. They are capable of prolonged work, provided it is routinized and does not require changes to which they cannot adapt.

Persons with obsessive-compulsive personality disorder have limited interpersonal skills. They are formal and serious and often lack a sense of humor. They alienate persons, are unable to compromise, and insist that others submit to their needs. They are eager to please those whom they see as more powerful than they are, however, and they carry out these persons' wishes in an authoritarian manner. Because they fear making mistakes, they are indecisive and ruminate about making decisions. Although a stable marriage and occupational adequacy are common, persons with obsessive-compulsive personality disorder have few friends. Anything that threatens to upset their perceived stability or the routine of their lives can precipitate much anxiety otherwise bound up in the rituals that they impose on their lives and try to impose on others.

Differential Diagnosis

When recurrent obsessions or compulsions are present, obsessive-compulsive disorder should be noted. Perhaps the most difficult distinction is between outpatients with some obsessive-compulsive traits and those with obsessive-compulsive personality disorder. The diagnosis of personality disorder is reserved for those with significant impairments in their occupational or social effectiveness. In some cases, delusional disorder coexists with personality disorders and should be noted.

Course and Prognosis

The course of obsessive-compulsive personality disorder is variable and unpredictable. From time to time, persons may develop obsessions or compulsions in the course of their disorder. Some adolescents with obsessive-compulsive personality disorder evolve into warm, open, and loving adults; in others, the disorder can be either the harbinger of schizophrenia or—decades later and exacerbated by the aging process—major depressive disorder.

Persons with obsessive-compulsive personality disorder may flourish in positions demanding methodical, deductive, or detailed work, but they are vulnerable to unexpected changes, and their personal lives may remain barren. Depressive disorders, especially those of late onset, are common.

Treatment

Psychotherapy. Unlike patients with the other personality disorders, those with obsessive-compulsive personality disorder are often aware of their suffering, and they seek treatment on their own. Overtrained and oversocialized, these patients value free association and non-directive therapy highly. Treatment, however, is often long and complex, and countertransference problems are common.

Group therapy and behavior therapy occasionally offer certain advantages. In both contexts, it is easy to interrupt the patients in the midst of their maladaptive interactions or explanations. Preventing the completion of their habitual behavior raises patients' anxiety and leaves them susceptible to learning new coping strategies. Patients can also receive direct rewards for change in group therapy, something less often possible in individual psychotherapies.

Pharmacotherapy. Clonazepam (Klonopin), a benzodiazepine with anticonvulsant use, has reduced symptoms in patients with severe obsessive-compulsive disorder. Whether it is of use in the personality disorder is unknown. Clomipramine (Anafranil) and such serotonergic agents as fluoxetine, usually at dosages of 60 to 80 mg a day, may be useful if obsessive-compulsive signs and symptoms break through. Nefazodone (Serzone) may benefit some patients.

OTHER SPECIFIED PERSONALITY DISORDER

In DSM-5, the category other specified personality disorder is reserved for disorders that do not fit into any of the personality disorder categories described above. Passive-aggressive personality and depressive personality are examples. A narrow spectrum of behavior or a particular trait—such as oppositionalism, sadism, or masochism—can also be classified in this category. A patient with features of more than one personality disorder but without the complete criteria of any one disorder can be assigned this classification.

Passive-Aggressive Personality

Although no longer an official diagnosis, persons with this personality type are not uncommon. Persons with passive-aggressive personality are characterized by covert obstructionism, procrastination, stubbornness, and inefficiency. Such behavior is a manifestation of passively expressed underlying aggression.

Epidemiology. No data are available about epidemiology. Sex ratio, familial patterns, and prevalence have not been adequately studied.

Clinical Features. Patients with passive-aggressive personality characteristically procrastinate, resist demands for adequate performance, find excuses for delays, and find fault with those on whom they depend, yet they refuse to extricate themselves from the dependent relationships. They usually lack assertiveness and are not direct about their own needs and wishes. They fail to ask needed questions about what is expected of them and may become anxious when forced to succeed or when their usual defense of turning anger against themselves is removed.

In interpersonal relationships, these persons attempt to manipulate themselves into a position of dependence, but others often experience this passive, self-detrimental behavior as punitive and manipulative. Persons with this personality type expect others to do their errands and to carry out their routine responsibilities. Friends and clinicians may become enmeshed in trying to assuage the patients' many claims of unjust treatment. The close relationships of persons with passive-aggressive personality, however, are rarely tranquil or happy. Because they are bound to their resentment more closely than to their satisfaction, they may never even formulate goals for finding enjoyment in life. Persons with passive-aggressive personality lack self-confidence and are typically pessimistic about the future.

Differential Diagnosis. Passive-aggressive personality must be differentiated from histrionic and borderline personality disorders. Passive-aggressive patients, however, are less flamboyant, dramatic, affective, and openly aggressive than those with histrionic and borderline personality disorders.

Course and Prognosis. In a follow-up study averaging 11 years of 100 inpatients diagnosed with passive-aggressive disorder, Ivor Small found that the primary diagnosis in 54 was passive-aggressive personality disorder; 18 were also alcohol abusers, and 30 could be clinically labeled as depressed. Of the 73 former patients located, 58 (79 percent) had persistent psychiatric difficulties, and 9 (12 percent) were considered symptom free. Most seemed irritable, anxious, and depressed; somatic complaints were numerous. Only 32 (44 percent) were employed full time as workers or homemakers. Although neglect of responsibility and suicide attempts were common, only one patient had committed suicide in the interim. Twenty-eight (38 percent) had been readmitted to a hospital, but only three had been diagnosed as having schizophrenia.

Treatment. Patients with passive-aggressive personality who receive supportive psychotherapy have good outcomes, but psychotherapy for these patients has many pitfalls. Fulfilling their demands often supports their pathology, but refusing their demands rejects them. Therapy sessions, thus, can become a battleground on which a patient expresses feelings of resentment against a therapist on whom the patient wishes to become dependent. With these patients, clinicians must treat suicide gestures as any covert expression of anger and not as object loss in major depressive disorder. Therapists must point out the probable consequences of passive-aggressive behaviors as they occur. Such confrontations may be more helpful than a correct interpretation in changing patients' behavior.

Antidepressants should be prescribed only when clinical indications of depression and the possibility of suicide exist. Otherwise, medication is not indicated.

Depressive Personality

Persons with depressive personality are characterized by lifelong traits that fall along the depressive spectrum. They are pessimistic, anhedonic, duty bound, self-doubting, and chronically unhappy. Melancholic personality was described by early 20th century European psychiatrists such as Ernst Kretschmer.

Epidemiology. No epidemiological data are currently available; however, depressive personality type seems to be common, to occur equally in men and women, and to occur in families in which depressive disorders are found.

Etiology. The cause of depressive personality is unknown, but the same factors involved in dysthymic disorder and major depressive disorder may be at work. Psychological theories involve early loss, poor parenting, punitive superegos, and extreme feelings of guilt. Biological theories involve the hypothalamic-pituitary-adrenal-thyroid axis, including the noradrenergic and serotonergic amine systems. Genetic predisposition, as indicated by Stella Chess's studies of temperament, may also play a role.

Clinical Features. Patients with depressive personality feel little of the normal joy of living and are inclined to be lonely and solemn, gloomy, submissive, pessimistic, and self-deprecatory. They are prone to express regrets and feelings of inadequacy and hopelessness. They are often meticulous, perfectionistic, overconscientious, and preoccupied with work; feel responsibility keenly; and are easily discouraged under new conditions. They are fearful of disapproval; tend to suffer in silence; and perhaps to cry easily, although usually not in the presence of others. A tendency to hesitation, indecision, and caution betrays an inherent feeling of insecurity.

More recently, Hagop Akiskal described seven groups of depressive traits: (1) quiet, introverted, passive, and nonassertive; (2) gloomy, pessimistic, serious, and incapable of fun; (3) self-critical, self-reproachful, and self-derogatory; (4) skeptical, critical of others, and hard to please; (5) conscientious, responsible, and self-disciplined; (6) brooding and given to worry; and (7) preoccupied with negative events, feelings of inadequacy, and personal shortcomings.

Patients with depressive personality complain of chronic feelings of unhappiness. They admit to low self-esteem and difficulty finding anything in their lives about which they are joyful, hopeful, or optimistic. They are self-critical and derogatory and are likely to denigrate their work, themselves, and their relationships with others. Their physiognomy often reflects their mood—poor posture, depressed facies, hoarse voice, and psychomotor retardation.

Differential Diagnosis. Dysthymic disorder is a mood disorder characterized by greater fluctuations in mood than occur in depressive personality. Dysthymic disorder is episodic, can occur at any time, and usually has a precipitating stressor. The depressive personality can be conceptualized as part of a spectrum of affective conditions in which dysthymic disorder and major depressive disorder are more severe variants. Patients with avoidant personality disorder are introverted and dependent, but they tend to be more anxious than depressed compared with persons with depressive personality.

Course and Prognosis. Persons with depressive personality may be at great risk for dysthymic disorder and major depressive disorder. In a study by Donald Klein and Gregory Mills, subjects with depressive personality exhibited significantly higher rates of current mood disorder, lifetime mood disorder, major depression, and dysthymia than subjects without depressive personality.

Treatment. Psychotherapy is the treatment of choice for depressive personality. Patients respond to insight-oriented psychotherapy, and because their reality testing is good, they can gain insight into the psychodynamics of their illness and appreciate its effects on their interpersonal relationships. Treatment is likely to be long term. Cognitive therapy helps patients understand the cognitive manifestations of their low self-esteem and pessimism. Group psychotherapy and interpersonal therapy are also useful. Some persons respond to self-help measures.

Psychopharmacological approaches include the use of antidepressant medications, especially such serotonergic agents as sertraline (Zoloft), 50 mg a day. Some patients respond to small dosages of psychostimulants, such as amphetamine, 5 to 15 mg a day. In all cases, psychopharmacological agents should be combined with psychotherapy to achieve maximum effects.

Sadomasochistic Personality

Some personality types are characterized by elements of sadism or masochism or a combination of both. Sadomasochistic personality is listed here because it is of major clinical and historical interest in psychiatry. It is not an official diagnostic category in DSM-5, but it can be diagnosed as personality disorder not otherwise classified.

Sadism is the desire to cause others pain by being either sexually abusive or generally physically or psychologically abusive. It is named for the Marquis de Sade, a late 18th century writer of erotica, describing persons who experienced sexual pleasure while inflicting pain on others. Freud believed that sadists ward off castration anxiety and are able to achieve sexual pleasure only when they can do to others what they fear will be done to them.

Masochism, named for Leopold von Sacher-Masoch, a 19th century German novelist, is the achievement of sexual gratification by inflicting pain on the self. So-called moral masochists generally seek humiliation and failure rather than physical pain. Freud believed that masochists' ability to achieve orgasm is disturbed by anxiety and guilt feelings about sex, which are alleviated by suffering and punishment.

Clinical observations indicate that elements of both sadistic and masochistic behavior are usually present in the same person. Treatment with insight-oriented psychotherapy, including psychoanalysis, has been effective in some cases. As a result of therapy, patients become aware of the need for self-punishment secondary to excessive unconscious guilt and come to recognize their repressed aggressive impulses, which originate in early childhood.

Sadistic Personality

Sadistic personality is not included in DSM-5, but it still appears in the literature and may be of descriptive use. Beginning in early adulthood, persons with sadistic personality show a pervasive pattern of cruel, demeaning, and aggressive behavior that is directed toward others. Physical cruelty or violence is used to inflict pain on others, not to achieve another goal, such as mugging a person to steal. Persons with sadistic personality like to humiliate or demean persons in front of others and have usually treated or disciplined persons uncommonly harshly, especially children. In general, persons with sadistic personality are fascinated by violence, weapons, injury, or torture. To be included in this category, such persons cannot be motivated solely by the desire to derive sexual arousal from their behavior; if they are so motivated, the paraphilia of sexual sadism should be diagnosed.

PERSONALITY CHANGE DUE TO A GENERAL MEDICAL CONDITION

Personality change due to a general medical condition is a significant occurrence. ICD-10 includes the category personality and behavioral disorders due to brain disease, damage, and dysfunction, which includes organic personality disorder, postencephalitic syndrome, and postconcussional syndrome. Personality change due to a general medical condition is characterized by a marked change in personality style and traits from a previous level of functioning. Patients must show evidence of a causative organic factor antedating the onset of the personality change.

Etiology

Structural damage to the brain is usually the cause of the personality change, and head trauma is probably the most common cause. Cerebral neoplasms and vascular accidents, particularly of the temporal and frontal lobes, are also common causes. The conditions most often associated with personality change are listed in [Table 22-11](#).

Table 22-11
Medical Conditions Associated with Personality Change

Head trauma
Cerebrovascular diseases
Cerebral tumors
Epilepsy (particularly, complex partial epilepsy)
Huntington's disease
Multiple sclerosis
Endocrine disorders
Heavy metal poisoning (manganese, mercury)
Neurosyphilis
Acquired immune deficiency syndrome (AIDS)

Diagnosis and Clinical Features

A change in personality from previous patterns of behavior or an exacerbation of previous personality characteristics is notable. Impaired control of the expression of emotions and impulses is a cardinal feature. Emotions are characteristically labile and shallow, although euphoria or apathy may be prominent. The euphoria may mimic hypomania, but true elation is absent, and patients may admit to not really feeling happy. There is a hollow and silly ring to their excitement and facile jocularity, particularly when the frontal lobes are involved. Also associated with damage to the frontal lobes, the so-called frontal lobe syndrome, consists of prominent indifference and apathy, characterized by a lack of concern for events in the immediate environment. Temper outbursts, which can occur with little or no provocation, especially after alcohol ingestion, can result in violent behavior. The expression of impulses may be manifested by inappropriate jokes; a coarse manner; improper sexual advances; and antisocial conduct resulting in conflicts with the law, such as assaults on others, sexual misdemeanors, and shoplifting. Foresight and the ability to anticipate the social or legal consequences of actions are typically diminished. Persons with temporal lobe epilepsy characteristically show humorlessness, hypergraphia, hyperreligiosity, and marked aggressiveness during seizures.

Persons with personality change due to a general medical condition have a clear sensorium. Mild disorders of cognitive function often coexist but do not amount to intellectual deterioration. Patients may be inattentive, which may account for disorders of recent memory. With some prodding, however, patients are likely to recall what they claim to have forgotten. The diagnosis should be suspected in patients who show marked changes in behavior or personality involving emotional lability and impaired impulse control, who have no history of mental disorder, and whose personality changes occur abruptly or over a relatively brief time.

Anabolic Steroids. An increasing number of high school and college athletes and bodybuilders are using anabolic steroids as a shortcut to maximize physical development. Anabolic steroids include oxymetholone (Anadrol), somatotropin (Humatrope), stanozolol (Winstrol), and testosterone.

It is unclear whether a personality change caused by steroid abuse is better diagnosed as personality change due to a general medical

condition or as one of the other (or unknown) substance use disorders. It is mentioned here because anabolic steroids can cause persistent alterations of personality and behavior. Anabolic steroid abuse is discussed in Section 12.13.

Differential Diagnosis

Dementia involves global deterioration in intellectual and behavioral capacities, of which personality change is just one category. A personality change may herald a cognitive disorder that eventually will evolve into dementia. In these cases, as deterioration begins to encompass significant memory and cognitive deficits, the diagnosis of the disorder changes from personality change caused by a general medical condition to dementia. In differentiating the specific syndrome from other disorders in which personality change may occur—such as schizophrenia, delusional disorder, mood disorders, and impulse control disorders—physicians must consider the most important factor, the presence in personality change disorder of a specific organic causative factor.

Course and Prognosis

Both the course and the prognosis of personality change due to a general medical condition depend on its cause. If the disorder results from structural damage to the brain, the disorder tends to persist. The disorder may follow a period of coma and delirium in cases of head trauma or vascular accident and may be permanent. The personality change can evolve into dementia in cases of brain tumor, multiple sclerosis, and Huntington’s disease. Personality changes produced by chronic intoxication, medical illness, or drug therapy (such as levodopa [Larodopa] for parkinsonism) may be reversed if the underlying cause is treated. Some patients require custodial care or at least close supervision to meet their basic needs, avoid repeated conflicts with the law, and protect themselves and their families from the hostility of others and from destitution resulting from impulsive and ill-considered actions.

Treatment

Management of personality change disorder involves treatment of the underlying organic condition when possible. Psychopharmacological treatment of specific symptoms may be indicated in some cases, such as imipramine or fluoxetine for depression.

Patients with severe cognitive impairment or weakened behavioral controls may need counseling to help avoid difficulties at work or to prevent social embarrassment. As a rule, patients’ families need emotional support and concrete advice on how to help minimize patients’ undesirable conduct. Alcohol should be avoided, and social engagements should be curtailed when patients tend to act in a grossly offensive manner.

PSYCHOBIOLOGICAL MODEL OF TREATMENT

The psychobiological model of treatment combines psychotherapy and pharmacotherapy and is based on the established structural, clinical, and postulated neurochemical characteristics of temperament and character. Pharmacotherapy and psychotherapy can be systematically matched to the personality structure and stage of character development of each patient—clearly a unique advantage over other available approaches.

The newest development is treating personality disorders pharmacologically. Target symptoms are identified, and particular drugs with known effects on personality traits (e.g., harm avoidance) are used. Table 22-12 summarizes drug choices for various target symptoms of personality disorders.

Table 22-12
Pharmacotherapy of Target Symptom Domains of Personality Disorders

Target Symptom	Drug of Choice	Contraindication ^a
I. Behavior dyscontrol		
Aggression or impulsivity		
Affective aggression (hot temper with normal EEG)	Lithium ^a Serotonergic drugs ^a Anticonvulsants ^a Low-dosage antipsychotics	? Benzodiazepines Stimulants
Predatory aggression (hostility or cruelty)	Antipsychotics ^a Lithium β -Adrenergic receptor antagonists	Benzodiazepines Stimulants
Organic-like aggression	Imipramine ^a Cholinergic agonists (donepezil)	
Ictal aggression (abnormal EEG)	Carbamazepine ^a Diphenylhydantoin ^a Benzodiazepines	Antipsychotics Stimulants
II. Mood dysregulation		
Emotional lability		
	Lithium ^a Antipsychotics	? Tricyclic drugs
Depression		
Atypical depression, dysphoria	MAOIs ^a Serotonergic drugs ^a Antipsychotics	
Emotional detachment	Serotonin-dopamine antagonists ^a Atypical antipsychotics	? Tricyclic drugs
III. Anxiety		
Chronic cognitive		
	Serotonergic drugs ^a MAOIs ^a Benzodiazepines	Stimulants
Chronic somatic	MAOIs ^a β -Adrenergic receptor antagonists	
Severe anxiety	Low-dose antipsychotics MAOIs	
IV. Psychotic symptoms		
Acute and psychosis		
	Antipsychotics ^a	Stimulants
Chronic and low-level psychotic-like symptoms		
	Low-dose antipsychotics ^a	

^aDrug of choice or major contraindication.
EEG, electroencephalogram; MAOI, monamine oxidase inhibitor.

In his book, *Listening to Prozac*, Peter Kramer described dramatic personality changes when serotonin levels are raised by fluoxetine administration, such as decreased sensitivity to rejection, increased assertiveness, improved self-esteem, and the ability to tolerate stress. These changes in personality traits occur in patients with a wide range of psychiatric conditions as well as in persons without diagnosable

mental disorders. Using medications to treat specific traits in a person who is otherwise normal (i.e., does not meet the criteria for a full-blown personality disorder) is controversial. It has been called “cosmetic psychopharmacology” by its critics.

Temperament

Temperament refers to the body’s biases in the modulation of conditioned behavioral responses to prescriptive physical stimuli. Behavioral conditioning (i.e., procedural learning) involves presemantic sensations that elicit basic emotions, such as fear or anger, independent of conscious recognition, descriptive observation, reflection, or reasoning. Pioneering work by A. Thomas and S. Chess conceptualized temperament as the stylistic component (“how”) of behavior, as differentiated from the motivation (“why”) and the content (“what”) of behavior. Modern concepts of temperament, however, emphasize its emotional, motivational, and adaptive aspects. Specifically, four major temperament traits have been identified and subjected to extensive neurobiological, psychosocial, and clinical investigation: harm avoidance, novelty seeking, reward dependence, and persistence. It is remarkable that this four-factor model of temperament can, in retrospect, be seen as a modern interpretation of the ancient four temperaments: Individuals differ in the degree to which they are melancholic (harm avoidance), choleric (novelty seeking), sanguine (reward dependence), and phlegmatic (persistence). However, the four temperaments are now understood to be genetically independent dimensions that occur in all possible combinations within the same individual rather than as mutually exclusive categories.

Biological Character Traits. Four character traits have been described, each with certain neurochemical and neurophysiological substrates. They share a common source of covariation that is strong and invariant regardless of changes in the environment and past experience. Table 22-13 summarizes contrasting sets of behaviors that distinguish extreme scorers on the four dimensions of temperament. Note that each extreme of these dimensions has specific adaptive advantages and disadvantages, so that neither high nor low scores inherently mean better adaptation. Each of the four temperament dimensions has unique genetic determinants according to family and twin studies, as well as studies of genetic associations with specific DNA markers. Some workers postulate specific genes for some traits, such as a novelty-seeking gene.

Table 22-13
Descriptors of Individuals Who Score High or Low on the Four Temperament Dimensions

Temperament Dimension	Descriptors of Extreme Variants	
	High	Low
Harm avoidance	Pessimistic	Optimistic
	Fearful	Daring
	Shy	Outgoing
	Fatigable	Energetic
Novelty seeking	Exploratory	Reserved
	Impulsive	Deliberate
	Extravagant	Thrifty
	Irritable	Stoical
Reward dependence	Sentimental	Detached
	Open	Aloof
	Warm	Cold
	Affectionate	Independent
Persistence	Industrious	Lazy
	Determined	Spoiled
	Enthusiastic	Underachiever
	Perfectionist	Pragmatist

HARM AVOIDANCE. Harm avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and nonreward. High harm avoidance is observed as fear of uncertainty, social inhibition, shyness with strangers, rapid fatigability, and pessimistic worry in anticipation of problems even in situations that do not worry other persons. Persons low in harm avoidance are carefree, courageous, energetic, outgoing, and optimistic even in situations that worry most persons.

The psychobiology of harm avoidance is complex. Benzodiazepines disinhibit avoidance by γ -aminobutyric acid (GABA)-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei.

Positron emission tomography (PET) at the National Institute of Mental Health (NIMH) with [^{18}F]-deoxyglucose (FDG) in 31 healthy adult volunteers during a simple, continuous performance task showed that harm avoidance was associated with increased activity in the anterior paralimbic circuit, specifically the right amygdala and insula, the right orbitofrontal cortex, and the left medial prefrontal cortex.

High GABA concentrations in plasma have also been correlated with low harm avoidance. Plasma GABA concentration has also been correlated with other measures of anxiety susceptibility, and it correlates highly with GABA concentration in the brain. Finally, a gene on chromosome 17q12 that regulates the expression of the serotonin transporter accounts for 4 to 9 percent of the total variance in harm avoidance. These findings support a role for both GABA and serotonergic projections from the dorsal raphe underlying individual differences in behavioral inhibition as measured by harm avoidance. Persons given serotonin drugs show decreased harm avoidance behavior.

NOVELTY SEEKING. Novelty seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and escape from unconditioned punishment (all of which are hypothesized to covary as part of one heritable system of learning). Novelty seeking is observed as exploratory activity in response to novelty, impulsiveness, extravagance in approach to cues of reward, and active avoidance of frustration. Individuals high in novelty seeking are quick tempered, curious, easily bored, impulsive, extravagant, and disorderly. Persons low in novelty seeking are slow tempered, uninquiring, stoical, reflective, frugal, reserved, tolerant of monotony, and orderly.

Dopaminergic projections have a crucial role in novelty seeking. Novelty seeking involves increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Novelty seeking leads to various pleasure-seeking behaviors, including cigarette smoking, which may explain the frequent observation of low platelet MAO type B (MAO_B) activity because cigarette smoking inhibits MAO_B activity in platelets and brain.

Studies of genes involved in dopamine neurotransmission, such as the dopamine transporter gene (*DAT1*) and the type 4 dopamine receptor gene (*DRD4*), have provided evidence of association with novelty seeking or risk-taking behavior.

REWARD DEPENDENCE. Reward dependence reflects maintenance of behavior in response to cues of social reward. Individuals high in reward dependence are tender hearted, sensitive, socially dependent, and sociable. Individuals low in reward dependence are practical, tough minded, cold, socially insensitive, irresolute, and indifferent if alone.

Noradrenergic projections from the locus ceruleus and serotonergic projections from the median raphe are thought to influence such reward conditioning. High reward dependence is associated with increased activity in the thalamus. The 3-methoxy-4-hydroxyphenylglycol

(MHPG) concentration is low in persons with high reward dependence.

PERSISTENCE. Persistence reflects maintenance of behavior despite frustration, fatigue, and intermittent reinforcement. Highly persistent persons are hard-working, perseverant, and ambitious overachievers who tend to intensify their effort in response to anticipated rewards and view frustration and fatigue as personal challenges. Individuals low in persistence are indolent, inactive, unstable, and erratic; they tend to give up easily when faced with frustration, rarely strive for higher accomplishments, and manifest little perseverance even in response to intermittent reward.

Recent work in rodents related the integrity of the partial reinforcement extinction effect to hippocampal connections and glutamate metabolism. Persistence may be enhanced by psychostimulants.

Psychobiology of Temperament. Temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence are defined as heritable differences underlying automatic responses to danger, novelty, social approval, and intermittent reward, respectively. The component traits (“facets”) for each of the four temperament dimensions have distinct learning characteristics and correlate more strongly with one another than with other components of temperament. The most comprehensive neurobiological model of learning in animals that has been systematically related to the structure of human temperament is summarized in Table 22-14. This model distinguishes four dissociable brain systems for behavioral inhibition (harm avoidance), behavioral activation (novelty seeking), social attachment (reward dependence), and partial reinforcement (persistence).

Table 22-14
Four Dissociable Brain Systems Influencing Stimulus–Response Patterns Underlying Temperament

Brain System (Related Personality Dimension)	Principal Neuromodulators	Relevant Stimuli	Behavioral Response
Behavioral inhibition (harm avoidance)	GABA Serotonin (dorsal raphe)	Aversive conditioning (pairing CS and UCS) Conditioned signals for punishment and frustrative nonreward	Formation of aversive CS Passive avoidance Extinction
Behavioral activation (novelty seeking)	Dopamine	Novelty CS of reward CS or UCS of relief of monotony or punishment	Exploratory pursuit Appetitive approach Active Avoidance Escape
Social attachment (reward dependence)	Norepinephrine Serotonin (median raphe)	Reward conditioning (pairing CS and UCS)	Formation of appetitive CS
Partial reinforcement (persistence)	Glutamate Serotonin (dorsal raphe)	Intermittent (partial) reinforcement	Resistance to extinction

CS, conditioned stimulus; GABA, γ -aminobutyric acid; UCS, unconditioned stimulus.

Adapted from Cloninger CR. A systematic method for clinical description and classification of personality variables. *Arch Gen Psychiatry*. 1987;44:573.

Individual differences in temperament and basic emotions modify the processing of sensory information and shape early learning characteristics, especially associative conditioning of unconscious behavior responses. Temperament is conceptualized in terms of heritable biases in emotionality and learning that underlie the acquisition of emotion-based, automatic behavioral traits and habits observable early in life and relatively stable over an individual’s lifespan.

Each of the four major dimensions is a normally distributed quantitative trait, moderately heritable, observable early in childhood, relatively stable in time, and moderately predictive of adolescent and adult behavior. The four dimensions have been shown to be genetically homogeneous and independently inherited from one another in large, independent twin studies in the United States, Australia, and Japan. Temperamental differences, which are not very stable initially, tend to stabilize during the second and third years of life. Accordingly, ratings of these four temperament traits at age 10 to 11 years were moderately predictive of personality traits at ages 15, 18, and 27 years in a large sample of Swedish children.

The four dimensions have been repeatedly shown to be universal across different cultures, ethnic groups, and political systems on every inhabited continent. In summary, these aspects of personality are called temperament because they are heritable, manifest early in life, are developmentally stable, and are consistent in different cultures. Temperament traits are similar to crystallized intelligence in that they do not show the rapid changes with increasing age or across birth cohorts that are observed for fluid intelligence and character traits.

23.1 Suicide

Suicide is derived from the Latin word for “self-murder.” It is a fatal act that represents the person’s wish to die. There is a range, however, between thinking about suicide and acting it out. Some plan for days, weeks, or even years before acting, while others take their lives seemingly on impulse without premeditation. Lost in the definition are intentional misclassifications of the cause of death, accidents of undetermined cause, and so-called chronic suicide (e.g., deaths through alcohol and substance abuse and consciously poor adherence to medical regimens for addiction, obesity, and hypertension). For other terms in the literature on suicide, see [Table 23.1-1](#).

Table 23.1-1
Terms Comprising Suicidal Ideation and Behavior

Aborted suicide attempt: Potentially self-injurious behavior with explicit or implicit evidence that the person intended to die but stopped the attempt before physical damage occurred.

Deliberate self-harm: Willful self-inflicting of painful, destructive, or injurious acts without intent to die.

Lethality of suicidal behavior: Objective danger to life associated with a suicide method or action. Note that lethality is distinct from and may not always coincide with an individual’s expectation of what is medically dangerous.

Suicidal ideation: Thought of serving as the agent of one’s own death; seriousness may vary depending on the specificity of suicidal plans and the degree of suicidal intent.

Suicidal intent: Subjective expectation and desire for a self-destructive act to end in death.

Suicide attempt: Self-injurious behavior with a nonfatal outcome accompanied by explicit or implicit evidence that the person intended to die.

Suicide: Self-inflicted death with explicit or implicit evidence that the person intended to die.

In psychiatry, suicide is the primary emergency, with homicide and failure to diagnose an underlying potentially fatal illness representing other, less common psychiatric emergencies. Suicide is to the psychiatrist as cancer is to the internist—the psychiatrist may provide optimal care, yet the patient may die by suicide nonetheless. Thus, suicide is impossible to predict, but numerous clues can be seen. There are also some generally accepted standards of care that facilitate risk reduction, as well as lessen the likelihood of successful litigation, should a patient death occur and a lawsuit be filed. Suicide also needs to be considered in terms of the devastating legacy that it leaves for those who have survived a loved one’s suicide, the impact it has on the treating physician, and the ramification for the clinicians who cared for the decedents. Perhaps the most important concept regarding suicide is that it is almost always the result of mental illness, usually depression, and is amenable to psychological and pharmacological treatment.

EPIDEMIOLOGY

There are over 35,000 deaths per year (approximately 100 per day) in the United States attributed to suicide. This is in contrast to approximately 20,000 deaths annually from homicide. It is estimated that there is a 25 to 1 ratio between suicide attempts and completed suicides. Although significant shifts were seen in the suicide death rates for certain subpopulations during the past century (e.g., increase adolescent and decreased elderly rates), the rate remains fairly constant, averaging about 12 per 100,000 through the 20th century and into the first decade of the 21st century. Suicide is currently ranked the tenth overall cause of death in the United States, after heart disease, cancer, chronic lower respiratory diseases, cerebrovascular diseases, accidents, Alzheimer’s disease, diabetes, influenza and pneumonia, and kidney disease.

Suicide rates in the United States are the midpoint of the rates for industrialized countries. Internationally, suicide rates range from highs of more than 25 per 100,000 persons in Lithuania, South Korea, Sri Lanka, Russia, Belarus, and Guyana to fewer than 10 per 100,000 in Portugal, the Netherlands, Australia, Spain, South Africa, Italy, Egypt, and others.

A state-by-state analysis of suicides in the past decade revealed that New Jersey had the nation’s lowest suicide rate for both sexes and Montana had the nation’s highest rate. Montana and Wyoming had the highest rates for men, and Alaska and Idaho had the highest rates for women. The prime suicide site in the world is the Golden Gate Bridge in San Francisco, with 1,600 suicides committed there since the bridge opened in 1937.

Risk Factors

Gender Differences. Men commit suicide more than four times as often as women, regardless of age or race, in the United States—despite the fact that women attempt suicide or have suicidal thoughts three times as often as men. Although this disparity remains unclear, it may be related to the methods used. Men are more likely than women to commit suicide using firearms, hanging, or jumping from high places. Women, on the other hand, more commonly take an overdose of psychoactive substances or poison. The use of firearms among women, however, is increasing. In states with gun control laws, the use of firearms has decreased as a method of suicide. Globally, the most common method of suicide is hanging.

Age. For all groups, suicide is rare before puberty. Suicide rates increase with age and underscore the significance of the midlife crisis. Among men, suicides peak after age 45; among women, the greatest number of completed suicides occurs after age 55. Rates of 29 per 100,000 population occur in men age 65 or older. Older persons attempt suicide less often than younger persons, but are more often successful. Although they represent only 13 percent of the total population, older persons account for 16 percent of suicides.

The suicide rate, however, is rising among young persons. Suicide is the third leading cause of death in those aged 15 to 24 years, after accidents and homicides. Attempted suicides in this age group number between 1 million and 2 million annually. Most suicides now are among those aged 35 to 64.

Race. Suicide rates among white men and women are approximately two to three times as high as for African American men and women across the life cycle. Among young persons who live in inner cities and certain Native American and Alaskan Native groups, suicide rates have greatly exceeded the national rate. Suicide rates among immigrants are higher than those in the native-born population.

Religion. Historically, Protestants and Jews in the United States have had higher suicide rates than Catholics. Muslims have much lower

rates. The degree of orthodoxy and integration may be a more accurate measure of risk in this category than simple institutional religious affiliation.

Marital Status. Marriage lessens the risk of suicide significantly, especially if there are children in the home. Single, never-married persons register an overall rate nearly double that of married persons. Divorce increases suicide risk, with divorced men three times more likely to kill themselves as divorced women. Widows and widowers also have high rates. Suicide occurs more frequently than usual in persons who are socially isolated and have a family history of suicide (attempted or real). Persons who commit so-called anniversary suicides take their lives on the day a member of their family did. Homosexual men and women appear to have higher rates of suicide than heterosexuals.

Occupation. The higher the person's social status, the greater the risk of suicide, but a drop in social status also increases the risk. Work, in general, protects against suicide. Among occupational rankings, professionals, particularly physicians, have traditionally been considered to be at greatest risk. Other high-risk occupations include law enforcement, dentists, artists, mechanics, lawyers, and insurance agents. Suicide is higher among the unemployed than among employed persons. The suicide rates increase during economic recessions and depressions and decrease during times of high employment and during wars.

PHYSICIAN SUICIDES. The weight of current evidence supports the conclusion that both male and female physicians in the United States have elevated rates of suicide. It is estimated that approximately 400 physicians commit suicide each year in the United States. United Kingdom and Scandinavian data show that the suicide rate for male physicians is two to three times that found in the general male population of the same age. Female physicians have a higher risk of suicide than other women. In the United States, the annual suicide rate for female physicians is about 41 per 100,000, compared with 12 per 100,000 among all white women over 25 years of age. Studies show that physicians who commit suicide have a mental disorder, most often depressive disorder, substance dependence, or both. Both male and female physicians commit suicide significantly more often by substance overdoses and less often by firearms than persons in the general population; drug availability and knowledge about toxicity are important factors in physician suicides. Among physicians, psychiatrists are considered to be at greatest risk, followed by ophthalmologists and anesthesiologists, but all specialties are vulnerable.

Climate. No significant seasonal correlation with suicide has been found. Suicides increase slightly in spring and fall but, contrary to popular belief, not during December and holiday periods.

Physical Health. The relation of physical health and illness to suicide is significant. Previous medical care appears to be a positively correlated risk indicator of suicide: About one third of all persons who commit suicide have had medical attention within 6 months of death, and a physical illness is estimated to be an important contributing factor in about half of all suicides.

Factors associated with illness that contribute to both suicides and suicide attempts are loss of mobility, especially when physical activity is important to occupation or recreation; disfigurement, particularly among women; and chronic, intractable pain. Patients on hemodialysis are at high risk. In addition to the direct effects of illness, the secondary effects—for example, disruption of relationships and loss of occupational status—are prognostic factors.

Certain drugs can produce depression, which may lead to suicide in some cases. Among these drugs are reserpine (Serpasil), corticosteroids, antihypertensives, and some anticancer agents. Alcohol-related illnesses, such as cirrhosis, are associated with higher suicide rates.

Mental Illness. Almost 95 percent of all persons who commit or attempt suicide have a diagnosed mental disorder. Depressive disorders account for 80 percent of this figure, schizophrenia accounts for 10 percent, and dementia or delirium for 5 percent. Among all persons with mental disorders, 25 percent are also alcohol dependent and have dual diagnoses. Persons with delusional depression are at highest risk of suicide. A history of impulsive behavior or violent acts increases the risk of suicide as does previous psychiatric hospitalization for any reason. Among adults who commit suicide, significant differences between young and old exist for both psychiatric diagnoses and antecedent stressors. Diagnoses of substance abuse and antisocial personality disorder occurred most often among suicides in persons less than 30 years of age and diagnoses of mood disorders and cognitive disorders most often among suicides in those age 30 and above. Stressors associated with suicide in those under 30 were separation, rejection, unemployment, and legal troubles; illness stressors most often occurred among suicide victims over age 30.

Psychiatric Patients. Psychiatric patients' risk for suicide is 3 to 12 times that of nonpatients. The degree of risk varies, depending on age, sex, diagnosis, and inpatient or outpatient status. Male and female psychiatric patients who have at some time been inpatients have five and ten times higher suicide risks, respectively, than their counterparts in the general population. For male and female outpatients who have never been admitted to a hospital for psychiatric treatment, the suicide risks are three and four times greater, respectively, than those of their counterparts in the general population. The higher suicide risk for psychiatric patients who have been inpatients reflects that patients with severe mental disorders tend to be hospitalized—for example, patients with depressive disorder who require electroconvulsive therapy (ECT). The psychiatric diagnosis with greatest risk of suicide in both sexes is a mood disorder.

Those in the general population who commit suicide tend to be middle aged or older, but studies increasingly report that psychiatric patients who commit suicide tend to be relatively young. In one study, the mean age of male suicides was 29.5 years and that of women 38.4 years. The relative youthfulness in these suicide cases was partly attributed to two early-onset, chronic mental disorders—schizophrenia and recurrent major depressive disorder—which account for just over half of these suicides, and so reflects an age and diagnostic pattern found in most studies of psychiatric patient suicides.

A small, but significant, percentage of psychiatric patients who commit suicide do so while they are inpatients. Most of these do not kill themselves in the psychiatric ward itself, but on the hospital grounds, while on a pass or weekend leave, or when absent without leave. For both sexes, the suicide risk is highest in the first week of the psychiatric admission; after 3 to 5 weeks, inpatients have the same risk as the general population. Times of staff rotation, particularly of the psychiatric residents, are periods associated with inpatient suicides. Epidemics of inpatient suicides tend to be associated with periods of ideological change on the ward, staff disorganization, and staff demoralization.

The period after discharge from the hospital is also a time of increased suicide risk. A follow-up study of 5,000 patients discharged from an Iowa psychiatric hospital showed that in the first 3 months after discharge, the rate of suicide for female patients was 275 times that of all Iowa women; the rate of suicide for male patients was 70 times that of all Iowa men. Studies show that one third or more of depressed patients who commit suicide do so within 6 months of leaving a hospital; presumably they have relapsed.

The main risk groups are patients with depressive disorders, schizophrenia, and substance abuse and patients who make repeated visits to the emergency room. Patients, especially those with panic disorder, who frequent emergency services, also have an increased suicide risk. Thus, mental health professionals working in emergency services must be well trained in assessing suicidal risk and making appropriate dispositions. They must also be aware of the need to contact patients at risk who fail to keep follow-up appointments.

DEPRESSIVE DISORDERS. Mood disorders are the ones most closely linked to suicide. Approximately 60 to 70 percent of suicide victims suffered a significant depression at the time of their deaths. The lifetime risk of death by suicide among individuals with bipolar disorder is approximately 15 to 20 percent, and suicide is more likely during depressed states rather than manic states.

More patients with depressive disorders commit suicide early in the illness rather than later; more depressed men than women commit suicide; and the chance of depressed persons' killing themselves increases if they are single, separated, divorced, widowed, or recently bereaved. Patients with depressive disorder in the community who commit suicide tend to be middle aged or older.

Social isolation enhances suicidal tendencies among depressed patients. This finding is in accord with the data from epidemiological studies showing that persons who commit suicide may be poorly integrated into society. Suicide among depressed patients is likely at the onset or the end of a depressive episode. As with other psychiatric patients, the months after discharge from a hospital are a time of high risk.

Regarding outpatient treatment, most depressed suicidal patients had a history of therapy; however, less than half were receiving psychiatric treatment at the time of suicide. Of those who were in treatment, studies have shown that treatment was less than adequate. For example, most patients who received antidepressants were prescribed subtherapeutic doses of the medication.

SCHIZOPHRENIA. The suicide risk is high among patients with schizophrenia: Up to 10 percent die by committing suicide. In the United States, an estimated 4,000 patients with schizophrenia commit suicide each year. The onset of schizophrenia is typically in adolescence or early adulthood, and most of these patients who commit suicide do so during the first few years of their illness; therefore, those patients with schizophrenia who commit suicide are young.

Thus, the risk factors for suicide among patients with schizophrenia are young age, male gender, single marital status, a previous suicide attempt, a vulnerability to depressive symptoms, and a recent discharge from a hospital. Having three or four hospitalizations during their 20s probably undermines the social, occupational, and sexual adjustment of possibly suicidal patients with schizophrenia. Consequently, potential suicide victims are likely to be male, unmarried, unemployed, socially isolated, and living alone—perhaps in a single room. After discharge from their last hospitalization, they may experience a new adversity or return to ongoing difficulties. As a result, they become dejected, experience feelings of helplessness and hopelessness, reach a depressed state, and have, and eventually act on, suicidal ideas. Only a small percentage committed suicide because of hallucinated instructions or a need to escape persecutory delusions. Up to 50 percent of suicides among patients with schizophrenia occur during the first few weeks and months after discharge from a hospital; only a minority commit suicide while inpatients.

ALCOHOL DEPENDENCE. Up to 15 percent of all alcohol-dependent persons commit suicide. The suicide rate for those who are alcoholic is estimated to be about 270 per 100,000 annually; in the United States, between 7,000 and 13,000 alcohol-dependent persons commit suicide each year.

About 80 percent of all alcohol-dependent suicide victims are male, a percentage that largely reflects the sex ratio for alcohol dependence. Alcohol-dependent suicide victims tend to be white, middle aged, unmarried, friendless, socially isolated, and currently drinking. Up to 40 percent have made a previous suicide attempt. Up to 40 percent of all suicides by persons who are alcohol dependent occur within a year of the patient's last hospitalization; older alcohol-dependent patients are at particular risk during the postdischarge period.

Studies show that many alcohol-dependent patients who eventually commit suicide are rated depressed during hospitalization and up to two thirds are assessed as having mood disorder symptoms during the period in which they commit suicide. As many as 50 percent of all alcohol-dependent suicide victims have experienced the loss of a close, affectionate relationship during the previous year. Such interpersonal losses and other types of undesirable life events are probably brought about by the alcohol dependence and contribute to the development of the mood disorder symptoms, which are often present in the weeks and months before the suicide.

The largest group of male alcohol-dependent patients is composed of those with an associated antisocial personality disorder. Studies show that such patients are particularly likely to attempt suicide; to abuse other substances; to exhibit impulsive, aggressive, and criminal behaviors; and to be found among alcohol-dependent suicide victims.

OTHER SUBSTANCE DEPENDENCE. Studies in various countries have found an increased suicide risk among those who abuse substances. The suicide rate for persons who are heroin dependent is about 20 times the rate for the general population. Adolescent girls who use intravenous substances also have a high suicide rate. The availability of a lethal amount of substances, intravenous use, associated antisocial personality disorder, a chaotic lifestyle, and impulsivity are some of the factors that predispose substance-dependent persons to suicidal behavior, particularly when they are dysphoric, depressed, or intoxicated.

PERSONALITY DISORDERS. A high proportion of those who commit suicide have various associated personality difficulties or disorders. Having a personality disorder may be a determinant of suicidal behavior in several ways: by predisposing to major mental disorders such as depressive disorders or alcohol dependence; by leading to difficulties in relationships and social adjustment; by precipitating undesirable life events; by impairing the ability to cope with a mental or physical disorder; and by drawing persons into conflicts with those around them, including family members, physicians, and hospital staff members.

An estimated 5 percent of patients with antisocial personality disorder commit suicide. Suicide is three times more common among prisoners than among the general population. More than one third of prisoner suicides have had past psychiatric treatment, and half have made a previous suicide threat or attempt, often in the previous 6 months.

ANXIETY DISORDER. Uncompleted suicide attempts are made by almost 20 percent of patients with a panic disorder and social phobia. If depression is an associated feature, however, the risk of completed suicide rises.

Previous Suicidal Behavior. A past suicide attempt is perhaps the best indicator that a patient is at increased risk of suicide. Studies show that about 40 percent of depressed patients who commit suicide have made a previous attempt. The risk of a second suicide attempt is highest within 3 months of the first attempt. The relation between a mood disorder, completed suicide, and attempts at suicide is shown in Figure 23.1-1.

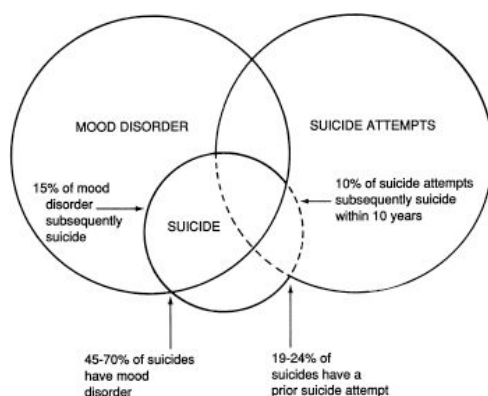

FIGURE 23.1-1 Venn diagram summarizing suicide data and its relation to mood disorder and suicide attempts. (Courtesy of Alec Roy, M.D.)

Depression is associated with both completed suicide and serious attempts at suicide. The clinical feature most often associated with the seriousness of the intent to die is a diagnosis of a depressive disorder. This is shown by studies that relate the clinical characteristics of suicidal patients with various measures of the medical seriousness of the attempt or of the intent to die. Also, intent-to-die scores correlate significantly with both suicide risk scores and the number and severity of depressive symptoms. Patients having high suicide intent are more often male, older, single or separated, and living alone than those with low intent. In other words, depressed patients who seriously attempt suicide more closely resemble suicide victims than they do suicide attempters.

ETIOLOGY

Sociological Factors

Durkheim's Theory. The first major contribution to the study of the social and cultural influences on suicide was made at the end of the 19th century by the French sociologist Emile Durkheim. In an attempt to explain statistical patterns, Durkheim divided suicides into three social categories: egoistic, altruistic, and anomic. Egoistic suicide applies to those who are not strongly integrated into any social group. The lack of family integration explains why unmarried persons are more vulnerable to suicide than married ones and why couples with children are the best protected group. Rural communities have more social integration than urban areas and, thus, fewer suicides. Protestantism is a less cohesive religion than Roman Catholicism, and so Protestants have a higher suicide rate than Catholics.

Altruistic suicide applies to those susceptible to suicide stemming from their excessive integration into a group, with suicide being the outgrowth of the integration—for example, a Japanese soldier who sacrifices his life in battle. Anomic suicide applies to persons whose integration into society is disturbed so that they cannot follow customary norms of behavior. Anomie explains why a drastic change in economic situation makes persons more vulnerable than they were before their change in fortune. In Durkheim's theory, anomie also refers to social instability and a general breakdown of society's standards and values.

Psychological Factors

Freud's Theory. Sigmund Freud offered the first important psychological insight into suicide. He described only one patient who made a suicide attempt, but he saw many depressed patients. In his paper "Mourning and Melancholia," Freud stated his belief that suicide represents aggression turned inward against an introjected, ambivalently cathected love object. Freud doubted that there would be a suicide without an earlier repressed desire to kill someone else.

Menninger's Theory. Building on Freud's ideas, Karl Menninger, in *Man against Himself*, conceived of suicide as inverted homicide because of a patient's anger toward another person. This retroflected murder is either turned inward or used as an excuse for punishment. He also described a self-directed death instinct (Freud's concept of Thanatos) plus three components of hostility in suicide: the wish to kill, the wish to be killed, and the wish to die.

Recent Theories. Contemporary suicidologists are not persuaded that a specific psychodynamic or personality structure is associated with suicide. They believe that much can be learned about the psychodynamics of suicidal patients from their fantasies about what would happen and what the consequences would be if they commit suicide. Such fantasies often include wishes for revenge, power, control, or punishment; atonement, sacrifice, or restitution; escape or sleep; rescue, rebirth, reunion with the dead; or a new life. The suicidal patients most likely to act out suicidal fantasies may have lost a love object or received a narcissistic injury, may experience overwhelming affects like rage and guilt, or may identify with a suicide victim. Group dynamics underlie mass suicides such as those at Masada, at Jonestown, and by the Heaven's Gate cult.

Depressed persons may attempt suicide just as they appear to be recovering from their depression. A suicide attempt can cause a long-standing depression to disappear, especially if it fulfills a patient's need for punishment. Of equal relevance, many suicidal patients use a preoccupation with suicide as a way of fighting off intolerable depression and a sense of hopelessness. A study by Aaron Beck showed that hopelessness was one of the most accurate indicators of long-term suicidal risk.

Biological Factors. Diminished central serotonin plays a role in suicidal behavior. A group at the Karolinska Institute in Sweden first noted that low concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the lumbar cerebrospinal fluid (CSF) were associated with suicidal behavior. This finding has been replicated many times and in different diagnostic groups. Postmortem neurochemical studies have reported modest decreases in serotonin itself or 5-HIAA in either the brainstem or the frontal cortex of suicide victims. Postmortem receptor studies have reported significant changes in presynaptic and postsynaptic serotonin binding sites in suicide victims. Together, these CSF, neurochemical, and receptor studies support the hypothesis that reduced central serotonin is associated with suicide. Recent studies also report some changes in the noradrenergic system of suicide victims.

Low concentrations of 5-HIAA in CSF also predict future suicidal behavior. For example, the Karolinska group examined completed suicide in a sample of 92 depressed patients who had attempted suicide. They found that 8 of the 11 patients who committed suicide within 1 year belonged to the subgroup with below-median concentrations of 5-HIAA in CSF. The suicide risk in that subgroup was 17 percent, compared with 7 percent among those with above-median concentrations of 5-HIAA in CSF (Fig. 23.1-2). Also, the cumulative number of patient-months survived during the first year after attempted suicide was significantly lower in the subgroup with low 5-HIAA concentrations. The Karolinska group concluded that low 5-HIAA concentrations in CSF predict short-range suicide risk in the high-risk group of depressed patients who have attempted suicide. Low 5-HIAA concentrations in CSF have also been demonstrated in adolescents who kill themselves.

FIGURE 23.1-2

Cumulative suicide risk during first year after attempted suicide in patients with low versus high cerebrospinal fluid (CSF) concentrations of 5-hydroxyindoleacetic acid (5-HIAA). Filled circles indicate CSF 5-HIAA concentrations below the sample median and filled squares indicate concentrations above the sample median (87 nM). (From Nördstrom P, Samuelsson M, Asberg M, Träskman-Bendz L, Aberg-Wistedt A, Nordin C, Bertilsson L. CSF concentrations 5-HIAA predicts suicide risk after attempted suicide. *Suicide Life Threat Behav.* 1994;24:1, with permission.)

Genetic Factors. Suicidal behavior, as with other psychiatric disorders, tends to run in families. In psychiatric patients, a family history of suicide increases the risk of attempted suicide and that of completed suicide in most diagnostic groups. In medicine, the strongest evidence for involvement of genetic factors comes from twin and adoption studies and from molecular genetics. Such studies in suicide are reviewed below.

Twin Studies. A landmark study in 1991 investigated 176 twin pairs in which one twin had committed suicide. In nine of these twin

pairs, both twins had committed suicide. Seven of these nine pairs concordant for suicide were found among the 62 monozygotic pairs, whereas two pairs concordant for suicide were found among the 114 dizygotic twin pairs. This twin group difference for concordance for suicide (11.3 vs. 1.8 percent) is statistically significant ($P < .01$).

Another study collected a group of 35 twin pairs in which one twin had committed suicide and the living co-twin was interviewed. Ten of the 26 living monozygotic cotwins had themselves attempted suicide, compared with 0 of the 9 living dizygotic cotwins ($P < .04$). Although monozygotic and dizygotic twins may have some differing developmental experiences, these results show that monozygotic twin pairs have significantly higher concordance for both suicide and attempted suicide, which suggests that genetic factors may play a role in suicidal behavior.

Danish-American Adoption Studies. The strongest evidence suggesting the presence of genetic factors in suicide comes from adoption studies carried out in Denmark. A screening of the registers of causes of death revealed that 57 of 5,483 adoptees in Copenhagen eventually committed suicide. They were matched with adopted controls. Searches of the causes of death revealed that 12 of the 269 biological relatives of these 57 adopted suicide victims had themselves committed suicide, compared with only 2 of the 269 biological relatives of the 57 adopted controls. This is a highly significant difference for suicide between the two groups of relatives. None of the adopting relatives of either the suicide or control group had committed suicide.

In a further study of 71 adoptees with mood disorder, adoptee suicide victims with a situational crisis or impulsive suicide attempt or both (particularly) had more biological relatives who had committed suicide than controls had. This led to the suggestion that a genetic factor lowering the threshold for suicidal behavior may lead to an inability to control impulsive behavior. Psychiatric disorders or environmental stress may serve “as potentiating mechanisms which foster or trigger the impulsive behavior, directing it toward a suicidal outcome.”

Molecular Genetic Studies. Tryptophan hydroxylase (TPH) is an enzyme involved in the biosynthesis of serotonin. A polymorphism in the human *TPH* gene has been identified, with two alleles—U and L. Because low concentrations of 5-HIAA in CSF are associated with suicidal behavior, it was hypothesized that such individuals may have alterations in genes controlling serotonin synthesis and metabolism. It was found that impulsive alcoholics, who had low CSF 5-HIAA concentrations, had more LL and UL genotypes. Furthermore, a history of suicide attempts was significantly associated with TPH genotype in all the violent alcoholics; 34 of the 36 violent subjects who attempted suicide had either the UL or LL genotype. Thus, it was concluded that the presence of the L allele was associated with an increased risk of suicide attempts.

Also, a history of multiple suicide attempts was found most often in subjects with the LL genotype and to a lesser extent among those with the UL genotype (Fig. 23.1-3). This led to the suggestion that the L allele was associated with repetitive suicidal behavior. The presence of one TPH*L allele may indicate a reduced capacity to hydroxylate tryptophan to 5-hydroxytryptophan in the synthesis of serotonin, producing low central serotonin turnover and, thus, a low concentration of 5-HIAA in CSF.

FIGURE 23.1-3

Relation between tryptophan hydroxylase (TPH) genotype and lifetime history of multiple suicide attempts. For each genotype, the fraction of subjects having each genotype (UU, squares; UL, circles; LL, triangles) is plotted against the number of suicide attempts they have made in their lives. (From Nielsen D, Goldman D, Virkkunen M, Tokola R, Rawlings R, Linnoila M. Suicidality and 5-hydroxyindoleacetic acid concentration associated with a tryptophan hydroxylase polymorphism. *Arch Gen Psychiatry*. 1994;51:34, with permission.)

Parasuicidal Behavior. *Parasuicide* is a term introduced to describe patients who injure themselves by self-mutilation (e.g., cutting the skin), but who usually do not wish to die. Studies show that about 4 percent of all patients in psychiatric hospitals have cut themselves; the female-to-male ratio is almost 3 to 1. The incidence of self-injury in psychiatric patients is estimated to be more than 50 times that in the general population. Psychiatrists note that so-called cutters have cut themselves over several years. Self-injury is found in about 30 percent of all abusers of oral substances and 10 percent of all intravenous users admitted to substance-treatment units.

These patients are usually in their 20s and may be single or married. Most cut delicately, not coarsely, usually in private with a razor blade, knife, broken glass, or mirror. The wrists, arms, thighs, and legs are most commonly cut; the face, breasts, and abdomen are cut infrequently. Most persons who cut themselves claim to experience no pain and give reasons for this behavior such as anger at themselves or others, relief of tension, and the wish to die. Most are classified as having personality disorders and are significantly more introverted, neurotic, and hostile than controls. Alcohol abuse and other substance abuse are common, and most cutters have attempted suicide. Self-mutilation has been viewed as localized self-destruction, with mishandling of aggressive impulses caused by a person’s unconscious wish to punish himself or herself or an introjected object.

PREDICTION

Clinicians must assess an individual patient’s risk for suicide on the basis of a clinical examination. The predictive items associated with suicide risk are listed in Table 23.1-2. Suicide is grouped into high-risk-related and low-risk-related factors (Table 23.1-3). High-risk characteristics include more than 45 years of age, male gender, alcohol dependence (the suicide rate is 50 times higher in alcohol-dependent persons than in those who are not alcohol dependent), violent behavior, previous suicidal behavior, and previous psychiatric hospitalization.

Table 23.1-2
Variables Enhancing Risk of Suicide among Vulnerable Groups

Adolescence and late life
 Bisexual or homosexual gender identity
 Criminal behavior
 Cultural sanctions for suicide
 Delusions
 Disposition of personal property
 Divorced, separated, or single marital status
 Early loss or separation from parents
 Family history of suicide
 Hallucinations
 Homicide
 Hopelessness
 Hypochondriasis
 Impulsivity
 Increasing agitation
 Increasing stress
 Insomnia
 Lack of future plans
 Lack of sleep
 Lethality of previous attempt
 Living alone
 Low self-esteem
 Male sex
 Physical illness or impairment
 Previous attempts that could have resulted in death
 Protestant or nonreligious status
 Recent childbirth
 Recent loss
 Repression as a defense
 Secondary gain
 Severe family pathology
 Severe psychiatric illness
 Sexual abuse
 Signals of intent to die
 Suicide epidemics
 Unemployment
 White race

(From Slaby AE. Outpatient management of suicidal patients in the era of managed care. *Prim Psychiatry*. 1995;Apr:43, with permission.)

Table 23.1-3
Evaluation of Suicide Risk

Variable	High Risk	Low Risk
Demographic and Social Profile		
Age	Over 45 years	Below 45 years
Sex	Male	Female
Marital status	Divorced or widowed	Married
Employment	Unemployed	Employed
Interpersonal relationship	Conflictual	Stable
Family background	Chaotic or conflictual	Stable
Health		
Physical	Chronic illness	Good health
	Hypochondriac	Feels healthy
Mental	Excessive substance intake	Low substance use
	Severe depression	Mild depression
	Psychosis	Neurosis
	Severe personality disorder	Normal personality
	Substance abuse	Social drinker
	Hopelessness	Optimism
Suicidal activity		
Suicidal ideation	Frequent, intense, prolonged	Infrequent, low intensity, transient
Suicide attempt	Multiple attempts	First attempt
	Planned	Impulsive
	Rescue unlikely	Rescue inevitable
	Unambiguous wish to die	Primary wish for change
	Communication internalized (self-blame)	Communication externalized (anger)
	Method lethal and available	Method of low lethality or not readily available
Resources		
Personal	Poor achievement	Good achievement
	Poor insight	Insightful
	Affect unavailable or poorly controlled	Affect available and appropriately controlled
Social	Poor rapport	Good rapport
	Socially isolated	Socially integrated
	Unresponsive family	Concerned family

(From Adam K. Attempted suicide. *Psychiatr Clin North Am*. 1985;8:183, with permission.)

It is important that questions about suicidal feelings and behaviors be asked, often directly. Asking depressed patients whether or not they have had thoughts of wanting to kill themselves does not plant the seed of suicide. To the contrary, it may be the first opportunity a patient has had to talk about suicidal ideation that may have been present for some time.

The American Psychiatric Association (APA) developed practice guidelines for treating patients with suicidal behaviors, and Table 23.1-4 lists a host of questions that can help the clinician assess suicide risk.

Table 23.1-4
Questions about Suicidal Feelings and Behaviors

Begin with questions that address the patient's feeling about living

Have you ever felt that life was not worth living?
Did you ever wish you could go to sleep and just not wake up?

Follow on with specific questions that ask about thoughts of death, self-harm, or suicide

Is death something you have thought about recently?
Have things ever reached the point that you have thought of harming yourself?

For individuals who have thoughts of self-harm or suicide

When did you first notice such thoughts?
What led up to the thoughts (e.g., interpersonal and psychosocial precipitants, including real or imagined losses; specific symptoms such as mood changes, anhedonia, hopelessness, anxiety, agitation, psychosis)?
How often have those thoughts occurred, including frequency, obsessional quality, controllability?
How close have you come to acting on those thoughts?
How likely do you think it is that you will act on them in the future?

Have you ever started to harm (or kill) yourself but stopped before doing something (e.g., holding knife or gun to your body but stopping before acting, going to edge of bridge but not jumping)?

What do you envision happening if you actually killed yourself (e.g., escape, reunion with significant other, rebirth, reactions of others)?

Have you made a specific plan to harm or kill yourself? (If so, what does the plan include?)

Do you have guns or other weapons available to you?

Have you made any particular preparations (e.g., purchasing specific items, writing a note or a will, making financial arrangements, taking steps to avoid discovery, rehearsing the plan)?

Have you spoken to anyone about your plans?

How does the future look to you?

What things would lead you to feel more (or less) hopeful about the future (e.g., treatment, reconciliation of relationship, resolution of stressors)?

What things would make it more (or less) likely that you would try to kill yourself?

What things in your life would lead you to want to escape from life or be dead?

What things in your life make you want to go on living?

If you began to have thoughts of harming or killing yourself again, what would you do?

For individuals who have attempted suicide or engaged in self-damaging action(s), parallel questions to those in the previous section can address the prior attempt(s). Additional questions can be asked in general terms or can refer to the specific method used and may include:

Can you describe what happened (e.g., circumstances, precipitants, view of future, use of alcohol or other substances, method, intent, seriousness of injury)?

What thoughts were you having beforehand that led up to the attempt?

What did you think would happen (e.g., going to sleep versus injury versus dying, getting a reaction out of a particular person)?

Were other people present at the time?

Did you seek help afterward yourself, or did someone get help for you?

Had you planned to be discovered, or were you found accidentally?

How did you feel afterward (e.g., relief versus regret at being alive)?

Did you receive treatment afterward (e.g., medical versus psychiatric, emergency department versus inpatient versus outpatient)?

Has your view of things changed, or is anything different for you since the attempt?

Are there other times in the past when you have tried to harm (or kill) yourself?

For individuals with repeated suicidal thoughts or attempts

About how often have you tried to harm (or kill) yourself?

When was the most recent time?

Can you describe your thoughts at the time that you were thinking most seriously about suicide?

When was your most serious attempt at harming or killing yourself?

What led up to it, and what happened afterward?

For individuals with psychosis, ask specifically about hallucinations and delusions

Can you describe the voices (e.g., single versus multiple, male versus female, internal versus external, recognizable versus nonrecognizable)?

What do the voices say (e.g., positive remarks versus negative remarks versus threats)? (If the remarks are commands, determine if they are for harmless versus harmful acts; ask for examples.)

How do you cope with (or respond to) the voices?

Have you ever done what the voices ask you to do? (What led you to obey the voices? If you tried to resist them, what made it difficult?)

Have there been times when the voices told you to hurt or kill yourself? (How often? What happened?)

Are you worried about having a serious illness or that your body is rotting?

Are you concerned about your financial situation even when others tell you there's nothing to worry about?

Are there things that you've been feeling guilty about or blaming yourself for?

Consider assessing the patient's potential to harm others in addition to himself or herself

Are there others who you think may be responsible for what you are experiencing (e.g., persecutory ideas, passivity experiences)?

Are you having any thoughts of harming them?

Are there other people you would want to die with you?

Are there others who you think would be unable to go on without you?

Direct and specific questions about suicide are essential in suicide assessment. The psychiatrist should ask about suicidal thoughts, plans, and behaviors.

Accepting a negative response to an initial question about suicidal ideation may not be enough to determine actual suicide risk. A denial of suicidal ideation that is inconsistent with the patient's presentation or current depressive symptomatology may indicate a need for additional questioning or collateral sources of information. These questions may be helpful when asking about specific aspects of a patient's suicidal thoughts, plans, and behaviors. (From the *Practice Guidelines for Assessment and Treatment of the Suicidal Patient*, 2nd ed. American Psychiatric Association Practice Guidelines for the Treatment of Psychiatric Disorders Compendium [Copyright 2004], with permission.)

Treatment

Most suicides among psychiatric patients are preventable, because evidence indicates that inadequate assessment or treatment is often associated with suicide. Some patients experience suffering so great and intense, or so chronic and unresponsive to treatment, that their eventual suicides may be perceived as inevitable. Such patients are relatively uncommon, however (see discussion of inevitable suicide below). Other patients have severe personality disorders, are highly impulsive, and commit suicide spontaneously, often when dysphoric, intoxicated, or both.

The evaluation for suicide potential involves a complete psychiatric history; a thorough examination of the patient's mental state; and an inquiry about depressive symptoms, suicidal thoughts, intents, plans, and attempts. A lack of future plans, giving away personal property, making a will, and having recently experienced a loss all imply increased risk of suicide. The decision to hospitalize a patient depends on diagnosis, depression severity and suicidal ideation, the patient's and the family's coping abilities, the patient's living situation, availability of social support, and the absence or presence of risk factors for suicide.

Inpatient versus Outpatient Treatment

Whether to hospitalize patients with suicidal ideation is the most important clinical decision to be made. Not all such patients require hospitalization; some can be treated on an outpatient basis. But the absence of a strong social support system, a history of impulsive behavior, and a suicidal plan of action are indications for hospitalization. To decide whether outpatient treatment is feasible, clinicians should use a straightforward clinical approach: Ask patients who are considered suicidal to agree to call when they become uncertain about their ability to control their suicidal impulses. Patients who can make such an agreement with a doctor with whom they have a relationship reaffirm the belief that they have sufficient strength to control such impulses and to seek help.

In return for a patient's commitment, clinicians should be available to the patient 24 hours a day. If a patient who is considered seriously suicidal cannot make the commitment, immediate emergency hospitalization is indicated; both the patient and the patient's family should be so advised. If, however, the patient is to be treated on an outpatient basis, the therapist should note the patient's home and work telephone numbers for emergency reference; occasionally, a patient hangs up unexpectedly during a late night call or gives only a name to the answering service. If the patient refuses hospitalization, the family must take the responsibility to be with the patient 24 hours a day.

According to Edwin S. Shneidman, a clinician has several practical preventive measures for dealing with a suicidal person: reducing the psychological pain by modifying the patient's stressful environment, enlisting the aid of the spouse, the employer, or a friend; building realistic support by recognizing that the patient may have a legitimate complaint; and offering alternatives to suicide.

Many psychiatrists believe that any patient who has attempted suicide, despite its lethality, should be hospitalized. Although most of these patients voluntarily enter a hospital, the danger to self is one of the few clear-cut indications currently acceptable in all states for involuntary hospitalization. In a hospital, patients can receive antidepressant or antipsychotic medications as indicated; individual therapy, group

therapy, and family therapy are available, and patients receive the hospital's social support and sense of security. Other therapeutic measures depend on patients' underlying diagnoses. For example, if alcohol dependence is an associated problem, treatment must be directed toward alleviating that condition.

Although patients classified as acutely suicidal may have favorable prognoses, chronically suicidal patients are difficult to treat, and they exhaust the caretakers. Constant observation by special nurses, seclusion, and restraints cannot prevent suicide when a patient is resolute. ECT may be necessary for some severely depressed patients, who may require several treatment courses.

Useful measures for the treatment of depressed suicidal inpatients include searching patients and their belongings on arrival in the ward for objects that could be used for suicide and repeating the search at times of exacerbation of the suicidal ideation. Ideally, suicidally depressed inpatients should be treated on a locked ward where the windows are shatterproof, and the patient's room should be located near the nursing station to maximize observation by the nursing staff. The treatment team must assess how much to restrict the patient and whether to make regular checks or use continuous direct observation.

Vigorous treatment with antidepressant or antipsychotic medication should be initiated, depending on the underlying disorder. Some medications (e.g., risperidone [Risperdal]) have both antipsychotic and antidepressant effects and are useful when the patient has signs and symptoms of both psychosis and depression.

Supportive psychotherapy by a psychiatrist shows concern and may alleviate some of a patient's intense suffering. Some patients may be able to accept the idea that they are suffering from a recognized illness and that they will probably make a complete recovery. Patients should be dissuaded from making major life decisions while they are suicidally depressed, because such decisions are often morbidly determined and may be irrevocable. The consequences of such bad decisions can cause further anguish and misery when the patient has recovered.

Patients recovering from a suicidal depression are at particular risk. As the depression lifts, patients become energized and, thus, are able to put their suicidal plans into action (paradoxical suicide). A further complication is the activating effect of serotonergic drugs, such as fluoxetine (Prozac), which are effective antidepressants, especially with suicidally depressed patients. Such agents may improve psychomotor withdrawal, thus permitting the patient to act on preexisting suicidal impulses because they have more energy. Sometimes, depressed patients, with or without treatment, suddenly appear to be at peace with themselves because they have reached a secret decision to commit suicide. Clinicians should be especially suspicious of such a dramatic clinical change, which may portend a suicide attempt. Although rare, some patients lie to the psychiatrist about their suicidal intent, thus subverting the most careful clinical assessment.

A patient may commit suicide even when in the hospital. According to one survey, about 1 percent of all suicides were committed by patients who were being treated in general medical-surgical or psychiatric hospitals, but the annual suicide rate in psychiatric hospitals is only 0.003 percent.

Table 23.1-5 lists guidelines for selecting a treatment setting for suicidal patients.

Table 23.1-5
Guidelines for Selecting a Treatment Setting for Patients at Risk for Suicide or Suicidal Behaviors

<p>Admission generally indicated: high risk of suicide <i>After a suicide attempt or aborted suicide attempt if:</i> Patient is psychotic Attempt was violent, near-lethal, or premeditated Precautions were taken to avoid rescue or discovery Persistent plan and/or intent is present Distress is increased or patient regrets surviving Patient is male, >45 years of age, especially with new onset of psychiatric illness or suicidal thinking Patient has limited family and/or social support, including lack of stable living situation Current impulsive behavior, severe agitation, poor judgment, or refusal of help is evident Patient has change in mental status with a metabolic, toxic, infectious, or other etiology requiring further workup in a structured setting <i>In the presence of suicidal ideation with:</i> Specific plan with high lethality High suicidal intent</p> <p>Admission may be necessary: moderate risk of suicide <i>After a suicide attempt or aborted suicide attempt, except in circumstances for which admission is generally indicated in the presence of suicidal ideation with:</i> Psychosis Major psychiatric disorder Past attempts, particularly if medically serious Possibly contributing medical condition (e.g., acute neurological disorder, cancer, infection) Lack of response to or inability to cooperate with partial hospital or outpatient treatment</p>	<p>Need for supervised setting for medication trial or electroconvulsive therapy Need for skilled observation, clinical tests, or diagnostic assessments that require a structured setting Limited family and/or social support, including lack of stable living situation Lack of an ongoing clinician-patient relationship or lack of access to timely outpatient follow-up In the absence of suicide attempts or reported suicidal ideation/plan/intent but evidence from the psychiatric evaluation and/or history from others suggests a high level of suicide risk and a recent acute increase in risk</p> <p>Release from emergency department with follow-up recommendations may be possible: lesser risk <i>After a suicide attempt or in the presence of suicidal ideation/plan when:</i> Suicidality is a reaction to precipitating events (e.g., exam failure, relationship difficulties), particularly if the patient's view of situation has changed since coming to emergency department Plan/method and intent have low lethality Patient has stable and supportive living situation Patient is able to cooperate with recommendations for follow-up, with treater contacted, if possible, if patient is currently in treatment</p> <p>Outpatient treatment may be more beneficial than hospitalization: lesser risk of suicide Patient has chronic suicidal ideation and/or self-injury without prior medically serious attempts, if a safe and supportive living situation is available and outpatient psychiatric care is ongoing</p>
--	--

Suicide occurs infrequently, even in high-risk populations. This statistical rarity makes suicide prediction, based on risk factors, either alone or in combination, impossible. Psychiatrists, however, can use knowledge of suicide risk factors to help determine appropriate treatment settings and individual treatment plans. The objective of suicide risk assessment is to clarify the presence or absence of risk and protective factors, and then estimate the patient's individual risk for suicide. The primary and ongoing goal of this assessment is to reduce the patient's suicide risk.
 (From the *Practice Guidelines for Assessment and Treatment of the Suicidal Patient*, 2nd ed. *The American Psychiatric Association Practice Guidelines for the Treatment of Psychiatric Disorders Compendium* [Copyright 2004], with permission.)

Legal and Ethical Factors

Liability issues stemming from suicides in psychiatric hospitals frequently involve questions about a patient's rate of deterioration, the presence during hospitalization of clinical signs indicating risk, and psychiatrists' and staff members' awareness of, and response to, these clinical signs.

In about half of the cases in which suicides occur while patients are on a psychiatric unit, a lawsuit results. Courts expect suicides to occur; do not require zero suicide rates, but do require periodic patient evaluation for suicidal risk, formulation of a treatment plan with a high level of security, and having staff members follow the treatment plan.

Currently, suicide and attempted suicide are variously viewed as a felony and a misdemeanor, respectively; in some states, the acts are not considered crimes but unlawful under common law and statutes. Aiding and abetting a suicide adds another dimension to the legal morass; some court decisions have held that although neither suicide nor attempted suicide is punishable, anyone who assists in the act may be punished.

National Strategy for Suicide Prevention

In 2001, Surgeon General David Satcher organized the National Strategy for Suicide Prevention, under the auspices of the National Institutes of Health (NIH). The National Strategy for Suicide Prevention has set specific goals and objectives to reduce suicide (Table 23.1-6).

Table 23.1-6
Goals to Reduce Suicide

1. Promote awareness that suicide is a public health problem that is preventable
2. Develop broad-based support for suicide prevention
3. Develop and implement strategies to reduce the stigma associated with being a consumer of mental health, substance abuse, and suicide prevention services
4. Develop and implement suicide prevention programs
5. Promote efforts to reduce access to lethal means and methods of self-harm
6. Implement training for recognition of at-risk behavior and delivery of effective treatment
7. Develop and promote effective clinical and professional practices
8. Improve access to, and community linkages with, mental health and substance abuse services
9. Improve reporting and portrayals of suicidal behavior, mental illness, and substance abuse in the entertainment and news media
10. Promote and support research on suicide and suicide prevention
11. Improve and expand surveillance systems

The National Strategy for Suicide Prevention creates a framework for suicide prevention for the nation. It is designed to encourage and empower groups and individuals to work together. The stronger and broader the support and collaboration on suicide prevention, the greater the chance of success for this public health initiative. Suicide and suicidal behaviors can be reduced as the general public gains more understanding about (1) the extent to which suicide is a problem, (2) the ways in which it can be prevented, and (3) the roles individuals and groups can play in prevention efforts.

SUICIDES INVOLVING OTHER DEATHS

Victim-Precipitated Homicide

The phenomenon of using others, usually police, to kill oneself is well known to law enforcement personnel. Described by Marvin Wolfgang, the classic situation is exemplified by a person holding up a gas station or all-night store and brandishing a gun, which he threatens to use on the police when they arrive. They then shoot him, thinking that it is in self-defense. The psychology of such victims is not clear, except that they apparently believe this is the only way they can die.

A 25-year-old white divorced father of twin 3-year-old boys had been threatening to his wife, and, consequently, she had an order of restraint placed on him. Nonetheless, one evening, he went to her home, carrying a realistic-looking toy pistol in his pocket “to give her a scare.” She refused to admit him, and, when he began to create a scene, she called the police. When three police officers arrived, he refused to leave, pointed the toy pistol at them and taunted them to shoot him. They drew their revolvers, ordered him to drop his “weapon” (which he did), and restrained him. They took him to a local emergency department, where the nurse’s admission note read: “divorced and angry man threatened others with a toy pistol.” The on-call psychiatrist saw him briefly; the patient denied suicidal or homicidal intent; and the psychiatrist concluded that it was safe to discharge him (as a “situational problem—marital issues”). The following day, he killed himself by using carbon monoxide. Although this was not a case of “completed” victim-precipitated homicide, hospital staff failed to perceive that this represented “attempted” victim-precipitated homicide and was an act of high risk. Noting that he “threatened others with a toy pistol” trivialized the gravity of pointing what appears to be a genuine gun at armed police and telling them to shoot. In effect, he had given up control over this life-threatening situation to the police, and only their self-restraint protected him from being killed that evening.

Murder-Suicides

Murder-suicides receive a disproportionate amount of attention because they are dramatic and tragic. Unless it is a pact between two truly consenting adults, such events testify to the enormous amount of aggression inherent in many suicides—in addition to the depression. Furthermore, what appears to be a pact is often, in fact, more of a coercion (or flat-out murder) than a true pact among equals. Pacts tend to be made more often by females or elderly couples.

Terrorist Suicides. Terrorist-bomber suicides represent a special category of murder-suicides, one in which there is no question of willingness of the victim’s part and in which the victims are unknown to the perpetrators except in some generic, group sense (e.g., Jews, Westerners). Some suicide experts do not classify these as “true” suicides because they differ in so many domains from typical suicides (Table 23.1-7).

Table 23.1-7
Differences between Terrorist-Bomber Suicides and Typical Suicides

	Terrorist Bombers	Typical Suicides
Goal	To create terror	Death or escape
Expectations	Entry into paradise	Death
Motivation	Vengeance and mass murder	Sadness or escape
Psychological/ Psychiatric disorder	Rarely evident	Present in most cases

Although many terrorists are recruited from poorer and less-educated classes, it is surprising that a very large proportion of terrorist bombers are instead from middle-class, well-educated, and possibly less-fundamentalist populations. Because suicide means to take one’s life, it is hard to exclude these terrorist deaths from such a classification.

INEVITABLE SUICIDE

Not all suicides are preventable; some may be inevitable. In fact, over one third of all completed suicides occur in persons who are receiving

treatment for a psychiatric disorder, most commonly depression, bipolar disorder, or schizophrenia. It is not unreasonable to assume that some of those patients received the best care available, but that their suicides could not be prevented.

Some clinicians believe that viewing certain suicides as being inevitable may lead to therapeutic nihilism, others feel it may cause both clinicians and patients to lose hope. But inevitable suicide can only be determined a posteriori, after all known facts of a particular suicide have been analyzed and synthesized. And if it cannot be predicted there is no reason for therapeutic nihilism or for treatment efforts to be influenced negatively; indeed viewing some suicides as possibly inevitable may encourage clinicians to increase their therapeutic zeal to prevent or postpone the inevitable from happening.

Certain criteria must be met for a particular suicide to be considered inevitable. Most important is a strong genetic history of suicide in one or more family members as well as heavy genetic loading for mental illness. Although a strong genetic diathesis for suicide is associated with completed suicide, it is not, in and of itself, sufficient. Other risk factors must also be present, numerous, and at the extreme end of profound pathology. Among the many risk factors (as described above) are a history of physical, emotional, or sexual abuse, especially during childhood; divorce; unemployment; male gender; recent discharge from a psychiatric hospital; prior suicide attempts; alcoholism or other substance abuse; a history of panic attacks; and the presence of a medical illness. Persistent suicidal thoughts, especially coupled with a plan, are particularly dangerous. As mentioned above, inevitability presumes that these risk factors are numerous, severe, and present in severe degrees.

Finally, to consider suicide inevitable the patient must have received the highest standard of treatment and that treatment must have failed. Inevitability assumes, among many other factors, that everything that could have been done was done—and done correctly—yet the patient died.

The case of Ernest Hemingway may be an example of inevitable suicide. Including Ernest, five people committed suicide in the Hemingway family. His father, brother, sister, and granddaughter all killed themselves. In addition, one of his sons suffered from major depression and underwent several courses of ECT during his lifetime.

Toward the end of his life, Hemingway had several hospitalizations for depression accompanied by suicide attempts. His last hospitalization was in 1961 at the Mayo Clinic, where he had been admitted in a severely depressed state after yet another suicide attempt. He was delusional (thinking that people were following him with deadly intent), had cognitive difficulties that prevented him from writing creatively, was physically ill with cardiovascular disease, and had been drinking heavily. He was hospitalized for 7 weeks, during which time he was treated with antidepressants, ECT, and psychotherapy. On June 26, 1961, he was discharged from the hospital. As Hemingway was leaving the hospital, in a last conversation, he was purported to have said, “You and I both know what I am going to do to myself one day.”

On July 2, 1961, at 7:30 in the morning, 6 days after discharge, Hemingway put a shotgun to his head and pulled the trigger.

Hemingway had all of the biopsychosocial determinants of an inevitable suicide. There was heavy genetic loading for suicide, severe psychiatric disorder characterized by persecutory delusions, substance abuse, and other risk factors such as profound suicidal ideation and prior suicide attempts. In addition, Hemingway was the victim of severe childhood trauma, which increased his vulnerability to suicide.

As yet, there are insufficient data to predict the inevitability of a particular suicide. The paradigm of inevitability, however, may serve as a stimulus to increase root cause analysis into this phenomenon. The history of medicine is replete with disorders that inexorably led to death but which are now curable and suicide may one day join those ranks.

SURVIVING SUICIDE

To be a *suicide survivor* refers to those who have lost a loved one to suicide, not to someone who has attempted suicide but lived. The toll on suicide survivors appears greater than that by other deaths, mainly because the opportunities for guilt are so great. Survivors feel that the loved one intentionally and willfully took his or her life and that if only the survivor had done something differently, the decedent would still be here. Because the decedent cannot tell them otherwise, survivors are at the mercy of their often merciless consciences.

What is generally more accurate is that the decedents were not entirely willful but were themselves victims of their own genetic or lifetime experience predispositions to depression and suicide. For children, in particular, the loss of a parent to suicide feels like a shameful abandonment for which the child may blame himself or herself. For parents of children who have killed themselves, their grief is compounded not only by having lost a part of themselves, but also by having failed in what they perceive as their responsibility for the total feelings of their child. To provide mutual support, survivors of suicide groups have appeared throughout the United States, generally led by nonprofessional survivors themselves. Therapists who have lost patients to suicide comprise another survivor group—one too often ignored and unsupported, despite their own considerable suffering and sense of guilt and compounded by the specter of litigation potentially being brought to bear.

23.2 Psychiatric Emergencies in Adults

A psychiatric emergency is any disturbance in thoughts, feelings, or actions for which immediate therapeutic intervention is necessary. For a variety of reasons—such as the growing incidence of violence, the increased appreciation of the role of medical disease in altered mental status, and the epidemic of alcoholism and other substance use disorders—the number of emergency patients is on the rise. The widening scope of emergency psychiatry goes beyond general psychiatric practice to include such specialized problems as the abuse of substances, children, and spouses; violence in the form of suicide, homicide, and rape; and such social issues as homelessness, aging, competence, and acquired immune deficiency syndrome (AIDS). The emergency psychiatrist must be up to date on medicolegal issues and managed care. This section provides an overview of psychiatric emergencies in general and in adults in particular. Section 23.3 covers psychiatric emergencies in children.

TREATMENT SETTINGS

Most emergency psychiatric evaluations are done by nonpsychiatrists in a general medical emergency room setting, but specialized psychiatric services are increasingly favored. Regardless of the type of setting, an atmosphere of safety and security must prevail. An adequate number of staff members—including psychiatrists, nurses, aides, and social workers—must be present at all times. Additional personnel to help out in times of overcrowding should be available. Specific responsibilities, such as the use of restraints, should be clearly defined and practiced by the entire emergency team. Clear communication and lines of authority are essential. The organization of the staff into multidisciplinary teams is desirable.

Children and young adolescents are best served in a pediatric setting (see [Section 23.3](#)). Unless there is a risk of behavioral problems or of their leaving the hospital against advice, they need not be sent to the adult psychiatric emergency service.

Immediate access to the medical emergency room and to appropriate diagnostic services is necessary because one third of medical conditions present with psychiatric manifestations. The full spectrum of psychopharmacological options should be available to the psychiatrist.

Violence in the emergency service cannot be condoned or tolerated. The code of conduct expected of staff members and patients must be posted and understood from the time of the patient's arrival in the emergency room. Security is best managed as a clinical issue by the clinical staff, not by law enforcement personnel. Whenever possible, agitated and threatening patients should be sequestered from the nonagitated. Seclusion and restraint rooms should be located close to the nursing station for close observation.

The entire staff must understand that patients in physical and emotional distress are fragile and that various expectations and fantasies, often unrealistic, influence their responses to treatment. For example, a man with impaired reality testing who is brought in by the police against his will may not understand that the clinician is interested in helping him. Other patients, influenced by previous unsatisfactory treatment experiences, may be hostile. A high percentage of patients believe that psychiatrists can read minds or are only interested in admitting patients to lock them away. Such people see little point in openly discussing their problems. Many people have an inaccurate understanding of their rights as patients. All clinical interventions must take those expectations and attitudes into account to minimize the possibility of misunderstanding and consequent problems.

EPIDEMIOLOGY

Psychiatric emergency rooms are used equally by men and women and more by single than by married persons. About 20 percent of these patients are suicidal, and about 10 percent are violent. The most common diagnoses are mood disorders (including depressive disorders and manic episodes), schizophrenia, and alcohol dependence. About 40 percent of all patients seen in psychiatric emergency rooms require hospitalization. Most visits occur during the night hours, but usage difference is not based on the day of the week or the month of the year. Contrary to popular belief, studies have not found that use of psychiatric emergency rooms increases during the full moon or the Christmas season.

EVALUATION

The primary goal of an emergency psychiatric evaluation is the timely assessment of the patient in crisis. To that end, the physician must make an initial diagnosis, identify the precipitating factors and immediate needs, and begin treatment or refer the patient to the most appropriate treatment setting. In view of the unpredictable nature of emergency room work, with many patients presenting both physical and emotional complaints, and in view of the limited space and the competition for ancillary services, a pragmatic approach to the patient is required. Sometimes, moving the patient out of the emergency room into the most appropriate diagnostic or treatment setting is best for the patient. Medical emergencies are generally better managed elsewhere in the system. Keeping the number of emergency patients in one place to a minimum reduces the chance of agitation and violence.

The standard psychiatric interview—consisting of a history, a mental status examination, and, when appropriate and depending on the rules of the emergency room, a full physical examination and ancillary tests—is the cornerstone of the emergency room evaluation. The emergency room psychiatrist, however, must be ready to introduce modifications as needed. For example, the emergency psychiatrist may have to structure the interview with a rambling manic patient, medicate or restrain an agitated patient, or forgo the usual rules of confidentiality to assess an adolescent's risk of suicide. In general, any strategy introduced in the emergency room to accomplish the goal of assessing the patient is considered consistent with good clinical practice as long as the rationale for the strategy is documented in the medical record.

What constitutes a psychiatric emergency is highly subjective. The emergency room has increasingly come to serve as an admitting area, a holding room, a detoxification center, and a private medical office. Such medical conditions as head traumas, acute intoxications, withdrawal states, and AIDS encephalopathies may present with acute psychiatric manifestations. The emergency psychiatrists must rapidly assess and distinguish the truly emergency psychiatric patients from those who are less acutely ill and from nonpsychiatric emergencies. A triage system using psychiatrists, nurses, and psychiatric social workers is an efficient and effective way to identify emergency, urgent, and nonurgent patients, who can then be prioritized for care ([Fig. 23.2-1](#)).

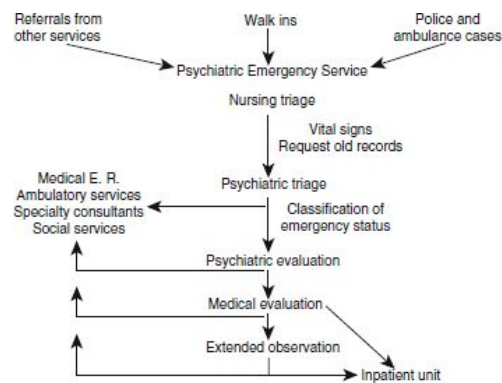

FIGURE 23.2-1
Evaluation and treatment of psychiatric emergencies.

In one model, every patient who comes to the emergency room is assessed by a triage nurse on arrival to ascertain the patient's chief complaint, clinical condition, and vital signs. The psychiatrist then briefly meets with the patient and other significant people involved in the case—family members, emergency medical service technicians, and police—to assign the patient to one of the three categories—emergency, urgent, and nonurgent—or to refer the patient to an appropriate treatment setting, such as the medical emergency room. Having a senior clinician perform that task ensures rapid identification of the most urgent and troublesome cases, an appropriate allocation of resources, and an answer to the most common question heard in the emergency room: “When am I going to see a doctor?”

The psychiatrist then assigns clinical responsibility for each patient to the appropriate personnel. As the evaluation often stretches over more than one shift, a careful procedure to transfer responsibility and to pass along information from tour to tour must be built into the system by using visual, oral, and written communications. A request for old records should be made automatically for every patient who is assigned to the emergency room. Each emergency should be judged on its own merits, but information from previous records and from workers in the field and family members can be of crucial importance in assessing patients, especially patients who are psychotic, frightened, or otherwise unable or unwilling to cooperate in giving a good history.

A multilingual staff and a hospital language bank that lists bilingual staff members and other translation services should be readily available to the psychiatrist. The use of the patient's friends or family members as translators is not desirable because of the possibility of unconscious or deliberate denial or distortion of the clinical picture stemming from their involvement with the patient.

An initial assessment of the patient's total biopsychosocial needs is optimal, but the patient's emergency status, other patients waiting to be seen, and the constraints of the emergency room setting often make such a full assessment a moot point. At a minimum, the emergency evaluation should address the following five questions before any disposition is decided on: (1) Is it safe for the patient to be in the emergency room? (2) Is the problem organic, functional, or a combination? (3) Is the patient psychotic? (4) Is the patient suicidal or homicidal? (5) To what degree is the patient capable of self-care? Table 23.2-1 provides a general strategy for evaluating patients.

Table 23.2-1
General Strategy in Evaluating the Patient

I. Self-protection

- A. Know as much as possible about the patients before meeting them.
- B. Leave physical restraint procedures to those who are trained.
- C. Be alert to risks of impending violence.
- D. Attend to the safety of the physical surroundings (e.g., door access, room objects).
- E. Have others present during the assessment if needed.
- F. Have others in the vicinity.
- G. Attend to developing an alliance with the patient (e.g., do not confront or threaten patients with paranoid psychoses).

II. Prevent harm

- A. Prevent self-injury and suicide. Use whatever methods are necessary to prevent patients from hurting themselves during the evaluation.
- B. Prevent violence toward others. During the evaluation, briefly assess the patient for the risk of violence. If the risk is deemed significant, consider the following options:
 - 1. Inform the patient that violence is not acceptable.
 - 2. Approach the patient in a nonthreatening manner.
 - 3. Reassure, calm, or assist the patient's reality testing.
 - 4. Offer medication.
 - 5. Inform the patient that restraint or seclusion will be used if necessary.
 - 6. Have teams ready to restrain the patient.
 - 7. When patients are restrained, always closely observe them, and frequently check their vital signs. Isolate restrained patients from surrounding agitating stimuli. Immediately plan a further approach—medication, reassurance, medical evaluation.

III. Rule out organic mental disorders.

IV. Rule out impending psychosis.

Patient Safety

Physicians should consider the question of the patient's safety before evaluating every patient. The answer must address the issues of the emergency room's physical layout, staffing patterns and communication, and patient population. Psychiatrists must then take stock of themselves: Are they in the proper frame of mind to conduct an evaluation? Do any issues in the case spark countertransference reactions? The self-assessment should go on throughout the evaluation. The physical and emotional safety of the patient takes priority over all other considerations. If verbal interventions fail or are contraindicated, the use of medication or restraints must be considered and, if necessary, ordered. Careful attention to the possible outbreak of agitation or disruptive behavior beyond acceptable limits is often the best insurance against untoward occurrences.

Medical or Psychiatric?

The most important question for the emergency psychiatrist to address is whether the problem is medical, psychiatric, or both. Medical

conditions—such as diabetes mellitus, thyroid disease, acute intoxications, withdrawal states, AIDS, and head traumas—can present with prominent mental status changes that mimic common psychiatric illnesses (Fig. 23.2-2). Such conditions may be life-threatening if not treated promptly. Generally, the treatment of a medical illness is more definitive and the prognosis is better than for a functional psychiatric disorder. The psychiatrist must consider all casual possibilities.

FIGURE 23.2-2
 Bellevue Hospital emergency ward: a drug addict brought in after having taken an overdose. (Courtesy of Leonard Freed for Magnum Photos, Inc.)

Once patients are labeled psychiatric, their complaints may not be taken seriously by nonmental health professionals, however, and such patients' conditions may deteriorate, especially if they have a major Axis I syndrome. Because of such factors as deinstitutionalization, homelessness, and chronic alcoholism, the mentally ill are at great risk of tuberculosis, vitamin deficiencies, and other easily overlooked, but easily treated, conditions. Symptoms such as paranoia, internal preoccupation, and acute psychosis can make a routine medical diagnosis exceedingly difficult. Each patient must be assessed for the possibility that an organic illness is combined with an underlying psychiatric illness. A young man who comes to the emergency room intoxicated or in alcohol withdrawal two or three times a month may one day come with a subdural hematoma as a result of a fall. Table 23.2-2 lists features that point to a medical cause of a mental disorder.

Table 23.2-2
Features that Point to a Medical Cause of a Mental Disorder

Acute onset (within hours or minutes, with prevailing symptoms)
First episode
Geriatric age
Current medical illness or injury
Significant substance abuse
Nonauditory disturbances of perception
Neurological symptoms—loss of consciousness, seizures, head injury, change in headache pattern, change in vision
Classic mental status signs—diminished alertness, disorientation, memory impairment, impairment in concentration and attention, dyscalculia, concreteness
Other mental status signs—speech, movement, or gait disorders
Constructional apraxia—difficulties in drawing clock, cube, intersecting pentagons, Bender gestalt design

SPECIFIC INTERVIEW SITUATIONS

Psychosis

Whether the patient is psychotic refers not so much to the diagnosis as to the severity of the patient's symptoms and the degree of life disruption. The patient's degree of withdrawal from objective reality, level of affectivity, intellectual functioning, and degree of regression are other important parameters. Impairment in any of those areas may lead to difficulties in conducting an evaluation. Agitated, assaultive behavior or failure to comply with treatment recommendations may also result. A paranoid, hypervigilant patient may misperceive a staff member's offer of help as an attack and may lash out in self-defense. Command auditory hallucinations may cause a patient to deny symptoms and to throw prescriptions in the garbage immediately after leaving the emergency room. The psychiatrist should be alert to the complications that can arise with patients whose reality testing is impaired and the psychiatrist should modify the approach accordingly.

All communication with patients must be straightforward. All clinical interventions should be briefly explained in language the patient can understand. Psychiatrists should not assume that the patient trusts or believes them or even wants their help. Clinicians must be prepared to structure or to terminate an interview to limit the potential for agitation and regression.

Depression and Potentially Suicidal Patients

The clinician should always ask about suicidal ideas as part of every mental status examination, especially if the patient is depressed. The patient may not realize that such symptoms as waking during the night and increased somatic complaints are related to depressive disorders. The patient should be asked directly, "Are you or have you ever been suicidal?" "Do you want to die?" "Do you feel so bad that you might hurt yourself?" Eight of ten persons who eventually kill themselves give warnings of their intent. If the patient admits to a plan of action, that is a particularly dangerous sign. If a patient who has been threatening suicide becomes quiet and less agitated than before, that may be an ominous sign. The clinician should be especially concerned with the factors listed in Table 23.2-3.

**Table 23.2-3****History, Signs, and Symptoms of Suicidal Risk**

1. Previous attempt or fantasized suicide
2. Anxiety, depression, exhaustion
3. Availability of means of suicide
4. Concern for effect of suicide on family members
5. Verbalized suicidal ideation
6. Preparation of a will, resignation after agitated depression
7. Proximal life crisis, such as mourning or impending surgery
8. Family history of suicide
9. Pervasive pessimism or hopelessness

A suicide note, a family history of suicide, or previous suicidal behavior on the part of the patient increases the risk of suicide. Evidence of impulsivity or of pervasive pessimism about the future also places the patient at risk. If the physician decides that the patient is in imminent risk for suicidal behavior, the patient must be hospitalized or otherwise protected. A difficult situation arises when the risk does not seem to be immediate but the potential for suicide is present as long as the patient remains depressed. If the psychiatrist decides not to hospitalize the patient immediately, the doctor should insist that the patient promise to call whenever the suicidal pressure mounts.

Violent Patients

Patients may be violent for many reasons, and the interview with a violent patient must attempt to ascertain the underlying cause of the violent behavior, because cause determines intervention. The differential diagnosis of violent behavior includes psychoactive substance-induced organic mental disorder, antisocial personality disorder, catatonic schizophrenia, medical infections, cerebral neoplasms, decompensating obsessive-compulsive personality disorder, dissociative disorders, impulse control disorders, sexual disorders, alcohol idiosyncratic intoxication, delusional disorder, paranoid personality disorder, schizophrenia, temporal lobe epilepsy, bipolar disorder, and uncontrollable violence secondary to interpersonal stress. The psychiatric interview must include questions that attempt to sort out the differential for violent behavior and questions directed toward the prediction of violence.

The best predictors of violent behavior are (1) excessive alcohol intake; (2) a history of violent acts, with arrests or criminal activity; and (3) a history of childhood abuse. [Table 23.2-4](#) lists some of the most significant factors in assessing and predicting violence.

**Table 23.2-4****Assessing and Predicting Violent Behavior**

1. Signs of impending violence
 - a. Very recent acts of violence, including property violence
 - b. Verbal or physical threats (menacing)
 - c. Carrying weapons or other objects that may be used as weapons (e.g., forks, ashtrays)
 - d. Progressive psychomotor agitation
 - e. Alcohol or drug intoxication
 - f. Paranoid features in a psychotic patient
 - g. Command violent auditory hallucinations—some but not all patients are at high risk
 - h. Organic mental disorders, global or with frontal lobe findings; less commonly with temporal lobe findings (controversial)
 - i. Patients with catatonic excitement
 - j. Certain patients with mania
 - k. Certain patients with agitated depression
 - l. Personality disorder patients prone to rage, violence, or impulse dyscontrol
2. Assess the risk of violence
 - a. Consider violent ideation, wish, intention, plan, availability of means, implementation of plan, wish for help.
 - b. Consider demographics—sex (male), age (15–24), socioeconomic status (low), social supports (few).
 - c. Consider past history: violence, nonviolent antisocial acts, impulse dyscontrol (e.g., gambling, substance abuse, suicide or self-injury, psychosis).
 - d. Consider overt stressors (e.g., marital conflict, real or symbolic loss).

Rape and Sexual Abuse

Rape is the forceful coercion of an unwilling victim to engage in a sexual act, usually sexual intercourse, although anal intercourse and fellatio can also be acts of rape. As with other acts of violence, rape is a psychiatric emergency that requires immediate, appropriate intervention. Rape victims may suffer sequelae that persist for a lifetime. Rape is a life-threatening experience in which the victim has almost always been threatened with physical harm, often with a weapon. In addition to rape, other forms of sexual abuse include genital manipulation with foreign objects, infliction of pain, and forced sexual activity.

Most rapists are male, and most victims are female. Male rape does occur, however, often in institutions where men are detained (e.g., prisons). Women between the ages of 16 and 24 years are in the highest risk category, but female victims as young as 15 months and as old as 82 years have been raped. More than a third of all rapes are committed by rapists known to the victim, 7 percent by close relatives. A fifth of all rapes involve more than one rapist (gang rape).

Typical reactions in both rape and sexual abuse victims include shame, humiliation, anxiety, confusion, and outrage. Many victims wonder whether they are partly responsible and somehow invited the assault. In fact, victim behavior is less important in precipitating a rape than it is in precipitating a homicide or a robbery. Rape and sexual abuse victims are often confused after the assault. Clinicians should be reassuring, supportive, and nonjudgmental. Inform the patient about the availability of medical and legal services and about rape crisis centers that provide multidisciplinary services.

If possible, a female clinician should evaluate the patient, because the victim may find it easier to talk with a woman than with a man. The evaluation should take place in private. When rape or sexual abuse has not been acknowledged openly, it is usually because many victims hesitate to discuss the assault and thus avoid the topic. If the patient appears to be anxious when questioned about sexual history and avoids the discussion, it is important to validate the patient's avoidance. Recognize that the rape victim has undergone an unanticipated, life-threatening stress. It is legally and therapeutically important to take a detailed and complete history of the attack.

With the patient's written consent, collect evidence, such as semen and pubic hair, that may be used to identify the rapist. Take photographs of the evidence, if possible. The medical record may be used as evidence in criminal proceedings; therefore, meticulous objective documentation of all aspects of the evaluation is essential.

TREATMENT OF EMERGENCIES

Psychotherapy

In an emergency psychiatric intervention, all attempts are made to help patients' self-esteem. Empathy is critical to healing in a psychiatric emergency. The acquired knowledge of how biogenetic, situational, developmental, and existential forces converge at one point in history to create a psychiatric emergency is tantamount to the maturation of skill in emergency psychiatry. Adjustment disorder in all age groups may

result in tantrum-like outbursts of rage. These outbursts are particularly common in marital quarrels, and police are often summoned by neighbors distressed by the sounds of a violent altercation. Such family quarrels should be approached with caution, because they may be complicated by alcohol use and the presence of dangerous weapons. The warring couple frequently turns their combined fury on an unwary outsider. Wounded self-esteem is a major issue, and clinicians must avoid patronizing or contemptuous attitudes and try to communicate an attitude of respect and an authentic peacemaking concern.

In family violence, psychiatrists should note the special vulnerability of selected close relatives. A wife or husband may have a curious masochistic attachment to the spouse and can provoke violence by taunting and otherwise undermining a partner's self-esteem. Such relationships often end in the murder of the provoking partner and sometimes in the suicide of the other partner—the dynamics behind most so-called suicide pacts. As with many suicidal patients, many violent patients require hospitalization and usually accept the offer of inpatient care with a sense of relief.

More than one psychotherapist or type of psychotherapy is frequently used in emergency therapy. For example, a 28-year-old man, depressed and suicidal after a colostomy for intractable colitis, whose wife was threatening to leave him because of his irritability and their constant altercations, may be referred to a psychiatrist for supportive psychotherapy and antidepressant medication, to a marital therapist with his wife to improve their marital functioning, and to a colostomy support group to learn ways of coping with a colostomy. Emergency psychiatric clinicians are pragmatic; they use every necessary mode of therapeutic intervention available to resolve the crisis and facilitate value exploration and growth, with less concern than usual about diluting a therapeutic relationship. Emergency therapy emphasizes how various psychiatric modalities act synergistically to enhance recovery.

No single approach is appropriate for all persons in similar situations. What does a doctor say to a patient and a family experiencing a psychiatric emergency, such as a suicide attempt or a schizophrenic break? For some, a genetic rationale helps; the information that an illness has a strong biological component relieves some persons. For others, however, this approach underlines a lack of control and increases depression and anxiety. All feel helpless because neither the family nor the patient can alter the behavior to minimize the likelihood of recurrence. Some persons may benefit from an explanation of family or individual dynamics. Others only want someone to listen to them; in time, they reach their own understanding.

In an emergency situation as in any other psychiatric situation, when a clinician does not know what to say, the best approach is to listen. Persons in crisis reveal how much they need support, denial, ventilation, and words to conceptualize the meaning of their crisis and to discover paths to resolution.

Pharmacotherapy

The major indications for the use of psychotropic medication in an emergency room include violent or assaultive behavior, massive anxiety or panic, and extrapyramidal reactions, such as dystonia and akathisia as adverse effects of psychiatric drugs. Laryngospasm is a rare form of dystonia, and psychiatrists should be prepared to maintain an open airway with intubation if necessary.

Persons who are paranoid or in a state of catatonic excitement require tranquilization. Episodic outbursts of violence respond to haloperidol (Haldol), β -adrenergic receptor antagonists (β -blockers), carbamazepine (Tegretol), and lithium (Eskalith). If a history suggests a seizure disorder, use clinical studies to confirm the diagnosis and an evaluation to ascertain the cause. If the findings are positive, anticonvulsant therapy is initiated or appropriate surgery is provided (e.g., in the case of a cerebral mass). Conservative measures may suffice for intoxication from drugs of abuse. Sometimes, drugs such as haloperidol (5 to 10 mg every half-hour to an hour) are needed until a patient is stabilized. Benzodiazepines may be used instead of, or in addition to, antipsychotics (to reduce the antipsychotic dosage). When a recreational drug has strong anticholinergic properties, benzodiazepines are more appropriate than antipsychotics. Persons with allergic or aberrant responses to antipsychotics and benzodiazepines are treated with amobarbital (Amytal; 130 mg orally or intramuscularly [IM]), paraldehyde, or diphenhydramine (Benadryl; 50 to 100 mg orally or IM).

Violent, struggling patients are subdued most effectively with an appropriate sedative or antipsychotic. Diazepam (Valium; 5 to 10 mg) or lorazepam (Ativan; 2 to 4 mg) may be given slowly intravenously (IV) over 2 minutes. Clinicians must give IV medication with great care to avoid respiratory arrest. Patients who require IM medication can be sedated with haloperidol (5 to 10 mg IM). If the furor is caused by alcohol or is part of a postseizure psychomotor disturbance, the sleep produced by a relatively small amount of an IV medication may go on for hours. On awakening, patients are often entirely alert and rational and typically have complete amnesia about the violent episode.

If the disturbance is part of an ongoing psychotic process and returns as soon as the IV medication wears off, continuous medication may be given. It is sometimes better to use small IM or oral doses at half-hour to 1-hour intervals (e.g., haloperidol, 2 to 5 mg, or diazepam, 20 mg) until the patient is controlled than to use large dosages initially, which can result in an overmedicated patient. As the disturbed behavior is brought under control, successively smaller and less frequent doses should be used. During the preliminary treatment, a patient's blood pressure and other vital signs should be monitored.

Restraints

Restraints are used when patients are so dangerous to themselves or others that they pose a severe threat that cannot be controlled in any other way. Patients may be restrained temporarily to receive medication or for long periods if medication cannot be used. Usually, patients in restraints quiet down after a time. On a psychodynamic level, such patients may even welcome the control of their impulses provided by restraints. [Table 23.2-5](#) provides a summary of the use of restraints.

Table 23.2-5
Use of Restraints

Preferably five or a minimum of four persons should be used to restrain the patient. Leather restraints are the safest and surest type of restraint.

Explain to the patient why he or she is going into restraints.

A staff member should always be visible and reassuring the patient who is being restrained. Reassurance helps alleviate the patient's fear of helplessness, impotence, and loss of control.

Patients should be restrained with legs spread-eagled and one arm restrained to one side and the other arm restrained over the patient's head.

Restraints should be placed so that intravenous fluids can be given, if necessary.

The patient's head is raised slightly to decrease the patient's feelings of vulnerability and to reduce the possibility of aspiration.

The restraints should be checked periodically for safety and comfort.

After the patient is in restraints, the clinician begins treatment, using verbal intervention.

Even in restraints, most patients still take antipsychotic medication in concentrated form.

After the patient is under control, one restraint at a time should be removed at 5-minute intervals until the patient has only two restraints on. Both of the remaining restraints should be removed at the same time, because it is inadvisable to keep a patient in only one restraint.

Always thoroughly document the reason for the restraints, the course of treatment, and the patient's response to treatment while in restraints.

(Data from Dubin WR, Weiss KJ. Emergency psychiatry. In: Michaels R, Cooper A, Guze SB, et al., eds. *Psychiatry*. Vol. 2. Philadelphia: Lippincott; 1991.)

Disposition

In some cases, the usual option of admitting or discharging the patient is not considered optimal. Suspected toxic psychoses, brief decompensations in a patient with a personality disorder, and adjustment reactions to traumatic events, for example, may be best managed in an extended-observation setting. Allowing the patient additional time in a secure environment can result in sufficient improvement or clarification of the issues to make traditional inpatient treatment unnecessary. It can also spare the patient the trauma and stigma of a psychiatric admission and can free up bed space for needier patients. Crisis intervention for victims of rape and other traumas can also be done in an extended-observation setting.

When the decision is to admit the patient to the hospital, it is preferable to do so on a voluntary basis. Allowing patients that option gives them a sense of control over their lives and of participation in the treatment decisions. Patients who clearly meet involuntary admission criteria on the basis of dangerousness to themselves or to others cannot leave the hospital without further review and can always be converted to involuntary status if warranted.

Because the initial evaluation is often inconclusive, definitive treatment is best deferred until the patient can be further assessed in the inpatient unit or in the outpatient department. When the diagnosis is clear, however, and the patient's response to previous treatment is known, nothing is gained by delay. For example, a patient with chronic schizophrenia that has decompensated after discontinuing the usual regimen of antipsychotic medication is best served by prompt resumption of treatment.

Even if patients feel comfortable coming to the emergency room in times of need, the emergency psychiatrist should always direct or redirect them to the most appropriate treatment setting. Patients in the psychopharmacology clinic who have missed their regular appointments should be given only enough medication to sustain them until they can be seen in the clinic. Feedback to others treating them should be a matter of course.

The emergency room is often the gateway to the department of psychiatry or the general hospital. First impressions carry a great deal of weight. The kind of attention and concern shown to patients on arrival in the emergency room strongly affects how they will respond to staff members and treatment recommendations and even their treatment compliance long after they have left the emergency room.

Documentation

In the interests of good care, respect for patients' rights, cost control, and medicolegal concerns, documentation has become a central focus for the emergency physician. The medical record should convey a concise picture of the patient, highlighting all pertinent positive and negative findings. Gaps in information and their reason should be mentioned. The names and the telephone numbers of interested parties should be noted. A provisional diagnosis or differential diagnosis must be made. An initial treatment plan or recommendations should clearly follow from the findings of the patient's history, mental status examination and other diagnostic tests, and the medical evaluation. The writing must be legible. The emergency physician has unusual latitude under the law to perform an adequate initial assessment; however, all interventions and decisions must be thought out, discussed, and documented in the patient's record.

Specific Psychiatric Emergencies

Table 23.2-6 outlines common psychiatric emergencies in alphabetical order. Readers are referred to the index and to specific chapters of this textbook for a thorough discussion of each disorder.

Table 23.2-6 Common Psychiatric Emergencies

Syndrome	Emergency Manifestations	Treatment Issues
Abuse of child or adult	Signs of physical trauma	Management of medical problems; psychiatric evaluation; report to authorities
Acquired immune deficiency syndrome (AIDS)	Changes in behavior secondary to organic causes; changes in behavior secondary to fear and anxiety; suicidal behavior	Management of neurological illness; management of psychological concomitants; reinforcement of social support
Adolescent crises	Suicidal attempts and ideation; substance abuse, truancy, trouble with law, pregnancy, running away; eating disorders; psychosis	Evaluation of suicidal potential, extent of substance abuse, family dynamics; crisis-oriented family and individual therapy; hospitalization if necessary; consultation with appropriate extrafamilial authorities
Agoraphobia	Panic; depression	Alprazolam (Xanax), 0.25 mg to 2 mg; propranolol (Inderal); antidepressant medication
Agranulocytosis (clozapine [Clozaril]-induced)	High fever, pharyngitis, oral and perianal ulcerations	Discontinue medication immediately; administer granulocyte colony-stimulating factor
Akathisia	Agitation, restlessness, muscle discomfort; dysphoria	Reduce antipsychotic dosage; propranolol (30 to 120 mg a day); benzodiazepines; diphenhydramine (Benadryl) orally or IV; benztropine (Cogentin) IM
Alcohol-related emergencies		
Alcohol delirium	Confusion, disorientation, fluctuating consciousness and perception, autonomic hyperactivity; may be fatal	Chlordiazepoxide (Librium); haloperidol (Haldol) for psychotic symptoms may be added if necessary
Alcohol intoxication	Disinhibited behavior, sedation at high doses	With time and protective environment, symptoms abate
Alcohol persisting amnesic disorder	Confusion, loss of memory even for all personal identification data	Hospitalization; hypnosis; amobarbital (Amytal) interview; rule out organic cause
Alcohol persisting dementia	Confusion, agitation, impulsivity	Rule out other causes for dementia; no effective treatment; hospitalization if necessary
Alcohol psychotic disorder with hallucinations	Vivid auditory (at times visual) hallucinations with affect appropriate to content (often fearful); clear sensorium	Haloperidol for psychotic symptoms
Alcohol seizures	Grand mal seizures; rarely status epilepticus	Diazepam (Valium), phenytoin (Dilantin); prevent by using chlordiazepoxide (Librium) during detoxification
Alcohol withdrawal	Irritability, nausea, vomiting, insomnia, malaise, autonomic hyperactivity, shakiness	Fluid and electrolytes maintained; sedation with benzodiazepines; restraints; monitoring of vital signs; 100 mg thiamine IM
Idiosyncratic alcohol intoxication	Marked aggressive or assaultive behavior	Generally no treatment required other than protective environment
Korsakoff's syndrome	Alcohol stigmata, amnesia, confabulation	No effective treatment; institutionalization often needed
Wernicke's encephalopathy	Oculomotor disturbances, cerebellar ataxia; mental confusion	Thiamine, 100 mg IV or IM, with MgSO ₄ given before glucose loading
Amphetamine (or related substance) intoxication	Delusions, paranoia; violence; depression (from withdrawal); anxiety, delirium	Antipsychotics; restraints; hospitalization if necessary; no need for gradual withdrawal; antidepressants may be necessary
Anorexia nervosa	Loss of 25% of body weight of the norm for age and sex	Hospitalization; electrocardiogram (ECG), fluid and electrolytes; neuroendocrine evaluation
Anticholinergic intoxication	Psychotic symptoms, dry skin and mouth, hyperpyrexia, mydriasis, tachycardia, restlessness, visual hallucinations	Discontinue drug, IV physostigmine (Antilirium), 0.5 to 2 mg, for severe agitation or fever, benzodiazepines; antipsychotics contraindicated
Anticonvulsant intoxication	Psychosis; delirium	Dosage of anticonvulsant is reduced
Benzodiazepine intoxication	Sedation, somnolence, and ataxia	Supportive measures; flumazenil (Romazicon), 7.5 to 45 mg a day, titrated as needed, should be used only by skilled personnel with resuscitative equipment available
Bereavement	Guilt feelings, irritability; insomnia; somatic complaints	Must be differentiated from major depressive disorder; antidepressants not indicated; benzodiazepines for sleep; encouragement of ventilation
Borderline personality disorder	Suicidal ideation and gestures; homicidal ideations and gestures; substance abuse; micropsychotic episodes; burns, cut marks on body	Suicidal and homicidal evaluation (if great, hospitalization); small dosages of antipsychotics; clear follow-up plan
Brief psychotic disorder	Emotional turmoil, extreme lability; acutely impaired reality testing after obvious psychosocial stress	Hospitalization often necessary; low dosage of antipsychotics may be necessary but often resolves spontaneously
Bromide intoxication	Delirium; mania; depression; psychosis	Serum levels obtained (>50 mg a day); bromide intake discontinued; large quantities of sodium chloride IV or orally; if agitation, paraldehyde or antipsychotic is used
Caffeine intoxication	Severe anxiety, resembling panic disorder; mania; delirium; agitated depression; sleep disturbance	Cessation of caffeine-containing substances; benzodiazepines
Cannabis intoxication	Delusions; panic; dysphoria; cognitive impairment	Benzodiazepines and antipsychotics as needed; evaluation of suicidal or homicidal risk; symptoms usually abate with time and reassurance
Catatonic schizophrenia	Marked psychomotor disturbance (either excitement or stupor); exhaustion; can be fatal	Rapid tranquilization with antipsychotics; monitor vital signs; amobarbital may release patient from catatonic mutism or stupor but can precipitate violent behavior
Cimetidine psychotic disorder	Delirium; delusions	Reduce dosage or discontinue drug
Clonidine withdrawal	Irritability; psychosis; violence; seizures	Symptoms abate with time, but antipsychotics may be necessary; gradual lowering of dosage
Cocaine intoxication and withdrawal	Paranoia and violence; severe anxiety; manic state; delirium: schizophreniform psychosis; tachycardia, hypertension, myocardial infarction, cerebrovascular disease; depression and suicidal ideation	Antipsychotics and benzodiazepines; antidepressants or electroconvulsive therapy (ECT) for withdrawal depression if persistent; hospitalization
Delirium	Fluctuating sensorium; suicidal and homicidal risk; cognitive clouding; visual, tactile, and auditory hallucinations; paranoia	Evaluate all potential contributing factors and treat each accordingly; reassurance, structure, clues to orientation; benzodiazepines and low-dosage, high-potency antipsychotics must be used with extreme care because of their potential to act paradoxically and increase agitation

Delusional disorder	Most often brought into emergency room involuntarily; threats directed toward others	Antipsychotics if patient will comply (IM if necessary); intensive family intervention; hospitalization if necessary
Dementia	Unable to care for self; violent outbursts; psychosis; depression and suicidal ideation; confusion	Small dosages of high-potency antipsychotics; clues to orientation; organic evaluation, including medication use; family intervention
Depressive disorders	Suicidal ideation and attempts; self-neglect; substance abuse	Assessment of danger to self; hospitalization if necessary, nonpsychiatric causes of depression must be evaluated
L-Dopa intoxication	Mania; depression; schizophreniform disorder, may induce rapid cycling in patients with bipolar I disorder	Lower dosage or discontinue drug
Dystonia, acute	Intense involuntary spasm of muscles of neck, tongue, face, jaw, eyes, or trunk	Decrease dosage of antipsychotic; benztropine or diphenhydramine IM
Group hysteria	Groups of people exhibit extremes of grief or other disruptive behavior	Group is dispersed with help of other health care workers; ventilation, crisis-oriented therapy; if necessary, small dosages of benzodiazepines
Hallucinogen-induced psychotic disorder with hallucinations	Symptom picture is result of interaction of type of substance, dose taken, duration of action, user's premorbid personality, setting; panic; agitation; atropine psychosis	Serum and urine screens; rule out underlying medical or mental disorder; benzodiazepines (2 to 20 mg) orally; reassurance and orientation; rapid tranquilization; often responds spontaneously
Homicidal and assaultive behavior	Marked agitation with verbal threats	Seclusion, restraints, medication
Homosexual panic	Not seen with men or women who are comfortable with their sexual orientation; occurs in those who adamantly deny having any homoerotic impulses; impulses are aroused by talk, a physical overture, or play among same-sex friends, such as wrestling, sleeping together, or touching each other in a shower or hot tub; panicked person sees others as sexually interested in him or her and defends against them	Ventilation, environmental structuring, and, in some instances, medication for acute panic (e.g., alprazolam, 0.25 to 2 mg) or antipsychotics may be required; opposite-sex clinician should evaluate the patient whenever possible, and the patient should not be touched save for the routine examination; patients have attacked physicians who were examining an abdomen or performing a rectal examination (e.g., on a man who harbors thinly veiled unintegrated homosexual impulses)
Hypertensive crisis	Life-threatening hypertensive reaction secondary to ingestion of tyramine-containing foods in combination with monoamine oxidase inhibitors (MAOIs); headache, stiff neck, sweating, nausea, vomiting	α -Adrenergic blockers (e.g., phentolamine [Rogitine]); nifedipine (Procardia) 10 mg orally; chlorpromazine (Thorazine); make sure symptoms are not secondary to hypotension (side effect of MAOIs alone)
Hyperthermia	Extreme excitement or catatonic stupor or both; extremely elevated temperature; violent hyperagitation	Hydrate and cool; may be drug reaction, so discontinue any drug; rule out infection
Hyperventilation	Anxiety, terror, clouded consciousness; giddiness, faintness; blurring vision	Shift alkalosis by having patient breathe into paper bag; patient education; antianxiety agents
Hypothermia	Confusion; lethargy; combativeness; low body temperature and shivering; paradoxical feeling of warmth	IV fluids and rewarming, cardiac status must be carefully monitored; avoidance of alcohol
Incest and sexual abuse of child	Suicidal behavior; adolescent crises; substance abuse	Corroboration of charge, protection of victim; contact social services; medical and psychiatric evaluation; crisis intervention
Insomnia	Depression and irritability; early morning agitation; frightening dreams; fatigue	Hypnotics only in short term (e.g., triazolam [Halcion], 0.25 to 0.5 mg, at bedtime); treat any underlying mental disorder; rules of sleep hygiene
Intermittent explosive disorder	Brief outbursts of violence; periodic episodes of suicide attempts	Benzodiazepines or antipsychotics for short term; long-term evaluation with computed tomography (CT) scan, sleep-deprived electroencephalogram (EEG), glucose tolerance curve
Jaundice	Uncommon complication of low-potency phenothiazine use (e.g., chlorpromazine)	Change drug to low dosage of a low-potency agent in a different class
Leukopenia and agranulocytosis	Side effects within the first 2 months of treatment with antipsychotics	Patient should call immediately for sore throat, fever, etc., and obtain immediate blood count; discontinue drug; hospitalize if necessary
Lithium (Eskalith) toxicity	Vomiting; abdominal pain; profuse diarrhea; severe tremor, ataxia; coma; seizures; confusion; dysarthria; focal neurological signs	Lavage with wide-bore tube; osmotic diuresis; medical consultation; may require intensive care unit treatment

Major depressive episode with psychotic features	Major depressive episode symptoms with delusions; agitation, severe guilt; ideas of reference; suicide and homicide risk	Antipsychotics plus antidepressants; evaluation of suicide and homicide risk; hospitalization and ECT if necessary
Manic episode	Violent, impulsive behavior; indiscriminate sexual or spending behavior; psychosis; substance abuse	Hospitalization; restraints if necessary; rapid tranquilization with antipsychotics; restoration of lithium levels
Marital crises	Precipitant may be discovery of an extramarital affair, onset of serious illness, announcement of intent to divorce, or problems with children or work; one or both members of the couple may be in therapy or may be psychiatrically ill; one spouse may be seeking hospitalization for the other	Each should be questioned alone regarding extramarital affairs, consultations with lawyers regarding divorce, and willingness to work in crisis-oriented or long-term therapy to resolve the problem; sexual, financial, and psychiatric treatment histories from both, psychiatric evaluation at the time of presentation; may be precipitated by onset of untreated mood disorder or affective symptoms caused by medical illness or insidious-onset dementia; referral for management of the illness reduces immediate stress and enhances the healthier spouse's coping capacity; children may give insights available only to someone intimately involved in the social system
Migraine	Throbbing, unilateral headache	Sumatriptan (Imitrex) 6 mg IM
Mitral valve prolapse	Associated with panic disorder; dyspnea and palpitations; fear and anxiety	Echocardiogram; alprazolam or propranolol
Neuroleptic malignant syndrome	Hyperthermia; muscle rigidity; autonomic instability; parkinsonian symptoms; catatonic stupor; neurological signs; 10% to 30% fatality; elevated creatine phosphokinase (CPK)	Discontinue antipsychotic; IV dantrolene (Dantrium); bromocriptine (Parlodel) orally; hydration and cooling; monitor CPK levels
Nitrous oxide toxicity	Euphoria and light-headedness	Symptoms abate without treatment within hours of use
Nutmeg intoxication	Agitation; hallucinations; severe headaches; numbness in extremities	Symptoms abate within hours of use without treatment
Opioid intoxication and withdrawal	Intoxication can lead to coma and death; withdrawal is not life-threatening	IV naloxone, narcotic antagonist; urine and serum screens; psychiatric and medical illnesses (e.g., AIDS) may complicate picture
Panic disorder	Panic, terror; acute onset	Must differentiate from other anxiety-producing disorders, both medical and psychiatric; ECG to rule out mitral valve prolapse; propranolol (10 to 30 mg); alprazolam (0.25 to 2.0 mg); long-term management may include an antidepressant
Paranoid schizophrenia	Command hallucinations; threat to others or themselves	Rapid tranquilization; hospitalization; long-acting depot medication; threatened persons must be notified and protected
Parkinsonism	Stiffness, tremor, bradykinesia, flattened affect, shuffling gait, salivation, secondary to antipsychotic medication	Oral antiparkinsonian drug for 4 weeks to 3 months; decrease dosage of the antipsychotic
Perioral (rabbit) tremor	Perioral tumor (rabbit-like facial grimacing) usually appearing after long-term therapy with antipsychotics	Decrease dosage or change to a medication in another class
Phencyclidine (or phencyclidine-like intoxication)	Paranoid psychosis; can lead to death; acute danger to self and others	Serum and urine assay; benzodiazepines may interfere with excretion; antipsychotics may worsen symptoms because of anticholinergic side effects; medical monitoring and hospitalization for severe intoxication
Phenelzine-induced psychotic disorder	Psychosis and mania in predisposed people	Reduce dosage or discontinue drug
Phenylpropranolamine toxicity	Psychosis; paranoia; insomnia; restlessness; nervousness; headache	Symptoms abate with dosage reduction or discontinuation (found in over-the-counter diet aids and oral and nasal decongestants)
Phobias	Panic, anxiety; fear	Treatment same as for panic disorder
Photosensitivity	Easy sunburning secondary to use of antipsychotic medication	Patient should avoid strong sunlight and use high-level sunscreens
Pigmentary retinopathy	Reported with dosages of thioridazine (Mellaril) of 800 mg a day or above	Remain below 800 mg a day of thioridazine

Postpartum psychosis	Childbirth can precipitate schizophrenia, depression, reactive psychoses, mania, and depression; affective symptoms are most common; suicide risk is reduced during pregnancy but increased in the postpartum period	Danger to self and others (including infant) must be evaluated and proper precautions taken; medical illness presenting with behavioral aberrations is included in the differential diagnosis and must be sought and treated; care must be paid to the effects on father, infant, grandparents, and other children
Posttraumatic stress disorder	Panic, terror; suicidal ideation; flashbacks	Reassurance; encouragement of return to responsibilities; avoid hospitalization if possible to prevent chronic invalidism; monitor suicidal ideation
Priapism (trazodone [Desyre]-induced)	Persistent penile erection accompanied by severe pain	Intracorporeal epinephrine; mechanical or surgical drainage
Propranolol toxicity	Profound depression; confusional states	Reduce dosage or discontinue drug; monitor suicidality
Rape	Not all sexual violations are reported; silent rape reaction is characterized by loss of appetite, sleep disturbance, anxiety, and, sometimes, agoraphobia; long periods of silence, mounting anxiety, stuttering, blocking, and physical symptoms during the interview when the sexual history is taken; fear of violence and death and of contracting a sexually transmitted disease or being pregnant	Rape is a major psychiatric emergency; victim may have enduring patterns of sexual dysfunction; crisis-oriented therapy, social support, ventilation, reinforcement of healthy traits, and encouragement to return to the previous level of functioning as rapidly as possible; legal counsel; thorough medical examination and tests to identify the assailant (e.g., obtaining samples of pubic hairs with a pubic hair comb, vaginal smear to identify blood antigens in semen); if a woman, methoxyprogesterone or diethylstilbestrol orally for 5 days to prevent pregnancy; if menstruation does not commence within 1 week of cessation of the estrogen, all alternatives to pregnancy, including abortion, should be offered; if the victim has contracted a venereal disease, appropriate antibiotics; witnessed written permission is required for the physician to examine, photograph, collect specimens, and release information to the authorities; obtain consent, record the history in the patient's own words, obtain required tests, record the results of the examination, save all clothing, defer diagnosis, and provide protection against disease, psychic trauma, and pregnancy; men's and women's responses to rape affectively are reported similarly, although men are more hesitant to talk about homosexual assault for fear they will be assumed to have consented
Reserpine intoxication	Major depressive episodes; suicidal ideation; nightmares	Evaluation of suicidal ideation; lower dosage or change drug; antidepressants or ECT may be indicated
Schizoaffective disorder	Severe depression; manic symptoms; paranoia	Evaluation of dangerousness to self or others; rapid tranquilization if necessary; treatment of depression (antidepressants alone can enhance schizophrenic symptoms); use of antimanic agents
Schizophrenia	Extreme self-neglect; severe paranoia; suicidal ideation or assaultiveness; extreme psychotic symptoms	Evaluation of suicidal and homicidal potential; identification of any illness other than schizophrenia; rapid tranquilization
Schizophrenia in exacerbation	Withdrawn; agitation; suicidal and homicidal risk	Suicide and homicide evaluation; screen for medical illness; restraints and rapid tranquilization if necessary; hospitalization if necessary; reevaluation of medication regimen
Sedative, hypnotic, or anxiolytic intoxication and withdrawal	Alterations in mood, behavior, thought—delirium; derealization and depersonalization; untreated, can be fatal; seizures	Naloxone (Narcan) to differentiate from opioid intoxication; slow withdrawal with phenobarbital (Luminal) or sodium thiopental or benzodiazepine; hospitalization
Seizure disorder	Confusion; anxiety; derealization and depersonalization; feelings of impending doom; gustatory or olfactory hallucinations; fugue-like state	Immediate EEG; admission and sleep-deprived and 24-hour EEG; rule out pseudoseizures; anticonvulsants
Substance withdrawal	Abdominal pain; insomnia, drowsiness; delirium; seizures; symptoms of tardive dyskinesia may emerge; eruption of manic or schizophrenic symptoms	Symptoms of psychotropic drug withdrawal disappear with time or disappear with reinstatement of the substance; symptoms of antidepressant withdrawal can be successfully treated with anticholinergic agents, such as atropine; gradual withdrawal of psychotropic substances over 2 to 4 weeks generally obviates development of symptoms
Sudden death associated with antipsychotic medication	Seizures; asphyxiation; cardiovascular causes; postural hypotension; laryngeal-pharyngeal dystonia; suppression of gag reflex	Specific medical treatments
Sudden death of psychogenic origin	Myocardial infarction after sudden psychic stress; voodoo and hexes; hopelessness, especially associated with serious physical illness	Specific medical treatments; folk healers
Suicide	Suicidal ideation; hopelessness	Hospitalization, antidepressants
Sympathomimetic withdrawal	Paranoia; confusional states; depression	Most symptoms abate without treatment; antipsychotics; antidepressants if necessary
Tardive dyskinesia	Dyskinesia of mouth, tongue, face, neck, and trunk; choreoathetoid movements of extremities; usually but not always appearing after long-term treatment with antipsychotics, especially after a reduction in dosage; incidence highest in the elderly and brain damaged; symptoms are intensified by antiparkinsonian drugs and masked but not cured by increased dosages of antipsychotic	No effective treatment reported; may be prevented by prescribing the least amount of drug possible for as little time as is clinically feasible and using drug-free holidays for patients who need to continue taking the drug; decrease or discontinue drug at first sign of dyskinetic movements
Thyrotoxicosis	Tachycardia; gastrointestinal dysfunction; hyperthermia; panic, anxiety, agitation; mania; dementia; psychosis	Thyroid function test (T ₃ , T ₄ , thyroid-stimulating hormone [TSH]); medical consultation
Toluene abuse	Anxiety; confusion; cognitive impairment	Neurological damage is nonprogressive and reversible if toluene use is discontinued early
Vitamin B ₁₂ deficiency	Confusion; mood and behavior changes; ataxia	Treatment with vitamin B ₁₂
Volatile nitrates	Alternations of mood and behavior; light-headedness; pulsating headache	Symptoms abate with cessation of use

23.3 Psychiatric Emergencies in Children

Few children or adolescents seek psychiatric intervention on their own, even during crisis; thus, most of their emergency evaluations are initiated by parents, relatives, teachers, therapists, physicians, and child protective service workers. Some referrals are for the evaluation of life-threatening situations for the child or for others, such as suicidal behavior, physical abuse, and violent or homicidal behavior. Other urgent but non-life-threatening referrals pertain to children and adolescents with exacerbations of clear-cut serious psychiatric disorders, such as mania, depression, florid psychosis, and school referral. Less diagnostically obvious situations occur when children and adolescents present with a history of a wide range of disruptive, aberrant behaviors, and are accompanied by an overwhelmed, anxious, and distraught adult who perceives the child's actions as an emergency, despite the absence of life-threatening behavior of an obvious psychiatric disorder. In those cases, the spectrum of contributing factors is not immediately clear, and the emergency psychiatrist must assess the entire family or system involved with the child. Familial stressors and parental discord can contribute to the evolution of a crisis for a child. For example, immediate evaluations are sometimes legitimately indicated for a child caught in the crossfire of feuding parents or in a seemingly irreconcilable conflict between a set of parents and a school, therapist, or protective service worker regarding the needs of the child (Table 23.3-1).

Table 23.3-1
Familial Risk Factors

Physical and sexual abuse
Recent family crisis: loss of a parent, divorce, loss of job, family move
Severe family dysfunction, including parental mental illness

An emergency setting is often the site of an initial evaluation of a chronic problem behavior. For example, an identified problem—such as severe tantrums, violence, and destructive behavior in a child—may have been present for months or even years. Yet the initial contact with the mental health system in the emergency room or private office may be the first opportunity for the child or adolescent to disclose underlying stressors, such as physical or sexual abuse.

In view of the integral relation of severe family dysfunction to childhood behavioral disturbance, the emergency psychiatrist must assess familial discord and psychiatric disorder in family members during an urgent evaluation. One way to make the assessment is to interview the child and the individual family members, both alone and together, and to obtain a history from informants outside the family whenever possible. Noncustodial parents, therapists, and teachers may add valuable information regarding the child's daily functioning. Many families, especially those with mental illness and severe dysfunction, may have little or no inclination to seek psychiatric help on a nonurgent basis; therefore, the emergency evaluation becomes the only way to engage them in an extensive psychiatric treatment program.

LIFE-THREATENING EMERGENCIES

Suicidal Behavior

Assessment. Suicidal behavior is the most common reason for an emergency evaluation in adolescents. Despite the minimal risk for a complete suicide in a child less than 12 years of age, suicidal ideation or behavior in a child of any age must be carefully evaluated, with particular attention to the psychiatric status of the child and the ability of the family or the guardians to provide the appropriate supervision. The assessment must determine the circumstances of the suicidal ideation or behavior, its lethality, and the persistence of the suicidal intention. An evaluation of the family's sensitivity, supportiveness, and competence must be done to assess their ability to monitor the child's suicidal potential. Ultimately, during the course of an emergency evaluation, the psychiatrist must decide whether the child may return home to a safe environment and receive outpatient follow-up care or whether hospitalization is necessary. A psychiatric history, a mental status examination, and an assessment of family functioning help establish the general level of risk.

Management. When self-injurious behavior has occurred, the adolescent likely requires hospitalization in a pediatric unit for treatment of the injury or for the observation of medical sequelae after a toxic ingestion. If the adolescent is medically clear, the psychiatrist must decide whether the adolescent needs psychiatric admission. If the patient persists in suicidal ideation and shows signs of psychosis, severe depression (including hopelessness), or marked ambivalence about suicide, psychiatric admission is indicated. An adolescent who is taking drugs or alcohol should not be released until an assessment can be done when the patient is in a nonintoxicated state. Patients with high-risk profiles—such as late-adolescent males, especially those with substance abuse and aggressive behavior disorders, and those who have severe depression or who have made prior suicide attempts, particularly with lethal weapons—warrant hospitalization. Young children who have made suicide attempts, even when the attempt had a low lethality, need psychiatric admission if the family is so chaotic, dysfunctional, and incompetent that follow-up treatment is unlikely.

Violent Behavior and Tantrums

Assessment. The first task in an emergency evaluation of a violent child or adolescent is to make sure that both the child and the staff members are physically protected so that nobody gets hurt. If the child appears to be calming down in the emergency area, the clinician may indicate to the child that it would be helpful if the child recounted what happened and may ask whether the child feels in sufficient control to do so. If the child agrees and the clinician judges the child to be in good control, the clinician may approach the child with the appropriate backup close at hand. If not, the clinician may either give the child several minutes to calm down before reassessing the situation or, with an adolescent, suggest that a medication may help the adolescent relax.

If the adolescent is clearly combative, physical restraint may be necessary before anything else is attempted. Some rageful children and adolescents brought to an emergency setting by overwhelmed families are able to regain control of themselves without the use of physical or pharmacological restraint. Children and adolescents are most likely to calm down if approached calmly in a nonthreatening manner and given a chance to tell their side of the story to a nonjudgmental adult. At this time, the psychiatrist should look for any underlying psychiatric disorder that may be mediating the aggression. The psychiatrist should speak to family members and others who have been witnessing the episode to understand the context in which it occurred and the extent to which the child has been out of control.

Management. Prepubertal children, in the absence of major psychiatric illness, rarely require medication to keep them safe, because they are generally small enough to be physically restrained if they begin to hurt themselves or others. It is not immediately necessary to administer medication to a child or an adolescent who was in a rage but is in a calm state when examined. Adolescents and older children who are assaultive, extremely agitated, or overtly self-injurious and who may be difficult to subdue physically may require medication before a dialogue can take place.

Children who have a history of repeated, self-limited, severe tantrums may not require admission to a hospital if they are able to calm down during the course of the evaluation. Yet the pattern, no doubt, will reoccur unless ongoing outpatient treatment for the child and the family is arranged. For adolescents who continue to pose a danger to themselves or others during the evaluation period, admission to a hospital is necessary.

Fire Setting

Assessment. A sense of emergency and panic often surrounds the parents of a child who has set a fire. Parents or teachers often request an emergency evaluation, even for a very young child who has accidentally lit a fire. Many children, during the course of normal development, become interested in fire, but in most cases, a school-aged child who has set a fire has done so accidentally while playing with matches and seeks help to put it out. When a child has a strong interest in playing with matches, the level of supervision by family members must be clarified, so that no further accidental fires occur. The clinician must distinguish between a child who accidentally or even impulsively sets a single fire and a child who engages in repeated fire setting with premeditation and subsequently leaves the fire without making any attempt to extinguish it. In repeated fire setting, the risk is obviously greater than in a single occurrence, and the psychiatrist must determine whether underlying psychopathology exists in the child or in the family members. The psychiatrist should also evaluate family interactions, because any factors that interfere with effective supervision and communication—such as high levels of marital discord and harsh, punitive parenting styles—can impede appropriate intervention.

Fire setting is one of a triad of symptoms—enuresis, cruelty to animals, and fire setting—that were believed, some years ago, to be typical of children with conduct disorders; however, no evidence indicates that the three symptoms are truly linked, although conduct disorder is the most frequent psychiatric disorder that occurs with pathological fire setting.

Management. The critical component of management and treatment for fire setters is to prevent further incidents while treating any underlying psychopathology. In general, fire setting alone is not an indication for hospitalization, unless a continued direct threat exists that the patient will set another fire. The parents of children with a pattern of fire setting must be emphatically counseled that the child must not be left alone at home and should never be left to take care of younger siblings without direct adult supervision. Children who exhibit a pattern of concurrent aggressive behaviors and other forms of destructive behavior are likely to have a poor outcome. Outpatient treatment should be arranged for children who repeatedly set fires. Behavioral techniques that involve both the child and the family are helpful in decreasing the risk for further fire setting, as is positive reinforcement for alternate behaviors.

Child Abuse: Physical and Sexual

Assessment. Physical and sexual abuse occurs in girls and boys of all ages, in all ethnic groups, and at all socioeconomic levels. The abuses vary widely with respect to severity and duration, but any form of continued abuse constitutes an emergency situation for a child. No single psychiatric syndrome is a sine qua non of physical or sexual abuse, but fear, guilt, anxiety, depression, and ambivalence regarding disclosure commonly surround the child who has been abused.

Young children who are being sexually abused may exhibit precocious sexual behavior with peers and present a detailed sexual knowledge that reflects exposure beyond their developmental level. Children who endure sexual or physical abuse often display sadistic and aggressive behaviors themselves. Children who are abused in any manner are likely to have been threatened with severe and frightening consequences by the perpetrator if they reveal the situation to anyone. Frequently, an abused child who is victimized by a family member is placed in the irreconcilable position of having either to endure continued abuse silently or to defy the abuser by disclosing the experiences and be responsible for destroying the family and risk being disbelieved or abandoned by the family.

In cases of suspected abuse, the child and other family members must be interviewed individually to give each member a chance to speak privately. If possible, the clinician should observe the child with each parent individually to get a sense of the spontaneity, warmth, fear, anxiety, or other prominent features of the relationships. One observation is generally not sufficient to make a final judgment about the family relationship, however; abused children almost always have mixed emotions toward abusive parents.

Physical indicators of sexual abuse in children include sexually transmitted diseases (e.g., gonorrhea); pain, irritation, and itching of the genitalia and the urinary tract; and discomfort while sitting and walking. In many instances of suspected sexual abuse, however, physical evidence is not present. Thus, a careful history is essential. The physician should speak directly about the issues without leading the child in any direction, because already frightened children may be easily influenced to endorse what they think the examiner wants to hear. Furthermore, children who have been abused often retract all or part of what has been disclosed during the course of an interview.

The use of anatomically correct dolls in the assessment of sexual abuse can help the child identify body parts and show what has happened, but no conclusive evidence supports sexual play with dolls as a means of validating abuse.

Neglect: Failure to Thrive

Assessment. In child neglect, a child's physical, mental, or emotional condition has been impaired because of the inability of a parent or caretaker to provide adequate food, shelter, education, or supervision. Similar to abuse, any form of continued neglect is an emergency situation for the child. Parents who neglect their children range widely and may include parents who are very young and ignorant about the emotional and concrete needs of a child, parents with depression and significant passivity, substance-abusing parents, and parents with a variety of incapacitating mental illnesses.

In its extreme form, neglect can contribute to failure to thrive—that is, an infant, usually under 1 year of age, becomes malnourished in the absence of an organic cause (Figs. 23.3-1 and 23.3-2). Failure to thrive typically occurs under circumstances in which adequate nourishment is available, but a disturbance within the relationship between the caretaker and the child results in a child who does not eat sufficiently to grow and develop. A negative pattern may exist between the mother and the child in which the child

refuses feedings and the mother feels rejected and eventually withdraws. She may then avoid offering food as frequently as the infant needs it. Observation of the mother and the child together may reveal a nonspontaneous, tense interaction, with withdrawal on both sides, resulting in a seeming apathy in the mother. Both the mother and the child may seem depressed.

FIGURE 23.3-1

FIGURE 23.3-2

The same infant as in Figure 23.3-1, 3 weeks later, after hospitalization. (Courtesy of Barbon Schmitt, M.D., Children's Hospital, Denver, CO.)

A rare form of failure to thrive in children who are at least several years old and are not necessarily malnourished is the syndrome of psychosocial dwarfism. In that syndrome, marked growth retardation and delayed epiphyseal maturation accompany a disturbed relationship between the parent and the child, along with bizarre social and eating behaviors in the child. Those behaviors sometimes include eating from garbage cans, drinking toilet water, bingeing and vomiting, and diminished outward response to pain. Half of the children with the syndrome have decreased growth hormone. Once the children are removed from the troubled environment and placed in another setting, such as a psychiatric hospital with appropriate supervision and guidance regarding meals, the endocrine abnormalities normalize, and the children begin to grow at a more rapid rate.

Management. In cases of child neglect, as with physical and sexual abuse, the most important decision to be made during the initial evaluation is whether the child is safe in the home environment. Whenever neglect is suspected, it must be reported to the local child protective service agency. In mild cases, the decision to refer the family for outpatient services, as opposed to hospitalizing the child, depends on the clinician's conviction that the family is cooperative and willing to be educated and to enter into treatment and that the child is not in danger. Before a neglected child is released from an emergency setting, a follow-up appointment must be made.

Education for the family must begin during the evaluation; the family must be told, in a nonthreatening manner, that failure to thrive can become life-threatening, that the entire family needs to monitor the child's progress, and that they will receive some help in overcoming the many possible obstacles interfering with the child's emotional and physical well-being.

Anorexia Nervosa

Anorexia nervosa occurs in females about ten times as often as in males. It is characterized by the refusal to maintain body weight, leading to a weight at least 15 percent below the expected weight, by a distorted body image, by a persistent fear of becoming fat, and by the absence of at least three menstrual cycles. The disorder usually begins after puberty, but it has occurred in children of 9 to 10 years of age, in whom expected weight gain does not occur, rather than a loss of 15 percent of body weight. The disorder reaches medical emergency proportions when the weight loss approaches 30 percent of body weight or when metabolic disturbances become severe. Hospitalization then becomes necessary to control the ongoing process of starvation, potential dehydration, and the medical complications of starvation, including electrolyte imbalances, cardiac arrhythmias, and hormonal changes.

Acquired Immune Deficiency Syndrome

Assessment. Acquired immune deficiency syndrome (AIDS), which is caused by the human immunodeficiency virus (HIV), occurs in neonate through perinatal transmission from an infected mother, in children and adolescents secondary to sexual abuse by an infected person, and in adolescents through intravenous drug abuse with an infected person or through intravenous drug abuse with infected needles and through sexual activities with infected partners. Child and adolescent hemophiliac patients may contract AIDS through tainted blood transfusions.

Children and adolescents may present for emergency evaluations at the urging of a family member or a peer; in some cases, they take the initiative themselves when they are faced with anxiety or panic about high-risk behavior. Early screening of high-risk persons may lead to the treatment of asymptomatic infected patients with such drugs as azidothymidine (AZT) and possibly other new medications that may slow the course of the disease. During the assessment of the risks for HIV infection, an educational process can be initiated with both the patient and the rest of the family so that an adolescent who is not infected, but exhibits high-risk behavior, can be counseled about that behavior and about safe-sex practices.

In children, the brain is often a primary site for HIV infection; encephalitis, decreased brain development, and such neuropsychiatric symptoms as impairment in memory, concentration, and attention span may be present before the diagnosis is made. The virus can be present in the cerebrospinal fluid before it shows up in the bloodstream. Changes in cognitive function, frontal lobe disinhibition, social withdrawal, slowed information processing, and apathy constitute some common symptoms of the AIDS dementia complex. Organic mood disorders, organic personality disorder, and frank psychosis can also occur in patients infected with HIV.

URGENT NON-LIFE-THREATENING SITUATIONS

School Refusal

Assessment. Refusal to go to school may occur in a young child who is first entering school or in an older child or adolescent who is making a transition into a new grade or school, or it may emerge in a vulnerable child without an obvious external stressor. In any case, school refusal requires immediate intervention, because the longer the dysfunctional pattern continues, the more difficult it is to interrupt.

School refusal is generally associated with separation anxiety, in which the child's distress is related to the consequences of being separated from the parent, so the child resists going to school. School refusal can also occur in children with school phobia, in which the fear and the distress are targeted on the school itself. In either case, a serious disruption of the child's life occurs. Although mild separation anxiety is universal, particularly among very young children who are first facing school, treatment is required when a child actually cannot attend school. Severe psychopathology, including anxiety and depressive disorders, is often present when school refusal occurs for the first time in an adolescent. Children with separation anxiety disorder typically present extreme worries that catastrophic events will befall their mothers, attachment, or themselves as a result of the separation. Children with separation anxiety disorder may also exhibit many other fears and symptoms of depression, including such somatic complaints such as headaches, stomachaches, and nausea. Severe tantrums and desperate pleas may ensue when preoccupation that a parent will be harmed during the separation is frequently verbalized; in adolescents, the stated reasons for refusing to go to school are often physical complaints.

As part of an urgent assessment, the psychiatrist must ascertain the duration of the patient's absence from school and must assess the parents' ability to participate in a treatment plan that will undoubtedly involve firm parental guidelines to ensure the child's return to school. The parents of a child with separation anxiety disorder often exhibit excessive separation anxiety or other anxiety disorders themselves, thereby compounding the child's problem. When the parents are unable to participate in a treatment program from home, hospitalization should be considered.

Management. When school refusal caused by separation anxiety is identified during an emergency evaluation, the underlying disorder can be explained to the family, and an intervention can be started immediately. In severe cases, however, a multidimensional, long-term family-oriented treatment plan is necessary. Whenever possible, a separation-anxious child should be brought back to school the next school day, despite the distress, and a contact person within the school (counselor, guidance counselor, or teacher) should be involved to help the child stay in school while praising the child for tolerating the school situation.

When school refusal has been going on for months or years or when the family members are unable to cooperate, a treatment program to move the child back to school from the hospital should be considered. When the child's anxiety is not diminished by behavioral methods alone, tricyclic antidepressants, such as imipramine (Tofranil), are helpful. Medication is generally prescribed not at the initial evaluation but after a behavioral intervention has been tried.

Munchausen Syndrome by Proxy

Assessment. Munchausen syndrome by proxy, essentially, is a form of child abuse in which a parent, usually the mother, or a caretaker repeatedly fabricates or actually inflicts injury or illness in a child for whom medical intervention is then sought, often in an emergency setting. Although it is a rare scenario, mothers who inflict injury often have some prior knowledge of medicine, leading to sophisticated symptoms; the mothers sometimes engage in inappropriate camaraderie with the medical staff regarding the treatment of the child. Careful observation may reveal that the mothers often do not exhibit appropriate signs of distress on hearing the details of the child's medical symptoms. Prototypically, such mothers tend to present themselves as highly accomplished professionals in ways that seem inflated or blatantly untrue.

The illnesses appearing in the child can involve any organ system, but certain symptoms are commonly presented: bleeding from one or many sites, including the gastrointestinal (GI) tract, the genitourinary system, and the respiratory system; seizures; and central nervous system (CNS) depression. At times, the illness is simulated, rather than actually inflicted.

OTHER CHILDHOOD DISTURBANCES

Posttraumatic Stress Disorder

Children who have been subjected to a severe catastrophic or traumatic event may present for a prompt evaluation because they have extreme fears of the specific trauma occurring again or sudden discomfort with familiar places, people, or situations that previously did not evoke anxiety. Within weeks of a traumatic event, a child may re-create the event in play, in stories, and in dreams that directly replay the terrifying situation. A sense of reliving the experience may occur, including hallucinations and flashback (dissociative) experiences, and intrusive memories of the event come and go. Many traumatized children, over time, go on to reproduce parts of the event through their own victimization behaviors toward others, without being aware that those behaviors reflect their own traumatic experiences.

Dissociative Disorders

Dissociative states—including the extreme form, multiple personality disorder—are believed most likely to occur in children who have been subjected to severe and repetitive physical, sexual, or emotional abuse. Children with dissociative symptoms may be referred for evaluation because family members or teachers observe that the children sometimes seem to be spaced out or distracted or act like different persons. Dissociative states are occasionally identified during the evaluation of violent and aggressive behavior, particularly in patients who truly do not remember chunks of their own behavior.

When a child who dissociates is violent or self-destructive or endangers others, hospitalization is necessary. A variety of psychotherapy methods have been used in the complex treatment of children with dissociative disorders, including play techniques and, in some cases, hypnosis.

Complementary and Alternative Medicine in Psychiatry

The science and art of “healing” as well as the concept of “illness” have always been significantly influenced by the cultural context in which they developed. What most Western medical practitioners conceive of as “health care” is actually quite in its infancy compared with many practices aimed at curing or ameliorating illness that developed across the world for many centuries past. Major advances in biomedical research and in the scientific method in general over the past century have brought that discovery of revolutionary medical interventions that have saved countless lives, most notably through the treatment of infectious illnesses. Yet, many practitioners and patients alike sense that the biological and reductionist concepts of illness and its treatment that have come to guide much of Western medical care often minimize the role of psychosocial factors in health and wellness. Psychiatry itself, supposed champion among medical fields in addressing psychosocial etiologies of illness, has also become increasingly biological in its focus. Although this approach has undoubtedly benefited persons with mental illness and has increased public awareness that the brain is no less a physical organ than the heart or kidney (susceptible to maladies at times through no fault of the person suffering mental illness), some mental health practitioners worry that the “listening care” in psychiatry will become increasingly marginalized. After all, addressing psychosocial aspects of health is almost always more time-consuming than biological interventions and thus, in a short-sighted vision of health outcomes, often seems inefficient and expensive.

The term *complementary and alternative medicine* (CAM) refers to the various disease-treating or disease-preventing practices whose methods and efficacies differ from traditional or conventional biomedical treatment. Other terms used to describe these therapeutic approaches are *integrative medicine* and *holistic medicine*. This is not a new concept in psychiatry. The idea of emphasizing the whole patient and the need to evaluate psychosocial, environmental, and lifestyle factors in health and disease is subsumed under the heading of psychosomatic or mind–body medicine.

Traditional medicine, as practiced in the United States and elsewhere in the Western world, is based on the scientific method—the use of experiments to validate a hypothesis or determine the probability of a theory being correct. Traditional medicine presumes that the body is a biological and physiological system and that disorders have a cause that can be treated with medications, surgery, and complex technological methods to produce a cure. Traditional medicine is thus also referred to as *biomedicine* or *technomedicine*.

Traditional medicine is also known as *allopathic medicine*. The term *allopathy*, derived from the Greek word *allos* (“other”), refers to the use of outside agents or medications to counteract the signs and symptoms of disease; for example, antipyretics to treat fever. *Allopathy* is the type of medicine taught in medical schools in the United States. Samuel Hahnemann (1755–1843), a German physician, coined the term to distinguish this form of medicine from *homeopathy* (derived from the Greek word *homos* [“same”]), in which specially formulated medicinal remedies, different from allopathic medicine, are used. Allopathy is the most prevalent form of medicine practiced in the Western world. (Homeopathy is discussed more fully later in this chapter.)

NATIONAL CENTER FOR COMPLEMENTARY MEDICINE AND ALTERNATIVE MEDICINE

The widespread adoption of CAM practices led the US government to establish the National Center for Complementary Medicine and Alternative Medicine (NCCAM) within the National Institutes of Health (NIH). NCCAM’s mission is to evaluate the usefulness and safety of a broad range of unrelated, nonorthodox healing practices and provide scientific explanations for their possible effectiveness, train CAM researchers, and disseminate information to the public. NCCAM has proposed changing its name to the National Center for Research on Complementary and Integrative Health Care (NCRCI).

An NCCAM study in 2011 revealed that close to 40 percent of Americans used some form of CAM within a 12-month period. When prayer was included, the percentage rose to more than 60 percent. Prayer for one’s own health was most prominent, followed by prayer by others for one’s own health, natural products, deep-breathing exercises, group prayer, meditation, chiropractic care, yoga, massage, and diet-based therapies. Echinacea, ginseng, Ginkgo biloba, garlic supplements, glucosamine, and St. John’s wort were among the most common natural products used. Back, head, and neck pain were the most common conditions treated. The CAM practices were most likely to be embraced by those with more education, women, former smokers, and those who had been recently hospitalized. Most users of CAM practices believed the greatest benefits were achieved in combination with conventional treatment.

NCCAM conducts clinical trials at the NIH and academic research institutions to investigate the benefits of various CAM practices on a spectrum of diseases and disorders, ranging from psychiatric conditions to cancer, osteoporosis, and multiple sclerosis, among others. Some completed studies have validated the following: acupuncture is beneficial to treat functional impairment and osteoarthritic pain of the knee; no prophylactic benefit was found for low-dose *Echinacea augustifolia* in the prevention of cold symptoms; combined glucosamine and chondroitin sulfate supplements do not provide significant relief for osteoarthritic pain in most cases, but does benefit a smaller subset with more severe pain; and St. John’s wort (*Hypericum perforatum*) is no more effective for treating major depression of moderate severity than placebo. St. John’s wort is being further investigated as a treatment for posttraumatic stress disorder (PTSD), anxiety, and minor depression (see “Herbal Medicine” below).

The NCCAM has compiled a classification of alternative medical practices designed to support research (Table 24-1). Including a practice in the classification does not imply an endorsement of the method. Indeed, many complementary and alternative health practices are based on no known scientific principles and are considered quackery.

Table 24-1
Complementary and Alternative Medicine Practices

Whole Medical Systems	Biologically Based Practices	Manipulative and Body-Based Practice
Anthroposophically extended medicine	Cell treatment	Acupressure or acupuncture
Ayurveda	Chelation therapy	Alexander technique
Environmental medicine	Diet	
Homeopathy	Atkins diet	Aromatherapy
Kampo medicine	Macrobiotic diet	Biofield therapeutics
Native American medicine	Ornish diet	Chiropractic medicine
Naturopathic medicine	Pritikin diet	Feldenkrais method
Tibetan medicine	Vegetarian diet	Massage therapy
	Zone diet	Osteopathic medicine
Mind–Body Interventions	Dietary supplements	Reflexology
Art therapy	Gerson therapy	Rolling
Biofeedback	Herbal products	Therapeutic touch
Dance therapy	Echinacea	Trager method
Guided imagery	St. John's wort	Energy Medicine
Humor therapy	Ginkgo biloba extract	Blue light treatment and artificial treatment
Meditation	Ginseng root	Electroacupuncture
Mental healing	Garlic supplements	Electromagnetic field therapy
Past life therapy	Peppermint	Electrostimulation and neuromagnetic stimulation
Prayer and counseling	Metabolic therapy	Magnetoacoustic therapy
Psychotherapy	Megavitamin	<i>Qi gong</i>
Sound, music therapy	Nutritional supplements	<i>Reiki</i>
Yoga exercise	Oxidizing agents (ozone, hydrogen peroxide)	Therapeutic touch
Traditional Chinese medicine		Zone therapy

Many systems of treatment discussed in this chapter are centuries old, and it would be presumptuous for traditional biomedical practitioners to dismiss them lightly as worthless. Nevertheless, without rigorous scientific evidence to the contrary, physicians must approach many of these treatments with skepticism. The influence of the mind on the body and the effect of psychological factors in health and disease are well known to physicians, especially to psychiatrists. Suggestion is a potent remedy, and the well-established placebo effect, in which an inert substance is effective in curing a disorder, serves to confirm the importance of mind–body interaction in health and disease.

Currently, more than half of the medical schools in the United States offer some form of complementary and alternative medicine education. Several have developed centers for alternative medicine research, with professors of mind–body or integrative medicine drawn largely from the ranks of such traditional specialties as internal medicine and psychiatry. This trend is likely to continue, with the goal of determining which of the many existing alternative medical systems have scientific merit. Only when and if they can withstand rigorous clinical trials can these techniques be integrated into traditional medicine.

Listed below in alphabetical order are some of the most visible complementary and alternative health practices that have been used in the treatment of (broadly defined) psychiatric conditions. The discussion of therapies should not be considered definitive; new therapies continue to emerge. The number of alternative healing practices available in the United States is unknown and probably soars into the hundreds and their practitioners into the tens of thousands, and there are no national standards set to credential such practitioners.

ACUPRESSURE AND ACUPUNCTURE

Acupressure and acupuncture are Chinese healing techniques that are mentioned in ancient medical texts dating back to 5000 B.C. and continue to be an important medical intervention in the East. A basic tenet of Chinese medicine is the belief that vital energy (*qi* or *chi*) flows along specific pathways (meridians) that have about 350 major points (acupoints) whose manipulation corrects imbalances by stimulating or removing blockages to energy flow. Another fundamental concept is the idea of two opposing energy fields (*yin* and *yang*) that must be in balance for health to be sustained. In acupressure, the acupoints are manipulated by the fingers; in acupuncture, sterilized silver or gold needles (some the diameter of a human hair) are inserted into the skin to varying depths (0.5 mm to 1.5 cm) and are rotated or left in place for varying periods to correct any imbalance of *qi*.

In the West, acupressure and acupuncture are explained on the basis of nerve stimulation that releases endogenous neurotransmitters, endorphins, and enkephalins to help cure illness. The benefits of acupuncture have been validated in a variety of conditions, most notably pain management, postoperative nausea and vomiting, osteoarthritis of the knee, fibromyalgia, and headaches. Other conditions treated with these techniques are asthma, dysmenorrhea, cervical pain, insomnia, anxiety, depression, and substance abuse, including smoking cessation (see the description of moxibustion below). Most pain management clinics in the United Kingdom use acupuncture treatment. A variation of acupuncture, which uses mild electric current to augment therapeutic effects (electroacupuncture), is most often used for analgesia or during surgery. Acupuncture applied to the ear (auriculopuncture) is also common.

ALEXANDER TECHNIQUE

The Alexander technique was developed by F. M. Alexander (1869–1955), who was born in Tasmania and eventually became a well-known stage actor. After developing aphonia, he experimented on himself by changing his body posture and eventually regained his voice. Alexander developed a theory of the proper use of body musculature to help alleviate somatic and mental illnesses. Alexander's approach is an educational process that reduces habitual, unnecessary muscular tension in everyday movements (i.e., unintentionally straining the neck while sitting at a computer) by improving sensory awareness and conscious control of these maladaptive physical habits (Fig. 24-1). Treatment improves cardiovascular, respiratory, and gastrointestinal functioning as well as mood. A small, devoted group of Alexander practitioners is found in the United States and throughout the world. The Alexander technique holds promise as an approach to pain management; it has been shown to be effective in treating chronic back pain in several recent independent studies (Fig. 24-1).

FIGURE 24-1A. Position of pelvis, back, neck, and head in slumped position. **B.** Standing in hunched position (*left*) and well balanced (*right*). (From Barlow W. *The Alexander Principle*. London: Gollancz; 1973, with permission.)

ANTHROPOSOPHICALLY EXTENDED MEDICINE

Anthroposophically extended medicine is a form of healing developed by the Austrian philosopher Rudolf Steiner (1861–1925). The healing process involves the use of conscious understanding, which Steiner called anthroposophy, or the “wisdom of life.” Anthroposophy focuses on mental exercises that enable persons to find a balance between mind and body to ensure health maintenance. Steiner founded a school of thought represented in this country by the Rudolf Steiner School, which teaches children these concepts as they apply to civilization, besides a standard educational curriculum.

AROMATHERAPY

Aromatherapy is the therapeutic use of plant oils. Named by the French chemist Maurice René-Maurice Gattefossé in 1928, aromatherapy is one of the fastest growing alternative therapies in the United States and Europe. The essential oils of plants are organic compounds that are benzene derivatives. Aromatic substances were used in ancient civilization as both medicines and perfumes. Today, plant oils are inhaled using atomizers or are absorbed through the skin using massage (aromatherapy massage). Plant oils have many therapeutic effects—analgesic, psychological, antimicrobial—some of which have been demonstrated scientifically. One NCCAM study, for example, found the scent of lavender helped promote sleep. Aromatherapy is used to reduce stress and anxiety and to alleviate gastrointestinal and musculoskeletal disorders. In psychiatry, olfactory stimulation has been used to elicit feeling tones, memories, and emotions during psychotherapy. Aromatherapy can cause skin irritation or allergic reactions in some people. [Table 24-2](#) lists the essential oils and their effects.

 **Table 24-2**
Common Aromatherapies

Compound	Possible Properties	Purported Psychiatric Use	Other Purported Uses	Aroma
Angelica	Sedative, muscle relaxant, antibiotic, antifungal	Anorexia, anxiety, insomnia	Gastrointestinal (GI) spasm, ulcers, asthma, gout, bronchitis	Woody, pepper, sweet
Basil	Antispasmodic, active on sympathetic nervous system, narcotic, antiviral, insect repellent, aphrodisiac, anti-inflammatory, stimulant for the adrenal cortex, GI and urogenital tracts, cerebral or memory stimulator, hepatostimulative	Fatigue, memory problems, depression, anxiety, delirium, alcoholism	Prostatitis, hair loss, asthma, coronary spasm, epilepsy	Warm, spicy, sweet, woody
Bergamot	Antidepressant, sedative, antiseptic, anti-inflammatory	Depression, hyperactivity, anxiety, insomnia	Acne, cold sores, eczema, psoriasis	Citrus, floral
Frankincense or oil of olibanum	Antitumor, antidepressant, expectorant, immunostimulant, anti-inflammatory	Depression	Asthma, bronchitis, pain relief	Woody, fruity
Geranium (<i>Pg</i> or <i>P.x a</i>) pelargonium	Pancreatic stimulant, anti-inflammatory, antibiotic, relaxant, hemostatic	Anxiety, agitation, fatigue	Premenstrual syndrome (PMS), menopause	Floral, dry
Jasmine	Antidepressant, stimulant, analgesic	Depression, stress, fatigue	Menstrual problems, headaches	Floral, musky
Lavender	Sedative, muscular relaxant, anti-inflammatory	Depression, jet lag, insomnia, restlessness	Acne, burns, hiccups, ulcers	Powder, floral
Mandarin	Antispasmodic, sedative, hypnotic	Hyperactivity, anxiety, insomnia	Cardiovascular spasm, pain, dyspnea	Sweet, fruity
Marjoram	Diuretic, analgesic, spasmolytic, parasympathotonic	Anxiety, excessive sexual desire, psychosis, insomnia	Hyperthyroid, cardiovascular disease, vertigo, epilepsy	Nutty, woody, warm
Melissa	Sedative, anti-inflammatory, antispasmodic	Anger, agitation, insomnia	Herpes, hypertension, asthma	Citrus, herb
Myrrh	Anti-inflammatory, analgesic, antifungal	Sexual overexcitation	Dysentery, hemorrhoids	Fruity, clean
Neroli	Antidepressant, stimulant	Depression, fatigue, insomnia, anxiety, postpartum depression	Hemorrhoids, tuberculosis	Floral, powder, spicy
Spikenard	Sedative, antifungal, antiseptic, insect repellent	Insomnia, depression, anxiety	Psoriasis, epilepsy	Earthy, woody
Tuberose	Anxiety, sedative, analgesic	Agitation	Pain	Earthy, tropical

Pheromones are chemical substances secreted and smelled by humans, which affect their physiological and behavioral responses, usually related to sex. Women who are exposed to the smell of androstenol, which occurs in male underarm sweat, show increased social exchanges with men, heightened sexual arousal, and improved mood. Androstenol also affects the length and timing of the menstrual cycle as a result of changes in the level and release of gonadotrophic-releasing hormone (GnRH) and luteinizing hormone (LH). Female pheromones, known as copulins, are present in female underarm sweat and in vaginal secretions. Males perceive the odor of copulins as most pleasant during the woman's ovulatory cycle when such odors are most volatile. The synchronization of the menstrual cycle of women living together (a well-documented phenomenon) is also related to the effect of copulins. Olfactory sexual signaling is being investigated extensively, and whether these studies show therapeutic potential remains to be seen.

AYURVEDA

Ayurveda means "knowledge of life." The technique originated in India about 3000 B.C. and is believed to be one of the oldest and most comprehensive medical systems in the world. Ayurveda is similar to Chinese medicine in its beliefs about energy points on the body and a vital force (*prana*) that must be in balance to maintain health. Ayurveda practitioners diagnose illness by examining the pulse, the urine, and the heat or coldness of the body. Treatment relies on diet, medicines, purification, enemas, and bloodletting. (See also "Tibetan Medicine" below.)

BATES METHOD

The Bates method, designed to treat vision problems, was devised by William H. Bates. It is aimed at naturally strengthening the eye muscles and includes the following basic exercises: splashing closed eyes 20 times with warm water, then 20 times with cold water; alternately focusing on near and distant objects; focusing on an object while gently swaying the body; remembering objects in the mind's eye to facilitate the actual perception of these objects in reality; and closing the eyes, cupping them with the palms of both hands (without touching the eyes), and focusing on pleasant thoughts. Bates practitioners claim that persons who need glasses to correct refraction errors will not need them if these methods are followed rigorously.

BIOENERGETICS

Bioenergetics, based on the belief that dammed-up energy produces maladaptive behavioral patterns, evolved from the work of the Austrian psychoanalyst Wilhelm Reich (1897–1957), who studied with Sigmund Freud. Reich believed that energy fields were propelled by sexual impulses called ergs and that satisfactory orgasms indicated healthy bodily functioning. Modern-day practitioners look for areas of muscular tension in the body that are thought to be associated with repressed memories and emotions. Therapists try to bring these repressions to consciousness through a variety of relaxation techniques, including massage.

CHELATION

Chelation therapy is a traditional medical procedure used to treat accidental poisoning with heavy metals, such as lead, arsenic, and mercury. A chelating agent (ethylenediaminetetraacetic acid [EDTA]) is infused into the bloodstream and binds to the metal, which is then excreted from the body. As an alternative medical practice, chelation therapy is used as a form of preventive medicine to remove lead, cadmium, and aluminum from the body. These substances are presumed by some to be associated with premature aging, memory loss, and the symptoms of Alzheimer's disease. Chelation therapy has also been used to treat atherosclerosis and coronary artery disease. One NCCAM study showed that chelation treatments reduced cardiovascular events such as heart attacks and death in patients with diabetes; however, chelation therapy is not yet approved by the U.S. Food and Drug Administration (FDA) as a treatment for this condition.

CHIROPRACTIC

Chiropractic is concerned with the diagnosis and treatment of disorders of the musculoskeletal system, especially those of the spine. It was developed by a Canadian, Daniel David Palmer (1845–1913) (Fig. 24-2), who moved to the United States in 1895. Palmer believed that disease could be attributed to spinal misalignment, leading to abnormal nerve transmission.

FIGURE 24-2 Daniel David Palmer (1845–1913), the founder of chiropractic. (Reprinted with permission from Shealy CN, ed. *The Complete Family Guide to Alternative Medicine: An Illustrated Encyclopedia of Natural Healing*. New York: Barnes & Noble Books; 1996:39.)

Chiropractors diagnose illness by clinical examination and X-ray. Treatment involves manual manipulation of bones, joints, and musculature to restore biomechanical function. Chiropractic is the largest independent alternative health profession in the Western world, with more than 50,000 chiropractors in the United States. They are recognized by government and insurance agencies and treat more than 20 million persons in the United States annually.

COLONIC IRRIGATION

Colonic irrigation is a technique known since antiquity that consists of flushing the intestinal colon with large quantities of water, sometimes with minerals or other substances (e.g., coffee) added. It is a method used to eliminate autointoxication, a concept originating from the Pasteur Institute in France in 1908 that holds that retained fecal matter and undigested food ferment in the bowel producing toxins that cause disease. Special colon hydrotherapy machines force fluids via the rectum to clean the colon of this matter, thus eliminating such toxins. Colon cleansing using powerful laxatives and enemas is an alternative way of achieving the same result. Anecdotal reports of improved general health as a result of such practices are common; however, there are risks of electrolyte imbalance and intestinal perforation. The practice is poorly regulated, although some states attempt to monitor therapists and equipment.

COLOR THERAPY

In color therapy, different colors are thought to affect mood, and this has been used to address specific health problems. For example, blue is believed to be sedating, and red, excitatory. A Swiss psychologist, Max Lüscher, devised a color test in which a subject's mood at a particular time is determined by exposing the subject to various colors. Lüscher also experimented with the effect of color on the autonomic nervous system and found that pure red is sympathomimetic and can cause an increase in blood pressure, heart rate, and respiration. Blue is parasympathomimetic and produces the opposite effects.

DANCE THERAPY

Dance therapy was formally recognized in 1942, with the hiring of pioneer dance therapist Marian Chace (1896–1970) at St. Elisabeth's Hospital in Washington, D.C. The terms *dance* and *movement* are used synonymously; however, each actually describes a point of view. *Movement* encompasses the world of physical motion, whereas *dance* is a specific creative act within that world. The American Dance Therapy Association defines dance therapy as “the psychotherapeutic use of movement which furthers the emotional and physical integration of the individual.” Dance therapy sessions have four basic goals: the development of body awareness; the expression of feelings; the fostering of interaction and communication; and the integration of the physical, emotional, and social experiences that result in a sense of increased self-confidence and contentment.

DIET AND NUTRITION

Nutritional methods to prevent or cure disease have an important place in modern medicine, and their efficacy has been proved by scientific evidence. The federal government has established recommended daily allowances (RDAs) to meet the nutritional needs of average persons in the United States. Table 24-3 depicts the recommendations for a 40-year-old sedentary man. Whole grain, lean meat, and green vegetable consumption are encouraged, and excess intake of unrefined sugar products is discouraged. Critics have faulted the federal guidelines for being unduly influenced by the meat and dairy industries. Nutritional experts and dieticians have developed alternate recommendations, especially for children, adolescents, diabetics, and pregnant women.

 **Table 24-3**
United States Department of Agriculture Food Guide for a 40-Year-Old Sedentary Male

Grains	Vegetables	Fruits	Milk	Meat and Beans
8 Ounces Make half your grains whole Aim for at least 4 ounces of whole grains a day	3 Cups Vary your veggies Aim for these amounts each week : Dark green veggies = 3 cups Orange veggies = 2 cups Dry beans & peas = 3 cups Starchy veggies = 6 cups Other veggies = 7 cups	2 Cups Focus on fruits Eat a variety of fruit Go easy on fruit juices	3 Cups Get your calcium-rich foods Go low-fat or fat-free when you choose milk, yogurt, or cheese	6.5 Ounces Go lean with protein Choose low-fat or lean meats and poultry Vary your protein routine—choose more fish, beans, peas, nuts, and seeds
Find your balance between food and physical activity. Be physically active for at least 30 minutes most days of the week.		Know your limits on fats, sugars, and sodium. Your allowance for oils is 7 teaspoons a day . Limit extras—solid fats and sugars—to 360 calories a day .		
Your results are based on a 2,400 calorie pattern.				

(Referenced from USDA site: <http://www.mypyramid.gov>.)

Many alternative diets exist, and specific vitamin and mineral supplementation programs have been developed to deal with specific diseases or bodily processes. Diets low in fat have been recommended for the treatment of cardiovascular disease and diabetes. The Pritikin diet developed by Nathan Pritikin is extremely low in fat (less than 10 percent of daily calories), high in complex carbohydrates, and high in fiber. The Ornish diet, developed by physician Dean Ornish, is vegetarian: No meat, poultry, or fish is allowed, and only 10 percent of calories are obtained from fat. The low carbohydrate, high protein diet developed by Robert Atkins, M.D. (1930–2003) has proved effective in short-term weight loss, most likely because of increased compliance. Concern exists around the risk of ketoacidosis and the lack of long-term studies on health. This diet has also been used to treat refractory childhood epilepsy. All of these diets include an exercise program, a component proved to increase cardiac performance. Studies have shown that weight loss alone can reduce cholesterol, decrease blood pressure, and eliminate the need for drugs in newly diagnosed cases of adult-onset diabetes.

Diets from other cultures may have certain health benefits. In Asia, diets are low in fat, and there is a low incidence of cardiac disease; diets in Mediterranean countries are high in olive oil, garlic, and grains and are associated with a low incidence of colon cancer and cardiac disease. Food allergies have been implicated in many conditions: arthritis, asthma, hyperactivity, and ulcerative colitis, among others.

DIETARY SUPPLEMENTS

In addition to herbs (discussed below), a variety of dietary supplements are used to promote health. Dietary supplements are products that contain vitamins, minerals, or amino acids. In many cases, the supplement is actually an extract, metabolite, or combination of those. They are intended to *supplement* a healthy diet; they do not comprise a diet or meal. Nutritional supplements have long been familiar to Americans in the form of multivitamins, but they are now available in a vast array of other compounds that can be purchased in grocery stores, pharmacies, health food stores, and over the Internet. Annual sales of dietary supplements in the United States exceeds \$20 billion. Of Americans, 75 percent currently use some form of nutritional supplement on a regular basis. Although medicinal benefits are well documented in some supplements, especially vitamins, others vary greatly in safety and consistency. As a general rule, supplements should not be taken by pregnant or lactating women. In psychiatry, nutritional supplements are being used to treat a wide spectrum of illness including cognitive, mood, psychotic, sleep, and conduct disorders; however, little scientific evidence currently supports their efficacy. [Table 24-4](#) lists some of the more common supplements being used to treat psychiatric illness.

Table 24-4
Some Dietary Supplements Used in Psychiatry

Name	Ingredients/What Is It?	Uses	Adverse Effects	Interactions	Dosage	Comments
Docosahexaenoic acid (DHA)	Omega-3 polyunsaturated fatty acid	ADD, dyslexia, cognitive impairment, dementia	Anticoagulant properties, mild GI distress	Warfarin	Varies with indication	Stop using prior to surgery
Choline	Choline	Fetal brain development, manic conditions, cognitive disorders, tardive dyskinesia, cancers	Restrict in patients with primary genetic trimethylaminuria, sweating, hypotension, depression	Methotrexate, works with B ₆ , B ₁₂ and folic acid in metabolism of homocysteine	300–1,200 mg doses >3 g associated with fishy body odor	Needed for structure and function of all cells
L-α-Glyceryl-phosphorylcholine (α-GPC)	Derived from soy lecithin	To increase growth hormone secretion, cognitive disorders	None known	None known	500 mg–1 g daily	Remains poorly understood
Phosphatidylcholine	Phospholipid that is part of cell membranes	Manic conditions, Alzheimer's disease and cognitive disorders, tardive dyskinesia	Diarrhea, steatorrhea in those with malabsorption, avoid with antiphospholipid antibody syndrome	None known	3–9 g per day in divided doses	Soybeans, sunflower, rapeseed are major sources
Phosphatidylserine	Phospholipid isolated from soy and egg yolks	Cognitive impairment including Alzheimer's disease, may reverse memory problems	Avoid with antiphospholipid antibody syndrome, GI side effects	None known	For soya-derived variety, 100 mg tid	Type derived from bovine brain carries hypothetical risk of bovine spongiform encephalopathy
Zinc	Metallic element	Immune impairment, wound healing, cognitive disorders, prevention of neural tube defects	GI distress; high doses can cause copper deficiency, immunosuppression	Bisphosphonates, quinolones, tetracycline, penicillamine, copper, cysteine-containing foods, caffeine, iron	Typical dose 15 mg per day; adverse effects >30 mg	Claims that zinc can prevent and treat the common cold are supported in some studies but not in others; more research needed
Acetyl-L-carnitine	Acetyl ester of L-carnitine	Neuroprotection, Alzheimer's disease, Down's syndrome, strokes, antiaging, depression in geriatric patients	Mild GI distress, seizures, increased agitation in some with Alzheimer's disease	Nucleoside analogs, valproic acid and pivalic acid-containing antibiotics	500 mg–2 g daily in divided doses	Found in small amounts in milk and meat
Huperzine A	Plant alkaloid derived from Chinese club moss	Alzheimer's disease, age-related memory loss, inflammatory disorders	Seizures, arrhythmias, asthma, irritable bowel disease	Acetylcholinesterase inhibitors and cholinergic drugs	60–200 µg per day	Huperzia serrata has been used in Chinese folk medicine for the treatment of fevers and inflammation
NADH (nicotinamide adenine dinucleotide)	Dinucleotide located in mitochondria and cytosol of cells	Parkinson's disease, Alzheimer's disease, chronic fatigue, CV disease	GI distress	None known	5 mg per day or 5 mg bid	Precursor of NADH is nicotinic acid
S-Adenosyl-L-methionine (SAMe)	Metabolite of essential amino acid L-methionine	Mood elevation, osteoarthritis	Hypomania, hyperactive muscle movement, caution in patients with cancer	None known	200–1,600 mg daily in divided doses	Several trials demonstrate some efficacy in the treatment of depression

(continued)

5-Hydroxytryptophan (5-HTP)	Immediate precursor of serotonin	Depression, obesity, insomnia, fibromyalgia, headaches	Possible risk of serotonin syndrome in those with carcinoid tumors or taking MAOIs	SSRIs, MAOIs, methyldopa, St. John's wort, phenoxylbenzamine, 5-HT antagonists, 5-HT receptor agonists	100 mg–2 g daily, safer with carbidoopa	5-HTP along with carbidoopa is used in Europe for the treatment of depression
Phenylalanine	Essential amino acid	Depression, analgesia, vitiligo	Contraindicated in patients with PKU, may exacerbate tardive dyskinesia or hypertension	MAOIs and neuroleptic drugs	Comes in 2 forms: 500 mg–1.5 g daily for D-phenylalanine, 3.75 mg–2.25 g for L-phenylalanine	Found in vegetables, juices, yogurt, and miso
Myoinositol	Major nutritionally active form of inositol	Depression, panic attacks, OCD	Caution in patients with bipolar disorder, GI distress	Possible additive effects with SSRIs and 5-HT receptor agonists (sumatriptan)	12 g in divided doses for depression and panic attacks	Studies have not shown effectiveness in treating Alzheimer's disease, autism, or schizophrenia
Vinpocetine	Semisynthetic derivative of vincamine (plant derivative)	Cerebral ischemic stroke, dementias	GI distress, dizziness, insomnia, dry mouth, tachycardia, hypotension, flushing	Warfarin	5–10 mg daily with food, no more than 20 mg per day	Used in Europe, Mexico, and Japan as pharmaceutical agent for treatment of cerebrovascular and cognitive disorders
Vitamin E family	Essential fat-soluble vitamin, family made of tocopherols and tocotrienols	Immune-enhancing, antioxidant, some cancers, protection in CV disease, neurologic disorders, diabetes, premenstrual syndrome	May increase bleeding in those with propensity to bleed, possible increased risk of hemorrhagic stroke, thrombophlebitis	Warfarin, antiplatelet drugs, neomycin, may be additive with statins	Depends on form: tocotrienols, 200–300 mg daily with food; tocopherols, 200 mg per day	Stop members of vitamin E family 1 month prior to surgical procedures
Glycine	Amino acid	Schizophrenia, alleviating spasticity and seizures	Avoid in those who are anemic or have hepatic failure	Additive with antispasmodics	1 g per day in divided doses for supplement; 40–90 g per day for schizophrenia	
Melatonin	Hormone of pineal gland	Insomnia, sleep disturbances, jet lag, cancer	May inhibit ovulation in 1 g doses, seizures, grogginess, depression, headache, amnesia	Aspirin, NSAIDs, β -blockers, INH, sedating drugs, corticosteroids, valerian, kava kava, 5-HTP, alcohol	0.3–3 mg hs for short periods of time	Melatonin sets the timing of circadian rhythms and regulates seasonal responses
Fish oil	Lipids found in fish	Bipolar disorder, lowering triglycerides, hypertension, decrease blood clotting	Caution in hemophiliacs, mild GI upset, "fishy" smelling excretions	Coumadin, aspirin, NSAIDs, garlic, ginkgo	Varies depending on form and indication—usually about 3–5 g daily	Stop prior to any surgical procedure

ADD, attention-deficit disorder; CV, cardiovascular; OCD, obsessive-compulsive disorder; GI, gastrointestinal; MAOIs, monoamine oxidase inhibitors; PKU, phenylketonuria; SSRIs, selective serotonin reuptake inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs; INH, isoniazid; 5-HTP, 5-hydroxytryptophan. (Table by Mercedes Blackstone, M.D.)

Nutritional status has long been deemed important in mental health, and vitamin deficiencies can produce psychiatric symptoms. Severe niacin deficiency results in pellagra with its characteristic triad of skin lesions, gastrointestinal disorders, and psychiatric symptoms. The psychiatric symptoms include irritability and emotional instability progressing to severe depression and then to disorientation, memory impairment, hallucinations, and paranoia. Folic acid deficiency is associated with depression and dementia, whereas vitamin B₁₂ deficiency is associated with cognitive impairment, depression, and other affective symptoms. Severe malnutrition can result in apathy and emotional instability.

In 1968, the eminent chemist and Nobel Prize-winner Linus Pauling coined the term *orthomolecular* to refer to the connection between the mind and nutrition. In his book *Orthomolecular Psychiatry*, research articles were compiled supporting the notion that taking many times the recommended minimal daily dose of vitamins is useful in the treatment of schizophrenia and other psychiatric disorders. As mentioned, some severe vitamin deficiencies can result in syndromes with a psychiatric component; however, empirical data and an American Psychiatric Association (APA) task force failed to find evidence supporting the notion that schizophrenia and other disorders respond to vitamin therapies.

Thiamine, Vitamin B₁₂, and Folate

In industrialized societies, severe vitamin deficiencies are rarely encountered except in certain populations. Those who are elderly, alcohol dependent, or chronically ill or who have certain types of gastrointestinal surgeries are at greatest risk. Among the forms of vitamin deficiency most commonly encountered in the emergency room is acute thiamine depletion from alcohol dependence. Whereas the chronic forms of thiamine deficiency that lead to beriberi are rarely seen in the Western world, the fulminant depletion of already low stores of thiamine results in Wernicke's encephalopathy and Korsakoff's syndrome.

Wernicke's encephalopathy classically presents with the triad of ataxia, ophthalmoplegia, and mental confusion, but confusion and a staggering gait are perhaps most common. Although Wernicke's encephalopathy is an acute process, Korsakoff's syndrome may be the permanent residue of this encephalopathy. Patients with Korsakoff's syndrome exhibit a well-circumscribed retrograde and anterograde amnesia that results from destruction of the mammillary bodies, and psychotic symptoms are also reported. Wernicke's encephalopathy is a medical emergency that responds to short-term treatment with 50 mg of thiamine intravenously followed by 250-mg intramuscular injections daily until a normal diet is attained. The treatment of uncomplicated acute thiamine deficiencies usually involves 100 mg given orally one to three times a day.

Vitamin B₁₂ deficiency or pernicious anemia is often seen in elderly adults, patients who have had gastric surgery, and malnourished depressed patients. The most typical psychiatric presentations include apathy, malaise, depressed mood, confusion, and memory deficits. Vitamin B₁₂ concentrations of 150 mg/mL of serum are sometimes associated

with these symptoms. Vitamin B₁₂ deficiency is a more common cause of reversible dementia and is typically assessed in dementia evaluations. The treatment of pernicious anemia usually involves daily intramuscular injections of 1,000 mg of vitamin B₁₂ for approximately 1 week, followed by maintenance doses of 1,000 mg every 1 to 2 months.

Folate deficiency has been associated with depression, paranoia, psychosis, agitation, and dementia. Folate deficiency can result from anorexia in depressed patients and can also contribute to depression by interfering with the synthesis of norepinephrine and serotonin. Folate deficiency has been associated with anticonvulsant use, particularly phenytoin (Dilantin), primidone (Mysoline), and phenobarbital (Solfoton), and the sex steroids, including oral contraceptives and estrogen replacement. The most common cause of folate deficiency is the malnourishment associated with alcoholism. Many folate deficiencies respond to 1 mg of folate orally per day; however, some more severe forms may require dosages of 5 mg up to three times a day. Folate deficiency in pregnancy is associated with neural tube defects (e.g., spina bifida, anencephaly).

Mr. S was diagnosed with dysthymic disorder by a psychiatrist in his early 20s and was started on sertraline (Zoloft). After 4 weeks Mr. S's mood improved dramatically, but he experienced night sweats and reduced libido. Over the ensuing years he was tried on paroxetine (Paxil), citalopram (Celexa), and fluoxetine (Prozac). Although his mood improved, his sex drive did not. Mr. S heard about an integrative mental health clinic that offered conventional medications, herbal medications, acupuncture, and *Reiki*. Mr. S was interviewed by a Western physician who had also studied Chinese medicine. The Chinese pulse diagnosis of stagnant liver *qi* was consistent with his Western diagnosis of moderate depressed mood. The doctor ordered a thyroid panel, red blood cell (RBC) folate, and B₁₂ levels and suggested an integrative treatment plan including supplementation with folate, B₁₂, omega-3 fatty acids, and S-Adenosyl-L-methionine (SAME), regular exercise, and acupuncture. The initial treatment plan consisted of daily exercise, SAME (titrating to 400 mg twice daily), folate 5 mg, B₁₂ 800 µg, and omega-3s (eicosapentaenoic acid [EPA] 2 g per day). Three weeks later, Mr. S was frustrated at his lack of progress, remained depressed, and had not started to exercise. His RBC folate level was low, and the other studies were within normal limits. Mr. S had been taking an inexpensive generic brand of SAME and had stayed at 200 mg per day. He was encouraged to follow the original treatment plan. Two weeks later, Mr. S appeared brighter. He was exercising daily and taking the B vitamins and a quality brand of SAME at 400 mg twice daily without significant adverse effects. (Adapted from James H. Lake, M.D.)

ENVIRONMENTAL MEDICINE

The field of environmental medicine began to emerge in the 1950s when physicians such as Theron Randolph, professor of allergy and immunology at Northwestern University School of Medicine, began to examine some persons' allergic reactions to various foods. Other workers studied the effects on the body of pollutants in water and air, and eventually the field expanded to include the total environment in which humans exist. As a result, environmental medicine now concerns itself with issues such as food additives; electromagnetic fields from electric utility wires; fertilizers and hormones used in food production; microwaves from appliances such as microwave ovens, television sets, and cellular telephones; and nuclear radiation. Practitioners of environmental medicine believe that many persons are extraordinarily sensitive to environmental contaminants that can trigger a disease process. Some issues are highly controversial. For instance, despite claims to the contrary, studies fail to demonstrate a higher incidence of cancer in persons exposed to electromagnetic fields; however, a correlation exists between higher cancer rates and living near oil refineries and chemical plants. Environmental medicine is a form of preventative medicine that focuses on increased individual awareness of environmental hazards and the control or elimination of these hazards. (See also "Naturopathy" below.)

EXERCISE

Exercise improves quality of life through better physical function, reduced morbidities, and improved mental health. The positive effects of exercise on immune system functions are well documented. These benefits extend to the cognitive and emotional realms and, thus, validate the mind-body connection that is central to many CAM physical practices—yoga, *tai chi*, *qi gong*. Exercise has been shown to ameliorate depression, anxiety, and PTSD; improve cognitive function and self-esteem; and reduce psychotic symptoms in schizophrenic populations. These effects can be accounted for neurochemically, because exercise promotes secretion of neurotransmitters, such as serotonin, adrenaline, and endogenous opiates. Studies have also associated weight loss with increased social interaction, distraction from stress, recreational enjoyment, and mastery of challenge.

Exercise offers many benefits to people with serious mental illness because they more likely suffer from serious medical conditions, such as obesity, diabetes, and hypertension; live sedentary lifestyles; and smoke. Studies of adults with schizophrenia have shown a moderate exercise program reduces body mass index, improves aerobic fitness, raises self-esteem, and results in fewer psychiatric symptoms. Exercise may prove useful in remediating the weight gain from antipsychotic medications and improve compliance.

Although presently underused, exercise holds significant potential benefit as a therapeutic intervention in the mental health care setting. A structured aerobic exercise program consisting of 45-minute sessions three times per week showed significant gains in cardiovascular fitness, self-esteem, and quality of life and in altering mood and depression. Unstructured programs benefited those who adhere to the exercise regimen. No drawbacks are found to moderate exercise, and the health gains are significant.

FELDENKRAIS METHOD

The Feldenkrais method was developed by Moshé Feldenkrais (1904–1984), a Russian-born physicist who developed a theory evolved from Freud's work. Feldenkrais thought that the body should be emphasized as much as the mind and that proprioception (somatic sensations from muscles and other organs) can influence behavior. He believed that posture and the positions of the body reflected conflict; therefore, retraining the body was part of his treatment program. Practitioners of the Feldenkrais method are active throughout the world. Those learning the Feldenkrais method are referred to as students rather than patients, to reinforce the view that the work is primarily an educational process. Lessons generally last from 30 to 60 minutes and consist of structured movement that involves thinking, sensing, moving, and imagining. The method has been used in central nervous system disorders, such as multiple sclerosis, cerebral palsy, and stroke. Older persons who use the method claim that they retain or regain their ability to move without strain or discomfort.

HERBAL MEDICINE

Herbal medicine relies on plants to cure illnesses and to maintain health. Probably the oldest known system of medicine, it originated in China about 4000 B.C. Ancient texts of Chinese medicine are still in use, and modern Chinese medicine relies on herbs in addition to other methods, such as acupuncture, massage, diet, and exercise, to correct imbalances in the body. A Greco-Roman medical text by Pedanius Dioscorides, *De Materia Medica*, describes the use of more than 500 plants and herbs to cure disease.

The decline of herbal medicine in the late 20th century was related to scientific and technological advances that led to the use of synthetic pharmaceuticals; nevertheless, according to some estimates, at least 25 percent of current medicines are derived from the active ingredients of plants. The examples are many: digitalis from foxglove; ephedrine from ephedra; morphine from the opium poppy; paclitaxel (Taxol) from the yew tree; and quinine from the bark of the cinchona tree.

Herbal medicine is becoming more and more popular. Approximately \$4 billion a year is spent in the United States on herbal medicines, which are classified as dietary supplements. Western herbalists use plants to treat various disorders related to the respiratory, gastrointestinal, cardiovascular, and nervous systems; as with most prescription medicines, these plants contain active compounds that produce physiological effects. As a result, they must be used in appropriate doses if toxic results are to be prevented. They are not subject to FDA approval, and no uniform standards exist for quality control or potency in herbal preparations. Indeed, some preparations have no active ingredients or are adulterated. Herbal supplement producers need only prove safety and truth in labeling, not efficacy, to be sold. The herbal industry attempts to regulate itself through organizations such as the Council for Responsible Nutrition and the American Herbal Association, but according to the Federal Trade Commission, fraudulent practices and false advertising still exist. In 2003, the FDA banned ephedra (ma huang)-based diet products because of significant risk to cardiovascular health. There is now a *Physicians Desk Reference* for both herbal products and nutritional supplements.

One herb that has caught the attention of Western psychiatry is St. John's wort (*Hypericum*) for the treatment of major depressive disorders (Fig. 24-3). St. John's wort has been used in folk medicine for hundreds of years and is still commonly used in Europe. In Germany, several million prescriptions for *Hypericum* are obtained annually and covered by insurance for the treatment of depression, anxiety, and sleep problems. Studies have compared St. John's wort with placebo, tricyclic drugs, and selective serotonin reuptake inhibitors (SSRIs) and found that *Hypericum* extracts were more effective than placebo in the treatment of mild to moderate depression. Many of these studies lacked rigor in the diagnosis of depression, sample size, and the assessment of efficacy. NCCAM sponsored studies and other researchers are working to determine the active ingredients, effective dosing, and toxicities associated this plant and other biologically derived supplements using spectrographic and other scientific analyses.

FIGURE 24-3 St. John's wort (*Hypericum perforatum*).

Mrs. J, a 68-year-old retired schoolteacher in good health, was experiencing anhedonia after the death of her spouse and was started on a low-dose SSRI by her psychiatrist. After several weeks, her symptoms began to improve. One morning, while at the local health food store, she inquired if there were any natural products that improved mood. The store manager informed her that St. John's wort "works just like an SSRI." The patient proceeded to take the recommended daily dose of three capsules that day, each containing 300 mg of 0.3 percent *Hypericin*. Later that evening, she began to feel anxious and could not fall asleep. After several hours of doing needlework to pass the time, she began to sweat profusely. She became concerned for her health when she felt her heart racing. She drove herself to the emergency room of a local hospital. On examination, she was observed to be extremely anxious and hyperactive, tachycardic, and mildly hypertensive. She was given a short-acting, fast-onset benzodiazepine. After 4 hours, the patient reported feeling calm and her vital signs had returned to baseline. The emergency room physician informed Mrs. J that although she had only taken a single daily dose of St. John's wort, she had most likely experienced the side effects of an interaction between the plant extract and the SSRI. Known interactions include a manic reaction and serotonin syndrome. The patient agreed to discontinue the St. John's wort. She was discharged and a follow-up appointment was scheduled with her psychiatrist to discuss treatment options.

Psychoactive Herbs

Many phytomedicinals (from the Greek *phyto*, meaning "plant") have psychoactive properties that are used, or have been used, to treat a variety of psychiatric conditions. Adverse effects are possible, and toxic interactions with other drugs can occur with all phytomedicinals. Clinicians should always attempt to obtain a history of herbal use during the psychiatric evaluation. Adulteration is common, and no consistent standard preparations are available for most herbs. Safety profiles and knowledge of adverse effects of most of these substances are lacking; many, if not all, of these herbs are secreted in breast milk and are contraindicated during lactation and should be avoided during pregnancy.

Many cultures have used hallucinogens, including mescaline, psilocybin, and ergots, for thousands of years to gain spiritual and personal insight. Lysergic acid diethylamide (LSD), synthesized in the 1930s, was marketed to psychiatrists and other practitioners in the late 1940s under the trade name Delysid as a tool for understanding psychosis and for facilitating psychotherapy. Using LSD reportedly helped patients capture repressed memories and deal with anxiety, and it allowed patients to gain insight through an analysis of the primary process induced by the hallucinogen. Oral doses of 150 to 250 mg were administered occasionally by psychiatrists throughout the 1950s and early 1960s to facilitate psychotherapy with some patients. In the 1960s, Timothy Leary advocated the widespread use of hallucinogens, but the drugs were outlawed as class I controlled substances in 1965.

Although no longer used for therapeutic purposes in the United States, LSD has fulfilled part of its early promise as a probe for psychosis. More recent understanding of the pharmacology of LSD and its affinity to serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT₂) receptors has supported the interest in developing serotonin-dopamine antagonists (atypical antipsychotics) with the 5-HT₂-receptor blocking properties. Recently, studies using methylenedioxymethamphetamine (MDMA, "ecstasy") have been approved by the NIH to determine whether psychotherapy is facilitated when the patient is under the influence of the drug, which can affect interpersonal relationships positively by promoting feelings of empathy.

It is important not to be judgmental in dealing with patients who use phytomedicinals. They are used for various reasons: (1) as part of their cultural tradition, (2) because patients mistrust physicians or are dissatisfied with conventional medicine, or (3) because they experience relief of symptoms. If psychotropic agents are prescribed, the clinician must be extraordinarily alert to the possibility of adverse effects as a result of drug-drug interactions, because many phytomedicinals have ingredients that produce physiological changes in the body. More than 200 herbal drugs are in use; only those with psychoactive properties are listed in Table 24-5.

Table 24-5
Phytomedicinals with Psychoactive Effect

Name	Ingredients	Use	Adverse Effects ^a	Interactions	Dosage ^a	Comments
Areca, areca nut, betel nut, <i>L. Areca catechu</i>	Arecoline, guvacoline	For alteration of consciousness to reduce pain and elevate mood	Parasympathomimetic overload; increased salivation, tremors, bradycardia, spasms, gastrointestinal disturbances, ulcers of the mouth	Avoid with parasympathomimetic drugs; atropine-like compounds reduce effect	Undetermined; 8–10 g is toxic dose for humans	Used by chewing the nut; used in the past as a chewing balm for gum disease and as a vomituge; long-term use may result in malignant tumors of the oral cavity
Belladonna, <i>L. Atropa belladonna</i> , deadly nightshade	Atropine, scopolamine, flavonoids ^b	Anxiolytic	Tachycardia, arrhythmias, xerostomia, mydriasis, difficulties with micturition and constipation	Synergistic with anti-cholinergic drugs; acid with tricyclic anti-depressants, amantadine, and quinine	0.05–0.10 mg a day; maximum single dose is 0.20 mg	Has a strong smell, tastes sharp and bitter, and is poisonous
Bitter orange flower, <i>Citrus aurantium</i>	Flavonoids, limonene	Sedative, anxiolytic, hypnotic	Photosensitization	Undetermined	Tincture: 2–3 g per day, drug: 4–6 g per day, extract 1–2 g per day	Contradictory evidence; some refer to it as a gastric stimulant
Black cohosh, <i>L. Cimicifuga racemosa</i>	Triterpenes, isoferulic acid	For premenstrual syndrome, menopausal symptoms, dysmenorrhea	Weight gain, gastrointestinal disturbances	Possible adverse interaction with male or female hormones	1–2 g per day; over 5 g can cause vomiting, headache, dizziness, cardiovascular collapse	Estrogen-like effects
Black haw, cramp bark, <i>L. Viburnum prunifolium</i>	Scopoletin, flavonoids, caffeic acids, triterpenes	Sedative, antispasmodic action on uterus; for dysmenorrhea	Undetermined	Anticoagulant-enhanced effects	1–3 g per day	questionable because root may act as estrogen-receptor blocker
California poppy, <i>L. Eschscholtzia californica</i>	Isoquinoline alkaloids, cyanogenic glycosides	Sedative, hypnotic, anxiolytic; for depression	Lethargy	Combination of California poppy, valerian, St. John's wort, and passion flowers can result in agitation	2 g per day	Clinical or experimental documentation of effects is unavailable
Catnip, <i>L. Nepeta cataria</i>	Valeric acid	Sedative, antispasmodic; for migraine	Headache, malaise, nausea, hallucinogenic effects	Undetermined	Undetermined	Delirium produced in children
Chamomile, <i>L. Matricaria chamomilla</i>	Flavonoids	Sedative, anxiolytic	Allergic reaction	Undetermined	2–4 g per day	May be GABAergic
Corydalis, <i>L. Corydalis cava</i>	Isoquinoline alkaloids	Sedative, antidepressant; for mild depression	Hallucination, lethargy	Undetermined	Undetermined	Clonic spasms and muscular tremor with overdose
Cyclamen, <i>L. Cyclamen europaeum</i>	Triterpene	Anxiolytic; for menstrual complaints	Small doses (e.g., 300 mg) can lead to nausea, vomiting, and diarrhea	Undetermined	Undetermined	High doses can lead to respiratory collapse

Echinacea, <i>L. Echinacea purpurea</i>	Flavonoids, polysaccharides, caffeic acid derivatives, alkaloids	Stimulates immune system; for lethargy, malaise, respiratory and lower urinary tract infections	Allergic reaction, fever, nausea, vomiting	Undetermined	1–3 g per day	Use in HIV and AIDS patients is controversial; potential for immunosuppression with long-term use. NCCAM studied.
Ephedra, ma-huang <i>L. Ephedra sinica</i>	Ephedrine, pseudoephedrine	Stimulant; for lethargy, malaise, diseases of respiratory tract	Sympathomimetic overload; arrhythmias, increased blood pressure, headache, irritability, nausea, vomiting	Synergistic with sympathomimetics; serotonergic agents; avoid with MAOIs	1–2 g per day	Administer for short periods as tachyphylaxis and dependence can occur; risk of myocardial ischemia and stroke. Banned in US diet supplement.
Ginkgo, <i>L. Ginkgo biloba</i>	Flavonoids, ginkgolide A, B	Symptomatic relief of delirium; improves concentration and memory deficits; possible antidote to SSRI-induced sexual dysfunction	Allergic skin reactions, gastrointestinal upset, muscle spasms, headache	Anticoagulant; use with caution because of its inhibitory effect on PAF; increased bleeding possible	120–240 mg per day	Studies indicate improved cognition in Alzheimer's patients after 4–5 weeks of use, possibly because of increased blood flow
Ginseng, <i>L. Panax ginseng</i>	Triterpenes, ginsenosides	Stimulant; for fatigue, elevation of mood, immune system	Insomnia, hypertension, and edema (called ginseng abuse syndrome)	Not to be used with sedatives, hypnotic agents, MAOIs, antidiabetic agents, or steroids; has anticoagulant action (discontinue 7 days before surgery)	1–2 g per day	Several varieties exist: Korean (most highly valued), Chinese, Japanese, American (<i>Panax quinquefolius</i>)
Heather, <i>L. Calluna vulgaris</i>	Flavonoids, catechin, triterpenes, β -sitosterol	Anxiolytic, hypnotic	Undetermined	Undetermined	Undetermined	Efficacy for claimed uses is not documented
Hops, <i>L. Humulus lupulus</i>	Humulone, lupulone, flavonoids	Sedative, anxiolytic, hypnotic; for mood disturbances, restlessness	Contraindicated in patients with estrogen-dependent tumors (breast, uterine, cervical)	Hyperthermia effects with phenothiazine antipsychotics and with CNS depressants	0.5 g per day	May decrease plasma levels of drugs metabolized by CYP450 system
Horehound, <i>L. Ballota nigra</i>	Diterpenes, tannins	Sedative	Arrhythmias, diarrhea, hypoglycemia, possible spontaneous abortions	May enhance serotonergic drug effects, may augment hypoglycemic effects of drugs	1–4 g per day	May cause abortion
Jambolan, <i>L. Syzygium cumini</i>	Oleic acid, myristic acid, palmitic acid, linoleic acid, tannins	Anxiolytic, antidepressant	Undetermined	Undetermined	1–2 g per day	In folk medicine, a single dose is 30 seeds (1.9 g) of powder

(continued)

Kava kava, <i>L. Piperis methysticum</i>	Kava lactones, kava pyrone	Sedative, hypnotic antispasmodic	Lethargy, impaired cognition, dermatitis with long-term unreported usage	Synergistic with anxiolytics, alcohol; avoid with levodopa and dopaminergic agents	600–800 mg per day	May be GABAergic; contraindicated in patients with endogenous depression; may increase the danger of suicide
Lavender, <i>L. Lavandula angustifolia</i>	Hydroxycoumarin, tannins, caffeic acid	Sedative, hypnotic	Headache, nausea, confusion	Synergistic with other sedatives	3–5 g per day	May cause death in overdose
Lemon balm, sweet Mary, <i>L. Melissa officinalis</i>	Flavonoids, caffeic acid, triterpenes	Hypnotic, anxiolytic, sedative	Undetermined	Potentiates CNS depressant; adverse reaction with thyroid hormone	8–10 g per day	
Mistletoe, <i>L. Viscum album</i>	Flavonoids, triterpenes, lectins, polypeptides	Anxiolytic; for mental and physical exhaustion	Berries said to have emetic and laxative effects	Contra indicated in patients with chronic infections (e.g., tuberculosis)	10 per day	Berries have caused death in children
Mugwort, <i>L. Artemisia vulgaris</i>	Sesquiterpene lactones, flavonoids	Sedative, antidepressant, anxiolytic	Anaphylaxis, contact dermatitis	Potentiates anticoagulants	5–15 g per day	May stimulate uterine contractions
Nux vomica, <i>L. strychnos nux vomica</i> , poison nut	Indole alkaloids: strychnine and brucine, polysaccharides	Antidepressant; for migraine, menopausal symptoms	Convulsions, liver damage, death; severely toxic because of strychnine	Undetermined	0.02–0.05 g per day	Symptoms of poisoning can occur after ingestion of one bean; lethal dose is 1–2 g
Oats, <i>L. Avena sativa</i>	Flavonoids, oligo- and polysaccharides	Anxiolytic, hypnotic; for stress, insomnia, opium and tobacco withdrawal	Bowel obstruction or other bowel dysmotility syndromes, flatulence	Undetermined	3 g per day	Oats have sometimes been contaminated with aflatoxin, a fungal toxin linked with some cancers
Passion flower, <i>L. Passiflora incarnata</i>	Flavonoids, cyanogenic glycosides	Anxiolytic, sedative, hypnotic	Cognitive impairment	Undetermined	4–8 g per day	Overdose causes depression

St. John's wort, <i>L. Hypericum perforatum</i>	Hypericin, flavonoids, xanthones	Antidepressant, sedative, anxiolytic	Headaches, photosensitivity (may be severe), constipation	Report of manic reaction when used with sertraline (Zoloft); do not combine with SSRIs or MAOIs; possible serotonin syndrome; do not use with alcohol, opioids; discontinue 5 days before surgery	100–950 mg per day	Under investigation by the NIH; may act as MAOI or SSRI; 4- to 6-week trial for mild depressive moods if no apparent improvement; another therapy should be tried
Scarlet pimpernel, <i>L. Anagallis arvensis</i>	Flavonoids, triterpenes, cucurbitacins, caffeic acids	Antidepressant	Overdose or long-term doses may lead to gastroenteritis and nephritis	Undetermined	1.8 g of powder 4 times a day	Flowers are poisonous
Skullcap, <i>L. Scutellaria lateriflora</i>	Flavonoid, monoterpenes	Anxiolytic, sedative, hypnotic	Cognitive impairment, hepatotoxicity	Disulfiram-like reaction may occur if used with alcohol	1–2 g per day	Little information exists to support the use of this herb in humans
Strawberry leaf, <i>L. Fragaria vesca</i>	Flavonoids, tannins	Anxiolytic	Contraindicated with strawberry allergy	Undetermined	1 g per day	Little information exists to support the use of this herb in humans
Tarragon, <i>L. Artemisia dracunculids</i>	Flavonoids, hydroxycoumarins	Hypnotic, appetite stimulant	Undetermined	Undetermined	Undetermined	Little information exists to support the use of this herb in humans
Valerian, <i>L. Valeriana officinalis</i>	Valepotriates, valerenic acid, caffeic acid	Sedative, muscle relaxant, hypnotic	Cognitive and motor impairment, gastrointestinal upset, hepatotoxicity; long-term use: contact allergy, headache, restlessness, insomnia, mydriasis, cardiac dysfunction	Avoid concomitant use with alcohol or CNS depressants	1–2 g per day	Little information exists to support the use of this herb in humans May be chemically unstable

*No reliable, consistent, or valid data exist on dosages or adverse effects of most phytochemicals.

[†]Flavonoids are common to many herbs. They are plant by-products that act as antioxidants (i.e., agents that prevent the deterioration of material such as DNA (deoxyribonucleic acid) via oxidation).
[‡]AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; GABA, γ -aminobutyric acid; HIV, human immunodeficiency syndrome; MAOIs, monoamine oxidase inhibitors; NIH, National Institutes of Health; PAF, platelet-activating factor; SSRIs, serotonin reuptake inhibitors; NCCAM, National Center for Complementary Medicine and Alternative Medicine.

HOMEOPATHY

Homeopathic healing was developed in the early 1800s by Samuel Hahnemann, a German physician (Fig. 24-4). It is based on the concept that self-healing is a basic characteristic of human life and that special medications can aid this inherent process. The homeopathic pharmacopoeia is unique in several ways. First, it contains more than 2,000 medications, including those from plants, such as aconite, ergot, and hellebore; minerals, such as silver, copper, gold, and iodine; and animals, such as snake and jellyfish venom and tissue extracts. Second, medications are prepared as tinctures (i.e., mixed with 95 percent grain alcohol) or as pills with lactose fillers. Finally, medications are dispersed in infinitesimally dilute solutions, such as 1 to 1,020,000, which prevents the medication from being detected by conventional chemical methods. Homeopaths claim that the therapeutic effect is based on “molecular medicine.”

FIGURE 24-4 Samuel Hahnemann (1755–1843). (From the New York Academy of Medicine, New York, NY, with permission.)

Hahnemann based his drug treatment on the following assumptions: medical substances elicit a standard array of signs and symptoms in healthy people, and the medicine whose effect in normal persons most closely resembles the illness being treated is the one most likely to initiate a curative response. Thus, a medication that produces nausea would be used to treat nausea, except that it would be given in dilute amounts. This law of similars—*Similia similibus curantur* (“Let like be cured by like”)—led to coining of the word homeopathy (“similar experiences”). In traditional medicine, such highly dilute substances are considered to have no effect, and no pharmacological research studies demonstrate otherwise.

Homeopathic medical schools are no longer found in the United States (the last one was Hahnemann University Medical School, which closed in 1994); nevertheless, the practice of homeopathy is increasing in the United States and around the world. In Europe, homeopathy is extraordinarily popular. Homeopathic medicines are sold over the counter in the United States. Homeopathic remedies sold in the United States must meet the standards of monographs in the Homeopathic Pharmacopoeia of the United States (HPUS), which was recognized in the Food, Drug and Cosmetic Act with authority equivalent to that of the United States Pharmacopeia (USP). To date, no NCCAM studies have been done on homeopathic methods.

LIGHT AND MELATONIN THERAPY

Light therapy is based on the concept that humans are subject to circadian rhythms (from the Latin words *circa* [“around”] and *dies* [“day”]) that affect physiological processes in predictable ways. There are 24-hour cycles of rest and activity that include changing levels of corticosteroids, electrolyte excretion, and physiological processes; for instance, blood pressure is higher during the day than at night. By varying light exposure, circadian rhythms can be altered. The concentration of the hormone melatonin, produced by the pineal gland, is highest in the bloodstream at night and is low or absent during the daylight. Melatonin is believed to regulate sleep, and exogenous melatonin (available over the counter) produces drowsiness in normal people. Artificial bright-light therapy (over 2,500 lux) is a proven method used to treat depressive disorder with seasonal pattern, which is seen during the winter months when daylight hours are reduced.

MACROBIOTICS

Macrobiotics (from the Greek words *makros* [“long”] and *bios* [“life”]) is a health practice that focuses on living in harmony with nature, using mainly a balanced diet. Macrobiotics became associated with the biblical patriarchs, the Chinese sages, and the Ethiopians of Africa, who were said to live 120 years or more. In 1797, a German physician and philosopher, Christoph W. Hufeland wrote an influential book on diet and health, *Macrobiotics or the Art of Prolonging Life*.

Macrobiotic foods are classified as *yin* (cold and wet) and *yang* (hot and dry); the goal is to keep *yin* and *yang* in balance. The diet consists of 50 percent grain products, 25 percent cooked or raw vegetables, 10 percent protein, 10 percent vegetable or fish soup, and 5 percent teas and fruits. Prolonged use of the diet can result in vitamin and mineral deficiencies.

MASSAGE

Massage is a treatment that involves manipulation of the soft tissues and the surfaces of the body. It was prescribed for the treatment of diseases more than 5,000 years ago by Chinese physicians, and Hippocrates considered it to be a method of maintaining health.

Massage is believed to affect the body in several ways: it increases blood circulation, improves the flow of lymph through the lymphatic vessels, improves the tone of the musculoskeletal system, and has a tranquilizing effect on the mind. Massage techniques have been described in various ways: stroking, kneading, pinching, rubbing, knuckling, tapping, or applying friction. Massage is most often done with the hands and fingers, but vibrating machines and electrical stimulation are also used. The different types of massage therapies that have evolved over the years are more similar than different. These include Swedish, Oriental, Shiatsu, and Esalen massages. Studies have proved massage useful to reduce anxiety and pain perception. Most persons who experience massage find it physically and mentally restorative. NCCAM studies have shown massage to be of benefit in the treatment of pain, especially pain related to joint disease.

MEDITATION

Meditation is a technique that involves entering a trance state by focusing thought on a word or sound (a mantra), an object (e.g., a burning candle), or a movement (e.g., an oscillating disk). During the trance, the person experiences a state of calm. A meditative trance has physiological effects, all associated with decreased anxiety: heart and respiratory rates slow, blood pressure decreases, and alpha brain waves increase.

Transcendental meditation (TM), developed by the Indian mystic Maharishi Mahesh Yogi, was introduced into the United States in the 1950s. TM uses mantras based on personal characteristics to induce a trance state. In the 1960s, a physician, Herbert Benson, developed the relaxation response, which used mantras and breath control as a treatment for stress and stress-related disorders.

Mindfulness Meditation

Mindfulness meditation is derived from Buddhist practices of meditation and refers to paying attention to the present and being aware of the present using all sensory modalities. As thoughts flow through the mind during meditation, they are viewed nonjudgmentally, accepted for what they are, reflective of our “true nature.” It is a process of self-exploration and self-inquiry. NCCAM studies have shown changes in brain, particularly left side anterior activation during meditation also associated with significant improvement in subjective and objective symptoms of anxiety and panic. One study reported improvement in women with irritable bowel syndrome.

Mindfulness Therapy

The concept of mindfulness and has been translated into a type of psychotherapy in which therapist and patient focus are on the here and now rather than past events. Patients are encouraged to become aware of how they are feeling and what they are thinking in the moment. As they examine their experienced emotion about current events or conflicts, insights leading to change in behavior or attitudes occur.

MOXIBUSTION

Moxibustion is based on theories of Oriental medicine in which energy forces are balanced by applying heat to stimulate specific acupoints. The heat is generated by burning dry mugwort leaves (*Artemisia vulgaris*, known as *moxa*). Heat is applied either directly or indirectly. In the direct method, dried moxa is rolled into small cones and placed on the skin. The tops of the cones are lit, but they are extinguished as soon as heat is felt. In the indirect method, a burning cigar-like moxa is held near the skin at acupoints.

Moxibustion is used in musculoskeletal disorder, arthritis, asthma, and eczema. As with many other alternative therapies, however, no scientific clinical trials are available to show its effectiveness.

NATUROPATHY

Naturopathy is a health care system intended to ensure a healthy mind and body based on maintaining healthy nutrition, pollution-free air and water supplies, and exercising regularly. The treatment is based on the belief that the body has the power to heal itself; it requires the patient's active participation in the health maintenance program.

Naturopathy developed in Germany in the later 19th century under the guidance of Benedict Lust, who prescribed hydrotherapy (alternating hot and cold water) as a form of natural healing. Lust came to the United States, became an osteopathic physician, and founded the American School of Naturopathy in 1902. Since then, naturopathic medicine has grown into a major form of health care, which uses an eclectic group of methods in addition to hydrotherapy. These methods include eating specialized diets, homeopathy, breathing ionized air, using fomentations (the application of hot and cold compresses), taking colonic irrigations and enemas, drinking pollution-free water, eating foods grown organically, and using massage therapy, herbs, and rest therapy. Naturopathic physicians are licensed in several states (Alaska, Connecticut, New Hampshire, among others), but because no standard regulation of the field exists, persons with minimal or no educational background set up practices.

ORIENTAL MEDICINE

Oriental medicine is a broad term covering the traditional medicines of China, Korea, Japan, Vietnam, Tibet, and other Asian countries. In general, the techniques of Oriental medicine were first developed in China and include acupuncture, moxibustion, herbology, massage, cupping, *gwa sha* (scraping away toxins), breath work, *qi gong* (see below), and exercise (*tai chi*). Chinese medicine is a coherent and independent system of thought and practice based on ancient texts. It is the result of a continuous process of critical thinking, extensive clinical observation, and testing, and it represents a thorough exposition of material by respected clinicians and theoreticians. It is rooted in philosophy, logic, sensibility, and habits of civilization foreign to Western civilization and, therefore, is difficult for Western physicians to understand. The basic theory is that a life force, called *chi* energy, flows in us in a harmonious, balanced way. This harmony and balance signify health. When the life force does not flow properly, disharmony and imbalance, or illness, result.

OSTEOPATHIC MEDICINE

The scope of osteopathic medicine is similar to allopathic medicine and is best indicated by the fact that doctors of osteopathy (DO) are licensed to practice in every state and are accepted into medical, surgical, and psychiatric residency programs and the military on the same basis as medical doctors (MD); they are qualified to practice in every branch of clinical medicine and take the same licensure examinations as MDs. Their medical education is identical to that of MDs, except that they have additional training in disorders of the musculoskeletal system, in which DOs consider themselves more knowledgeable than MDs.

As of 2012 there were 29 osteopathic medical schools in the United States. Approximately 82,000 osteopaths treat about 30 million patients each year. Osteopathy was developed by Andrew Taylor Still, M.D. (1828–1917), who founded the American School of Osteopathy in Kirksville, Missouri (now Kirksville College of Osteopathic Medicine), in 1892. Disease is viewed in the same way as in allopathic medicine; however, special emphasis is placed on proper musculoskeletal alignment as a prerequisite for health maintenance. Osteopaths may rely on the manipulation of body parts, particularly the craniosacral spinal axis, as part of a treatment plan. Osteopathic manipulation therapy is perceived as an adjunct, not a substitute, to traditional medical, surgical, and pharmacological intervention.

OZONE THERAPY

Ozone, which acts as an antioxidant and disinfectant, is used conventionally for water purification, odor control, and air purification. Ozone therapy is based on the assumption that most illness is caused by viral and bacterial infection; ozone is used to treat medical conditions that range from influenza to cancer and acquired immunodeficiency syndrome (AIDS). The first ozone generators were developed by Werner von Siemens in Germany in 1857, and ozone was used therapeutically to purify blood shortly thereafter in Germany and other European countries.

Ozone therapy introduces ozone into the body in various ways. These include drinking ozonated water; ozone limb bagging, in which ozone is pumped into an airtight bag that covers an arm or leg; breathing ozone bubbled through olive oil or topically applying ozonated olive oil; insufflations, in which a catheter is inserted into the rectum or vagina with ozone administered at a slow flow rate; and autohemotherapy, in which a person's own ozonized blood is reintroduced into the body.

PAST LIFE MEDICINE

In past life medicine, the healing process is aided by contact with spiritual beings that are believed to have the ability to reverse illness and maintain health. The spirits are approached through the use of altered states of consciousness, so-called *channeling*, higher states of awareness, and transmissions from spiritually evolved beings. Past life regression using hypnosis allows a person to experience past life events (via imagery).

A 40-year-old man, in good health, with an obsessive fear of death was referred to an integrative psychiatrist to deal with his preoccupations about dying. The patient was placed in a trance state under hypnosis and asked to imagine and describe a past life. He described himself as an itinerant silk merchant living in 16th-century France. He was married, had eight children, and was content with his life. He was asked to describe his death and proceeded to do so. He was 90 years old when he died, surrounded by his family who were at his bedside. He knew he was dying and described the process as a "peaceful falling away." Following the session, his fears about dying diminished; when he became anxious about death, he remembered the past life narrative and was able to relax.

PRAYER

The pervasive interest in faith healing, the curative anecdotes of television evangelists, and the millions of hopeful individuals visiting religious shrines in search of relief give witness to the continuing interest in, and prevalence of, prayer and spirituality in the process of healing. Some religious groups specifically recommend against standard psychiatric therapies and offer their own approach as the only valid alternative for mental and spiritual health. Others view prayer as a form of distant healing defined by the psychic Elizabeth Targ as any purely mental effort undertaken by one person with the intention of improving the physical or emotional well-being of another.

Some advocate the use of shared prayer, silent prayer, and distant or “intercessory” prayer (praying on behalf of someone else for a specific purpose) to benefit patients. Studies to date are inconclusive, however, on the impact of prayer on medical outcomes. Surveys indicate that 92 percent of a sample of inner-city homeless women reported one or more spiritual or religious practices. Some 48 percent reported that prayer was significantly related to less use of alcohol or street drugs or both and fewer perceived worries and depression. Recent epidemiological research indicates that religious beliefs and practices are negatively correlated with substance abuse and positively correlated with health status. Also 12-step programs have a long history of successfully incorporating prayer and spirituality in the treatment of addictive behavior. Personal belief in religion and active attendance at worship has been correlated with a moderately decreased incidence of depression and hypertension.

QI GONG

Chinese *qi gong* has been practiced for more than 2,000 years. Translated directly, *qi gong* means the skill or work (*gong*) of cultivating energy (*qi*). It is a Chinese exercise system that attracts and directs the vital life energy (see “Oriental Medicine” above), enabling practitioners to build up their health, prevent illness, and increase vitality. “Still” *qi gong* is practiced as a motionless meditation with the emphasis on breath and intentional thoughts. “Moving” *qi gong* involves external movements under the conscious direction of the mind. Electroencephalogram studies have detected measurable differences in the brain patterns of practitioners. Purported benefits include increased autoimmune cell production, reduced hypertension, and decreased incidence of falls in the elderly.

REFLEXOLOGY

Reflexology is the gentle massaging of the feet, hands, and ears to stimulate the body’s natural healing power. It is used to alleviate tension by clearing crystalline deposits under the skin that may interfere with the natural flow of the body’s energy. Reflexologists believe that all body parts can be mapped out on the soles or sides of the feet; for instance, the tip of the second toe represents the eye. Applying pressure to a particular area of the foot can relieve disorders related to the represented body parts. NCCAM studies have shown some benefit from reflexology in patients with irritable bowel syndrome.

REIKI

Reiki is a Japanese word with the general meaning of “healing.” (*Rei* means “universal” or “spiritual,” and *ki* is “life force energy.”) It was developed by Mikao Usui in 1922 (Fig. 24-5). The two degrees of *Reiki* healing are as follows. First-degree *Reiki* practitioners use light, nonmanipulative touch to the head and torso to precipitate a flow of healing energy, called *Reiki*, drawn and into the patient according to the recipient’s needs. Second-degree healing enables practitioners to access this energy for distant healing when touch is impossible. *Reiki* treatment typically creates an almost immediate feeling of relaxation, which may reduce the biochemical effects of prolonged stress. First-degree *Reiki* is easily learned and is a method that patients use to decrease stress, anxiety, insomnia, and pain. *Reiki* is also used in hospices for pain management, to support a peaceful death, and to provide emotional support for family members. It is also beneficial in cardiovascular disease as a means to lower blood pressure and reduce cardiac arrhythmias. The mechanism of action is unknown, however, the autonomic nervous system is involved, especially parasympathetic impulses.

FIGURE 24-5 Mikao Usui (1865–1926), a Japanese philosopher who was the founder of *Reiki* healing.

ROLFING

Rolfing is a type of massage that was developed by an American biochemist, Ida Rolf (1896–1979), to relieve tension in muscle, connective tissue, and fascia, which she believed caused musculoskeletal diseases, such as arthritis and fibromyalgia. Therapy consists of deep, sometimes painful, massage to produce flexible planes between muscle groups throughout the body. Rolf discovered that she could achieve remarkable changes in posture and structure by manipulating the body’s myofascial system; as various parts of the body are massaged, past memories and emotional states are often released. In this sense, Rolfing is a psychophysiological experience. No NCCAM studies on Rolfing have been performed.

SHAMANISM

A shaman (Fig. 24-6) is an individual who is believed to have the power to heal the sick and communicate with the spirit world. Individuals having this designation can be found in many parts of the world, including American aboriginal groups (Native Americans and Alaskan

natives). Qualifications of a medicine man (or woman) are determined by a series of initiatory trials and teaching and “certification” by qualified, recognized elders. Shamanistic practices often include cleansing ceremonies, such as fasting or sweating, and so-called vision quests, which are accompanied by hallucinations. The ceremony is sometimes facilitated by rhythmic sounds, dancing, physical pain or privation, and the use of “spiritual herbs.” Through this process, the shaman escorts the soul of the dying to the afterlife. Shamanistic practices are also used to provide solutions to insolvable personal or social problems.

FIGURE 24-6 Wooden statue of shaman. North Pacific coast.

SNOEZELEN

This is a term for a system of multisensory stimulation (e.g., lighting effects, tactile surfaces, meditative music, and smell of essential oils) generally conducted in special rooms for 30 to 60 minutes per session. Snoezelen originated in the Netherlands in the field of learning disability and autism with children but has been adapted for use in dementia. Snoezelen may also improve behavioral disturbances such as apathy, mood, and restless or repetitive behaviors. One study showed Snoezelen to be comparable to “reminiscence therapy” (e.g., using newspapers of nostalgic items to allow a person to talk about old memories) for acute agitation in dementia. Lack of widespread availability and potentially high costs for maintaining the therapy may limit its applicability.

SOUND AND MUSIC THERAPY

Sound therapy is an ancient technique in which sounds (e.g., chants, bell rings, or drum beats) are used to create vibrations in the body and believed to have healing powers. Practitioners claim that a sense of relaxation can also be achieved. Sound therapy is used in Ayurveda to promote health, with claims of reducing tumor growth by using certain sounds known as *Sama Veda*. Music therapy uses the sound of musical instruments, such as the flute, to achieve similar results. In the Bible, David attempted to treat King Saul’s depression by playing the harp. The effect of music and sound on psychophysiological processes is under investigation at various academic centers.

TAI CHI

Tai chi, or *tai chi chuan*, is one of the most popular Asian movement arts used in the West. This ancient Chinese technique is designed to increase the life force in the body through a series of slow circular movements. It is a moving form of meditation and is based, as are other Chinese methods, on the search for perfect balance between *yin* and *yang* energies.

The practitioner performs sequences of movements that last from 5 to 30 minutes. A session may last a couple of hours and is typically performed in early morning. The practitioner is expected to focus on breathing and its precise synchronization with the movements. *Tai chi chuan* is believed to help mainly stress-related problems and conditions and so is primarily used to treat anxiety, depression, muscular tension, high blood pressure, and other cardiovascular conditions. NCCAM studies have shown improvement in exercise tolerance in patients with cardiovascular disease who practice *tai chi*.

THERAPEUTIC TOUCH

Therapeutic touch is the technique of healing with hands. It was developed by a nurse, Dolores Krieger, in the 1970s. Energy is believed to be transferred by laying the hands over specific parts of the body to aid in the process of healing. Therapeutic touch has gained popularity in the nursing profession, as well as among some physicians. NCCAM studies have shown therapeutic touch to be of value in patients with chronic neck pain.

TIBETAN MEDICINE

The Tibetan health system dates to about the 7th century A.D. The Tibetan king Songsten Gampo is credited with its creation from the synthesis of various, more ancient sources. It has elements of Arabic, Indian, and Chinese health systems. In Tibet, its practice is closely related to religion and magic. Disease is believed to be the result of imbalance between the three components or humors of the living organism: wind (breathing and movement in general), bile (related to digestion and temperament), and phlegm (related to sleep, joint mobility, and skin elasticity). Imbalance can be caused by ignorance of health principles, environmental assaults, or improper diet. Treatment consists of restoring the balance between the different humors through the use of herbal medicine and accessory therapies, such as

massage, moxibustion, acupuncture, appropriate diet, religious rituals, and purification techniques.

TRAGER METHOD

The Trager method, developed by Milton Trager, a Chicago physician, is a technique of movement reduction to aid individuals suffering from polio and other neuromuscular disorders. The client, typically in 60- to 90-minute sessions, is instructed to relax all conscious muscles and to allow the unconscious to choose natural, less restrictive body movements, as guided by the practitioner. This method is particularly suitable to individuals with back pain and severely restricted movement.

YOGA

Yoga (“yoking” or “union” in Sanskrit) is a comprehensive philosophical system with the goal of preparing an individual to unite with the supreme being. The technique of early yoga seeks to bring into balance all the disparate aspects of body, mind, and personality. Early evidence of yoga practice dates back to 5,000 years ago in India, and it has been practiced as a religion and health system ever since. The West grew familiar with yoga through the practice of Hatha Yoga and an emphasis on the physical collection of *asanas* (postures). The other aspects of the system, *pranayama* (breathing exercises) and *dhyana* (meditation), and other forms of yoga are gaining adoption.

Recent studies in people with chronic low-back pain suggest that yoga poses may help reduce pain and improve function. Other health benefits such as reducing heart rate and blood pressure and reducing anxiety and depression have been reported.

According to the 2007 National Health Interview Survey (NHIS), yoga is the sixth most commonly used complementary health practice among adults. More than 13 million adults practice yoga. There are many training programs for yoga teachers throughout the country. These programs range from a few days to more than 2 years. Standards for teacher training vary and certification differs depending on the style of yoga.

INTEGRATIVE PSYCHIATRY

A new type of psychiatry, called *integrative psychiatry*, selectively incorporates elements of complementary and alternative medicine into practice methods. It emphasizes treatment rather than diagnosis and views the patient holistically, taking into account not only mind–body issues and interactions but spiritual values as well. Integrative psychiatry is also concerned with prevention of illness, emphasized by having the patient pay attention to lifestyle factors such as diet and exercise. Stress reduction involves use of yoga, meditation, or other relaxation exercises. Attention is paid to stress factors related to work and interpersonal relationships.

History

At one time, hypnosis and biofeedback were considered alternative therapies out of the mainstream of traditional psychiatric practice. These modalities are now incorporated into standard psychiatric practice. Hypnosis, for example, is used by psychiatrists for a variety of disorders, and dynamically oriented psychiatrists use hypnotherapy in their work to enable a patient to recover feelings and memories that are repressed and not otherwise available for analysis. In the middle of the 20th century, workers such as Paul Schilder, in his book *The Image and Appearance of the Human Body*, described how one's physiology and physiognomy could be influenced by psychological experiences during various developmental stages. More recently, mainstream psychiatrists, such as Brian Weiss, have described their use of past life regression as a therapeutic method and a means of accessing unconscious material.

Methods

Any of the complementary methods described in this section can be integrated into standard psychotherapeutic practice, although some lend themselves better than others. For example, during a *Reiki* treatment, a patient tends to be in a relaxed state and may have feeling tones, images, or thoughts that would not ordinarily be discussed. In an integrative therapy session, those mental and physical phenomena would be verbalized and subject to analysis and interpretation. Similarly, a patient having past life regression may have an elaborate narrative about his or her past life that would be carefully examined by the integrative psychiatrist for its relevance to current life experiences. Most integrative psychiatrists view past-life narratives as dynamic representations of the patient's unconscious wishes and fears; some view them as representations of actual past lives. In either case, the material is used to help patients gain greater insight and understanding of themselves in their current life.

Complementary and alternative techniques that involve body manipulation (e.g., craniosacral manipulation, massage, or the Alexander technique) lend themselves to integrative psychiatric therapy. As mentioned, the image persons have of their body and the way in which the body is held (e.g., stooped posture) are heavily influenced both by genetics and by life experiences. Depressive facies, Veraguth's folds, and other physiologic correlates of mood have long been recognized in the psychiatric literature. The integrative psychiatrist uses this and other bodily markers as a way to gain access to previously unrecognized neurotic conflict. Patients with somatic symptom disorders or dysmorphophobia are often helped by such approaches, as are patients with eating disorders who have major body image distortions.

Any technique that involves manipulation of a body part can potentially elicit an image, thought, or feeling related to the experience. A patient experiencing a back rub may have myriad associations to the experience that are examined in the session. Some patients cannot tolerate being touched, a trait that is almost always related to some past traumatic experience. Body manipulation can be geared to correcting abnormalities. In the Alexander technique, careful attention is paid to posture and body alignment. As the corrective procedures unfold, patients may gain understanding and insight into what caused the defective or inefficient postural attitude in the first place.

Finally, spiritual beliefs derived from Judeo-Christian, Native American, and Eastern religious thought can be integrated into traditional psychotherapy. Workers such as Alan Watts incorporated Zen Buddhism into Western psychotherapy more than 50 years ago. Psychiatrists are working with Native American healers to help patients diminish anxiety, especially regarding death and dying.

Other Issues

Ideally, the psychiatrist practicing integrative therapy should be schooled in one or more of the complementary methods he or she plans to employ. In some cases, a complementary practitioner may work in conjunction with the psychiatrist, especially if the psychiatrist is not schooled in a particular method. At times, patients may be expert in a field (e.g., yoga) and seek out the integrative psychiatrist to enlarge on their experience. Integrative psychiatrists may use psychoactive herbs and homeopathic medicinals alone or in conjunction with traditional psychopharmacologic agents, mindful of the possibility of adverse drug–drug interactions.

Ethical Issues

The same standards that apply to traditional psychiatric practice and psychotherapy apply to integrative psychiatry. Because some of the techniques involve a laying on of hands or place the patient in a more dependent and vulnerable state than traditional psychotherapy techniques, boundary issues must be carefully evaluated. Currently, no standards of practice exist for this method other than those to which physicians have always been held, including doing no harm. As in complementary and alternative medicine generally, careful outcome studies are needed if this new amalgam is to prove its worth.

Other Conditions that May be a Focus of Clinical Attention

In the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), in a section called Other Conditions That May Be a Focus of Clinical Attention, there is a list of conditions that are not mental disorders but that have led to contact with the mental health care system. In some instances, one of these conditions will be noted during the course of a psychiatric evaluation (e.g., divorce), although no mental disorder has been found. In other instances, the diagnostic evaluation reveals no mental disorder, but a need is seen to note the primary reason for contact with the mental health care system (e.g., homelessness).

In some cases, a mental disorder may eventually be found, but the focus of attention or treatment is on a condition that is not caused by a mental disorder. For example, a patient with an anxiety disorder may receive treatment for a marital problem that is unrelated to the anxiety disorder itself.

Table 25-1 lists the many conditions that may be a focus of clinical attention or that may influence the diagnosis, treatment, or course of a mental disorder that is contained in DSM-5. The list of conditions that make up this category cover the entire life cycle from infancy through childhood, adolescence, adulthood, and old age. The list of conditions covers almost every conceivable life circumstance from divorce to problems related to being in military service. In one sense, they represent the vicissitudes of life or, as Shakespeare has Hamlet state, “the slings and arrows of outrageous fortune.” Each of these conditions or circumstances is capable of having a profound input on a particular mental illness or on the human experience in general.

Table 25-1
Conditions That May Be a Focus of Clinical Attention

I) Relational Problems	2) Economic Problems
1) Problems Related to Family Upbringing	(i) Lack of Adequate Food or Safe Drinking Water
(i) Parent-Child Problem	(ii) Extreme Poverty
(ii) Sibling Problem	(iii) Low Income
(iii) Upbringing Away from Parents	V) Other Problems Related to the Social Environment
(iv) Parental Relationship Distress	1) Phase of Life Problem
2) Other Problems Related to Primary Support System	2) Acculturation Difficulty
(i) Relationship Distress with Spouse or Partner	3) Social Exclusion or Rejection
(ii) Separation or Divorce	4) Discrimination or Persecution
(iii) Emotional Distress within Family	VI) Problems Related to Crime or Interaction with the Legal System (e.g., Victim of Crime, Imprisonment, Release from Prison)
(iv) Uncomplicated Bereavement	VII) Other Health Service Encounters for Counseling and Medical Advice (e.g., Sexual Counseling)
II) Abuse and Neglect	VIII) Problems Related to Other Psychological, Personal, and Environmental Circumstances
1) Problems of Child Maltreatment and Neglect	1) Religious or Spiritual Problem
(i) Child Physical Abuse	2) Victim of Terrorism or Torture
(ii) Child Sexual Abuse	3) Exposure to Disaster or War
(iii) Child Neglect	IX) Other Circumstances of Personal History
(iv) Child Psychological Abuse	1) Adult Antisocial Behavior
2) Problems of Adult Maltreatment and Neglect	2) Child or Adolescent Antisocial Behavior
(i) Physical Violence of Spouse or Partner	3) Problems Related to Access to Medical and Other Health Care
(ii) Sexual Violence of Spouse or Partner	4) Nonadherence to Medical Treatment (e.g., Overweight or Obesity, Malingering, Wandering Associated with a Mental Disorder)
(iii) Spouse or Partner Neglect	5) Borderline Intellectual Functioning
(iv) Psychological Spouse or Partner Abuse	
(v) Adult Abuse by Non-spouse or Non-partner (e.g., Physical, Sexual, Psychological)	
III) Educational and Occupational Problems	
1) Educational Problems	
2) Occupational Problems	
(i) Related to Current Military Deployment Status	
(ii) Other (e.g., job change, loss of job, stress)	
IV) Housing and Economic Problems	
1) Housing Problems	
(i) Homelessness	
(ii) Inadequate Housing (e.g., lack of heat or electricity, insect or rodent infestation)	
(iii) Neighbor, Lodger, or Landlord Discord	
(iv) Residential Institution (does not include psychological reaction to change in living situation; see Adjustment Disorder)	

(Adapted from *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, American Psychiatric Association, 2013.)

The conditions discussed in this chapter include the following: (1) malingering, (2) bereavement, (3) occupational problems, (4) adult antisocial behavior, (5) religious or spiritual problem, (6) acculturation problem, (7) phase of life problem, (8) noncompliance with treatment for a mental disorder, and (9) relational problems. Problems related to the maltreatment and abuse of children is covered in Section 31.19c, and problems related to the physical and sexual abuse of adults is covered in [Chapter 26](#).

MALINGERING

Malingering is the deliberate falsification of physical or psychological symptoms in an attempt to achieve a secondary gain such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior—for example, as mentioned below, feigning illness while a captive of the enemy during wartime.

Malingering should be strongly suspected if any combination of the following is noted: (1) medicolegal context of presentation (e.g., the person is referred by an attorney to the clinician for examination or is incarcerated), (2) evident discrepancy between the individual's claimed stress or disability and the objective findings, (3) lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen, and (4) the presence of antisocial personality disorder.

Epidemiology

A 1 percent prevalence of malingering has been estimated among mental health patients in civilian clinical practice, with the estimate rising

to 5 percent in the military. In a litigious context, during interviews of criminal defendants, the estimated prevalence of malingering is much higher—between 10 and 20 percent. Approximately 50 percent of children presenting with conduct disorders are described as having serious lying-related issues.

Although no familial or genetic patterns have been reported and no clear sex bias or age at onset has been delineated, malingering does appear to be highly prevalent in certain military, prison, and litigious populations and, in Western society, in men from youth through middle age. Associated disorders include conduct disorder and anxiety disorders in children and antisocial, borderline, and narcissistic personality disorders in adults.

Etiology

Although no biological factors have been found to be causally related to malingering, its frequent association with antisocial personality disorder raises the possibility that hypoarousability may be an underlying metabolic factor. Still, no predisposing genetic, neurophysiological, neurochemical, or neuroendocrinological forces are presently known.

Diagnosis and Clinical Features

Avoidance of Criminal Responsibility, Trial, and Punishment. Criminals may pretend to be incompetent to avoid standing trial; they may feign insanity at the time of perpetration of the crime, malingering symptoms to receive a less harsh penalty, or attempt to act too incapacitated (incompetent) to be executed.

Avoidance of Military Service or of Particularly Hazardous Duties. Persons may malingering to avoid conscription into the armed forces and, after being conscripted, they may feign illness to escape from particularly onerous or hazardous duties.

Financial Gain. Modern malingerers may seek financial gain in the form of undeserved disability insurance, veterans' benefits, workers' compensation, or tort damages for purported psychological injury.

Avoidance of Work, Social Responsibility, and Social Consequences. Individuals may malingering to escape from unpleasant vocational or social circumstances or to avoid the social and litigation-related consequences of vocational or social improprieties.

An owner of a previously successful photographic equipment supplier declared bankruptcy in a way that the government maintained was illegal. Subsequently, the government indicted the defendant on various counts of fraud. The defendant's counsel maintained that the defendant was too depressed to cooperate with him and that, because of that depression, he experienced memory loss that made it impossible to understand what had occurred and therefore impossible to provide a meaningful defense. The government's forensic psychiatrist evaluated the defendant to ascertain the nature of his depression and to determine whether it was causing cognitive problems.

When asked early in his evaluation when his birthday was, he responded, "Oh, what does it matter? It was in the 40s or 50s." Similarly, when queried about where he was born, he said, "Some place in Hungary." Even when pressed for more specifics, he refused to elaborate. Yet, at many points later in his evaluation, he responded with complete, often detailed, information about transactions not related to those for which he had been indicted. It was the impression of the evaluator that the defendant was malingering in a gross and inconsistent fashion, incompatible with the kinds of decreases in cognitive skills that occasionally attend major depression. (Adapted from case of Mark J. Mills, J.D., M.D., and Mark S. Lipian, M.D., Ph.D.)

Facilitation of Transfer from Prison to Hospital. Prisoners may malingering (fake bad) with the goal of obtaining a transfer to a psychiatric hospital from which they may hope to escape or in which they expect to do "easier time." The prison context may also give rise to dissimulation (faking good), however; the prospect of an indeterminate number of days on a mental health ward may prompt an inmate with true psychiatric symptoms to make every effort to conceal them.

Admission to a Hospital. In this era of deinstitutionalization and homelessness, individuals may malingering in an effort to gain admission to a psychiatric hospital. Such institutions may be seen as providing free room and board, a safe haven from the police, or refuge from rival gang members or disgruntled drug cronies who have made street life even more unbearable and hazardous than it usually is.

A robust, neatly attired man presented to the psychiatric emergency department in the early-morning hours. He stated that "the voices" were worse and that he wished to be readmitted to the hospital. When the psychiatrist challenged him, observing that he had just been discharged that afternoon, that he routinely left the hospital in the morning and demanded rehospitalization at night, and that, despite multiple hospitalizations, his reported history of hallucinations had been increasingly doubted, the man became belligerent. When the psychiatrist still refused to admit him, the patient grabbed the psychiatrist's clothes, threatening him but inflicting no harm. The psychiatrist asked the hospital police to escort him off the grounds. The patient was told he could seek readmission to his regular ward during the day. Subsequent contact with the patient's ward revealed that their diagnoses were substance abuse and homelessness; his apparent schizophrenia appeared never to have been an actual issue in his treatment. (Courtesy of Mark J. Mills, J.D., M.D., and Mark S. Lipian, M.D., Ph.D.)

Drug Seeking. Malingerers may feign illness in an effort to obtain favored medications, either for personal use or, in a prison setting, as currency to barter for cigarettes, protection, or other inmate-provided favors.

The plaintiff, a woman in her late 20s, was injured while dancing at a club. Although her claim initially appeared bona fide, subsequent investigation cast doubt on the mechanism of injury that she claimed—namely, that a misplaced electrical cord under a carpet caused her to slip. This was true, she claimed, even though she had to been dancing in a particularly jerky manner that could have easily caused problems without tripping.

Subsequently, she sought medical and surgical treatment for torn cartilage in her injured knee. Even though the initial surgery went well, she kept reinjuring the knee with various "slips." As a result, she requested narcotic analgesics. A careful medical record review revealed that she was obtaining such medications from multiple practitioners and that she had apparently forged at least one prescription.

In reviewing the case before binding arbitration, it was the opinion of the orthopedic and psychiatric consultants that, although the initial injury and reported pain were real, the plaintiff consciously elaborated her injuries to obtain the desired narcotic analgesics. (Courtesy of Mark J. Mills, J.D., M.D., and Mark S. Lipian, M.D., Ph.D.)

Child Custody. Minimizing difficulties or faking good for the sake of obtaining child custody can occur when one party accurately accuses the other of being an unfit parent because of psychological conditions. The accused party may feel compelled to minimize symptoms or to portray him- or herself in a positive light to reduce chances of being deemed unfit and losing custody.

Differential Diagnosis

Malingering must be differentiated from the actual physical or psychiatric illness suspected of being feigned. Furthermore, the possibility of partial malingering, which is an exaggeration of existing symptoms, must be entertained. Also, the possibility exists of unintentional, dynamically driven misattribution of genuine symptoms (e.g., of depression) to an incorrect environmental cause (e.g., to sexual harassment rather than to narcissistic injury).

It should also be remembered that a real psychiatric disorder and malingering are not mutually exclusive.

Factitious disorder is distinguished from malingering by motivation (sick role vs. tangible pain), whereas the somatoform disorders involve no conscious volition. In conversion disorder, as in malingering, objective signs cannot account for subjective experience, and differentiation between the two disorders can be difficult. Table 25-2 lists some variables that may aid in distinguishing between these two conditions.

 **Table 25-2**
Factors Aiding in the Differentiation between Malingering and Conversion Disorder

1. Malingers are more likely to be suspicious, uncooperative, aloof, and unfriendly; patients with conversion disorder are likely to be friendly, cooperative, appealing, dependent, and clinging.
2. Malingers may try to avoid diagnostic evaluations and refuse recommended treatment; patients with conversion disorder likely welcome evaluation and treatment, "searching for an answer."
3. Malingers likely refuse employment opportunities designed to circumvent their disability; patients with conversion disorder likely accept such opportunities.
4. Malingers are more likely to provide extremely detailed and exacting descriptions of events precipitating their "illness;" patients with conversion disorder are more likely to report historical gaps, inaccuracies, and vagaries.

Course and Prognosis

Malingering persists as long as the malingeringer believes it will likely produce the desired rewards. In the absence of concurrent diagnoses, after the rewards have been attained, the feigned symptoms disappear. In some structured settings, such as the military or prison units, ignoring the malingering behavior may result in its disappearance, particularly if an expectation of continued productive performance, despite complaints, is made clear. In children, malingering is most likely associated with a predisposing anxiety or conduct disorder; proper attention to this developing problem may alleviate the child's propensity to malingering.

Treatment

The appropriate stance for the psychiatrist is clinical neutrality. If malingering is suspected, a careful differential investigation should ensue. If, at the conclusion of the diagnostic evaluation, malingering seems most likely, the patient should be tactfully but firmly confronted with the apparent outcome. The reasons underlying the ruse need to be elicited, however, and alternative pathways to the desired outcome explored. Coexisting psychiatric disorders should be thoroughly assessed. Only if the patient is utterly unwilling to interact with the physician under any terms other than manipulation should the therapeutic (or evaluative) interaction be abandoned.

BEREAVEMENT

Normal bereavement begins immediately after or within a few months of the loss of a loved one. Typical signs and symptoms include feelings of sadness, preoccupation with thoughts about the deceased, tearfulness, irritability, insomnia, and difficulties concentrating and carrying out daily activities. On the basis of the cultural group, bereavement is limited to a varying time, usually 6 months, but it can be longer. Normal bereavement, however, can lead to a full depressive disorder that requires treatment. Some grieving individuals present with symptoms characteristic of a major depressive episode such as depressed mood, insomnia, anorexia, and weight loss. The duration of grief and bereavement vary considerably among different cultural groups and with the same cultural group. The diagnosis of depressive disorder is generally not given unless the symptoms are still present 2 months after the loss. However, the presence of certain symptoms that are not characteristic of a "normal" grief reaction may be helpful in differentiating bereavement from depression. These include (1) guilt about things other than actions taken or not taken by the survivor at the time of the death, (2) thoughts of death other than the survivor feeling that he or she would be better off dead or should have died with the deceased person, (3) morbid preoccupation with worthlessness, (4) marked psychomotor retardation, (5) prolonged and marked functional impairment, and (6) hallucinatory experiences other than thinking that he or she hears the voice of or transiently sees the image of the deceased person.

OCCUPATIONAL PROBLEMS

Occupational problems often arise during stressful changes in work, namely, at initial entry into the workforce or when making job changes within the same organization to a higher position because of good performance or to a parallel position because of corporate need. Distress occurs particularly if these changes are not sought and no preparatory training has taken place, as well as during layoffs and at retirement, especially if retirement is mandatory and the person is unprepared for this event. Work distress can result if initially agreed-to conditions change to work overload or lack of challenge and opportunity to experience work satisfaction, if an individual feels unable to fulfill conflicting expectations or feels that work conditions prevent accomplishing assignments because of lack of legitimate power, or if an individual believes he or she works in a hierarchy with harsh and unreasonable superiors.

Work Choices and Changes

Young adults without role models or guidance from families, mentors, or others in their communities too often underestimate their lifetime potential abilities to learn a trade or earn a college or postgraduate degree. In addition, women and members of minority groups often feel less prepared to accept work challenges, fear rejection, and do not apply for jobs for which they are qualified. On the other hand, men, in fields in which they are underrepresented, often and confidently move up the career ladder faster (glass elevator). As part of initial interviews for evaluation of occupational problems, patients should be encouraged to consider their heretofore unrecognized, unadmitted talents; long-held, yet unexpressed, dreams and goals regarding work; actual successes in work and school; and motivation to risk learning what they would find satisfying.

Minorities and those in low-paying and low-skilled jobs too often have less job security. Business and institutional reorganization and consequent downsizing, factory closings, and moves affect many, often leaving these workers feeling hopeless and helpless about future employment, on welfare, angry, and depressed.

With ongoing and often sudden downsizing of corporations and businesses, men and women continue to struggle with unexpected job loss and premature retirement even when finances are not an issue. In addition, men, in particular, define themselves by their work roles, and thus experience more occupational distress from these changes. Women may adjust faster to retirement, but they often have less financial security than men do (white women earn approximately 80 cents on the dollar, and African American and Hispanic women earn even less for comparable work); women have generally been in lower status work positions, find themselves widowed more often than men, and are more likely to be caring for children, grandchildren, and elderly relatives. Women represent more of the single working parent group and the working poor.

Stress and the Workplace

More than 30 percent of workers report that they are under stress at work. Workplace distress is implicated in at least 15 percent of occupational disability claims. Expected distress follows recognized and uncontrollable work changes—downsizing; mergers and acquisitions; work overload; and chronic physical strains, including work noise, temperature, bodily injuries, and strain from performing computer work. According to one study, the top ten most stressful jobs in 1998 were (1) president of the United States, (2) firefighter, (3) senior corporate executive, (4) race car driver, (5) taxi driver, (6) surgeon, (7) astronaut, (8) police officer, (9) football player, and (10) air traffic controller. People who work under deadlines, such as bus drivers, are subject to hypertension.

Work frustration can also arise from an individual worker's unrecognized (and therefore unresolved) psychodynamic issues, such as working appropriately with superiors and not relating to one's supervisor as a parent figure. Other developmental issues include unresolved problems with competition, assertiveness, envy, fear of success, and inability to communicate verbally in a constructive manner.

After the September 11, 2001, World Trade Center tragedy, a 32-year-old, married male firefighter, who had been away on vacation that day with his wife and children, began to exhibit changed behaviors at home and at work. At home, he appeared not to listen to his two children and, instead, focused his attention on television sporting events. At work, he also appeared to be more focused on cooking the same dinners for his peers and watching television than on interacting verbally with his remaining peers and the new chief. In the course of several months, a chaplain visited the station several times and talked to the firefighters about survivor guilt and the 9/11 tragedy, and the firefighter began to return somewhat to his former healthier behaviors. (Courtesy of Leah J. Dickstein, M.D.)

Often, work conflicts reflect similar conflicts in the worker's personal life, and referral for treatment, unless there is insight, is in order. Some studies have found that massage therapy, meditation, and yoga at intervals during the work day relieve stress when used on a regular basis. Approaches using cognitive therapy have also helped people reduce work pressure.

Suicide Risk

Some occupations—health professionals, financial service workers, and police, the first and latter groups because of easier access to lethal drugs and weapons—both attract persons with a high suicide risk and involve increased chronic distress that may lead to higher suicide rates.

Career and Job Problems of Women

Most women work outside the home out of necessity to support themselves or their dependents (whether children or adults) or as part of a working couple. With the divorce rate remaining at the 50 percent level, many women find themselves economically poorer after a divorce than when married, although divorced men usually find their economic status improved. Despite more than four decades of increasing knowledge about and concern for women's status in the workplace, unique gender issues, bias, and lack of accommodation to their unique needs at certain life stages (i.e., pregnancy and postpartum, major responsibility for young healthy and ill children) continue. Yet, women were the largest group establishing new small businesses in the 1990s. Many have left large corporations where they were not valued for their efforts because of their gender. Women experience problems when they are the sole woman in a man's field. Despite increasing recognition of the need for men in relationships with women to assume home and family responsibilities, fewer than 25 percent of men do so equitably.

Women of childbearing and child-rearing ages continue to find themselves in conflict with job expectations, opportunities, and personal responsibilities. High-quality, on-site, dependent-care facilities with extended hours are rare and often out of range financially. Major unresolved work issues that are unique to women at certain life stages include flextime and paid and unpaid dependent leave options. Beyond dependent care issues, women in the workforce continue to experience distress after chronic and repeated sexual harassment, despite its illegality and media attention. Increasingly, more women have travel responsibilities, work long hours, work shifts beyond daylight hours, and experience personal workplace violence.

Among dual-career families and partners, the woman is more likely to move when the man chooses to move for a work opportunity than vice versa. Consequently, a woman's career is interrupted more often. Less reluctance is seen, however, to have the two members of a relationship work for the same organization than previously, albeit usually in different departments. Work distress may also stem from continuous miscommunication, especially that based on gender.

Working Teenagers

With unemployment increasing, many teenagers work part time while attending high school. Consequently, stress can arise because of less parent-teenager interaction and constructive parental control issues about teens' use of earnings, time spent away from home, and consequent behaviors both in and outside the home. When both parents or a single parent, as well as the teenager, work outside the home, often on different schedules, parent-teen verbal communication must be proactive, clear, and ongoing.

Working within the Home

Although most women with children of all ages must work outside the home, at times they may be home full time or part time or may work at home. When their husbands or partners work full time outside the home, problems may develop from each one's perceived expectations of the other. Women who care for children and their home exclusively may be seen by their partners as not only economically dependent and inferior but also not as competent and not understanding of the man's stressors and needs. Ongoing respectful listening and verbal communication must be encouraged.

People in organizations are increasingly taking work home as their work expectations increase. This work-at-home experience can and does interfere with personal lives and satisfaction, which can then have further repercussions at work.

Chronic Illness

As general and other medical and psychiatric treatments for chronic diseases improve, employers have been increasingly concerned about accommodating patients with acquired immunodeficiency syndrome (AIDS), diabetes mellitus, and other disorders. The issue of mandatory testing for AIDS and substance abuse (alcohol and other illegal substances) continues to be of concern. Employee assistance programs

offering education about general and mental health topics have proved timely and cost effective.

Domestic Violence

Although occurring in the home, signs and symptoms that interfere with work often trigger identification of those who experience domestic violence. Trained professionals must question all employees experiencing work distress about domestic violence and, when indicated, refer individuals for assistance, which includes safety in the workplace.

Job Loss

Regardless of the reason for job loss, most people experience distress, at least temporarily, including symptoms of normal grief, loss of self-esteem, anger, and reactive depressive and anxiety symptoms, as well as somatic symptoms and possibly the onset of or increase in substance abuse or domestic violence. Timely education, support programs, and vocational guidance should be instituted and access to treatment made available if indicated.

Vocational Rehabilitation

Rehabilitation is often necessary for those traumatized by stresses in the workplace, those who had to take a leave of absence because of medical or psychiatric reasons, and those who have been fired. Individual or group counseling enables persons to improve personal relationships, raise self-esteem, or learn new work skills. Patients with schizophrenia may benefit from sheltered workshops in which they perform work that is geared to their level of function. Some patients with schizophrenia or autism do well in tasks that are repetitive or require obsessive concern with details.

ADULT ANTISOCIAL BEHAVIOR

Characterized by activities that are illegal, immoral, or both, antisocial behavior usually begins in childhood and often persists throughout life. The term *antisocial behavior* somewhat confusingly applies both to persons' actions that are not due to a mental disorder and to actions by those who never received a neuropsychiatric workup to determine the presence or absence of a mental disorder. As Dorothy Lewis noted, the term can apply to behavior by normal persons who "struggle to make a dishonest living."

Epidemiology

Depending on the criteria and the sampling, estimates of the prevalence of adult antisocial behavior range from 5 to 15 percent of the population. Within prison populations, investigators report prevalence figures between 20 and 80 percent. Men account for more adult antisocial behavior than do women.

Etiology

Antisocial behaviors in adulthood are characteristic of a variety of persons, ranging from those with no demonstrable psychopathology to those who are severely impaired and have psychotic disorders, cognitive disorders, and retardation, among other conditions. A comprehensive neuropsychiatric assessment of antisocial adults is indicated and may reveal potentially treatable psychiatric and neurological impairments that can easily be overlooked. Only in the absence of mental disorders can patients be categorized as displaying adult antisocial behavior. Adult antisocial behavior may be influenced by genetic and social factors.

Genetic Factors. Data supporting the genetic transmission of antisocial behavior are based on studies that found a 60 percent concordance rate in monozygotic twins and about a 30 percent concordance rate in dizygotic twins. Adoption studies show a high rate of antisocial behavior in the biological relatives of adoptees identified with antisocial behavior and a high incidence of antisocial behavior in the adopted-away offspring of those with antisocial behavior. The prenatal and perinatal periods of those who subsequently display antisocial behavior often are associated with low birth weight, mental retardation, and prenatal exposure to alcohol and other drugs of abuse.

Social Factors. Studies have shown that in neighborhoods in which families with low socioeconomic status (SES) predominate, the sons of unskilled workers are more likely to commit more offenses and more serious criminal offenses than do the sons of middle-class and skilled workers, at least during adolescence and early adulthood. These data are not as clear for women, but the findings are generally similar in studies from many countries. Areas of family training differ by SES group. Middle-SES parents use love-oriented techniques in discipline. They withdraw affection rather than impose physical punishment as is done in low-SES groups. Negative parental attitudes toward aggressive behavior, attempts to curb aggressive behavior, and the ability to communicate parental values are more characteristic of middle- and high-SES groups than of low ones. Adult antisocial behavior is associated with the use and abuse of alcohol and other substances and with the easy availability of handguns.

Diagnosis and Clinical Features. The diagnosis of adult antisocial behavior is one of exclusion. Substance dependence in such behavior often makes it difficult to separate the antisocial behavior related primarily to substance dependence from disordered behaviors that occurred either before substance use or during episodes unrelated to substance dependence.

During the manic phases of bipolar I disorder, certain aspects of behavior, such as wanderlust, sexual promiscuity, and financial difficulties, can be similar to adult antisocial behavior. Patients with schizophrenia may have episodes of adult antisocial behavior, but the symptom picture is usually clear, especially regarding thought disorder, delusions, and hallucinations on the mental status examination.

Neurological conditions can be associated with adult antisocial behavior, and electroencephalograms (EEGs), computed tomography (CT) scans, magnetic resonance imaging (MRI), and complete neurological examinations are indicated. Temporal lobe epilepsy should be considered in the differential diagnosis. When a clear-cut diagnosis of temporal lobe epilepsy or encephalitis can be made, the disorder may be considered to contribute to the adult antisocial behavior. Abnormal EEG findings are prevalent among violent offenders: An estimated 50 percent of aggressive criminals have abnormal EEG findings.

Persons with adult antisocial behavior have difficulties in work, marriage, and money matters and conflicts with various authorities. The symptoms of adult antisocial behavior are summarized in [Table 25-3](#). (Antisocial personality disorder is discussed in [Chapter 22](#).)

Table 25-3
Symptoms of Adult Antisocial Behavior

Life Area	Antisocial Patients with Significant Problems in Area (%)
Work problems	85
Marital problems	81
Financial dependence	79
Arrests	75
Alcohol abuse	72
School problems	71
Impulsiveness	67
Sexual behavior	64
Wild adolescence	62
Vagrancy	60
Belligerence	58
Social isolation	56
Military record (of those serving)	53
Lack of guilt	40
Somatic complaints	31
Use of aliases	29
Pathological lying	16
Drug abuse	15
Suicide attempts	11

(Data from Robins L. *Deviant Children Grown Up: A Sociological and Psychiatric Study of Sociopathic Personality*. Baltimore: Williams & Wilkins; 1966.)

Treatment

In general, therapists are pessimistic about treating adult antisocial behavior. They have little hope of changing a pattern that has been present almost continuously throughout a person's life. Psychotherapy has not been effective, and no major breakthroughs with biological treatments, including medications, have occurred.

Therapists show more enthusiasm for the use of therapeutic communities and other forms of group treatment, although the data provide little basis for optimism. Many adult criminals who are incarcerated in institutional settings have shown some response to group therapy approaches. The history of violence, criminality, and antisocial behavior has shown that such behaviors seem to decrease after age 40 years. Recidivism in criminals, which can reach 90 percent in some studies, also decreases in middle age.

Prevention. Because antisocial behavior often begins during childhood, the major focus must be on delinquency prevention. Any measures that improve the physical and mental health of socioeconomically disadvantaged children and their families are likely to reduce delinquency and violent crime. Often, recurrently violent persons have sustained many insults to the central nervous system (CNS) prenatally and throughout childhood and adolescence. Consequently, programs must be developed to educate parents about the dangers to their children of CNS injury from maltreatment, including the effects of psychoactive substances on the brains of growing fetuses. Public education about the releasing effect of alcohol on violent behaviors (as well as its contribution to vehicular homicide) may also reduce crime.

In a Surgeon General's Report on Violence and Public Health, the Committee on the Prevention of Assault and Homicide emphasized the importance of discouraging corporal punishment in the home, forbidding it in the schools, and even abolishing capital punishment by the state, saying that all are models and sanctions for violence. Since that time, capital punishment has been instituted in states that did not have it, such as New York. No evidence indicates that capital punishment reduces crime in states that have it. Opponents of capital punishment see it as "vengeance," not punishment.

Although persons disagree about the contribution of violence in the media to violent crime, the propaganda potential of the media is universally recognized. The extent to which the media, such as television, can be used to transmit positive social values has not yet been realized. The guidelines issued by the television industry to indicate the amount of sex and violence in programs is an attempt to deal with the issue; however, program content that espouses traditional societal values would be beneficial.

The most successful preventive measures within the field of medicine have come from community-wide public health programs (e.g., campaigns against smoking) and from programs that detect individual vulnerabilities (e.g., individual monitoring of blood pressure). Studies of adult antisocial behavior reveal the contribution of broad cultural factors and constellations of individual biopsychosocial vulnerabilities. Prevention programs must recognize and address both kinds of factors.

RELIGIOUS OR SPIRITUAL PROBLEM

A religious or spiritual problem can bring the person to the psychiatrist under one of several circumstances. For example, a person may begin to question his or her faith and choose not to discuss the problem with a spiritual advisor. Or a person may wish to convert to a new faith in order to marry or to create harmony in a marriage in which husband and wife are of different faiths.

Psychiatrists must enable and assist patients to distinguish religious thought or experience from psychopathology and, if this is a problem, encourage patients to work through the issues independently or with assistance. Religious imagery may be recognized in mental illness when persons state they believe they have been commanded by God to take a dangerous or grandiose action.

Religious experience may factor into a person's life in unexpected ways as in the following case. A midcareer male surgeon who was very successful but long overcommitted to his private practice and his academic responsibilities revealed to his often-neglected wife that, at age 9 years, he was approached by his religious leader to get close physically and ultimately engaged in sexual acts over several years. Believing it was his fault, he never told anyone and decided never to have children. After telling his wife about the experience, they engaged in family therapy to work through the stresses the confession produced in their marriage.

Cults

Recently, cults have appeared to be less popular and less attractive to naïve late adolescents and young adults seeking assistance in discovering who they are as they struggle to develop more mature relationships with their parents. Cults are led by charismatic leaders, often out of control themselves, with inappropriate and often unethical values but purporting to offer acceptance and guidance to troubled followers. Cult members are strongly controlled and forced to dissolve allegiance to family and others to serve the cult leader's directives and personal needs. These young members often come from educated families who then seek professional help in persuading their children to leave the cult and enter deprogramming therapy to restore personal psychological stability to the former cult members. Deprogramming and adjustment back into family, society, and an independent life are time intensive and long term with resultant posttraumatic stress disorder (PTSD), which must be recognized and treated.

ACCULTURATION PROBLEM

Acculturation is the process whereby a person from one culture undergoes a change in manner, customs, and dress among others to adapt to a different culture. It leads to assimilation in which the person has identified with the new culture, usually without conflict or ambivalence. In some cases, however, major cultural change can evoke severe distress, termed *culture shock*. This condition arises when individuals suddenly find themselves in a new culture in which they feel completely alien. They may also feel conflict over which lifestyles to maintain, change, or adopt. Children and young adult immigrants often adapt more easily than do middle-aged and elderly immigrants. Younger immigrants often learn the new language more easily and continue to mature in the new culture, but those who are more senior, having had more stability and unchanging routines in their former culture, struggle more to adapt. Culture shock from immigration clearly differs from the restless and continuous moving of psychiatric patients secondary to their illness.

Culture shock can occur within a person's own country with geographic, school, and work changes, such as joining the military, experiencing school busing, moving across country, or moving to a vastly different neighborhood or from a rural area to a metropolis. Reactive symptoms, which are understandable, include anxiety, depression, isolation, fear, and a sense of loss of identity as the person adjusts. If the person is part of a family or group making this transition and the move is positive and planned, stress can be lower. Furthermore, if selected cultural mores can be safely maintained as persons integrate into the new culture, stress is also minimized.

Constant geographic moves because of chosen work opportunities or necessity involve a large proportion of workers in the United States. Joining activities in the new community and actively trying to meet neighbors and coworkers can lessen the culture shock.

An 18-year-old, first-year female college student offered an academic scholarship by a small Southern college with a major in her field of interest realized on her return home to the Midwest for winter break that she felt like a misfit among her dorm peers. They were friendly yet generally kept their distance from her after class. At home, she discussed her experiences with high school friends, who replied that they had heard about such cultural dissonance from peers at their Midwestern colleges. The student returned to college feeling that it was not her fault or imagination and slowly began to reach out more assertively to her peers so they could get to know her beyond stereotypical beliefs and so she could do the same.

Brainwashing. First practiced by the Chinese Communists on American prisoners during the Korean War, *brainwashing* is the deliberate creation of culture shock. Individuals are isolated, intimidated, and made to feel different and out of place to break their spirits and destroy their coping skills. When a person appears mentally weak and helpless, the aggressors impose new ideas on them that they would never have accepted in their normal state. As with those involved in cults, on release and return to their homes, brainwashed individuals with PTSD require deprogramming treatment, including reeducation and ongoing supportive psychotherapy, both on an individual and group basis. Treatment is usually long term to rebuild healthy self-esteem and coping skills. (See also Section 27.4: Disaster Psychiatry.)

Prisoners of War and Torture Victims. Prisoners who survive war or torture experiences do so because of personal inner strengths developed in their earlier lives, beginning within their emotionally strong and caring families; if they come from troubled families, they are more likely to commit suicide during imprisonment and torture. Prisoners must constantly cope with ongoing anxiety, fear, isolation from known lives, and complete loss of all control over their lives. Those who appear to cope best believe they must survive for a reason (e.g., to tell others what they experienced or to find and return to loved ones). Prisoners who cope best describe living simultaneously on two levels—coping in the here and now to survive the situation while maintaining constant mental connections to their past values and experiences and those important to them.

Beyond the surviving prisoner's personal difficulties, including PTSD disorder, if and when his or her survival behavior continues, his or her family may be affected by the surviving prisoner's inordinate fear of police and strangers, overprotection and overburdening of children to replace those significant others lost, lack of sharing of the past, continued isolation from current communities, or inappropriate expressed anger. Thus, another generation (i.e., children of survivors) can be affected in their personal development and psychological functioning and may require psychiatric evaluation and treatment. (See also [Chapter 11](#), Trauma and Stressor-Related Disorder, for further discussion of these topics).

A 75-year-old, Catholic, female survivor of the Pawiak prison in Warsaw, Poland, and then of a concentration camp after her capture as a member of the underground in World War II stated that she had wanted to become a painter. In camp, she carved the Madonna and Child on her toothbrush and sent it home to her mother. She made other clandestine carvings for several women in her barracks to send home to their families, which pleased everyone. After the war, she became a well-known sculptress with exhibits throughout Europe. Many of her art pieces taught people about suffering and respect for others who are of different religions and cultures.

PHASE OF LIFE PROBLEM

Phase of life problems may occur at any point along the life cycle: the first day of school as a child, the divorce of a parent during adolescence, starting college as a young adult, marriage, having children, illness, caring for aged parents, and many others. Although, on some level, adults recognize that life events will intrude on expected plans in the course of a lifetime, unexpected, multiple, major negative occurrences, especially if they are chronic, overwhelm a person's ability to recover and function constructively. Common phase of life problems include relationship changes, such as a changed significant personal relationship or its loss, job crises, and parenthood.

Because of sex role socialization and consequent cultural expectations, whereas men appear externally better able to handle these phases of life problems, women, people with lower SES, and minority group members appear more vulnerable to negative experiences, perhaps because they feel less empowered psychologically. Major life changes precipitate distress in the form of anxiety and depressive symptoms, an inability to express reactive emotions directly, and often difficulties in coping with ongoing or changed life responsibilities.

Individuals with positive attitudes, strong family and personal relationships, and mature defense mechanisms and coping styles, including basic trust in self and others, good verbal communication skills, a capacity for creative and positive thinking, and the ability to be flexible, reliable, and energetic, appear to be best able to cope with phase of life problems. Furthermore, a capacity for sublimation; adequate financial and work status; solid values; and healthy, feasible goals can enable people to face, accept, and deal realistically with expected and unexpected life problems and changes.

NONCOMPLIANCE WITH TREATMENT

Compliance is the degree to which a patient carries out the recommendations of the treating physician. It is fostered when the doctor-patient relationship is a positive one, but even in those circumstances, the patient may be reluctant to comply with a physician's advice. In psychiatry, a major concern is medication noncompliance, which may result from discomforting side effects, expense, personal value judgments, and denial of illness, among many others. This category should be used only when the problem is sufficiently severe to warrant independent clinical attention.

RELATIONAL PROBLEMS

An adult's psychological health and sense of well-being depend to a significant degree on the quality of his or her important relationships—that is, on patterns of interaction with a partner and children, parents and siblings, and friends and colleagues. Problems in the interaction between any of these significant others can lead to clinical symptoms and impaired functioning among one or more members of the relational unit. Relational problems may be a focus of clinical attention (1) when a relational unit is distressed and dysfunctional or threatened with dissolution and (2) when the relational problems precede, accompany, or follow other psychiatric or medical disorders. Indeed, other medical or psychiatric symptoms can be influenced by the relational context of the patient. Conversely, the functioning of a relational unit is affected by a member's general and other medical or psychiatric illness. Relational disorders require a different clinical approach than other disorders. Instead of focusing primarily on the link between symptoms, signs, and the workings of the individual mind, the clinician must also focus on interactions between the individuals involved and how these interactions are related to the general and other medical or psychiatric symptoms in a meaningful way.

Definition

Relational problems are patterns of interaction between members of a relational unit that are associated with significantly impaired functioning in one or more individual members. Thus one may have parent-child problems, sibling-related problems, or other dyad or triad impairments. At times the entire unit such as the family itself, may be dysfunctional.

Epidemiology

No reliable figures are available on the prevalence of relational problems. They can be assumed to be ubiquitous; however, most relational problems resolve without professional intervention. The nature, frequency, and effects of the problem on those involved are elements that must be considered before a diagnosis of relational problem is made. For example, divorce, which occurs in just under 50 percent of marriages, is a problem between partners that is resolved through the legal remedy of divorce and need not be diagnosed as a relational problem. If the persons cannot resolve their dispute and continue to live together in a sadomasochistic or pathologically depressed relationship with unhappiness and abuse, then they should be so labeled. Relationship problems between involved persons that cannot be resolved by friends, family, or clergy require professional intervention by psychiatrists, clinical psychologists, social workers, and other mental health professionals.

Relational Problem Related to a Mental Disorder or General Medical Condition

When a family member is ill either from a psychiatric or medical illness, there are reverberations throughout the family unit. Studies indicate that whereas satisfying relationships may have a health-protective influence, relationship distress tends to be associated with an increased incidence of illness. The influence of relational systems on health has been explained through psychophysiological mechanisms that link the intense emotions generated in human attachment systems to vascular reactivity and immune processes. Thus, stress-related psychological or physical symptoms can be an expression of family dysfunction.

Adults must often assume responsibility for caring for aging parents while they are still caring for their own children, and this dual obligation can create stress. When adults take care of their parents, both parties must adapt to a reversal of their former roles, and the caretakers not only face the potential loss of their parents but also must cope with evidence of their own mortality.

Some caretakers abuse their aging parents, a problem that is now receiving attention. Abuse is most likely to occur when the caretaking offspring have substance abuse problems, are under economic stress, and have no relief from their caretaking duties or when the parent is bedridden or has a chronic illness requiring constant nursing attention. More women are abused than men, and most abuse occurs in persons older than age 75 years.

The development of a chronic illness in a family member stresses the family system and requires adaptation by both the sick person and the other family members. The person who has become sick must frequently face a loss of autonomy, an increased sense of vulnerability, and sometimes a taxing medical regimen. The other family members must experience the loss of the person as he or she was before the illness, and they usually have substantial caretaking responsibility—for example, in debilitating neurological diseases, including dementia of the Alzheimer's type, and in diseases such as AIDS and cancer. In these cases, the whole family must deal with the stress of prospective death as well as the current illness. Some families use the anger engendered by such situations to create support organizations, increase public awareness of the disease, and rally around the sick member. But chronic illness frequently produces depression in family members and can cause them to withdraw from or attack one another. The burden of caring for ill family members falls disproportionately on the women in a family—mothers, daughters, and daughters-in-law.

Chronic emotional illness also requires major adaptations by families. For instance, family members may react with chaos or fear to the psychotic productions of a family member with schizophrenia. The regression, exaggerated emotions, frequent hospitalizations, and economic and social dependence of a person with schizophrenia can stress the family system. Family members may react with hostile feelings (referred to as expressed emotion) that are associated with a poor prognosis for the person who is sick. Similarly, a family member with bipolar I disorder can disrupt a family, particularly during manic episodes.

Family devastation can occur when illness (1) suddenly strikes a previously healthy person, (2) occurs earlier than expected in the life cycle (some impairment of physical capacities is expected in old age, although many older persons are healthy), (3) affects the economic stability of the family, and (4) when little can be done to improve or ease the condition of the sick family member.

Parent-Child Relational Problem

Parents differ widely in sensing the needs of their infants. Some quickly note their child's moods and needs; others are slow to respond. Parental responsiveness interacts with the children's temperament to affect the quality of the attachment between child and parent. The diagnosis of parent-child relational problem applies when the focus of clinical attention is a pattern of interaction between parent and child that is associated with clinically significant impairment in individual or family functioning or with clinically significant symptoms. Examples include impaired communication, overprotection, and inadequate discipline.

Research on parenting skills has isolated two major dimensions: (1) a permissive-restrictive dimension and (2) a warm and accepting versus a cold and hostile dimension. A typology that separates parents on these dimensions distinguishes among *authoritarian* (restrictive and cold), *permissive* (minimally restrictive and accepting), and *authoritative* (restrictive as needed but also warm and accepting) parenting styles. Children of authoritarian parents tend to be withdrawn or conflicted; those of permissive parents are likely to be more aggressive, impulsive, and low achievers; and children of authoritative parents seem to function at the highest level, socially and cognitively. Yet, switching from an authoritarian to a permissive mode may create a negative reinforcement pattern.

Difficulties in many situations stress the usual parent-child interaction. Substantial evidence indicates that marital discord leads to problems in children, from depression and withdrawal to conduct disorder and poor performance at school. This negative effect may be partly mediated through *triangulation* of the parent-child relationships, which is a process in which conflicted parents attempt to win the sympathy and support of their child, who is recruited by one parent as an ally in the struggle with the partner. Divorces and remarriages stress the parent-child relationship and may create painful loyalty conflicts. Stepparents often find it difficult to assume a parental role and may resent the special relationship that exists between their new marital partner and the children from that partner's previous marriages. The resentment of a stepparent by a stepchild and the favoring of a natural child are usual reactions in a new family's initial phases of adjustment. When a second child is born, both familial stress and happiness may result, although happiness is the dominant emotion in most families. The birth of a child can also be troublesome when parents had adopted a child in the belief that they were infertile. Single-parent families usually consist of a mother and children, and their relationship is often affected by financial and emotional problems.

Other situations that can produce a parent–child problem are the development of fatal, disabling, or chronic illness, such as leukemia, epilepsy, sickle-cell anemia, or spinal cord injury, in either the parent or child. The birth of a child with congenital defects, such as cerebral palsy, blindness, or deafness, may also produce parent–child problems. These situations, which are not rare, challenge the emotional resources of those involved. Parents and the child must face present and potential loss and must adjust their day-to-day lives physically, economically, and emotionally. These situations can strain the healthiest families and produce parent–child problems not only with the sick person but also with the unaffected family members. In a family with a severely sick child, parents may resent, prefer, or neglect the other children because the ill child requires so much time and attention.

Parents with children who have emotional disorders face particular problems, depending on the child’s illness. In families with a child with schizophrenia, family treatment is beneficial and improves the social adjustment of the patient. Similarly, family therapy is useful when a child has a mood disorder. In families with a substance-abusing child or adolescent, family involvement is crucial to help control the drug-seeking behavior and to allow family members to verbalize the feelings of frustration and anger that are invariably present.

Normal developmental crises can also be related to parent–child problems. For instance, adolescence is a time of frequent conflict as the adolescent resists rules and demands increasing autonomy and at the same time elicits protective control by displaying immature and dangerous behavior.

The parents of sons ages 18, 15, and 11 years presented with distress about the behavior of their middle child. The family had been cohesive with satisfactory relationships among all members until 6 months before this consultation. At that time, the 15-year-old son began seeing a girl from a comparatively unsupervised household. Frequent arguments had developed between parents and son regarding going out on school nights, curfews, and neglect of schoolwork. The son’s combativeness and lowered academic achievement upset his parents a great deal. They had not experienced similar conflicts with their oldest child. The adolescent, however, maintained a good relationship with his siblings and friends, did not have behavior problems at school, continued to participate on the school basketball team, and was not a substance user.

Day Care Centers. Quality of care during the first 3 years of life is crucial to neuropsychological development. The National Institute of Child Health and Human Development does not consider day care harmful to children, especially when the caregivers and day care teachers provide consistent, empathetic, nurturing care. Not all day care centers can meet that level of care, however, especially those located in poor urban areas. Children receiving less than optimal caring exhibit decreased intellectual and verbal skills that indicate delayed neurocognitive development. They may also become irritable, anxious, or depressed, which interferes with the parent–child bonding experience, and they are less assertive and less effectively toilet trained by the age of 5 years.

Currently, more than 55 percent of women are in the workforce, many of whom have no choice but to place their children in day care centers. Close to 50 percent of entering medical students are women; few medical centers, however, make adequate provisions for on-site day care centers for their students or staff. Similarly, corporations need to provide on-site, high-quality care for the children of their employees. Not only will that approach benefit the children, but also corporate economic benefits will accrue as a result of reduced absenteeism, increased productivity, and happier working mothers. Such programs have the added benefit of decreasing stresses on marriages.

Partner Relational Problem

Partner relational problems are characterized by negative communication (e.g., criticisms), distorted communication (e.g., unrealistic expectations), or noncommunication (e.g., withdrawal) associated with clinically significant impairment in individual or family functioning or symptoms in one or both partners.

When persons have partner relational problems, psychiatrists must assess whether a patient’s distress arises from the relationship or from a mental disorder. Mental disorders are more common in single persons—those who never married or who are widowed, separated, or divorced—than among married persons. Clinicians should evaluate developmental, sexual, and occupational and relationship histories, for purposes of diagnosis. (Couples therapy is discussed in [Chapter 28](#), Section 28.4.)

Marriage demands a sustained level of adaptation from both partners. In a troubled marriage, a therapist can encourage the partners to explore areas such as the extent of communication between the partners, their ways of solving disputes, their attitudes toward child bearing and child rearing, their relationships with their in-laws, their attitudes toward social life, their handling of finances, and their sexual interaction. The birth of a child, an abortion or miscarriage, economic stresses, moves to new areas, episodes of illness, major career changes, and any situations that involve a significant change in marital roles can precipitate stressful periods in a relationship. Illness in a child exerts the greatest strain on a marriage, and marriages in which a child has died through illness or accident more often than not end in divorce. Complaints of lifelong anorgasmia or impotence by marital partners usually indicate intrapsychic problems, although sexual dissatisfaction is involved in many cases of marital maladjustment.

Adjustment to marital roles can be a problem when partners are from different backgrounds and have grown up with different value systems. For example, members of low SES groups perceive a wife as making most of the decisions in the family, and they accept physical punishment as a way to discipline children. Middle-class persons perceive family decision-making processes as shared, with the husband often being the final arbiter, and they prefer to discipline children verbally. Problems involving conflicts in values, adjustment to new roles, and poor communication are handled most effectively when therapist and partners examine the couple’s relationship, as in marital therapy.

Epidemiological surveys show that unhappy marriages are a risk factor for major depressive disorder. Marital discord also affects physical health. For example, in a study of women age 30 to 65 years with coronary artery disease, marital stress worsened the prognosis 2.9 times for recurrent coronary events. Marital conflict was also associated with a 46 percent higher relative death risk among female patients having hemodialysis and with elevations in serum epinephrine, norepinephrine, and corticotrophin levels in both men and women. In one study, high levels of hostile marital behavior were associated with slower healing of wounds, lower production of proinflammatory cytokines, and higher cytokine production in peripheral blood. Overall, women show greater psychological and physiological responsiveness to conflict than men.

Physician Marriages. Physicians have a higher risk of divorce than other occupational groups. The incidence of divorce among physicians is about 25 to 30 percent. Specialty choice influenced divorce. The highest rate of divorce occurred in psychiatrists (50 percent) followed by surgeons (33 percent) and internists, pediatricians, and pathologists (31 percent). The average age at first marriage was 26 years among all groups.

It is not clear why physicians are at high risk for divorce. Factors implicated include the stresses of dealing with dying patients, making life-and-death decisions, working long hours, and the constant risk of malpractice litigation. Such stressors may predispose physicians to a variety of emotional ills, with the most common being depression and substance abuse, including alcoholism. Such persons generally cannot deal with the complex interactions required to maintain successful long-term relationships of any kind, and marriage requires the most interpersonal skills of all.

Sibling Relational Problem

Sibling relationships tend to be characterized by competition, comparison, and cooperation. Intense sibling rivalry can occur with the birth of a child and can persist as the children grow up, compete for parental approval, and measure their accomplishments against one another. Alliances between siblings are equally common. Siblings may learn to protect one another against parental control or aggression. In households with three children, one pair tends to become closely involved with one another, leaving the extra child in the position of

outsider.

Relational problems can arise when siblings are not treated equally; for instance, when one child is being idealized while another is cast in the role of the family scapegoat. Differences in gender roles and expectations expressed by the parents can underlie sibling rivalry. Parent-child relationships also are dependent on personality interactions. A child's resentment directed at a parental figure or a child's own disavowed dark emotions can be projected onto a sibling and can fuel an intense hate relationship.

A child's general, other medical or psychiatric condition always stresses the sibling relationships. Parental concern and attention to the sick child can elicit envy in the siblings. In addition, chronic disability can leave the sick child feeling devalued and rejected by siblings, and the latter may develop a sense of superiority and may feel embarrassed about having a disabled sister or brother. Twin relationships have become an area of increasing study. Preliminary data show that twins are more likely to be cooperative than competitive. Whether or not identical twins should be dressed differently during their toddler years in an effort to ensure a separate identity is open to question as is the issue of whether or not they should be in separate classrooms when they begin school.

Other Relational Problems

People, across the life cycle, may become involved in relational problems with leaders and others in their communities at large. In such relationships, conflicts are common and can bring about stress-related symptoms. Many relational problems of children occur in the school setting and involve peers. Impaired peer relationships can be the chief complaint in attention-deficit or conduct disorders, as well as in depressive and other psychiatric disorders of childhood, adolescence, and adulthood.

Racial, ethnic, and religious prejudices and ignorance cause problems in interpersonal relationships. In the workplace and in communities at large, sexual harassment is often a combination of inappropriate sexual interactions; inappropriate displays of abuse of power and dominance; and expressions of negative gender stereotypes, primarily toward women and gay men, although it is also geared toward children and adolescents of both sexes.

Physical and Sexual Abuse of Adults

Violence is an important public health concern in the United States. The majority of Americans will fall victim to a violent crime during their lifetime. Besides mortality, violence creates a heavy toll in medical costs, disability, and psychiatric sequelae.

Assault can be viewed in the context of two variables. The first involves who is being assaulted, and the second is where the assault occurs. With these parameters assault can be classified into several categories, the most common being violent crimes (aggravated and simple assault, robbery), rape, domestic violence, workplace violence, and torture. The prevalence of the different types of assaults is most often reported by two different data collection systems: (1) the Federal Bureau of Investigation's Uniform Crime Report (UCR), which collects reported crime information from local law enforcement agencies and (2) the Bureau of Justice Statistics' National Crime Victimization Survey (NCVS), which generates estimates of the likelihood of victimization from different types of assaults.

VIOLENT CRIME

Violent crime is defined as murder and nonnegligent manslaughter, forcible rape, robbery, and aggravated assault. These categories exclude simple assault, which is defined as an assault not involving a weapon and in which the victim was not seriously harmed. Simple assault has also been defined as stalking, intimidating, coercing, or hazing.

Prevalence

In 2011, the UCR reported over 1.2 million violent crimes occurred within the United States. Aggravated assault accounted for approximately 750,000 of this total, and robberies accounted for approximately 350,000. Ten-year trends show a decrease of 16 percent in violent crime since 2002. Aggravated assault was the most reported violent crime (62 percent), followed by robbery (29 percent), forcible rape (7 percent), and murder (1 percent). Also in 2011, firearms were found to be used in 21 percent of aggravated assaults and 41 percent of robberies.

Risk Factors

Gender and age play large roles in the rate of risk for assaults of all types. Males between the ages of 15 and 34 years are more likely to be assaulted than females and are 11 times more likely to be assaulted by strangers than by someone they know. Research suggests that race is an important factor as well, with African Americans being at greater risk of violence and having a death rate that is four or five times higher than age-matched whites during aggravated assaults. The NCVS found that males and females in households earning less than \$15,000 in annual income were twice as likely to be robbed and 1.5 times as likely to suffer a physical assault. Homelessness has also been shown to be a factor in increased physical assaults. Finally, substance abuse has been shown in multiple studies to increase the risk of victimization.

RAPE

Rape is the forceful coercion of an unwilling victim to engage in a sexual act, usually sexual intercourse, although anal intercourse and fellatio can also be acts of rape. The legal definition of rape varies from state to state. Some states strictly define rape, whereas other states describe any sex crime as varying degrees of sexual misconduct or sexual assault. Rape can occur between married partners and between persons of the same sex. Forced acts of fellatio and anal penetration, although they frequently accompany rape, are legally considered sodomy.

In some states the definition of rape has been changed to substitute the word *person* for *female*. In most states, male rape is legally defined as sodomy. Like other violent crimes, sexual assault is declining; however, every 2 minutes someone in the United States is sexually assaulted. Although much of the population believes in the stereotype of the culprit being a stranger, research has shown that only about 26 percent of all rapes are committed by a stranger.

Prevalence

Unfortunately, accurate statistics are difficult to obtain because of underreporting and unacknowledgment. The Rape, Abuse, and Incest National Network (RAINN) estimates that over half of rapes go unreported. Although in the United States, rapes have fallen in number since 1993, currently there is an average of 207,754 rapes and sexual assaults per year. RAINN estimates that 1 in 6 US women and 1 in 33 US men are victims of sexual assault.

In addition to being underreported, there are many rapes that go unacknowledged by the victim, who often refer to the assault in more benign terms such as a misunderstanding, despite the fact that it meets the legal definition of rape. Research has reported that this percentage is substantial; more than 50 percent of sexual assaults may go unacknowledged and, thus, unreported. Research has further revealed that victims who fail to acknowledge having been raped usually believe that rape involves two strangers and greater force, as opposed to the views of those who acknowledge their having been sexually assaulted.

Statistics show that most men who commit rapes are between 25 and 44 years of age; 51 percent are white and tend to rape white victims, 47 percent are black and tend to rape black victims, and the remaining 2 percent come from all other races. Alcohol is involved in 34 percent of all forcible rapes. Homosexual rape is much more frequent among men than among women and occurs frequently in closed institutions such as prisons and maximum security hospitals.

Risk Factors

Although women are usually the victim of rape and sexual assault, greater than 10 percent of victims are estimated to be men. Furthermore, most experts believe that men underreport more than women. Nevertheless, young women have four times the risk of any group of becoming a victim of sexual assault. Persons who are raped can be of any age. Cases have been reported in which the victims were as young as 15 months and as old as 82 years. However, 80 percent of all rape victims are under the age of 30 years and the Bureau of Justice statistics indicate that women age 16 to 24 years are at the greatest risk for rape in the United States. Having been a victim of childhood abuse or previous assault increases the likelihood of further assault of all types. Most rapes are premeditated; about half are committed by strangers and half by men known, to varying degrees, by the victims.

The Violence Against Women Act has had an important role to play in reducing rape and other types of violence (Table 26-1).

 **Table 26-1**
Violence Against Women Act (VAWA)

VAWA has **improved the criminal justice response** to violence against women by:

- ▶ Holding rapists accountable for their crimes by strengthening federal penalties for repeat sex offenders and creating a federal “rape shield law,” which is intended to prevent offenders from using victims’ past sexual conduct against them during a rape trial;
- ▶ Mandating that victims, no matter their income levels, are not forced to bear the expense of their own rape exams or for service of a protection order;
- ▶ Keeping victims safe by requiring that a victim’s protection order will be recognized and enforced in all state, tribal, and territorial jurisdictions within the United States;
- ▶ Increasing rates of prosecution, conviction, and sentencing of offenders by helping communities develop dedicated law enforcement and prosecution units and domestic violence dockets;
- ▶ Ensuring that police respond to crisis calls and judges understand the realities of domestic and sexual violence by training law enforcement officers, prosecutors, victim advocates and judges; VAWA funds train over 500,000 law enforcement officers, prosecutors, judges, and other personnel every year;
- ▶ Providing additional tools for protecting women in Indian country by creating a new federal habitual offender crime and authorizing warrantless arrest authority for federal law enforcement officers who determine there is probable cause when responding to domestic violence cases.

VAWA has **ensured that victims and their families have access to the services** they need to achieve safety and rebuild their lives by:

- ▶ Responding to urgent calls for help by establishing the National Domestic Violence Hotline, which has answered over 3 million calls and receives over 22,000 calls every month; 92 percent of callers report that it’s their first call for help;
- ▶ Improving safety and reducing recidivism by developing coordinated community responses that bring together diverse stakeholders to work together to prevent and respond to violence against women;
- ▶ Focusing attention on the needs of underserved communities, including creating legal relief for battered immigrants so that abusers cannot use the victim’s immigration status to prevent victims from calling the police or seeking safety, and supporting tribal governments in building their capacity to protect American Indian and Alaska Native women.

VAWA has **created positive change**. Since VAWA was passed:

- ▶ Fewer people are experiencing domestic violence.
 - ▶ Between 1993 to 2010, the rate of intimate partner violence declined 67 percent;
 - ▶ Between 1993 to 2007, the rate of intimate partner homicides of females decreased 35 percent and the rate of intimate partner homicides of males decreased 46 percent.
- ▶ More victims are reporting domestic and sexual violence to police, and reports to police are resulting in more arrests.
- ▶ States have reformed their laws to take violence against women more seriously:
 - ▶ All states have reformed laws that previously treated date or spousal rape as a lesser crime than stranger rape;
 - ▶ All states have passed laws making stalking a crime;
 - ▶ All states have authorized warrantless arrests in misdemeanor domestic violence cases where the responding officer determines that probable cause exists;
 - ▶ All states provide for criminal sanctions for the violation of a civil protection order;
 - ▶ Many states have passed laws prohibiting polygraphing of rape victims;
 - ▶ Over 35 states, the District of Columbia, and the US Virgin Islands have adopted laws addressing domestic and sexual violence and stalking in the workplace. These laws vary widely and may offer a victim time off from work to address the violence in their lives, protect victims from employment discrimination related to the violence, and provide unemployment insurance to survivors who must leave their jobs because of the abuse.

(From U.S. Government Fact Sheet, Washington, D.C.)

Perpetrators

In general, rape is considered a crime of power and aggression, not one of sexuality. Male rapist can be categorized into separate groups: sexual sadists, who are aroused by the pain of their victims; exploitive predators, who use their victims as objects for their gratification in an impulsive way; inadequate men, who believe that no woman would voluntarily sleep with them and who are obsessed with fantasies about sex; and men for whom rape is a displaced expression of anger and rage. Seven percent of all rapes are perpetrated by close relatives of the victim; 10 percent of rapes involve more than one attacker.

Rape often accompanies another crime. Rapists always threaten victims, with fists, a knife, or a gun, and frequently harm them in nonsexual ways as well. Victims can be beaten, wounded, and killed.

In cases of male or homosexual rape, the dynamics are identical to those of heterosexual rape. The crime enables the rapist to discharge aggression and to aggrandize himself. The victim is usually smaller than the rapist, is always perceived as passive and unmanly (weaker), and is used as an object. A rapist selecting male victims may be heterosexual, bisexual, or homosexual. The most common act is anal penetration of the victim; the second most common is fellatio.

SEXUAL COERCION

Sexual coercion is a term used for incidents in which a person dominates another by force or compels the other person to perform a sexual act.

STALKING

Stalking is defined as a pattern of harassing or menacing behavior coupled with a threat to do harm. The first antistalking law was passed in 1990 in California. Now most states prohibit stalking, although some will not intervene unless an act of violence has occurred. In states with stalking laws, the person can be arrested on the basis of a pattern of harassment and can be charged with either a misdemeanor or felony. Some stalkers continue the activity for years; others, for only a few months. The court may mandate that stalkers undergo counseling sessions. The best means of deterrent is to report all stalkers to law enforcement agencies. Most stalkers are men, but women who stalk are just as likely as men to attack their victims violently.

SEXUAL HARASSMENT

Sexual harassment refers to sexual advances, requests for sexual favors, or verbal or physical conduct of a sexual nature—all of which are unwelcomed by the victim. In more than 95 percent of cases the perpetrator is a man and the victim is a woman. If a man is being harassed, it is almost always by another man. A woman sexually harassing a man is an extremely rare event. The victim of harassment reacts to the experience in various ways. Some blame themselves and become depressed; others become anxious and angry. In general, harassment most commonly occurs in the workplace, and many organizations have developed procedures to deal with the problem. All too often, however, the victim is unwilling to step forward and lodge a complaint because of fear of retribution, of being humiliated, of being accused of lying, or ultimately of being fired from the job.

The types of behaviors that make up sexual harassment are broad. They include abusive language, requests for sexual favors, sexual jokes, staring, ogling, and giving massages, among others.

To reduce harassment, organizations may distribute educational material. Employees are obligated to investigate every complaint, which most often are addressed to the Equal Employment Opportunity Commission. Appropriate organizational responses range from a written warning to firing the offender.

DOMESTIC VIOLENCE

Domestic violence (also known as *spouse abuse*) is defined as physical assault within the home in which one spouse is repeatedly assaulted

by the other. It has been estimated that domestic violence occurs in one of every four families in the United States. Often domestic violence is broken down into two categories: “high-severity abuse,” which includes being threatened or hurt with a weapon, burned, choked, hit, or kicked, resulting in broken bones and head or internal injuries; and “low-severity abuse,” which includes being slapped, hit, or kicked without injury, but also could include bruising, minor cuts, and sprains.

Unfortunately, domestic violence does not end when a woman becomes pregnant. In fact, the surgeon general’s office has identified pregnancy as a high-risk period for battering; 15 to 25 percent of pregnant women are physically abused while pregnant, and the abuse often results in birth defects. In addition, pregnant and recently pregnant women are more likely to die from homicide than any other cause.

Some husband-beating wives have also been reported. Husbands complain of fear of ridicule if they expose the problem; they fear charges of counterassault and often feel unable to leave the situation because of financial difficulties. Husband abuse also been reported when a frail, elderly man is married to a much younger woman.

Prevalence

Estimates of the prevalence of domestic violence in the United States vary widely, and many studies include psychological or emotional abuse. Worldwide estimates state that one in every three women has experienced some form of physical or sexual abuse from a domestic partner. One study based on several internal medicine practices found that approximately 6 percent of women had experienced domestic violence in the year prior to presentation. It was found that of the women currently experiencing abuse, 49 percent experience high-severity abuse and 51 percent experience low-severity abuse.

Risk Factors

Domestic violence occurs in families of every racial and religious background and in all socioeconomic strata. Any person in an intimate relationship can be at risk. It is most frequently found in families with problems of substance abuse, particularly alcohol and crack abuse. Another risk factor is a history of childhood abuse. About 50 percent of battered wives grew up in violent homes and their most common trait is dependence. Abusive men are also likely to have come from violent homes where they witnessed wife beating or were abused themselves as children.

Women face risks when they leave an abusive husband; they have a 75 percent greater chance of being killed by their batterers than women who stay. New York State prepared a physician reference card to alert and guide doctors about domestic violence ([Table 26-2](#)).

Table 26-2
Physician Reference Card

RECOGNIZING AND TREATING VICTIMS OF DOMESTIC VIOLENCE BASED ON THE AMERICAN MEDICAL ASSOCIATION'S DIAGNOSTIC AND TREATMENT GUIDELINES ON DOMESTIC VIOLENCE

If you treat women, whether in private practice or a hospital setting, you are almost certainly treating some patients who are victims of domestic violence.

The following decision tree is designed to help you assess a patient's risk of domestic violence and offer appropriate help to those in need of it.

Identifying Victims of Domestic Violence

Although many women who are victims of abuse will not volunteer any information, they will discuss it if asked simple, direct questions in a nonjudgmental way and in a confidential setting. *The patient should be interviewed alone, without her partner present.*

You may want to offer a statement such as: "Because violence is so common in many women's lives, I've begun to ask about it routinely." Then you can ask a direct question, such as: "At any time, has your partner hit, kicked, or otherwise hurt or frightened you?"

IF PATIENT ANSWERS YES, THE FOLLOWING STEPS ARE SUGGESTED:

1. Encourage her to talk about it:

"Would you like to talk about what has happened to you?"

"How do you feel about it?"

"What would you like to do about this?"

2. Listen nonjudgmentally:

This serves both to begin the healing process for the woman and to give you an idea of what kind of referrals she needs.

3. Validate:

Victims of domestic violence are frequently not believed, and the fear they report is minimized. The physician can express support through simple statements such as:

- ▶ "You are not alone."
- ▶ "You don't deserve to be treated this way."
- ▶ "You are not to blame."
- ▶ "You are not crazy."
- ▶ "What happened to you is a crime."
- ▶ "Help is available for you."

4. Document:

- ▶ The patient's complaints and symptoms as well as the results of the observation and assessment. (Complaints should be described in the patient's own words whenever possible.)
- ▶ The patient's complete medical and trauma history and relevant social history.
- ▶ A detailed description of the injuries, including type, number, size, location, resolution, possible causes, and explanations given.
- ▶ An opinion on whether the injuries were inconsistent with the patient's explanation.
- ▶ Results of all pertinent laboratory and other diagnostic procedures.
- ▶ Color photographs and imaging studies, if applicable.
- ▶ If the police are called, the name of the investigating officer and any action taken (the police should be called only if the patient requests this or exhibits a reportable injury).
- ▶ Child abuse and neglect are reportable offenses. If you suspect that children in the patient's home are also being abused, you are mandated to report the situation to the Department of Social Services.

5. Assess the danger to your patient:

Assess your patient's safety *before she leaves the medical setting*. The most important determinants of risk are the woman's level of fear and her appraisal of her immediate and future safety. Discussing the following indicators with the patient can help you determine if she is in escalating danger:

- ▶ an increase in the frequency or severity of the assaults
- ▶ increasing or new threats of homicide or suicide by the partner
- ▶ threats to her children
- ▶ the presence or availability of a firearm

6. Provide appropriate treatment referral and support:

- ▶ Treat the patient's injuries as indicated. In prescribing medication, keep in mind that medications which hinder the patient's ability to protect herself or to flee from a violent partner may endanger her life.
- ▶ If your patient is in imminent danger, determine if she has friends or family with whom she can stay. If this is not an option, ask if she wants immediate access to a shelter for battered women. If none is available, can she be admitted to the hospital?
- ▶ If she doesn't need immediate access to a shelter, offer written information about shelters and other community resources. Remember that it may be dangerous for the woman to have these in her possession. Don't insist that she take them if she is reluctant to do so.

Give your patient the telephone number of the local domestic violence hotline or the toll-free Domestic Violence hotline. It may be safest for your patient if you write the number on a prescription blank or an appointment card. You may wish to give her the opportunity to call from a private phone in your office.

IF THE PATIENT ANSWERS NO, OR WILL NOT DISCUSS THE TOPIC:

1. Be aware of clinical findings that may indicate abuse:

- ▶ injury to the head, neck, torso, breasts, abdomen, or genitals
- ▶ bilateral or multiple injuries
- ▶ delay between onset of injury and seeking treatment
- ▶ explanation by the patient which is inconsistent with the type of injury
- ▶ any injury during pregnancy, especially to the abdomen or breasts
- ▶ prior history of trauma
- ▶ chronic pain symptoms for which no etiology is apparent
- ▶ psychological distress, such as depression, suicidal ideation, anxiety, and/or sleep disorders
- ▶ a partner who seems overly protective or who will not leave the woman's side

2. If any of the above clinical signs is present, it is appropriate to ask more specific questions. Be sure that the patient's partner is not present. Some examples of questions that may elicit more information about the patient's situation are:

- ▶ "It looks as though someone may have hurt you. Could you tell me how it happened?"
- ▶ "Sometimes when people come for health care with physical symptoms like yours, we find that there may be trouble at home. We are concerned that someone is hurting or abusing you. Is this happening?"
- ▶ "Sometimes when people feel the way you do, it's because they may have been hurt or abused at home. Is this happening to you?"

3. If patient answers YES:

See the suggestions for assessment and treatment that begin on the other side of this card.

If patient answers NO:

If the patient denies abuse, but you strongly suspect that it is taking place, you can let her know that your office can provide referrals to local programs, should she choose to pursue such options in the future.

- ▶ You may want to write the Domestic Violence hotline number on a prescription blank or on an appointment card.

Don't judge the success of the intervention by the patient's action. A woman is most at risk of serious injury or even homicide when she attempts to leave an abusive partner, and it may take her a long time before she can finally do so. It is frustrating for the physician when a patient stays in an abusive situation. Be reassured that if you have acknowledged and validated her situation and offered appropriate referrals, you have done what you can to help her.

(From Office for Prevention of Domestic Violence, Medical Society of the State of New York, New York State Department of Health, with permission.)

Perpetrators

The perpetrators of domestic violence come from all races and socioeconomic levels. However, having been a victim of abuse or witnessing

abuse in the home increases the risk of someone becoming an abuser. Alcohol abuse is usually involved in most offenses. The act of abuse itself is reinforcing; once a man has beaten his wife, he is likely to do so again. Many abusers are noted to be charming in public but cruel to their intimates.

Abusive husbands tend to be immature, dependent, and nonassertive and to suffer from strong feelings of inadequacy. The husband's aggression is bullying behavior designed to humiliate their wives and to build up their own low self-esteem. Impatient, impulsive, abusive husbands physically displace aggression provoked by others onto their wives. The abuse most likely occurs when a man feels threatened or frustrated at home, at work, or with his peers. The dynamics include identification with an aggressor (father, boss), testing behavior ("Will she stay with me, no matter how I treat her?"), distorted desires to express manhood, and dehumanization of women. As with rape, aggression is deemed permissible when a woman is perceived as property.

When an abused wife tries to leave her husband, he often becomes doubly intimidating and threatens to "get" her. If the woman has small children to care for, her problem is compounded. The abusive husband wages a conscious campaign to isolate his wife and make her feel worthless.

Some men feel remorse and guilt after an episode of violent behavior and so become particularly loving. If this behavior gives the wife hope, she remains until the next inevitable cycle of violence.

WORKPLACE VIOLENCE

Acts of violence at work are defined as simple assault, aggravated assault, robbery, rape/sexual abuse, and homicide.

Prevalence

Workplace violence accounts for approximately 15 percent of all violent crimes in the United States. According to the NCVS, in 2009 there were approximately 572,000 acts of violence committed against persons at work. During the same time, over 500 work-related homicides occurred. Approximately 78 percent of workplace assaults did not involve weapons, and 80 percent of workplace homicides involved firearms. With some variation, violent crime in the workplace has declined approximately 35 percent since 2002.

Risk Factors

Gender and race are important risk factors in workplace violence. The workplace violence rate for women has decreased approximately 43 percent since 2002, while the rate for men has decreased approximately 30 percent. Approximately two thirds of all workplace assaults (excluding rape/sexual assault) are committed against men. Workplace crime rates are higher among whites than other races.

An important component of workplace violence is the relationship between the risk of violence and the type of occupation. The NCVS found that police officers are at the highest risk for victimization (78 per 1,000) and constituted 9 percent of all workplace assaults. Other high-risk occupations include security guard (65 per 1,000), correction officer (33 per 1,000), bartender (80 per 1,000), technical/industrial schoolteacher (55 per 1,000), mental health custodial worker (38 per 1,000), gas station attendant (30 per 1,000), and mental health professionals (17 per 1,000).

Perpetrators

There are several distinct characteristics among offenders, of which gender is the most pronounced. As reported by victims, four fifths of all violent workplace crime is committed by men, and this is regardless of the victim's gender. The race of the offenders is most often white, followed by black, and most of the attacks are interracial. Unlike domestic violence, workplace violence is more often perpetrated by strangers or casual acquaintances than by known intimates. Mental health and teaching are the only fields in which attacks occur more often at the hands of a known perpetrator than by a stranger.

SEQUELAE OF VIOLENCE AND ASSAULT

Survivors of violence have varied reactions, but they are similar to those exposed to other types of trauma. Furthermore, the severity of the sequelae varies with the individual. However, multiple studies have shown that many of the people who experience violence have decreased physical and mental health, resulting in higher utilization of health care services.

The most common reported sequelae after sexual assault in women are posttraumatic stress disorder (PTSD), mood disorders, substance abuse, eating disorders, and sexual disorders. One of the most protective factors in ameliorating the development of PTSD is social support. Furthermore, the lack of social support and the perception of being treated differently can be quite detrimental to the survivor, causing an increase in PTSD symptoms.

Domestic violence has been associated with depression, anxiety, low self-esteem, substance abuse, sexual dysfunction, functional gastrointestinal disorder, headaches, chronic pain, and multiple somatic symptoms. Physical symptoms associated with current abuse include loss of appetite; frequent or serious bruises; nightmares; vaginal discharge; eating binges or self-induced vomiting; diarrhea; broken bones; sprains or serious cuts; pain in the pelvic or genital area; fainting; abdominal pain; breast pain; frequent or severe headaches; difficulty passing urine; chest pain; problems with sleeping; shortness of breath; and constipation. Many studies have shown that survivors of domestic violence attempt suicide more frequently than those who have not experienced violence.

Substance abuse seems to be a significant factor for both the survivor and the batterer. It is both a risk factor for abuse and a consequence of it.

The relationship between childhood abuse and adult abuse is complex. Childhood abuse is a risk factor for abuse as an adult, and childhood abuse increases both physical and mental health sequelae of adult abuse. Survivors of sexual assault or domestic violence who are older and without a history of childhood abuse have fewer symptoms

TREATMENT ISSUES

Initial Evaluation

Many victims of assault initially present to a medical doctor for treatment of their injuries. In emergency departments, patients may often be treated for their injuries without the assault being recognized or addressed. Consequently, it is important to consider any concerning injuries as being a potential stigma of assault. The patient may initially be avoidant when asked about the cause of injuries that appear related to assault. This may be further complicated by the need to complete specific tasks (i.e., rape kit, photo documentation, reporting of legal concerns) that require the patient to describe and relive the recent assault. It is paramount to build rapport with the patient while continuing to complete a thorough evaluation. To facilitate this process, it is important to reduce the victim's stress and anxiety regarding discussion of the event. The initial evaluation process should be explained to the patient before beginning. Allowing the patient some say in dictating the pace and content of the interview is preferable to having a patient feel a lack of control over the process. The crime may represent a time when the patient lacked control, and similar feelings in the initial interview can lead to a triggering of traumatic or anxious responses. Finally, the physician should remain attuned to nonverbal patient responses that signify discomfort and conduct the interview accordingly. Furthermore, when a patient discloses domestic violence, this should be documented in his or her chart for future follow-up and possible future legal documentation.

Safety

After an assault, it is imperative that a safety assessment be performed on the victim. The patient needs to be evaluated for suicidal and homicidal ideation as it pertains to the recent assault. The patient's safety from further assault also needs to be addressed, especially in a setting in which the perpetrator was a loved one or known acquaintance. Finally, the patient needs to be screened for severe psychological symptoms that would cause difficulty in self-care. These would include acute mood deterioration or affective instability, self-destructive behaviors, dissociative symptoms, or psychosis. If the evaluation shows that any of these areas are inadequate to ensure patient safety, then a plan needs to be developed. This plan should provide for the patient's physical safety and give the patient a place to sleep, recuperate, and eat.

Hospitalization

In the event that the patient's safety cannot be guaranteed, hospitalization of the assault victim may be necessary. Common indications for hospitalization include (1) severe medical injuries, (2) suicidality or homicidality, (3) dissociative or psychotic symptoms, (4) mood instability or affective dysregulation, (5) self-destructive behaviors, and (6) a continued serious threat to the patient's life or well-being. If the victim is admitted to the hospital, then an individualized multidisciplinary treatment plan should be developed. Safety, milieu therapy, mood stabilization, and medication evaluation are the primary treatment modalities provided in the hospital and reflect the short-stay nature of most psychiatric facilities. Because the assault victim will likely need longer treatment than what can be provided in the hospital, it is important that there is a coordinated inpatient-to-outpatient transition, which psychiatric, medical, and social work issues all being address prior to discharge.

Legal Issues

A physician evaluating an assault victim needs to adhere to mandatory reporting requirements for the state in which he or she is practicing. Mandatory reporting of child abuse, abuse of developmentally disabled children, and abuse of the elderly exist in all 50 states. In cases of assault secondary to domestic violence, states do not usually require mandatory reporting. However, many states do require physicians to report serious injuries due to acts of criminal violence. Thus, in the setting of injury secondary to domestic violence, this can sometimes be considered a de facto mandatory reporting situation.

Psychotherapy Treatment

After the patient's safety has been ensured and the initial evaluation is complete, there are a variety of psychological interventions that can be initiated. Cognitive-behavioral approaches are the most researched techniques demonstrating efficacy. Exposure therapy is a variant of cognitive-behavioral therapy (CBT) that has been shown to help victims emotionally process the assault by decreasing their fear to memories or cues of the event. There is evidence in the literature that brief early CBT may accelerate recovery in victims manifesting acute PTSD. Eye movement desensitization and reprocessing (EMDR) is another alternative treatment for the processing of distressing memories. These individual psychotherapies may be augmented with group psychotherapy, art therapy, dance and movement therapy, music therapy, and body-oriented approaches if they prove beneficial to the patient.

Psychopharmacological Treatment

Although medication is not recommended in the acute treatment of all assault victims, it may be beneficial in certain circumstances. The clinician may decide to medicate a patient with incapacitating anxiety, extreme aggression toward themselves or others, or dissociation or psychoses immediately after the assault. The patient's safety and the safety of those around the patient will help to decide the need for pharmacologic intervention. Most medication treatment will be initiated much later after the assault as the patient develops symptoms of PTSD, depression, anxiety, obsessive-compulsive disorder, or psychosis. Although medication may be useful in symptom management, they should not be viewed as a replacement for psychotherapy aimed at trauma symptom resolution.

Psychiatry and Reproductive Medicine

Reproductive events and processes have both physiological and psychological concomitants. Likewise, psychological states affect reproductive physiology and modulate reproductive events. This chapter examines these bidirectional relationships with the goal of introducing fundamental concepts related to the classic reproductive events, such as menarche, pregnancy, delivery, postpartum, and menopause. The fields of psychiatry and reproductive medicine continue to define the multiple mechanisms by which psyche and soma interact to determine a woman's gynecological and psychological health. For instance, premenstrual dysphoric disorder—the impairing symptoms and severe mood, cognitive, and behavioral changes that occur in association with the menstrual cycle—exemplifies a somatopsychic disorder in which biological changes occurring in the soma trigger changes in psychological state. In contrast, functional forms of hypothalamic anovulation represent psychosomatic illness that originates in the brain but alters somatic functioning.

REPRODUCTIVE PHYSIOLOGY

The physiological processes associated with menarche, menstrual cycling, pregnancy, postpartum, and menopause occur within the context of a woman's physiological and interpersonal life, interfacing with psychosocial functioning throughout adolescence, young adulthood, midlife, and late life. The fields of psychiatry and reproductive medicine are just beginning to elaborate the multiple mechanisms by which psyche and soma interact to determine a woman's gynecological and psychological function. This chapter illustrates how reproductive processes interact with psychosocial events and aims ultimately to improve the approach to both gynecologic and psychiatric treatments.

Menstrual Cycles

Menstrual cyclicality results directly from ovarian cyclicality. Each ovarian cycle starts with the development of a group or cohort of follicles, one of which becomes dominant. The follicles are composed of an oocyte surrounded by granulosa cells, which, in turn, are surrounded by theca cells.

As shown at the top of [Figure 27-1](#), follicular development is initiated by the hypothalamic release of gonadotropin-releasing hormones (GnRH) at a pulse frequency of approximately one pulse every 90 minutes. GnRH stimulates the release of the pituitary gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). In turn, LH stimulates ovarian theca cells to synthesize and secrete androgens; FSH induces granulosa cell development, including the enzyme aromatase, which converts the theca-produced androgens to estrogens. In the presence of a constant GnRH pulse frequency of one pulse every 90 minutes, the secretion of LH and FSH in the follicular phase will be regulated primarily by estradiol feedback at the level of the pituitary. Rising estradiol concentrations suppress FSH, thereby limiting the number of follicles that become mature oocytes capable of ovulating.

FIGURE 27-1 Schematization of the human menstrual cycle. Es, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; P, progesterone.

As illustrated in the middle panel of [Figure 27-1](#), when estradiol concentrations rise exponentially to exceed a critical threshold and remain elevated for at least 36 hours, which is the pattern one fully mature follicle produces, an LH surge is triggered and ovulation (release of the ovum from the follicle sac) ensues approximately 36 hours later. Thereafter, granulosa cells transform into progesterone-secreting luteal cells, and the ovulated follicle is then referred to as the *corpus luteum*, which secretes progesterone.

[Figure 27-1](#) displays the levels of LH, FSH, estradiol, and progesterone throughout the menstrual cycle and corresponding follicular events. The target tissues for ovarian steroids include the endometrium, whose developmental sequence is illustrated along the bottom panel, and the hypothalamic GnRH pulse generator, whose frequency, as indicated in the top right panel, is slowed dramatically by the combination of estrogen and progesterone secreted during the postovulatory or luteal phase of the menstrual cycle. This inhibition of GnRH is followed by decreased secretion of LH and FSH so that new follicular development is prevented until the corpus luteum regresses. As progesterone concentrations decline, GnRH pulsatility increases, and gonadotropin, especially FSH, secretion rises. The phases of the menstrual cycle can be termed *follicular* and *luteal* in reference to ovarian events or *proliferative* and *secretory* in reference to endometrial events.

PREGNANCY

Biology of Pregnancy

The first presumptive sign of pregnancy is the absence of menses for 1 week. Other presumptive signs are breast engorgement and

tenderness, changes in breast size and shape, nausea with or without vomiting (morning sickness), frequent urination, and fatigue. A diagnosis can be made 10 to 15 days after fertilization by testing for human chorionic gonadotropin (hCG), which is produced by the placenta. The definitive diagnosis requires a doubling of hCG levels and the presence of fetal heart sounds. Transvaginal ultrasound scanning can reveal a pregnant uterus as early as 4 weeks after fertilization, by visualization of a gestational sac.

Stages of Pregnancy

Pregnancy is commonly divided into three trimesters, starting from the first day of the last menstrual cycle and ending with the delivery of a baby. During the first trimester, the woman must adapt to changes in her body, such as fatigue, nausea and vomiting, breast tenderness, and mood lability. The second trimester is often the most rewarding for women. A return of energy and the end of nausea and vomiting allow women to feel better and experience the excitement of starting to look pregnant. The third trimester is associated with physical discomfort for many women. All systems—cardiovascular, renal, pulmonary, gastrointestinal, and endocrine—have undergone profound changes that can produce a heart murmur, weight gain, exertional dyspnea, and heartburn. Some women require reassurance that those changes are not evidence of disease and that they will return to normal shortly after delivery—generally in 4 to 6 weeks.

Psychology of Pregnancy

Pregnant women undergo marked psychological changes. Their attitudes toward pregnancy reflect deeply felt beliefs about all aspects of reproduction, including whether the pregnancy was planned and whether the baby is wanted. The relationship with the infant's father, the age of the mother, and her sense of identity also affect a woman's reaction to prospective motherhood. Prospective fathers also face psychological challenges.

Psychologically healthy women often find pregnancy a means of self-realization. Many women report that being pregnant is a creative act gratifying a fundamental need. Other women use pregnancy to diminish self-doubts about femininity or to reassure themselves that they can function as women in the most basic sense. Still others view pregnancy negatively; they may fear childbirth or feel inadequate about mothering.

During early stages of their own development, women must undergo the experience of separating from their mothers and of establishing an independent identity; this experience later affects their own success at mothering. If a woman's mother was a poor role model, a woman's sense of maternal competence may be impaired, and she may lack confidence before and after her baby's birth. Women's unconscious fears and fantasies during early pregnancy often center on the idea of fusion with their own mothers.

Psychological attachment to the fetus begins in utero and, by the beginning of the second trimester, most women have a mental picture of the infant. Even before being born, the fetus is viewed as a separate being, endowed with a prenatal personality. Many mothers talk to their unborn children. Recent evidence suggests that emotional talk with the fetus is related not only to early mother–infant bonding but also to the mother's efforts to have a healthy pregnancy, for example, by giving up cigarettes and caffeine. According to psychoanalytic theorists, the child-to-be is a blank screen on which a mother projects her hopes and fears. In rare instances, these projections account for postpartum pathological states, such as a mother's desire to harm her infant, whom she views as a hated part of herself. Normally, however, giving birth to a child fulfills a woman's need to create and nurture life.

Fathers are also profoundly affected by pregnancy. Impending parenthood demands a synthesis of such developmental issues as gender role and identity, separation or individuation from a man's own father, sexuality, and, as Erik Erikson proposed, generativity. Pregnancy fantasies in men and wishes to give birth in boys reflect early identification with their mothers as well as the wish to be as powerful and creative as they perceive mothers to be. For some men, getting a woman pregnant is proof of their potency, a dynamic that plays a large part in adolescent fatherhood.

Marriage and Pregnancy

The prospective mother–wife and father–husband must redefine his or her roles as a couple and as an individual. They face readjustments in their relationships with friends and relatives and must deal with new responsibilities as caretakers of the newborn and each other. Both parents may experience anxiety about their adequacy as parents; one or both partners may be consciously or unconsciously ambivalent about the addition of the child to the family and about the effects on the dyadic (two-person) relationship. A husband may feel guilty about his wife's discomfort during pregnancy and parturition, and some men experience jealousy or envy of the experience of pregnancy. Accustomed to gratifying each other's dependency needs, the couple must attend to the unremitting needs of a new infant and a developing child. Although most couples respond positively to these demands, some do not. Under ideal conditions, the decision to become a parent and have a child should be agreed on by both partners, but sometimes parenthood is rationalized as a way to achieve intimacy in a conflicted marriage or to avoid having to deal with other life circumstance problems.

Attitudes Toward the Pregnant Woman. In general, others' attitudes toward a pregnant woman reflect a variety of factors: intelligence, temperament, cultural practices, and myths of the society and the subculture into which the person was born. Married men's responses to pregnancy are generally positive. For some men, however, reactions vary from a misplaced sense of pride that they are able to impregnate the woman to fear of increased responsibility and subsequent termination of the relationship. A woman's risk of abuse by her husband or boyfriend increases during pregnancy, particularly during the first trimester. One study found that 6 percent of pregnant women are abused. Domestic abuse adds significantly to the cost of health care during pregnancy, and abused women are more likely than nonabused controls to have histories of miscarriage, abortion, and neonatal death. The reasons for abuse vary. Some men fear being neglected and not having excessive dependency needs gratified; others may see the fetus as a rival. In most cases, however, one finds a history of abuse before the woman became pregnant.

Same-Sex Partnering, Marriage, and Pregnancy

Some lesbian couples decide that one partner should become pregnant through artificial insemination. Societal attitudes may put stress on this arrangement, but if the two women have a secure relationship, they tend to bond strongly together as a family unit. Men in committed gay relationships are fathering children through artificial insemination with surrogate mothers. Recent studies show that children raised in same sex couple households are not measurably different from children raised by heterosexual parents with respect to personality development, psychological development, and gender identity. These children are also not more likely to be gay or lesbian themselves.

Some single, never-married women who do not wish to marry but do want to become pregnant may do so through artificial or natural insemination. Such women constitute a group who believe that motherhood is the fulfillment of female identity, without which they view their lives to be incomplete. Most of these women have considered the consequence of single parenthood and feel able to rise to the challenges.

Sexual Behavior

The effects of pregnancy on sexual behavior vary. Some women experience an increased sex drive as pelvic vasocongestion produces a more sexually responsive state. Others are more responsive than before the pregnancy, because they no longer fear becoming pregnant. Some have diminished desire or lose interest in sexual activity altogether. Libido may be decreased because of higher estrogen levels or feelings of unattractiveness. Avoidance of sex may also result from physical discomfort or an association of motherhood with

asexuality. Men with a madonna complex view pregnant women as sacred and not to be defiled by the sexual act. Either a man or a woman may erroneously consider intercourse potentially harmful to the developing fetus and, thus, something to be avoided. Men who have extramarital affairs during their wives' pregnancies usually do so during the last trimester.

Coitus. Most obstetricians place no prohibitions on coitus during pregnancy. Some suggest that sexual intercourse cease 4 to 5 weeks antepartum. If bleeding occurs early in pregnancy, an obstetrician may prohibit coitus temporarily as a therapeutic measure. Bleeding in the first 20 days of pregnancy occurs in 20 to 25 percent of women and approximately half of that group experience spontaneous abortion. Maternal death resulting from forcibly blowing air into the vagina during cunnilingus has been reported; the deaths presumably result from air emboli in the placental-maternal circulation.

Parturition

Fears regarding pain and bodily harm during delivery are universal and, to some extent, warranted. Preparation for childbirth affords a sense of familiarity and can ease anxieties, which facilitates delivery. Continuous emotional support during labor reduces the rate of cesarean section and forceps deliveries, the need for anesthesia, the use of oxytocin (Pitocin), and the duration of labor. A technically difficult or even painful delivery, however, does not appear to influence the decision to bear additional children.

Men's responses to pregnancy and labor have not been well studied, but the recent trend toward inclusion of fathers in the birth process eases their anxieties and elicits a fuller sense of participation. Fathers do not parent the same way as mothers, and new mothers sometimes need to be encouraged to respect these differences and view them positively.

Lamaze Method. Also known as natural childbirth, the Lamaze method originated with the French obstetrician Fernand Lamaze. In this method, women are fully conscious during labor and delivery, and no analgesic or anesthetic is used. The expectant mother and father attend special classes, during which they are taught relaxation and breathing exercises designed to facilitate the birth process. Women who have such training often report minimal pain during labor and delivery. Participating in the birth process may help a fearful or ambivalent father bond with his newborn infant.

Prenatal Screening

Prenatal screening for potential or actual fetal malformation is conducted in most pregnant women. Sonograms are noninvasive and can detect structural fetal abnormalities. Maternal α -fetoprotein (AFP) is measured between 15 and 20 weeks, screening for neural tube defects and Down syndrome. The sensitivity of Down syndrome testing is increased when a triple screen is done (AFP, hCG, and estriol). Amniocentesis is indicated for women over 35 years, those with a sibling or parent with a known chromosome anomaly, and those with abnormal AFP or any other risk for severe genetic disorder. Amniocentesis is usually done between 16 and 18 weeks and carries a risk that 1 in 300 women will miscarry after the procedure. In the first trimester, chorionic villus sampling (CVS) can be done, which reveals the same information concerning chromosomal status, enzyme levels, and DNA (deoxyribonucleic acid) patterns. With CVS, there is a risk that 1 in 100 women will have a spontaneous abortion after the procedure.

Screening in the first trimester allows women to choose early termination, which may be physically and emotionally easier on the woman. Profound ethical questions are involved in whether or not to abort a fetus with a known defect. Some women choose not to terminate and report a strong loving bond that lasts throughout the life of the child, who usually predeceases the parent.

Lactation

Lactation occurs because of a complex psychoneuroendocrine cascade that is triggered by the abrupt decline in estrogen and progesterone concentrations at parturition. In general, babies should be fed as needed, rather than by schedule. Breast-feeding has many benefits. The composition of breast milk supports timely neuronal development, confers passive immunity, and reduces food allergies in the child. In subsistence-level cultures in which children are allowed to nurse as long as they want (a practice supported by La Leche League, a breast-feeding advocacy group), most babies will wean themselves between ages 3 and 5 if not encouraged by the mother to do so earlier. Women who decide to breast-feed need good teaching and social support, which if lacking may lead to frustration and feelings of inadequacy. Women must not feel pressured or coerced into breast-feeding if they are opposed or ambivalent. In the long term, no discernible difference exists between bottle-fed and breast-fed children as adults.

An incidental finding about lactation is that some women experience sexual sensations during lactation, which in rare cases can lead to orgasm. In the early 1990s a woman who called a help line about such feelings was put in jail and had her infant taken from her on allegations of sexual abuse. Common sense ultimately prevailed, however, and mother and infant were reunited.

Perinatal Death

Perinatal death, defined as death sometime between the 20th week of gestation and the first month of life, includes spontaneous abortion (miscarriage), fetal demise, stillbirth, and neonatal death. In previous years, the intense bond between the expectant or new parent and the fetus or neonate was underestimated, but perinatal loss is now recognized as a significant trauma for both parents. Parents who experience such a loss go through a period of mourning much as that experienced when any loved one is lost.

Intrauterine fetal death, which can occur at any time during the pregnancy, is an emotionally traumatic experience. In the early months of pregnancy, a woman is usually unaware of fetal death and learns of it only from her doctor. Later in pregnancy, after fetal movements and heart tones have been experienced, a woman may be able to detect fetal demise. When given the diagnosis of fetal death, most women want the dead fetus removed; depending on the trimester, labor may be induced, or the woman may have to wait for spontaneous expulsion of the uterine contents. Many couples consider sexual relations during the period of waiting not only undesirable but psychologically unacceptable as well.

A sense of loss also accompanies the birth of a stillborn child and induced abortion of an abnormal fetus detected by antenatal diagnosis. As mentioned, attachment to an unborn child begins before birth, and grief and mourning occur after a loss at any time. The grief experienced after a third-trimester loss, however, is generally greater than that experienced after a first-trimester loss. Some parents do not wish to view a stillborn child, and their wishes should be respected. Others wish to hold the stillborn, and this act can assist the mourning process. A subsequent pregnancy may diminish overt feelings of grief, but it does not eliminate the need to mourn. So-called replacement children are at risk for overprotection and future emotional problems.

CONCEPTION

Infertility

Infertility is the inability of a couple to conceive after 1 year of coitus without the use of a contraceptive. In the United States, about 15 percent of married couples are unable to have children. In the past, women were blamed when couples did not have children, and feelings of guilt, depression, and inadequacy frequently accompanied the perception of being barren. Today, it is known that causes of infertility are

attributed to disorders in men in 40 percent of cases, disorders in women in 40 percent, and disorders of both in 20 percent. Separate histories obtained for each partner (Table 27-1) and tests in an infertility workup (Table 27-2) usually reveal the specific cause; however, 10 to 20 percent of couples have no identifiable cause.

Table 27-1
Focused History for Infertility Workup

Medical History	Female Partner	Male Partner
Medical history and review of systems	Current medical problems and medication, allergies, hirsutism, thyroid dysfunction, weight gain, diabetes mellitus	Current medical problems and medication, allergies, erectile function, exposure to high temperatures
Surgical history	Fallopian tube surgery, ectopic pregnancy, appendectomy, pelvic surgery	Hernia repair, testicular or varicocele surgery
Sexual history	Frequency of intercourse, timing of intercourse with ovulation kit, dyspareunia	History of contraception use, excessive use of lubricants
Infertility history	Prior fertility, history of infertility treatments, duration of infertility	Prior fertility or infertility
Social history	Use of tobacco, caffeine, tetrahydrocannabinol (THC), recreational drugs, exposure to chemotherapy or radiation, psychosocial stressors	Use of tobacco, caffeine, THC, recreational drugs, exposure to chemotherapy or radiation
Developmental history	Menarche, breast development, dysmenorrhea, history of sexually transmitted diseases, use of prior contraception, diethylstilbestrol (DES) exposure, history of abnormal Papanicolaou smear and subsequent treatment	Degree of virilization, testicular infections, genital trauma, undescended testes, pubertal development, history of sexually transmitted diseases

(Adapted from Frey KA, Patel KS. Initial evaluation and management of infertility. *Mayo Clin Proc.* 2004;79(11):1439-1443, with permission.)

Table 27-2
Tests in the Infertility Workup

Possible Cause	Test	Comments
Anovulation	Basal body temperature chart	Patient must do each morning
	Endometrial biopsy	Office procedure in the late luteal phase
	Serum progesterone	Single or multiple blood tests
	Urinary ovulation detection kit	Home use at midcycle to time intercourse
	Ultrasound	Visualizes ovarian follicles and their rupture
Anatomic disorder	Hysterosalpingography	X-ray done in the proliferative phase, in which a radio-opaque dye is introduced through the cervix into the uterus to define intrauterine contours and tubal patency
	Sonohysterography	Transvaginal ultrasound examination with instillation of saline into the uterine cavity to define contours
	Diagnostic laparoscopy	Views external surfaces of internal structures
Abnormal spermatogenesis	Hysteroscopy	Visualizes endometrial cavity directly
	Semen analysis	Normal value >20 million/mL, 2 mL volume, 60% motility
Immunological disorder	Postcoital test	Midcycle timing to look at sperm-cervical mucus interaction
	Antisperm antibodies	Male semen test
Azoospermia	Testicular biopsy	Determines eligibility for intracytoplasmic sperm injection
	Semen analysis for fructose	Determines if the vas deferens are patent

(Adapted from Beckmann CRB, Ling FW, Barzansky BM, Bates G, Herbert W: *Obstetrics and Gynecology for Medical Students*. Baltimore: Williams Wilkins; 1992.)

The inability to have a child can produce severe psychological stress on one or both partners in a marriage. Self-blame increases the likelihood of psychological problems. Women—but not men—are at increased risk for psychological distress if they are older and do not already have biological children. If one or both partners are unwilling to take advantage of assisted reproductive techniques, the marriage may falter. A psychiatric evaluation of the couple may be advisable. Marital disharmony or emotional conflicts about intimacy, sexual relations, or parenting roles can directly affect endocrine function and such physiological processes as erection, ejaculation, and ovulation. No evidence exists, however, for any simple, causal relation between stress and infertility.

When preexisting conflict gives rise to problems of identity, self-esteem, and guilt, the disturbance may be severe and may manifest through regression; extreme dependence on a physician, mate, or parent; diffuse anger; impulsive behavior; or depression. The problem is further complicated when hormone therapy is used to treat the infertility, because the therapy may temporarily increase depression in some patients. Mood and cognition can be altered by pharmacological agents used to treat disorders of ovulation or to hyperstimulate the ovaries.

Persons who have difficulty conceiving may experience shock, disbelief, and a general sense of helplessness, and they develop an understandable preoccupation with the problem. Involvement in the infertility workup and the development of expertise about infertility can be a constructive defense against feelings of inadequacy and the humiliating, sometimes painful aspects of the workup itself. Worries about attractiveness and sexual desirability are common. Partners may feel ugly or impotent, and episodes of sexual dysfunction and loss of desire are reported. These problems are aggravated when a couple is scheduling sexual relations according to temperature charts or ovulatory cycles. Treatments for infertility (Table 27-3) are expensive and consume much time and energy. Both men and women can be overwhelmed by complexity, cost, invasiveness, and uncertainty associated with medical intervention.

Table 27-3
Assisted Reproduction Techniques

Method	Comments
Ovulation induction or augmentation (multiple agents, particularly recombinant or highly purified gonadotropins)	Stimulates multifollicular development and ovulation; may produce multiple births; used in anovulation, luteal phase deficiency, unexplained infertility, and assisted reproduction
Induction of spermatogenesis	Used in men with idiopathic hypothalamic hypogonadism of functional or organic nature
Artificial insemination	Donor sperm is injected into the uterine cavity or the fallopian tubes; the sperm of the male partner may be used if healthy
Gamete intrafallopian transfer	Transfer of collected oocytes and sperm into the fallopian tubes; zygote may also be transferred; used for infertility from endometriosis and unexplained infertility
In vitro fertilization and embryo transfer	Transfer of developing embryos into the uterus after extracorporeal incubation of collected sperm with oocytes retrieved by laparoscopic surgery or by ultrasound-guided transvaginal aspiration; used with occlusion of the fallopian tubes or significant sperm dysfunction; permits preimplantation genetic diagnosis
Intracytoplasmic sperm injection	Injection in vitro of sperm head or sperm DNA (deoxyribonucleic acid) to cause fertilization and production of embryos for transfer to receptive endometrium; may be used even if sperm are barely viable; genetic causes of male infertility may be transmitted to offspring
Gamete donors	Donation of sperm or oocytes to another couple; can include oocytes only, oocyte cytoplasm only to restore reproductive competence to aged oocyte, donor sperm alone, or any combination; cytoplasmic transfer considered unethical and is illegal in some states
Surrogate mother	Surrogate mother receives donated embryo and carries the baby to term; a highly controversial technique with unclear legal ramifications

(Data are taken in part from Susman V. *Pregnancy in Behavioral Sciences for Medical Students*. Baltimore: Williams & Wilkins; 1993. Table by S. L. Berga, M.D., B. L. Parry, M.D., and E. L. Moses-Kolko, M.D.)

Single persons who are aware of their own infertility may shy away from relationships for fear of being rejected once their “defect” is known. Persons who are infertile may have particular difficulty in their adult relationships with their own parents. The identification and equality that come from sharing the experience of parenthood must be replaced by internal reserves and other generative aspects of their lives.

Professional intervention may be necessary to help infertile couples ventilate their feelings and go through the process of mourning for their lost biological functions and the children they cannot have. Couples who remain infertile must cope with an actual loss. Couples who decide not to pursue parenthood may develop a renewed sense of love, dedication, and identity as a pair. Others may need help in exploring the options of husband or donor insemination, laboratory implantation, and adoption.

FAMILY PLANNING AND CONTRACEPTION

Family planning is the process of choosing when, and if, to bear children. One form of family planning is contraception, the prevention of fecundation, or fertilization of the ovum. The choice of a contraceptive method (Table 27-4) is a complex decision involving both women and their partners. Factors influencing the decision include a woman’s age and medical condition, her access to medical care, the couple’s religious beliefs, and the need for coital spontaneity. The woman and her partner can weigh the risks and benefits of the various forms of contraception and make their decision on the basis of their current lifestyle and other factors. The success of contraceptive technology has enabled career-minded couples to delay child-bearing into their 30s and 40s. Such a delay, however, may increase infertility problems. Consequently, many women with careers feel their biological clocks ticking and plan to have children while in their early 30s to avoid the risk of not being able to have them at all.

Table 27-4
Current Methods of Contraception

Type	Efficacy ^a	Advantages	Disadvantages	Potential Complications ^b
Spermicidal agents	Moderate	Readily available and easy to use	Messy; loss of spontaneity; requires forethought	Allergic reactions
Diaphragm, cervical cap	Moderate	Inexpensive; does not interfere with menstrual cycle	User familiarity required; prescription and fitting required; may interfere with spontaneity; requires forethought	Recurrent urinary tract infections with diaphragm; allergic reactions to latex or spermicide
Male condom	Moderate	Readily available and easy to use; protects against sexually transmitted infections	May interfere with spontaneity; requires forethought	Allergic reactions to latex or spermicide
Female condom	Moderate	Inconvenient to use; protects against sexually transmitted infections	May interfere with spontaneity; requires forethought	Allergic reactions to latex or spermicide
Hormonal (suppresses ovulation and/or impairs endometrial development)				
Oral contraceptives, contraceptive patches, and intravaginal rings	High	Protect against uterine and ovarian cancer, some sexually transmitted infections	Pharmacological side effects; require daily or weekly use, regardless of frequency of sex; must be prescribed and monitored by health care professional	Depression; breast tenderness; nausea; headaches; may be contraindicated in some medical conditions; can be taken continuously to achieve greater ovarian suppression and amenorrhea and to treat medical conditions
Postcoital steroids	High	Can be used after intercourse; inexpensive	Must be initiated within 72 hours; requires some medical supervision	Side effects, particularly nausea and headache; not universally available
Contraceptive implants (rods)	High	Implantable device that provides contraception for up to 1 year; once in place, no forethought required	Irregular bleeding and spotting due to endometrial effects and suppression of ovarian function; must be surgically placed and removed	Bone loss, depression; other medical sequelae of associated hormonal alterations unclear
Injectable steroids	High	Injectable progestin or combination of estrogen and progestin that prevents ovulation and suppresses ovarian activity; given intramuscularly at an interval that depends on the product	Slow return of ovarian activity after last dose; not removable	Bone loss and depression greater with progestin-only injections due to induction of greater hypoestrogenism; other consequences of hypoestrogenism unclear
Antiprogestins (RU-486)	High	Easy to use; does not disrupt menstrual cycle when administered in luteal phase; can be used postcoitally	Currently not available in the United States; must have predictable cycles	Impairs implantation rather than preventing conception
Sterilization				
Male sterilization (vasectomy)	High	Failure very rare; 20-minute office procedure	Morbidity in 1%–2% of patients includes infections, clots	Can be reversed in only 80% of cases; rare neurotic impotence reaction; used by 10.4% of men
Female sterilization	High	Almost 100% protection; no impairment of sexual function or pleasure	More complex procedure than vasectomy; reversal is complicated and difficult	Surgical morbidity; used by 13.6% of women
Other				
Intrauterine device	High	Once in place, no forethought required; impairs endometrial receptivity	May cause nonbacterial endometritis or heavy menses; requires professional insertion	Likelihood of pelvic infection may be increased and tubal damage with infertility may result; uterine perforation or spontaneous expulsion
Rhythm	Low	No cost	Imposed coital timing	None
Natural family planning	Moderate	Readily available	User must monitor cervical mucus and body temperature closely; imposed coital timing	None
Withdrawal, coitus interruptus	Low	Readily available	Difficult to implement	None

^aEstimates of efficacy are those associated with use rather than theoretically derived. High, <5% chance of contraceptive failure during the first year of use; moderate, <20% chance; low, >20% chance.

^bOther than failure (pregnancy).

(Table by S. L. Berga, M.D., B. L. Parry, M.D., and E. L. Moses-Kolko, M.D.)

Sterilization

Sterilization is a procedure that prevents a man or a woman from producing offspring. In a woman, the procedure is usually salpingectomy, ligation of the fallopian tubes, a procedure with low morbidity and low mortality. A man is usually sterilized by vasectomy, excision of part of the vas deferens, which is a simpler procedure than salpingectomy and can be performed in a physician's office. Voluntary sterilization, especially vasectomy, has become the most popular form of birth control in couples married for more than 10 years.

A small proportion of patients who elect sterilization may suffer from neurotic poststerilization syndrome, which can manifest through hypochondriasis, pain, loss of libido, sexual unresponsiveness, depression, and concerns about masculinity or femininity. One study of a group of women who regretted sterilization reported they had chosen the procedure while in poor relationships, frequently with abusive partners. Regret is most prevalent when a woman forms a new relationship and wishes to have a child with a new partner. Psychiatric consultation may be necessary to separate persons seeking sterilization for irrational or psychotic reasons from those who have made the decision after some time and thought.

The operative procedures for sterilization, namely vasectomy and tubal ligation, have assumed less importance than in the past because of the advent of contraceptives and the relative ease of obtaining abortions. Nonetheless, sterilization procedures are still chosen by men and women who, for a variety of reasons, want to permanently end their ability to produce children.

Abortion

Induced abortion is the planned termination of a pregnancy. About 1.3 million abortions are performed in the United States each year—246 abortions for every 1,000 live births. The various types of abortion are listed in Table 27-5. Over the past decade, the number of abortions has declined by about 15 percent. Family planning experts believe that more sex education and greater availability of contraceptive devices keep the number of abortions down. In Western countries, most women who obtain abortions are young, unmarried, and primiparous; in emerging countries, abortion is most common among married women with two or more children.

 **Table 27-5**
Types of Abortion

Spontaneous	Spontaneous expulsion of the products of conception before viability (500 g or approximately 24 weeks from last menses)
Recurrent	Three or more spontaneous abortions
Missed	Abnormal development of an intrauterine pregnancy; usually caused by the presence of a blighted ovum and lack of fetal development
Threatened	Uterine bleeding or cramping and positive pregnancy test; must be distinguished from an ectopic (usually tubal) pregnancy
Incomplete	Spontaneous passage of a portion of the products of conception and the retention of placental fragments that result in ongoing bleeding
Elective	Induced by medical or surgical techniques before fetal viability; techniques include dilation, evacuation, and curettage; suction curettage; injection into the amniotic sac of saline or prostaglandins; hysterotomy; prostaglandins with antiprogesterins (RU-486) or methotrexate; medical indications include the detection of fetal abnormalities by ultrasound or amniocentesis

(Table by S. L. Berga, M.D., B. L. Parry, M.D., and E. L. Moses-Kolko, M.D.)

Of abortions, 60 percent are performed before 8 weeks of gestation, 88 percent are performed before 13 weeks, and 4.1 percent between 16 and 20 weeks, with 1.4 percent occurring after 21 weeks. Table 27-6 summarizes the most common abortion techniques, and Table 27-7 compares medical and surgical abortion techniques.

Table 27-7
Comparison of Medical and Surgical Pregnancy Termination

Termination	Medical	Surgical
Timing	Up to 9 weeks' gestation	As soon as intrauterine pregnancy confirmed, as early as 5 weeks
Anesthesia	None	Required
Side effects	Pain, bleeding expected	Usually minimal side effects
Efficacy	92%–98% effective	98%–99% effective
Privacy	Termination likely to occur at home	Procedure in surgical suite or office

(Adapted from Brigham and Women's Hospital. *Contraception and Family Planning: A Guide to Counseling and Management*. Boston, MA: Brigham and Women's Hospital; 2005:15.)

Table 27-6
Abortion Techniques

Type	Benefits	Risks
Cervical dilation and evacuation of uterine contents by curettage or vacuum aspiration	Most commonly performed procedure for termination of pregnancy; can be done before 24 weeks' gestation	Uterine perforation, adhesions, hemorrhage, infection, incomplete removal of fetus and placenta (all rare)
Menstrual aspiration (miniabortion)	Can be done within 1–3 weeks of missed period	Implanted zygote not removed, uterine perforation (rare), failure to recognize ectopic pregnancy
Medical induction (cervical dilation with laminaria followed by intravaginal prostaglandin or intravenous oxytocin)	Can be used for second-trimester abortion	Water intoxication, uterine rupture, infection
Intra-amniotic hyperosmotic solutions (salting out)	Can be used for second-trimester abortions	Hyperosmolar crisis, heart failure, peritonitis, hemorrhage, water intoxication, myometrial necrosis
Prostaglandin (oral, intravaginal, cervical, or intra-amniotic)	Noninvasive procedure; can be used in conjunction with antiprogesterins (RU-486) or methotrexate	Expulsion of live fetus, missed ectopic, hemorrhage, incomplete abortion
Antiprogesterins (RU-486) with or without concomitant prostaglandin use	Nonsurgical; first trimester only	Incomplete abortion, hemorrhage
Methotrexate with or without prostaglandin use	Nonsurgical; first trimester only	Leukopenia, hemorrhage, incomplete results

(Table by S. L. Berga, M.D., B. L. Parry, M.D., and E. L. Moses-Kolko, M.D.)

Abortion has become a political and philosophical issue in the United States. The country is sharply divided between pro-choice and pro-life factions. In recent years, antiabortion demonstrators have picketed abortion clinics and have provoked angry confrontations with patients. The atmosphere of moral condemnation and intimidation may make the decision to terminate a pregnancy difficult.

Psychological Reactions to Abortion. Recent studies demonstrate that most women who have an abortion for an unwanted pregnancy (i.e., induced abortion) were satisfied with their decision, with few, if any, negative psychological sequelae. Women who had miscarriages, however (i.e., spontaneous abortion), reported a high rate of dysphoric reactions. The difference can be explained, in part, by the fact that most women who induced abortion did so because they did not want the child. Women who spontaneously miscarried presumably wanted their babies. In the long term, however, about 10 percent of women who had induced abortion regretted having had the procedure.

Second-trimester abortions are more psychologically traumatic than first-trimester abortions. The most common reason for late abortions is the discovery (via amniocentesis or ultrasound) of an abnormal karyotype or fetal anomaly. Thus, late abortions usually involve the loss of a wanted child with whom the mother has already formed a bond.

Before the legalization of abortion in the United States in 1973, many women sought illegal abortions, often performed by untrained practitioners under nonsterile conditions. Considerable morbidity and mortality were associated with these abortions, and women who were denied abortion sometimes chose suicide over continuation of an unwanted pregnancy. In general, however, the risk of suicide is low in pregnant women, even in those who do not want a child but who carry the baby to term. When a woman is forced to carry a fetus to term, even though the risk of suicide is low, the risk increases for infanticide, abandonment, and neglect of the unwanted newborn.

Abortion can also be a significant experience for men. If a man has a close relationship with the woman, he may wish to play an active

role in the abortion by accompanying her to the hospital or abortion clinic and providing emotional support. Fathers may experience considerable grief over the termination of a wanted pregnancy.

Reproductive Senescence

Both men and women age and experience an age-related decline in reproductive capacity, but only women experience complete gonadal cessation. Loss of reproductive capacity may present a psychological challenge to those who are not reconciled to the loss of fertility. Even with gonadal failure, however, the availability of donor oocytes and sperm means that pregnancy can be initiated in a menopausal woman with an intact uterus who elects to pursue that option. Studies have shown that older men may develop a genetic sperm mutation, giving rise to a higher incidence of autistic or schizophrenic offspring.

Menopause

Menopause, the cessation of ovulation, generally occurs between 47 and 53 years of age. The hypoestrogenism that follows can lead to hot flashes, sleep disturbances, vaginal atrophy and dryness, and cognitive and affective disturbances. Women are at increased risk for osteoporosis, dementia, and cardiovascular disease. Depression at menopause has been attributed to the “empty nest syndrome.” Many women, however, report an enhanced sense of well-being and enjoy opportunities to pursue goals postponed because of child rearing.

PSYCHIATRIC ASPECTS OF PREGNANCY

Postpartum Depression

Many women experience some affective symptoms during the postpartum period, 4 to 6 weeks following delivery. Most of these women report symptoms consistent with “baby blues,” a transient mood disturbance characterized by mood lability, sadness, dysphoria, subjective confusion, and tearfulness. These feelings, which may last several days, have been ascribed to rapid changes in women’s hormonal levels, the stress of childbirth, and the awareness of the increased responsibility that motherhood brings. No professional treatment is required other than education and support for the new mother. If the symptoms persist longer than 2 weeks, evaluation is indicated for postpartum depression.

Postpartum depression (coded as a subtype of major depressive disorder in the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5]) is characterized by a depressed mood, excessive anxiety, insomnia, and change in weight. The onset is generally within 12 weeks after delivery. No conclusive evidence indicates that “baby blues” will lead to a subsequent episode of depression. Several studies do indicate that an episode of postpartum depression increases the risk of lifetime episodes of major depression. Treatment of postpartum depression is not well studied because of the risk of transmitting antidepressants to newborns during lactation. [Table 27-8](#) differentiates postpartum “baby blues” from postpartum depression.

Table 27-8
Comparison of “Baby Blues” and Postpartum Depression

Characteristic	“Baby Blues”	Postpartum Depression
Incidence	30%–75% of women who give birth	10%–15% of women who give birth
Time of onset	3 to 5 days after delivery	Within 3 to 6 months after delivery
Duration	Days to weeks	Months to years, if untreated
Associated stressors	No	Yes, especially lack of support
Sociocultural influence	No; present in all cultures and socioeconomic classes	Strong association
History of mood disorder	No association	Strong association
Family history of mood disorder	No association	Some association
Tearfulness	Yes	Yes
Mood lability	Yes	Often present, but sometimes mood is uniformly depressed
Anhedonia	No	Often
Sleep disturbance	Sometimes	Nearly always
Suicidal thoughts	No	Sometimes
Thoughts of harming the baby	Rarely	Often
Feelings of guilt, inadequacy	Absent or mild	Often present and excessive

(From Miller LJ. How “baby blues” and postpartum depression differ. *Women’s Psychiatric Health*. 1995;13, with permission. Copyright 1995, The KSF Group.)

A syndrome described in fathers is characterized by mood changes during their wives’ pregnancies or after the babies are born. These fathers are affected by several factors: added responsibility, diminished sexual outlet, decreased attention from his wife, and the belief that the child is a binding force in an unsatisfactory marriage.

Postpartum Psychosis

Postpartum psychosis (sometimes called *puerperal psychosis*) is an example of a psychotic disorder that occurs in women who have recently delivered a baby. The syndrome is often characterized by the mother’s depression, delusions, and thoughts of harming either herself or her infant. Such ideation of suicide or infanticide must be carefully monitored; although rare, some mothers have acted on these ideas. Most available data suggest a close relation between postpartum psychosis and mood disorders, particularly bipolar disorder and major depressive disorder. It is coded as a subtype of bipolar disorder in DSM-5.

The incidence of postpartum psychosis is about 1 to 2 per 1,000 childbirths. About 50 to 60 percent of affected women have just had their first child, and about 50 percent of cases involve deliveries associated with nonpsychiatric perinatal complications. About 50 percent of the affected women have a family history of mood disorders. The most robust data indicate that an episode of postpartum psychosis is essentially an episode of a mood disorder, usually a bipolar disorder but possibly a depressive disorder. Relatives of those with postpartum psychosis have an incidence of mood disorders that is similar to the incidence in relatives of persons with mood disorders. As many as two thirds of the patients have a second episode of an underlying affective disorder during the year after a baby’s birth. The delivery process may best be seen as a nonspecific stress that causes the development of an episode of a major mood disorder, perhaps through a major hormonal mechanism.

The symptoms of postpartum psychosis can often begin within days of the delivery, although the mean time to onset is within 2 to 3 weeks and almost always within 8 weeks of delivery. Characteristically, patients begin to complain of fatigue, insomnia, and restlessness, and they may have episodes of tearfulness and emotional lability. Later, suspiciousness, confusion, incoherence, irrational statements, and obsessive concerns about the baby’s health and welfare may be present. Delusional material may involve the idea that the baby is dead or defective. Patients may deny the birth and express thoughts of being unmarried, virginal, persecuted, influenced, or perverse. Hallucinations with similar content may involve voices telling the patient to kill the baby or herself. Complaints regarding the inability to move, stand, or walk are also common.

The onset of florid psychotic symptoms is usually preceded by prodromal signs such as insomnia, restlessness, agitation, lability of mood, and mild cognitive deficits. Once the psychosis occurs, the patient may be a danger to herself or to her newborn, depending on the content of her delusional system and her degree of agitation. In one study, 5 percent of patients committed suicide and 4 percent committed infanticide. A favorable outcome is associated with a good premorbid adjustment and a supportive family network. Subsequent pregnancies are associated with an increased risk of another episode, sometimes as high as 50 percent.

As with any psychotic disorder, clinicians should consider the possibility of either a psychotic disorder caused by a general medical condition or a substance-induced psychotic disorder. Potential general medical conditions include hypothyroidism and Cushing's syndrome. Substance-induced psychotic disorder can be associated with the use of pain medications such as pentazocine (Talwin) or of antihypertensive drugs during pregnancy. Other potential medical causes include infections, toxemia, and neoplasms.

Postpartum psychosis is a psychiatric emergency. Antipsychotic medications and lithium (Eskalith), often in combination with an antidepressant, are the treatments of choice. No pharmacological agents should be prescribed to a woman who is breast-feeding. Suicidal patients may require transfer to a psychiatric unit to help prevent a suicide attempt.

The mother is usually helped by contact with her baby if she so desires, but the visits must be closely supervised, especially if the mother is preoccupied with harming the infant. Psychotherapy is indicated after the period of acute psychosis, and therapy is usually directed at helping the patient accept and be at ease with the mothering role. Changes in environmental factors may also be indicated, such as increased support from the husband and others in the environment. Most studies report high rates of recovery from the acute illness.

Mrs. Z is a 30-year-old high school teacher living in Lagos, Nigeria. She is married and has five children. The birth of her last child was complicated by hemorrhage and sepsis, and she was still hospitalized on the gynecology service for 13 days after delivery when her gynecologist requested a psychiatric consultation. Mrs. Z was agitated and seemed to be in a daze. She said to the psychiatrist: "I am a sinner. I have to die. My time is past. I cannot be a good Christian again. I need to be reborn. Jesus Christ should help me. He is not helping me." A diagnosis of postpartum psychosis was made. An antipsychotic drug, chlorpromazine (Thorazine), was prescribed, and Mrs. Z was soon well enough to go home. Three weeks later, she was readmitted, this time to the psychiatric ward, claiming she "had had a vision of the spirits" and was "wrestling with the spirits." Her relatives reported that at home she had been fasting and "keeping a vigil" through the nights and was not sleeping. She had complained to the neighbors that there was a witch in her house. The witch turned out to be her mother. Mrs. Z's husband, who was studying engineering in Europe, hurriedly returned and took over the running of the household, sending his mother-in-law away and supervising Mrs. Z's treatment himself. She improved rapidly on an antidepressant medication and was discharged in 2 weeks. Her improvement, however, was short-lived. She threw away her medications and began to attend mass whenever one was given, pursuing the priests to ask questions about scriptures. Within 1 week, she was readmitted. On the ward, she accused the psychiatrist of shining powerful torchlights on her and taking pictures of her, opening her chest, using her as a guinea pig, poisoning her food, and planning to bury her alive. She claimed to receive messages from Mars and Jupiter and announced that there was a riot in town. She clutched her Bible to her breast and accused all the doctors of being "idol worshippers," calling down the wrath of her god on all of them. After considerable resistance, Mrs. Z was finally convinced to accept electroconvulsive treatment, and she became symptom free after six treatments. At this point, she attributed her illness to a difficult childbirth, the absence of her husband, and her unreasonable mother. She saw no further role for doctors, called for her priest, and began to speak of her illness as a religious experience that was similar to the experience of religious leaders throughout history. However, her symptoms did not return, and she was discharged after 6 weeks of hospitalization. (Courtesy of Bushra Naz, M.D., Laura J. Fochtmann, M.D., and Evelyn J. Bromet, Ph.D.)

Psychotropic Medications in Pregnancy

No definitive answers exist to the questions of which psychotropic medications are safest during pregnancy and lactation. In patients with worsening psychiatric illness during pregnancy, outpatient psychotherapy, hospitalization, and milieu therapy should be attempted before routine use of psychotropic medication. The risks and benefits of treatment with psychotropics versus maternal psychiatric illness must be carefully evaluated on an individual basis. If the patient, her psychiatrist, and her obstetrician decide to continue psychiatric medications throughout pregnancy, the dosage should be calibrated to the physiological changes each trimester. Although no antidepressant medications have been associated with intrauterine death or major birth defects, both selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) are associated with a transient perinatal syndrome. Studies demonstrate that fluoxetine (Prozac) has been found in amniotic fluid. Mood stabilizers are associated with more consequential teratogenic risks, namely cardiac anomalies and neural tube defects, but women with bipolar disorder are at a significant risk of relapse without medication maintenance. Lithium has been associated with an increased risk of Ebstein's anomaly, a congenital downward displacement of the tricuspid valve into the right ventricle.

The U.S. Food and Drug Administration (FDA) rates drugs in five categories of safety for use in pregnancy, with categories of risk coded A, B, C, D, and X (Table 27-9). In general, all medications that are not absolutely essential should be avoided during pregnancy.

Table 27-9
Food and Drug Administration Rating of Drug Safety in Pregnancy

Category	Definition	Drug Examples
A	No fetal risks in controlled human studies	Iron
B	No fetal risk in animal studies, but no controlled human studies or fetal risk in animals, but no risk in well-controlled human studies	Acetaminophen
C	Adverse fetal effects in animals and no human data available	Aspirin, haloperidol, chlorpromazine
D	Human fetal risk seen (may be used in life-threatening situation)	Lithium, tetracycline, ethanol
X	Proved fetal risk in humans (no indication for use, even in life-threatening situations)	Valproic acid, thalidomide

Teratogens

Teratogens are drugs or other agents that cause abnormal fetal development. Infections such as varicella, toxoplasmosis, and herpes simplex, among others, can interfere with normal development. Pregnant women who smoke are subject to premature births, and congenital defects are more common in smokers than in nonsmokers. Alcohol abuse is associated with fetal alcohol syndrome (see Section 20.2). Other drugs of abuse, such as cocaine and heroin, produce drug-dependent newborns. In general, pregnant women should not use prescription and over-the-counter drugs and phytochemicals. Drugs given in the third trimester are rarely teratogenic. Retinoids (used to treat acne) taken early in

pregnancy have been associated with fetal abnormalities.

Premenstrual Dysphoric Disorder

Premenstrual dysphoric disorder (PMDD) is a somatopsychic illness triggered by changing levels of sex steroids that accompany an ovulatory menstrual cycle. It occurs about 1 week before the onset of menses and is characterized by irritability, emotional lability, headache, anxiety, and depression. Somatic symptoms include edema, weight gain, breast pain, syncope, and paresthesias. The diagnostic criteria for premenstrual dysphoric disorder according to DSM-5 are listed in Table 27-10. Approximately 5 percent of women have the disorder. Treatment is symptomatic and includes analgesics for pain and sedatives for anxiety and insomnia. Some patients respond to short courses of SSRIs. Fluid retention is relieved with diuretics.

Table 27-10
DSM-5 Criteria for Premenstrual Dysphoric Disorder

- A. In the majority of menstrual cycles, at least five symptoms must be present in the final week before the onset of menses, start to *improve* within a few days after the onset of menses, and become *minimal* or absent in the week postmenses.
- B. One (or more) of the following symptoms must be present:
1. Marked affective lability (e.g., mood swings; feeling suddenly sad or tearful, or increased sensitivity to rejection).
 2. Marked irritability or anger or increased interpersonal conflicts.
 3. Marked depressed mood, feelings of hopelessness, or self-deprecating thoughts.
 4. Marked anxiety, tension, and/or feelings of being keyed up or on edge.
- C. One (or more) of the following symptoms must additionally be present, to reach a total of *five* symptoms when combined with symptoms from Criterion B above.
1. Decreased interest in usual activities (e.g., work, school, friends, hobbies).
 2. Subjective difficulty in concentration.
 3. Lethargy, easy fatigability, or marked lack of energy.
 4. Marked change in appetite; overeating; or specific food cravings.
 5. Hypersomnia or insomnia.
 6. A sense of being overwhelmed or out of control.
 7. Physical symptoms such as breast tenderness or swelling, joint or muscle pain, a sensation of “bloating,” or weight gain.
- Note:** The symptoms in Criteria A–C must have been met for most menstrual cycles that occurred in the preceding year.
- D. The symptoms are associated with clinically significant distress or interference with work, school, usual social activities, or relationships with others (e.g., avoidance of social activities; decreased productivity and efficiency at work, school, or home).
- E. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as major depressive disorder, panic disorder, persistent depressive disorder (dysthymia), or a personality disorder (although it may co-occur with any of these disorders).
- F. Criterion A should be confirmed by prospective daily ratings during at least two symptomatic cycles. (**Note:** The diagnosis may be made provisionally prior to this confirmation.)
- G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition (e.g., hyperthyroidism).

(Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (Copyright ©2013). American Psychiatric Association. All Rights Reserved.)

The generally recognized syndrome involves mood symptoms (e.g., lability, irritability), behavior symptoms (e.g., changes in eating patterns, insomnia), and physical symptoms (e.g., breast tenderness, edema, and headaches). This pattern of symptoms occurs at a specific time during the menstrual cycle, and the symptoms resolve for some period of time between menstrual cycles. The hormonal changes that occur during the menstrual cycle are probably involved in producing the symptoms, although the exact etiology is unknown.

Because of the absence of generally agreed-upon diagnostic criteria, the epidemiology of premenstrual dysphoria is not known with certainty. Up to 80 percent of all women experience some alteration in mood, sleep, or somatic symptoms during the premenstrual period, and about 40 percent of these women have at least mild to moderate premenstrual symptoms prompting them to seek medical advice. Only 3 to 7 percent of women have symptoms that meet the full diagnostic criteria for PMDD.

Given that most women who experience changes in affect or somatic symptoms during the premenstrual period are not severely functionally impaired, it is important to distinguish these women from those who are diagnosed with PMDD. Premenstrual syndrome (PMS) is distinguished from PMDD by the severity and number of symptoms, as well as the degree to which function is impaired. Table 27-11 lists the diagnostic criteria for PMS in which the patient reports at least one of the affective or somatic symptoms during the 5 days before menses in each of the three prior menstrual cycles.

Table 27-11
Diagnostic Criteria for Premenstrual Syndrome

Affective Symptoms	Somatic Symptoms
Depression	Breast tenderness
Irritability	Abdominal bloating
Anxiety	Headache
Confusion	Swelling of extremities
Social withdrawal	

(Adapted from American College of Obstetricians and Gynecologists [ACOG] *Practice Bulletin #15*, April 2000, with permission.)

The course and the prognosis of PMDD have not been studied sufficiently to reach any reasonable conclusions. Anecdotally, the symptoms

tend to be chronic unless effective treatment is initiated. Treatment of PMDD includes support for the patient about the presence and recognition of the symptoms. SSRIs (e.g., fluoxetine) and alprazolam (Xanax) have been reported to be effective, although no treatment has been conclusively demonstrated to be effective in multiple, well-controlled trials. If symptoms are present throughout the menstrual cycle, with no intercycle symptom relief, clinicians should consider one of the nonmenstrual cycle-related mood disorders and anxiety disorders. The presence of especially severe symptoms, even if cyclical, should prompt clinicians to consider other mood disorders and anxiety disorders. A thorough medical workup is necessary to rule out medical or surgical conditions to account for symptoms (e.g., endometriosis).

OTHER ISSUES

Sexually Transmitted Diseases

A sexually transmitted disease (STD) is a contagious disease acquired as a result of a physical sexual interaction. From the 1950s through 1970s, the infections were considered treatable and not life-threatening. That was before acquired immune deficiency syndrome (AIDS) was recognized, which is caused by infection with human immunodeficiency virus (HIV) and is currently incurable, life-threatening, and transmissible from mother to fetus.

A sequela of STDs, such as gonorrhea and chlamydia, is pelvic inflammatory disease (PID). Untreated, PID can develop into bilateral tubo-ovarian abscesses and necessitate hysterectomy and bilateral salpingo-oophorectomy. Early antibiotic treatment is advocated to prevent development of the abscesses and to reduce the likelihood of infertility, chronic pelvic pain, and ectopic pregnancy from tubal damage. These infections also can lead to obstruction of the vas deferens and chronic prostatitis and subsequent male infertility.

Another STD that can have serious consequences is venereal warts, or human papillomavirus (HPV). Genital infections with certain subtypes of HPV can lead to premalignant changes of the penis, vulva, vagina, and cervix and are thought to cause cervical cancer. Venereal warts can be removed chemically or surgically but are difficult to eradicate completely. Women who contract HPV are encouraged to have regular gynecological examinations and Papanicolaou smears to detect premalignant lesions. An HPV vaccine exists, which is recommended for all girls 11 to 12 years of age to decrease the incidence of certain strains of HPV virus. This vaccine would then decrease the incidence of genital warts and cervical cancer.

Sexual monogamy and abstinence, which will prevent most STDs, are advocated as public health measures. Libidinal impulses, however, can be difficult to control and restrict. Therefore, measures such as condom use are strongly recommended as an alternative public health measure. Adolescents, in particular, need to know the potential consequences of sexual activity with regard to STDs and pregnancy. Admonishing teens to remain chaste is unlikely to be completely effective and may be counterproductive. The risks of sexual intercourse may be forgotten or seem minimal in comparison to the need for affection or escape. Persons with low self-esteem or under stress may view sex as a means of bolstering their self-image or escaping their stresses. The reinforcing properties of sex ensure that the problem of STDs will endure. Studies in Europe, especially Holland, have shown that easy availability of condoms (e.g., in schools) reduces both STDs and unwanted pregnancies.

Pelvic Pain

Pelvic pain can have many causes, including endometriosis, pelvic adhesions, ovarian or adnexal masses, hernias, and bowel or rectal disease. Pelvic pain can also be secondary to psychogenic causes such as guilt, fertility, or fears of infertility, and the emotional disturbances associated with ongoing or past incest or sexual abuse. Pelvic pain should not be attributed to psychogenic causes unless a thorough evaluation has excluded organic causes. In most instances, the evaluation should include a diagnostic laparoscopy. Likewise, dyspareunia or pain with intercourse should not be assumed to have a psychogenic origin unless all anatomical causes have been excluded.

Pseudocyesis

Pseudocyesis (false pregnancy) is the development of the classic symptoms of pregnancy—amenorrhea, nausea, breast enlargement and pigmentation, abdominal distention (Fig. 27-2), and labor pains—in a nonpregnant woman. Pseudocyesis demonstrates the ability of the psyche to dominate the soma, probably via central input at the level of the hypothalamus. Predisposing psychological processes are thought to include a pathological wish for, and fear of, pregnancy; ambivalence or conflict regarding gender, sexuality, or childbearing; and a grief reaction to loss following a miscarriage, tubal ligation, or hysterectomy. The patient may have a true somatic delusion that is not subject to reality testing, but often a negative pregnancy test result or pelvic ultrasound scan leads to resolution. Psychotherapy is recommended during or after a presentation of pseudocyesis to evaluate and treat the underlying psychological dysfunction. A related event, couvade, occurs in some cultures in which the father of the child undergoes simulated labor, as though he were giving birth. In those societies couvade is a normal phenomenon.

FIGURE 27-2Abdominal distention in patient at 36th week. Bimanual examination revealed uterus normal in size and position.

Miss S, aged 16, thought she had become pregnant after her first coital experience, which occurred without contraception. Shortly after she read about the signs and symptoms of pregnancy, her menses stopped. She related that she felt tingling in her breasts, which she believed were enlarged. She also reported nausea and vomiting in the morning, which was observed by her mother. On examination, the uterus was enlarged, breasts were developed with dark areola and contained milk, and a pigmented line was observed from the umbilicus to the pubis. The abdomen was not enlarged, but she believed she felt fetal movement. A pregnancy test had negative results

and the patient was so informed; however, she could not be dissuaded of her belief that she was pregnant. She entered psychotherapy, and within 2 months her menses returned and she accepted the fact that she was not pregnant.

Hyperemesis Gravidarum

Hyperemesis gravidarum is differentiated from morning sickness in that vomiting is chronic, persistent, and frequent, leading to ketosis, acidosis, weight loss, and dehydration. The prognosis is excellent for both mother and fetus with prompt treatment. Most women can be treated as outpatients, with changing to smaller meals, discontinuing iron supplements, and avoiding certain foods. In severe cases, hospitalization may be necessary. Although the cause is unknown, a psychological component may exist. Women with histories of anorexia nervosa or bulimia nervosa may be at risk.

Pica

Pica is the repeated ingestion of nonnutritive substances, such as dirt, clay, starch, sand, and feces. This eating disorder is most often seen in young children, but is common in pregnant women in some subcultures, most notably among African American women in the rural South, who may eat clay or starch (e.g., Argo). The cause of pica is unknown, but it may be related to nutritional deficiencies in the mother.

28.1 Psychoanalysis and Psychoanalytic Psychotherapy

As broadly practiced today, psychoanalytic treatment encompasses a wide range of uncovering strategies used in varied degrees and blends. Despite the inevitable blurring of boundaries in actual application, the original modality of classic psychoanalysis and major modes of psychoanalytic psychotherapy (expressive and supportive) are delineated separately here (Table 28.1-1). Analytical practice in all its complexity resides on a continuum. Individual technique is always a matter of emphasis, as the therapist titrates the treatment according to the needs and capacities of the patient at every moment.

Table 28.1-1
Scope of Psychoanalytic Practice: A Clinical Continuum^a

Feature	Psychoanalysis	Psychoanalytic Psychotherapy	
		Expressive Mode	Supportive Mode
Frequency	Regular four to five times per week; "50-minute hour"	Regular one to three times per week; half to full hour	Flexible one time per wk or less; or as needed half to full hour
Duration	Long-term; usually 3 to 5+ years	Short or long term; several sessions to months or years	Short or intermittent long term; single session to lifetime
Setting	Patient primarily on couch with analyst out of view	Patient and therapist face to face; occasional use of couch	Patient and therapist face to face; couch contraindicated
Modus operandi	Systematic analysis of all positive and negative transference and resistance; primary focus on analyst and intrasession events; transference neurosis facilitated; regression encouraged	Partial analysis of dynamics and defenses; focus on current interpersonal events and transference to others outside of sessions; analysis of negative transference; positive transference left unexplored unless impedes progress; limited regression encouraged	Formation of therapeutic alliance and real object relationship; analysis of transference contraindicated with rare exceptions; focus on conscious external events; regression discouraged
Analyst/therapist role	Absolute neutrality; frustration of patient; reflector/mirror role	Modified neutrality; implicit gratification of patient and greater activity	Neutrality suspended; limited explicit gratification, direction, and disclosure
Mutative change agents	Insight predominates within relatively deprived environment	Insight within more empathic environment; identification with benevolent object	Auxiliary or surrogate ego as temporary substitute; holding environment; insight to degree possible
Patient population	Neuroses; mild character psychopathology	Neuroses; mild to moderate character psychopathology, especially narcissistic and borderline disorders	Severe character disorders, latent or manifest psychoses, acute crises, physical illness
Patient requisites	High motivation, psychological mindedness; good previous object relationships; ability to maintain transference neurosis; good frustration tolerance	Moderate to high motivation and psychological mindedness; ability to form therapeutic alliance; some frustration tolerance	Some degree of motivation and ability to form therapeutic alliance
Basic goals	Structural reorganization of personality; resolution of unconscious conflicts; insight into intrapsychic events; symptom relief an indirect result	Partial reorganization of personality and defenses; resolution of preconscious and conscious derivatives of conflicts; insight into current interpersonal events; improved object relations; symptom relief a goal or prelude to further exploration	Reintegration of self and ability to cope; stabilization or restoration of preexisting equilibrium; strengthening of defenses; better adjustment or acceptance of pathology; symptom relief and environmental restructuring as primary goals
Major techniques	Free association method predominates; full dynamic interpretation (including confrontation, clarification, and working through), with emphasis on genetic reconstruction	Limited free association; confrontation, clarification, and partial interpretation predominate, with emphasis on here-and-now interpretation and limited genetic interpretation	Free association method contraindicated; suggestion (advise) predominates; abreaction useful; confrontation, clarification, and interpretation in the here-and-now secondary; genetic interpretation contraindicated
Adjunct treatment	Primarily avoided; if applied, all negative and positive meanings and implications are thoroughly analyzed	May be necessary (e.g., psychotropic drugs as temporary measure); if applied, its negative implications explored and diffused	Often necessary (e.g., psychotropic drugs, family rehabilitative therapy, or hospitalization); if applied, its positive implications are emphasized

^aThis division is not categorical; all practice resides on a clinical continuum.

Psychoanalysis is virtually synonymous with the renowned name of its founding father, Sigmund Freud (Freud and his theories are discussed in Section 4.1). It is also referred to as "classic" or "orthodox" psychoanalysis to distinguish it from more recent variations known as *psychoanalytic psychotherapy* (discussed below).

Psychoanalysis is based on the theory of sexual repression and traces the unfulfilled infantile libidinal wishes in the individual's unconscious memories. It remains unsurpassed as a method to discover the meaning and motivation of behavior, especially the unconscious elements that inform thoughts and feelings.

PSYCHOANALYSIS

Psychoanalytic Process

The psychoanalytic process involves bringing to the surface repressed memories and feelings by means of a scrupulous unraveling of hidden meanings of verbalized material and of the unwitting ways in which the patient wards off underlying conflicts through defensive forgetting and repetition of the past.

The overall process of analysis is one in which unconscious neurotic conflicts are recovered from memory and verbally expressed, reexperienced in the transference, reconstructed by the analyst, and, ultimately, resolved through understanding. Freud referred to these processes as *recollection*, *repetition*, and *working through*, which make up the totality of remembering, reliving, and gaining insight. *Recollection* entails the extension of memory back to early childhood events, a time in the distant past when the core of neurosis was formed. The actual reconstruction of these events comes through reminiscence, associations, and autobiographical linking of developmental

events. *Repetition* involves more than mere mental recall; it is an emotional replay of former interactions with significant individuals in the patient's life. The replay occurs within the special context of the analyst as projected parent, a fantasized object from the patient's past with whom the latter unwittingly reproduces forgotten, unresolved feelings and experiences from childhood. Finally, *working through* is both an affective and cognitive integration of previously repressed memories that have been brought into consciousness and through which the patient is gradually set free (cured of neurosis). The analytical course can be subdivided into three major stages (Table 28.1-2).

Table 28.1-2 Stages of Psychoanalysis

Stage one: Patient becomes familiar with the methods, routines, and requirements of analysis, and a realistic therapeutic alliance is formed between patient and analyst. Basic rules are established; the patient describes his or her problems; there is some review of history, and the patient gains initial relief through catharsis and a sense of security before delving more deeply into the source of the illness. The patient is primarily motivated by the wish to get well.

Stage two: Transference neurosis emerges that substitutes for the actual neurosis of the patient and in which the wish for health comes into direct conflict with the simultaneous wish to receive emotional gratification from the analyst. There is a gradual surfacing of unconscious conflicts; an increased irrational attachment to the analyst, with regressive and dependent concomitants of that bond; a developmental return to earlier forms of relating (sometimes compared with that of mother and infant); and a repetition of childhood patterns and recall of traumatic memories through transfer to the analyst of unresolved libidinal wishes.

Stage three: The termination phase is marked by the dissolution of the analytical bond as the patient prepares for leave-taking. The irrational attachment to the analyst in the transference neurosis has subsided because it has been worked through, and more rational aspects of the psyche preside, providing greater mastery and more mature adaptation to the patient's problems. Termination is not a hard-and-fast event, and the patient invariably has to continue to work through any problems outside of the therapy situation without the analyst or may need intermittent assistance after analysis has technically terminated.

Indications and Contraindications

In general, all of the so-called *psychoneuroses* are suitable for psychoanalysis. These include anxiety disorders, obsessional thinking, compulsive behavior, conversion disorder, sexual dysfunction, depressive states, and many other nonpsychotic conditions, such as personality disorders. Significant suffering must be present so that patients are motivated to make the sacrifices of time and financial resources required for psychoanalysis. Patients who enter analysis must have a genuine wish to understand themselves, not a desperate hunger for symptomatic relief. They must be able to withstand frustration, anxiety, and other strong affects that emerge in analysis without fleeing or acting out their feelings in a self-destructive manner. They must also have a reasonable, mature superego that allows them to be honest with the analyst. Intelligence must be at least average, and above all, they must be psychologically minded in the sense that they can think abstractly and symbolically about the unconscious meanings of their behavior.

Many contraindications for psychoanalysis are the flip side of the indications. The absence of suffering, poor impulse control, inability to tolerate frustration and anxiety, and low motivation to understand are all contraindications. The presence of extreme dishonesty or antisocial personality disorder contraindicates analytic treatment. Concrete thinking or the absence of psychological mindedness is another contraindication. Some patients who might ordinarily be psychologically minded are not suitable for analysis because they are in the midst of a major upheaval or life crisis, such as a job loss or a divorce. Serious physical illness can also interfere with a person's ability to invest in a long-term treatment process. Patients of low intelligence generally do not understand the procedure or cooperate in the process. An age older than 40 years was once considered a contraindication, but today analysts recognize that patients are malleable and analyzable in their 60s or 70s. One final contraindication is a close relationship with the analyst. Analysts should avoid analyzing friends, relatives, or persons with whom they have other involvements.

Patient Requisites

The most important patient requisites for psychoanalysis are listed in Table 28.1-3.

Table 28.1-3 Patient Prerequisites for Psychoanalysis

1. *High motivation.* The patient needs a strong motivation to persevere, in light of the rigors of intense and lengthy treatment. The desire for health and self-understanding must surpass the neurotic need for unhappiness. The patient must be willing to face issues of time and money and to endure the pain and frustration associated with sacrificing rapid relief in favor of future cure and with foregoing the secondary gains of illness.
2. *Ability to form a relationship.* The capacity to form and maintain, as well as to detach from, a trusting object relationship is essential. The patient also has to withstand a frustrating and regressive transference without decompensating or becoming excessively attached. Patients with a history of impaired or transient interpersonal relations who cannot establish a viable connection to another human make poor candidates for psychoanalysis.
3. *Psychological mindedness and capacity for insight.* As an introspective process, psychoanalysis requires curiosity about oneself and the capacity for self-scrutiny. Those who are unable to articulate and comprehend their inner thoughts and feelings cannot negotiate with the fundamental analytical coin words and their meanings. The inability to examine one's own motivations and behaviors precludes benefits from the analytical method.
4. *Ego strength.* Ego strength is the integrative capacity to oscillate appropriately between two antithetical types of ego functioning: On the one hand, the patient must be able to reflect temporarily, to relinquish reality for fantasy, and to be dependent and passive. On the other hand, the patient has to be able to accept analytical rules, to integrate interpretations, to defer important decisions, to shift perspectives to become an observer of his or her intrapsychic processes, and to function in a sustained interpersonal relationship as a responsible adult.

(Courtesy of T. Byram Karasu, M.D.)

Ms. M, a 29-year-old unmarried woman who worked in a low-level capacity for a magazine, presented for consultation with the chief complaints of considerable sadness and distress over her parent's reaction when they found that she had had a homosexual relationship. She also realized that she had been working far below her potential. She had never sought any treatment before. She was clearly intelligent, sensitive, self-reflective, and insightful. When the possibility of psychoanalysis was presented to her, she worried that meant she was "sicker." Ms. M, however, began reading Freud, realized that analysis was actually recommended for those who are higher functioning, and became intrigued by the idea. She agreed to come 4 days a week for 50-minute sessions.

She was the oldest of three children and the only girl. Ms. M's father, a successful professional, was described as very demanding and intrusive, someone who never thought anything was good enough. He had always expected his children to do the "extra credit" assignments as part of their regular work. Ms. M, however, was very proud of her father's accomplishments. She spoke of her mother in conflicting terms as well: She was a homemaker, weak, and sometimes acquiescent to the powerful father but also a woman in her own right who was involved in community volunteer work and could be a powerful public speaker.

Just prior to beginning her analysis, Ms. M had had her wallet stolen. In her first analytic session, she spoke of losing all of her identification cards, and to her it seemed as if she were starting analysis "with a completely new identity." Initially, she was somewhat hesitant to use the couch because she wanted to see her analyst's reactions, but she quickly appreciated that she could associate more easily without seeing the analyst.

As her analysis proceeded, through dreams and free associations, Ms. M became quite focused on the analyst. She became extremely curious about the analyst's life. What emerged from her associations to seeing the analyst's appointment book on the desk was that she felt "slotted in." Whenever Ms. M saw other patients, she felt the office was "like an assembly line." Further associations led to her feeling slotted in by her parents as they ran from one activity to another. Her resistance manifested itself in Ms. M's often coming as much or more than 15 minutes late to her sessions. Her associations led to her admitting that she did not want her analyst to think that she was "too eager." Ms. M was able to see that she needed to devalue her analyst and her importance to Ms. M as a defense against an overwhelming positive and even erotic transference toward her.

For example, Ms. M wanted to improve her appearance so that the therapist, who she called a "role model," would find her more attractive. Her negative transference, however, was never far from the surface, and she denigrated the analyst by wondering if the analyst were a "clotheshorse" who was financing her wardrobe with the patient's payments.

Her conflicts about her sexual orientation were a central preoccupation in the course of her analysis, particularly because her father was so homophobic. Early on, Ms. M felt awkward and uncomfortable when she went to a lesbian bar, and when asked if she qualified for the "lesbian discount," she said she did not. At one point, she began seeing several men, including a male psychologist. The analyst made the transference interpretation, which Ms. M accepted, that a date with this man seemed as if it were a date with the analyst and sleeping with him would be equivalent to sleeping with the analyst. Ms. M was also able to see that her transient choice of dating a male therapist was a defensive compromise. Although her homosexual object choice was multidetermined, Ms. M came to appreciate, through her work in analysis, that at least a part of her conflicts about homosexuality stemmed from her relationship toward her father. It was a means of securing his attention as well as infuriating him.

Over the course of 4 years, Ms. M began to do considerably better at work and was promoted to a job commensurate with her potential. She was also able to deal better with both her parents, and particularly her father, regarding her sexual orientation. She became much more comfortable with her "new identity" and became involved in a relationship with a professional woman. At the end of therapy, Ms. M and this woman were committed to each other and were thinking of adopting a child. (Courtesy of T. Byram Karasu, M.D., and S. R. Karasu, M.D.)

Goals

Stated in developmental terms, psychoanalysis aims at the gradual removal of amnesias rooted in early childhood based on the assumption that when all gaps in memory have been filled, the morbid condition will cease because the patient no longer needs to repeat or remain fixated to the past. The patient should be better able to relinquish former regressive patterns and to develop new, more adaptive ones, particularly as he or she learns the reasons for his or her behavior. A related goal of psychoanalysis is for the patient to achieve some measure of self-understanding or insight.

Psychoanalytic goals are often considered formidable (e.g., a total personality change), involving the radical reorganization of old developmental patterns based on earlier affects and the entrenched defenses built up against them. Goals may also be elusive, framed as they are in theoretical intrapsychic terms (e.g., greater ego strength) or conceptually ambiguous ones (resolution of the transference neurosis). Criteria for successful psychoanalysis may be largely intangible and subjective and they are best regarded as conceptual endpoints

of treatment that must be translated into more realistic and practical terms.

In practice, the goals of psychoanalysis for any patient naturally vary, as do the many manifestations of neuroses. The form that the neurosis takes—unsatisfactory sexual or object relationships, inability to enjoy life, underachievement, and fear of work or academic success, or excessive anxiety, guilt, or depressive ideation—determines the focus of attention and the general direction of treatment, as well as the specific goals. Such goals may change at any time during the course of analysis, especially as many years of treatment may be involved.

Major Approach and Techniques

Structurally, *psychoanalysis* usually refers to individual (dyadic) treatment that is frequent (four or five times per week) and long term (several years). All three features take their precedent from Freud himself.

The dyadic arrangement is a direct function of the Freudian theory of neurosis as an intrapsychic phenomenon, which takes place within the person as instinctual impulses continually seek discharge. Because dynamic conflicts must be internally resolved if structural personality reorganization is to take place, the individual's memory and perceptions of the repressed past are pivotal.

Freud initially saw patients 6 days a week for 1 hour each day, a routine now reduced to four or five sessions per week of the classic 50-minute hour, which leaves time for the analyst to take notes and organize relevant thoughts before the next patient. Long intervals between sessions are avoided so that the momentum gained in uncovering conflictual material is not lost and confronted defenses do not have time to restrengthen.

Freud's belief that successful psychoanalysis always takes a long time because profound changes in the mind occur slowly still holds. The process can be likened to the fluid sense of time that is characteristic of our unconscious processes. Moreover, because psychoanalysis involves a detailed recapitulation of present and past events, any compromise in time presents the risk of losing pace with the patient's mental life.

Psychoanalytic Setting. As with other forms of psychotherapy, psychoanalysis takes place in a professional setting, apart from the realities of everyday life, in which the patient is offered a temporary sanctuary in which to ease psychic pain and reveal intimate thoughts to an accepting expert. The psychoanalytic environment is designed to promote relaxation and regression. The setting is usually spartan and sensorially neutral, and external stimuli are minimized.

USE OF THE COUCH. The couch has several clinical advantages that are both real and symbolic: (1) the reclining position is relaxing because it is associated with sleep and so eases the patient's conscious control of thoughts; (2) it minimizes the intrusive influence of the analyst, thus curbing unnecessary cues; (3) it permits the analyst to make observations of the patient without interruption; and (4) it holds symbolic value for both parties, a tangible reminder of the Freudian legacy that gives credibility to the analyst's professional identity, allegiance, and expertise. The reclining position of the patient with analyst nearby can also generate threat and discomfort, however, as it recalls anxieties derived from the earlier parent-child configuration that it physically resembles. It may also have personal meanings—for some, a portent of dangerous impulses or of submission to an authority figure; for others, a relief from confrontation by the analyst (e.g., fear of use of the couch and overeagerness to lie down may reflect resistance and, thus, need to be analyzed). Although the use of the couch is requisite to analytical technique, it is not applied automatically; it is introduced gradually and can be suspended whenever additional regression is unnecessary or counter-therapeutic.

FUNDAMENTAL RULE. The fundamental rule of free association requires patients to tell the analyst everything that comes into their heads—however disagreeable, unimportant, or nonsensical—and to let themselves go as they would in a conversation that leads from “cabbages to kings.” It differs decidedly from ordinary conversation—instead of connecting personal remarks with a rational thread, the patient is asked to reveal those very thoughts and events that are objectionable precisely because of being averse to doing so.

This directive represents an ideal because free association does not arise freely but is guided and inhibited by a variety of conscious and unconscious forces. The analyst must not only encourage free association through the physical setting and a nonjudgmental attitude toward the patient's verbalizations, but also examine those very instances when the flow of associations is diminished or comes to a halt—they are as important analytically as the content of the associations. The analyst should also be alert to how individual patients use or misuse the fundamental rule.

Aside from its primary purpose of eliciting recall of deeply hidden early memories, the fundamental rule reflects the analytical priority placed on verbalization, which translates the patient's thoughts into words so they are not channeled physically or behaviorally. As a direct concomitant of the fundamental rule, which prohibits action in favor of verbal expression, patients are expected to postpone making major alterations in their lives, such as marrying or changing careers, until they discuss and analyze them within the context of treatment.

PRINCIPLE OF EVENLY SUSPENDED ATTENTION. As a reciprocal corollary to the rule that patients communicate everything that occurs to them without criticism or selection, the principle of evenly suspended attention requires the analyst to suspend judgment and to give impartial attention to every detail equally. The method consists simply of making no effort to concentrate on anything specific, while maintaining a neutral, quiet attentiveness to all that is said.

ANALYST AS MIRROR. A second principle is the recommendation that the analyst be impenetrable to the patient and, as a mirror, reflect only what is shown. Analysts are advised to be neutral blank screens and not to bring their own personalities into treatment. This means that they are not to bring their own values or attitudes into the discussion or to share personal reactions or mutual conflicts with their patients, although they may sometimes be tempted to do so. The bringing in of reality and external influences can interrupt or bias the patient's unconscious projections. Neutrality also allows the analyst to accept without censure all forbidden or objectionable responses.

RULE OF ABSTINENCE. The fundamental rule of abstinence does not mean corporal or sexual abstinence, but refers to the frustration of emotional needs and wishes that the patient may have toward the analyst or part of the transference. It allows the patient's longings to persist and serve as driving forces for analytical work and motivation to change. Freud advised that the analyst carry through the analytical treatment in a state of renunciation. The analyst must deny the patient who is longing for love the satisfaction he or she craves.

Limitations. At present, the predominant treatment constraints are often economic, relating to the high cost in time and money, both for patients and in the training of future practitioners. In addition, because clinical requirements emphasize such requisites as psychological mindedness, verbal and cognitive ability, and stable life situation, psychoanalysis may be unduly restricted to a diagnostically, socioeconomically, or intellectually advantaged patient population. Other intrinsic issues pertain to the use and misuse of its stringent rules, whereby overemphasis on technique may interfere with an authentic human encounter between analyst and patient, and to the major long-term risk of interminability, in which protracted treatment may become a substitute for life. Reification of the classic analytical tradition may interfere with a more open and flexible application of its tenets to meet changing needs. It may also obstruct a comprehensive view of patient care that includes a greater appreciation of other treatment modalities in conjunction with, or as an alternative to, psychoanalysis.

Ms. A, a 25-year-old articulate and introspective medical student, began analysis complaining of mild, chronic anxiety, dysphoria, and a sense of inadequacy, despite above-average intelligence and performance. She also expressed difficulty in long-term relationships with her male peers.

Ms. A began the initial phase of analysis with enthusiastic self-disclosure, frequent reports of dreams and fantasies, and overidealization of the analyst; she tried to please him by being a compliant, good patient, just as she had been a good daughter to her father (a professor of medicine) by going to medical school.

Over the next several months, Ms. A gradually developed a strong attachment to the analyst and settled into a phase of excessive preoccupation with him. Simultaneously, however, she began dating an older psychiatrist and proceeded to complain about the analyst's coldness and unresponsiveness, even considering dropping out of analysis because he did not meet her demands.

In the course of analysis, through dreams and associations, Ms. A recalled early memories of her ongoing competition with her mother for her father's attention and realized that, failing to obtain his exclusive love, she had tried to become like him. She was also able to see how her increasing interest in becoming a psychiatrist (rather than following her original plan to be a pediatrician), as well as her recent choice of a man to date, were recapitulations of the past vis-à-vis the analyst. As this repeated pattern was recognized, the patient began to relinquish her intense erotic and dependent tie to the analyst, viewing him more realistically and beginning to appreciate the ways in which his quiet presence reminded her of her mother. She also became less disturbed by the similarities she shared with her mother and was able to disengage from her father more comfortably. By the fifth year of analysis, she was happily married to a classmate, was pregnant, and was a pediatric chief resident. Her anxiety was now attenuated and situation specific (that is, she was concerned about motherhood and the termination of analysis). (Courtesy of T. Byram Karasu, M.D.)

PSYCHOANALYTIC PSYCHOTHERAPY

Psychoanalytic psychotherapy, which is based on fundamental dynamic formulations and techniques that derive from psychoanalysis, is designed to broaden its scope. Psychoanalytic psychotherapy, in its narrowest sense, is the use of insight-oriented methods only. As generically applied today to an ever-larger clinical spectrum, it incorporates a blend of uncovering and suppressive measures.

The strategies of psychoanalytic psychotherapy currently range from expressive (insight-oriented, uncovering, evocative, or interpretive) techniques to supportive (relationship-oriented, suggestive, suppressive, or repressive) techniques. Although those two types of methods are sometimes regarded as antithetical, their precise definitions and the distinctions between them are by no means absolute.

The duration of psychoanalytic psychotherapy is generally shorter and more variable than in psychoanalysis. Treatment may be brief, even with an initially agreed-upon or fixed time limit, or may extend to a less definite number of months or years. Brief treatment is chiefly used for selected problems or highly focused conflict, whereas longer treatment may be applied for more chronic conditions or for intermittent episodes that require ongoing attention to deal with pervasive conflict or recurrent decompensation. Unlike psychoanalysis, psychoanalytic psychotherapy rarely uses the couch; instead, patient and therapist sit face to face. This posture helps to prevent regression because it encourages the patient to look on the therapist as a real person from whom to receive direct cues, even though transference and fantasy will continue. The couch is considered unnecessary because the free-association method is rarely used, except when the therapist wishes to gain access to fantasy material or dreams to enlighten a particular issue.

Expressive Psychotherapy

Indications and Contraindications. Diagnostically, psychoanalytic psychotherapy in its expressive mode is suited to a range of psychopathology with mild to moderate ego weakening, including neurotic conflicts, symptom complexes, reactive conditions, and the whole realm of nonpsychotic character disorders, including those disorders of the self that are among the more transient and less profound on the severity-of-illness spectrum, such as narcissistic behavior disorders and narcissistic personality disorders. It is also one of the treatments recommended for patients with borderline personality disorders, although special variations may be required to deal with the associated turbulent personality characteristics, primitive defense mechanisms, tendencies toward regressive episodes, and irrational attachments to the analyst.

Ms. B, an intelligent and verbal 34-year-old divorced woman, presented with complaints of being unappreciated at work. Always angry and irritable, she considered quitting her job and even leaving the city. Her social life was also being negatively affected; her boyfriend had threatened to leave her because of her extremely hostile, clinging behavior (the same reason her ex-husband had given when he left her 9 years earlier after only 16 months of marriage).

Her past included promiscuity and experimentation with various drugs, and, currently, she indulged in heavy drinking on weekends and occasionally smoked marijuana. She had held many jobs and had lived in various cities. The eldest of three children of a middle-class family, she came from an unhappy and unstable home: her brother had been in and out of psychiatric hospitals; her sister had left home at the age of 16 after becoming pregnant and being forced to marry; and her overly controlling parents had subjected their children to psychological (and occasionally physical) abuse, alternating between heated arguments and passionate reconciliations.

Initially, Ms. B attempted to contain her rage in treatment, but it frequently surfaced and alternated with child-like helplessness; she interrogated the psychiatrist regarding his credentials, ridiculed psychodynamic concepts, constantly challenged statements, and would demand practical advice but then denigrate or fail to follow the guidance given. The psychiatrist remained unprovoked by her aggression and explored with her the need to engage him negatively. Her response was to question and test his continued concern.

When her boyfriend left her, she attempted suicide (she cut her wrists superficially), was briefly hospitalized, and, on discharge, was placed on selective serotonin reuptake inhibitors (SSRIs) for 6 months for her minor, but protracted, depression. The psychiatrist maintained their regular frequency of sessions despite her greater demands. Although she was puzzled by the steadiness of his interest, she gradually felt safe enough to express her vulnerabilities. As they explored her lack of full commitment to work, friends, and therapy, she began to understand the meaning of her anger in terms of the early abusive relationship with her parents and her tendency to bring it into contemporary relationships. With the psychiatrist's encouragement, she also began to seek work and make small strides in relationship-oriented efforts. By the end of her second year of treatment, she had decided to remain in the city, to stay at her place of employment, and to continue therapy. She needed to experience and practice her somewhat fragile new self, which included greater intimacy in relationships, additional mastery of work skills, and a more cohesive sense of self. (Courtesy of T. Byram Karasu, M.D.)

The persons best suited for the expressive psychotherapy approach have fairly well integrated egos and the capacity to both sustain and detach from a bond of dependency and trust. They are, to some degree, psychologically minded and self-motivated, and they are generally able, at least temporarily, to tolerate doses of frustration without decompensating. They must also have the ability to manage the re arousal of painful feelings outside the therapy hour without additional contact. Patients must have some capacity for introspection and impulse control, and they should be able to recognize the cognitive distinction between fantasy and reality.

Goals. The overall goals of expressive psychotherapy are to increase the patient's self-awareness and to improve object relations through exploration of current interpersonal events and perceptions. In contrast to psychoanalysis, major structural changes in ego function and defenses are modified in light of patient limitations. The aim is to achieve a more limited and, thus, select and focused understanding of one's problems. Rather than uncovering deeply hidden and past motives and tracing them back to their origins in infancy, the major thrust is to deal with preconscious or conscious derivatives of conflicts as they became manifest in present interactions. Although insight is sought, it

is less extensive; instead of delving to a genetic level, greater emphasis is on clarifying recent dynamic patterns and maladaptive behaviors in the present.

Major Approach and Techniques. The major modus operandi involves establishment of a therapeutic alliance and early recognition and interpretation of negative transference. Only limited or controlled regression is encouraged, and positive transference manifestations are generally left unexplored, unless they are impeding therapeutic progress; even here, the emphasis is on shedding light on current dynamic patterns and defenses.

Limitations. A general limitation of expressive psychotherapy, as of psychoanalysis, is the problem of emotional integration of cognitive awareness. The major danger for patients who are at the more disorganized end of the diagnostic spectrum, however, may have less to do with the overintellectualization that is sometimes seen in neurotic patients than with the threat of decompensation from, or acting out of, deep or frequent interpretations that the patient is unable to integrate properly.

Some therapists fail to accept the limitations of a modified insight-oriented approach and so apply it inappropriately to modulate the techniques and goals of psychoanalysis. Overemphasis on dreams and fantasies, zealous efforts to use the couch, indiscriminate deep interpretations, and continual focus on the analysis of transference may have less to do with the patient's needs than with those of a therapist who is unwilling or unable to be flexible.

Ms. S was an attractive 30-year-old unmarried woman working as a secretary when she presented for consultation. Her chief complaints at the time were feeling “only anger and tension” and an inability to apply herself to studying voice, “which is one of the most important things to me.”

In obtaining a history, the therapist noted that Ms. S had never completed anything: She had dropped out of college; never pursued a music degree; and switched from job to job, and even city to city. What initially seemed like a woman with diverse interests (e.g., jobs as a research assistant, freelance copyeditor, part-time radio announcer; manager of data entry for a software company; and, most recently, secretary) really reflected a woman with a chaotic lifestyle and serious difficulties committing to anyone or anything. Although obviously intelligent, Ms. S presented with unrealistic expectations regarding her consultation. For example, after the first consultative session, Ms. S said she felt good afterward but felt there were “no revelations yet.” Because of Ms. S's inability to commit and her somewhat disorganized life, the therapist recommended a course of psychotherapy, beginning twice a week, rather than something more intense like psychoanalysis. The therapist also realized over the course of the consultation that Ms. S would have difficulty with free association without getting disorganized. The therapist also thought that Ms. S might regress unproductively on the couch without visual contact with the therapist.

Ms. S was the second oldest of four children—two brothers and a younger sister, with whom she was most competitive and who clearly seemed the mother's favorite. She described her mother as a successful professor who was demanding and critical, as if she had a “raised eyebrow” in disapproval. For example, much to her mother's chagrin, Ms. S had once wanted a sandwich “with everything on it.” Ms. S was also disappointed when she was given one piece of luggage rather than a complete set for a Christmas gift. She was able to accept the therapist's interpretation that she felt “part of a set” by being one of four siblings. Ms. S initially idealized her father, who was active in the family church, but eventually saw him as disappointing and rejecting.

Ms. S's ideal therapist would be “flexible,” by which she meant a therapist who might do hypnosis one session, psychotherapy the next, and, maybe, analysis another session. In fact, within the first week of beginning therapy, Ms. S had simultaneously consulted a hypnotherapist, which she mentioned in passing only weeks later, for her neck pain and tension. Although she did not pursue hypnosis, she did maintain a chiropractor for most of her therapy, also something she mentioned many months after beginning therapy. She did speak of wanting to be “on best behavior” and “follow the rules.” Her tremendous sense of entitlement, however, was evident: She had an expectation of getting “cut-rate prices” on everything from haircuts and car repairs to doctors' visits. Her initial fee was a much-reduced one, which she paid late and begrudgingly.

Although she was seen only twice a week, Ms. S developed intense feelings for her therapist. Mostly she experienced rage when she saw evidence of the therapist's other patients, such as footprints on the waiting room floor after a snowstorm or a coat hanger turned around. She expressed the wish to keep some of her things, like bobby pins and hairspray, in the therapist's bathroom. She vacillated between feelings she wanted to move in and feelings that the therapist did not exist. For example, before she took a plane flight, she wondered who would tell her therapist if something happened to her. She had never given the therapist's name to anyone, nor did she have her name in her weekly appointment book. The therapist interpreted that she had a simultaneous wish to devalue her and not to share her with anyone else. Associations to a dream with an image of a string of baroque pearls led to thoughts that these pearls—irregular and imperfect—defective and even lopsided, represented how she viewed herself.

Over the course of the next few years, Ms. S was able to commit to coming regularly to therapy, although the course was somewhat tumultuous, with many threats of quitting and much withholding of information. At one point, she even tried to provoke the therapist by seeking a consultation with another therapist in order to “tattle” on her, just as she had tattled on her siblings. Her therapist remained unprovoked and continued to provide a safe environment for Ms. S to explore her ambivalence to the therapist and the therapeutic situation. The therapist was also able to contain Ms. S's tendency to regress, particularly with separations, by providing her with the therapist's telephone number.

She had actually entered therapy with an unconscious wish to become a world-famous singer who would win her mother's approval and praise. Her narcissism and sense of entitlement made it difficult for her to give up on that fantasy despite repeated evidence that she did not have sufficient talent. She was finally able to settle on a compromise: She began to work diligently and closely as a research assistant to her mother, who was writing a book, and as Ms. S became more focused and organized over time, she even thought she might write a book about the church. Supportive Psychotherapy

Supportive psychotherapy aims at the creation of a therapeutic relationship as a temporary buttress or bridge for the deficient patient. It has roots in virtually every therapy that recognizes the ameliorative effects of emotional support and a stable, caring atmosphere in the management of patients. As a nonspecific attitude toward mental illness, it predates scientific psychiatry, with foundations in 18th-century moral treatment, whereby for the first time patients were treated with understanding and kindness in a humane, interpersonal environment free from mechanical restraints.

Supportive psychotherapy has been the chief form used in the general practice of medicine and rehabilitation, frequently to augment extratherapeutic measures, such as prescriptions of medication to suppress symptoms, rest to remove the patient from excessive stimulation, or hospitalization to provide a structured therapeutic environment, protection, and control of the patient. It can be applied as primary or ancillary treatment. The global perspective of supportive psychotherapy (often part of a combined treatment approach) places major etiological emphasis on external rather than intrapsychic events, particularly on stressful environmental and interpersonal influences on a severely damaged self.

Indications and Contraindications. Supportive psychotherapy is generally indicated for those patients for whom classic psychoanalysis or insight-oriented psychoanalytic psychotherapy is typically contraindicated—those who have poor ego strength and whose potential for decompensation is high. Amenable patients fall into the following major areas: (1) individuals in acute crisis or a temporary state of disorganization and inability to cope (including those who might otherwise be well functioning) whose intolerable life circumstances have produced extreme anxiety or sudden turmoil (e.g., individuals going through grief reactions, illness, divorce, job loss, or who were victims of crime, abuse, natural disaster, or accident); (2) patients with chronic severe pathology with fragile or deficient ego functioning (e.g., those with latent psychosis, impulse disorder, or severe character disturbance); (3) patients whose cognitive deficits and physical symptoms make them particularly vulnerable and, thus, unsuitable for an insight-oriented approach (e.g., certain psychosomatic or medically ill persons); and (4) individuals who are psychologically unmotivated, although not necessarily characterologically resistant to a depth approach (e.g., patients who come to treatment in response to family or agency pressure and are interested only in immediate relief or those who need assistance in very specific problem areas of social adjustment as a possible prelude to more exploratory work).

Mr. C, a 50-year-old married man with two sons, the owner of a small construction company, was referred by his internist after recovery from bypass surgery because of frequent, unfounded physical complaints. He was taking minor tranquilizers in increasing doses, not complying with his daily regimen, avoiding sexual contact with his wife, and had dropped out of group therapy for postsurgical patients after one session.

He came to his first appointment 20 minutes late, after having “forgotten” two previous appointments. He was extremely anxious, often lost in his train of thought, and was semidelusional about his wife and sons, suggesting that they might want to have him locked up. He briefly told his life history, which included his coming from a strict and hard-working but caring middle-class family and the death of his mother when he was only 11 years old. He had joined his father’s business (taking over after his father’s death 2 years earlier), with both of his sons as associates. Describing himself as successful in work and marriage, he claimed that “the only test I ever failed was the stress test.”

Mr. C explained his lack of compliance with diet restrictions as a lack of will and his constant contact with the internist as his having real physical problems not yet diagnosed; he rejected the idea of addiction to tranquilizers, insisting that he could quit any time. He had no fantasy life, remembered no dreams, made it clear that he had entered treatment on his internist’s instruction only, and started each session by stating that he had nothing to talk about.

After suggesting that Mr. C was coming to sessions just to pass the “sanity test” and that there was no reason to have him locked up, the psychiatrist encouraged the patient to join him in figuring out the real reasons for his anxiety. Initial sessions were devoted to discussing the patient’s medical condition and providing factual information about heart and bypass surgery. The therapist likened the patient’s condition to that of an older house getting new plumbing, trying to allay his unrealistic fears of impending death. As Mr. C’s anxiety declined, he became less defensive and more psychologically accessible. As the therapist began to explore his difficulty in accepting help, Mr. C was able to talk about his inability to admit problems (i.e., weaknesses). The therapist’s explicit recognition of the patient’s strength in admitting his weaknesses encouraged the patient to reveal more about himself—how he had welcomed his father’s death and his belief that perhaps his illness was punishment. The psychiatrist also encouraged him to speak about his unrealistic guilt and, at the same time, helped him recognize his suspicion of his sons as the reflection of his own wishes concerning his father and his lack of commitment to his medical regimen as a wish to die so as to expiate guilt. After steady urging by the therapist, Mr. C returned to work. He agreed to meet monthly with the psychiatrist and to taper off his use of tranquilizers. He even agreed that he might see the psychiatrist for “deep analysis” in the future because his wife now jokingly complained of his obsessive dieting, his uncompromising exercise regimens, and his regularly scheduled sexual activities. (Courtesy of T. Byram Karasu, M.D.)

Because support forms a tacit part of every therapeutic modality, it is rarely contraindicated as such. The typical attitude regards better-functioning patients as unsuitable not because they will be harmed by a supportive approach, but because they will not be sufficiently benefited by it. In aiming to maximize the patient’s potential for further growth and change, supportive therapy tends to be regarded as relatively restricted and superficial and, thus, is not recommended as the treatment of choice if the patient is available for, and capable of, a more in-depth approach.

Goals. The general aim of supportive treatment is the amelioration or relief of symptoms through behavioral or environmental restructuring within the existing psychic framework. This often means helping the patient to adapt better to problems and to live more comfortably with his or her psychopathology. To restore the disorganized, fragile, or decompensated patient to a state of relative equilibrium, the major goal is to suppress or control symptomatology and to stabilize the patient in a protective and reassuring benign atmosphere that militates against overwhelming external and internal pressures. The ultimate goal is to maximize the integrative or adaptive capacities so that the patient increases the ability to cope, while decreasing vulnerability by reinforcing assets and strengthening defenses.

Major Approach and Techniques. Supportive therapy uses several methods, either singly or in combination, including warm, friendly, strong leadership; partial gratification of dependency needs; support in the ultimate development of legitimate independence; help in developing pleasurable activities (e.g., hobbies); adequate rest and diversion; removal of excessive strain, when possible; hospitalization, when indicated; medication to alleviate symptoms; and guidance and advice in dealing with current issues. This therapy uses techniques to help patients feel secure, accepted, protected, encouraged, safe, and not anxious.

Limitations. To the extent that much supportive therapy is spent on practical, everyday realities and on dealing with the external environment of the patient, it may be viewed as more mundane and superficial than depth approaches. Because those patients are seen intermittently and less frequently, the interpersonal commitment may not be as compelling on the part of either the patient or the therapist. Greater severity of illness (and possible psychoses) also makes such treatment potentially more erratic, demanding, and frustrating. The need for the therapist to deal with other family members, caretakers, or agencies (auxiliary treatment, hospitalization) can become an additional complication, because the therapist comes to serve as an ombudsman to negotiate with the outside world of the patient and with other professional peers. Finally, the supportive therapist must be able to accept personal limitations and the patient’s limited psychological resources and to tolerate the often unrewarded efforts until small gains are made.

Mr. W was a 42-year-old widowed businessman who was referred by his internist because of the sudden death of his wife, who had had an intracranial hemorrhage, about 2 months earlier. Mr. W had two children, a boy and a girl, ages 10 and 8 years, respectively.

Mr. W had never been to a psychiatrist before, and when he arrived he admitted he was not certain what a psychiatrist could do for him. He just had to get over his wife’s death. He was not sure how talking about anything could really help. He had been married for 15 years. He admitted to having difficulty sleeping, particularly awakening in the middle of the night with considerable anxiety about the future. One of his relatives had given him some of her own Klonopin for his anxiety, which helped tremendously, but he feared getting dependent on it. He was also drinking more than he thought he should. He was most concerned about raising his children alone and felt somewhat overwhelmed by the responsibility. He was beginning to appreciate just how wonderful a mother his wife had been and now

saw how critical he had been of her for spending so much time with the children. “It really does take a lot of effort,” he said.

Mr. W did admit to feelings of guilt. For one thing, he admitted to some sense that he could now start over. He had been somewhat restless in the marriage recently before his wife’s death and had actually been unfaithful for a brief period early in the marriage. He also felt some guilt that had he been awake the night of his wife’s hemorrhage, maybe he could have saved his wife. In reality, there was nothing he could have done.

Mr. W agreed to come for a few sessions to talk about his wife. At this point, only 2 months after her death, he seemed to have an uncomplicated mourning reaction. Although he talked easily in session, he was clearly worried that he might like “being here too much.” The therapist chose not to interpret his dependency conflicts. Mr. W seemed to have good coping skills and used humor as a high-functioning defense. For example, in giving a eulogy for his wife (who had been a very popular member of their congregation), he looked around at the enormous crowd of people at the church service and said he had never seen so many people attending church before, adding, “Sorry, Reverend.”

After about four sessions, Mr. W said he that felt better and no longer saw the need for further sessions. He was sleeping better and had stopped drinking excessively. The therapist suggested that he might want to continue to talk more about his guilt and his life as he went forward without his wife. The therapist was also reassuring that there seemed to be nothing else Mr. W could have done to save his wife. He also encouraged the patient to begin dating when he felt ready, something that Mr. W’s in-laws were clearly not encouraging. For now, however, Mr. W was not interested in any further therapy. He was appreciative of the therapist and felt that talking about his wife’s death had been helpful. The therapist accepted his wish to discontinue their sessions but encouraged Mr. W to keep in touch to let him know how he was doing. (Courtesy of T. Byram Karasu, M.D., and S. R. Karasu, M.D.)

CORRECTIVE EMOTIONAL EXPERIENCE. The relationship between therapist and patient gives a therapist an opportunity to display behavior different from the destructive or unproductive behavior of a patient’s parent. At times, such experiences seem to neutralize or reverse some effects of the parents’ mistakes. If the patient had overly authoritarian parents, the therapist’s friendly, flexible, nonjudgmental, nonauthoritarian—but at times firm and limit setting—attitude gives the patient an opportunity to adjust to, be led by, and identify with a new parent figure. Franz Alexander described this process as a corrective emotional experience. It draws on elements of both psychoanalysis and psychoanalytic psychotherapy.

28.2 Brief Psychodynamic Psychotherapy

The growth of psychotherapy in general and of dynamic psychotherapies derived from the psychoanalytic framework in particular represents a landmark achievement in the history of psychiatry. Brief psychodynamic psychotherapy has gained widespread popularity, partly because of the great pressure on health care professionals to contain treatment costs. It is also easier to evaluate treatment efficacy by comparing groups of persons who have had short-term therapy for mental illness with control groups than it is to measure the results of long-term psychotherapy. Thus, short-term therapies have been the subject of much research, especially on outcome measures, which have found them to be effective. Other short-term methods include interpersonal therapy (discussed in Section 28.10) and cognitive-behavioral therapy (discussed in Section 28.7).

Brief psychodynamic psychotherapy is a time-limited treatment (10 to 12 sessions) that is based on psychoanalysis and psychodynamic theory. It is used to help persons with depression, anxiety, and posttraumatic stress disorder, among others. There are several methods, each having its own treatment technique and specific criteria for selecting patients; however, they are more similar than different.

In 1946, Franz Alexander and Thomas French identified the basic characteristics of brief psychodynamic psychotherapy. They described a therapeutic experience designed to put patients at ease, to manipulate the transference, and to use trial interpretations flexibly. Alexander and French conceived psychotherapy as a corrective emotional experience capable of repairing traumatic events of the past and convincing patients that new ways of thinking, feeling, and behaving are possible. At about the same time, Eric Lindemann established a consultation service at Massachusetts General Hospital in Boston for persons experiencing a crisis. He developed new treatment methods to deal with these situations and eventually applied these techniques to persons who were not in crisis, but who were experiencing various kinds of emotional distress. Since then, the field has been influenced by many workers such as David Malan in England, Peter Sifneos in the United States, and Habib Davanloo in Canada.

TYPES

Brief Focal Psychotherapy (Tavistock–Malan)

Brief focal psychotherapy was originally developed in the 1950s by the Balint team at the Tavistock Clinic in London. Malan, a member of the team, reported the results of the therapy. Malan’s selection criteria for treatment included eliminating absolute contraindications, rejecting patients for whom certain dangers seemed inevitable, clearly assessing patients’ psychopathology, and determining patients’ capacities to consider problems in emotional terms, face disturbing material, respond to interpretations, and endure the stress of the treatment. Malan found that high motivation invariably correlated with a successful outcome. Contraindications to treatment were serious suicide attempts, substance dependence, chronic alcohol abuse, incapacitating chronic obsessional symptoms, incapacitating chronic phobic symptoms, and gross destructive or self-destructive acting out.

Requirements and Techniques. In Malan's routine, therapists should identify the transference early and interpret it and the negative transference. They should then link the transferences to patients' relationships with their parents. Both patients and therapists should be willing to become deeply involved and to bear the ensuing tension. Therapists should formulate a circumscribed focus and set a termination date in advance, and patients should work through grief and anger about termination. An experienced therapist should allow about 20 sessions as an average length for the therapy; a trainee should allow about 30 sessions. Malan himself did not exceed 40 interviews with his patients.

Time-Limited Psychotherapy (Boston University–Mann)

A psychotherapeutic model of exactly 12 interviews focusing on a specified central issue was developed at Boston University by James Mann and his colleagues in the early 1970s. In contrast with Malan's emphasis on clear-cut selection and rejection criteria, Mann has not been as explicit about the appropriate candidates for time-limited psychotherapy. Mann considered the major emphases of his theory to be determining a patient's central conflict reasonably correctly and exploring young persons' maturational crises with many psychological and somatic complaints. Mann's exceptions, similar to his rejection criteria, include persons with major depressive disorder that interferes with the treatment agreement, those with acute psychotic states, and desperate patients who need, but cannot tolerate, object relations.

Requirements and Techniques. Mann's technical requirements included strict limitation to 12 sessions, positive transference predominating early, specification and strict adherence to a central issue involving transference, positive identification, making separation a maturational event for patients, absolute prospect of termination to avoid development of dependence, clarification of present and past experiences and resistances, active therapists who support and encourage patients, and education of patients through direct information, reeducation, and manipulation. The conflicts likely to be encountered included independence versus dependence, activity versus passivity, unresolved or delayed grief, and adequate versus inadequate self-esteem.

Short-Term Dynamic Psychotherapy (McGill University–Davanloo)

As conducted by Davanloo at McGill University, short-term dynamic psychotherapy encompasses nearly all varieties of brief psychotherapy and crisis intervention. Patients treated in Davanloo's series are classified as those whose psychological conflicts are predominantly oedipal, those whose conflicts are not oedipal, and those whose conflicts have more than one focus. Davanloo also devised a specific psychotherapeutic technique for patients with severe, long-standing neurotic problems, specifically those with incapacitating obsessive-compulsive disorders and phobias.

Davanloo's selection criteria emphasize evaluating those ego functions of primary importance to psychotherapeutic work: the establishment of a psychotherapeutic focus; the psychodynamic formulation of the patient's psychological problems; the ability to interact emotionally with evaluators; a history of give-and-take relationships with a significant person in the patient's life; the patient's ability to experience and tolerate anxiety, guilt, and depression; the patient's motivations for change, psychological mindedness, and an ability to respond to interpretation and to link evaluators with persons in the present and past. Both Malan and Davanloo emphasized a patient's responses to interpretation as an important selection and prognostic criterion.

Requirements and Techniques. The highlights of Davanloo's psychotherapeutic approach are flexibility (therapists should adapt the technique to the patient's needs), control, the patient's regressive tendencies, active intervention to avoid having the patient develop overdependence on a therapist, and the patient's intellectual insight and emotional experiences in the transference. These emotional experiences become corrective as a result of the interpretation.

Ana, a divorced 60-year-old woman, sought psychiatric help following a severe depressive episode lasting several months. This episode, which was one of many in her life, was especially severe in terms of loss of energy, interest, and motivation, as well as in terms of the intensity of her sadness and her wish to die. Only her profound religious convictions protected her from acting on these wishes. Ana had lost a lot of weight, had trouble sleeping, experienced many nightmares, and had difficulty with concentration. She was plagued by pervasive feelings of hatred for her mother, who was very old, ill, and dependent on Ana, who was unable to forgive her for abandoning her in an orphanage when she was 5 or 6 years of age.

After an extensive assessment, the dynamic formulation of Ana's problem was represented as follows:

1. *Life problems:* Recurrent depressive episodes plagued by feelings of guilt and self-reproach; problems with men involving choosing partners who are commonly cold, distant, or otherwise unavailable; involuntary and painful emotional distance from her children, friends, and other close relationships; and unproductive and unrewarding work life, despite considerable intellectual gifts.

2. *Dynamics:* Ambivalent relationship with her mother, whom she blames for most of the tragedies of her life; guilt and need for punishment in relation to her unrelenting hatred for her mother; and pathological grief reaction for the loss of an idealized and more optimal relationship with her mother, the one she remembers she had prior to her orphanage placement. From this focus there flows a melancholic conviction of the inevitable failure of human relationships.

3. *Pathogenic foci:* Grief and inability to mourn the loss of her mother after she was placed in the orphanage, with attendant rage and guilt; pathological grief for the loss of her father, who, because of severe alcoholism, abandoned the family first, a move that caused the mother to place her children in an orphanage in order to be able to work and ultimately recover their care. Unconsciously, she blamed her mother for the family catastrophe, thus "protecting" an idealized view of her father, to whom she was profoundly attached.

For Ana, the initial phase of treatment focused on the clarification and the experience of her destructive impulses toward her mother, which, as they were worked through, made possible the appearance of a modicum of empathy with her mother's painful life situation around the time she placed Ana and her sisters in the orphanage. Next, the therapy focused on Ana's father. Deep feelings of idealization, disappointment, anger, and grief were experienced with increasing clarity and intensity, frequently via displaced feelings in the transference and after overcoming considerable resistance. The last phase of treatment permitted the development of realistic feelings of empathy and appreciation for her mother, now without anger or emotional distancing, and the reawakening within Ana of feelings of joy and hope, as well as professional ambition. (Courtesy of M. Trujillo, M.D.)

Short-Term Anxiety-Provoking Psychotherapy (Harvard University–Sifneos)

Sifneos developed short-term anxiety-provoking psychotherapy at the Massachusetts General Hospital in Boston during the 1950s. He used the following criteria for selection: a circumscribed chief complaint (implying a patient's ability to select one of a variety of problems to be given top priority and the patient's desire to resolve the problem in treatment), one meaningful or give-and-take relationship during early childhood, the ability to interact flexibly with an evaluator and to express feelings appropriately, above-average psychological sophistication (implying not only above-average intelligence but also an ability to respond to interpretations), a specific psychodynamic formulation (usually a set of psychological conflicts underlying a patient's difficulties and centering on an oedipal focus), a contract between therapist and patient to work on the specified focus and the formulation of minimal expectations of outcome, and good to excellent motivation for change, not just for symptom relief.

Chris, a 31-year-old single man, sought help for a moderate depressive episode precipitated by the loss of his relationship with his girlfriend, Joanna. She had broken off the relationship after approximately 1 year, tired of Chris's erratic work ethic and emotional instability and discouraged by his fear of commitment to the future of their relationship. This cycle of infatuation, increasing fear of commitment, and relationship loss had become a pattern in Chris's interpersonal life. His work life was plagued with similar problems. Jobs were frequently lost because of serious conflict and threatening confrontations with his superiors. As conflicts arose at both work and home, Chris typically suffered increasing anxiety and episodic panic attacks. After the loss of each relationship, Chris usually confronted moderate depressive feelings, at times accompanied by suicidal ideation.

After an assessment, the dynamic hologram for Chris was represented as follows:

1. *Life problems*: Recurrent episodes of anxiety and depression; work problems; unstable interpersonal relationships; conflict with authority figures; antagonism toward, and emotional distance from, his father, brother, and male friends; and fears of heterosexual intimacy and of commitment.

2. *Dynamic forces*: Ongoing hostility and envy toward males, authority figures, and successful people, and compulsive and possessive seeking of female love objects with a serious inability to consider, fulfill, or tolerate their independent needs.

3. *Genetic pathogenic foci*: Unconscious loss of maternal objects precipitated by birth of a brother when Chris was age 2 years; uncontrolled grief for that loss with a compulsive drive to experience child-like possession of love objects; and compulsive hostility toward others perceived as rivals.

The therapist's active inquiry yielded additional confirmation of the persistence of repressed sexual feelings toward his mother and the presence of hostile feelings toward all rivals for his mother's affection. A memory suffused with very visceral feelings emerged in this phase as a result of the therapist's active inquiry. In this memory, Chris saw himself in his mother's arms in a dark room. He remembered vividly the intense pleasure of the contact with the warm skin of his mother, the texture of her clothes, and the smell of her perfume. While narrating this memory to the therapist, Chris was so absorbed in the experience that he blushed intensely. He also described the painful termination of this moment of pleasure by his father's sudden and disruptive opening of the door and the flood of light that disturbed his pleasurable absorption. This sequence gave way to the experience of grief at the loss of the intense and exclusive bond with his mother after his brother's birth and to a reexperiencing of a sense of anger, impotence, and loneliness. These feelings were all too familiar in his present life when his romantic attachments would be threatened or lost. The affective link between this childhood experience and his intimacy problems in the present became very obvious to Chris, and the acceptance of this link enhanced his capacity to work through this essential component of his pathology. A parallel conflict appeared in the transference as the patient resented the "intrusion" of the inquiring therapist into the zealously guarded privacy of this primal fantasy of material possession. (Courtesy of M. Trujillo, M.D.)

Requirements and Techniques. Treatment can be divided into four major phases: patient-therapist encounter, early therapy, height of treatment, and evidence of change and termination. Therapists use the following techniques during the four phases.

PATIENT-THERAPIST ENCOUNTER. A therapist establishes a working alliance by using the patient's quick rapport with, and positive feelings for, the therapist that appear in this phase. Judicious use of open-ended and forced-choice questions enables the therapist to outline and concentrate on a therapeutic focus. The therapist specifies the minimal expectations of outcome to be achieved by the therapy.

EARLY THERAPY. In transference, feelings for the therapist are clarified as soon as they appear, a technique that leads to the establishment of a true therapeutic alliance.

HEIGHT OF THE TREATMENT. Height of treatment emphasizes active concentration on the oedipal conflicts that have been chosen as the therapeutic focus; repeated use of anxiety-provoking questions and confrontations; avoidance of pregenital characterological issues, which the patient uses defensively to avoid dealing with the therapist's anxiety-provoking techniques; avoidance at all costs of a transference neurosis; repetitive demonstration of the patient's neurotic ways or maladaptive patterns of behavior; concentration on the anxiety-laden material, even before the defense mechanisms have been clarified; repeated demonstrations of parent-transference links by the use of properly timed interpretations based on material given by the patient; establishment of a corrective emotional experience; encouragement and support of the patient, who becomes anxious while struggling to understand the conflicts; new learning and problem-solving patterns; and repeated presentations and recapitulations of the patient's psychodynamics until the defense mechanisms used in dealing with oedipal conflicts are understood.

EVIDENCE OF CHANGE AND TERMINATION OF PSYCHOTHERAPY. The final phase of therapy emphasizes the tangible demonstration of change in the patient's behavior outside therapy, evidence that adaptive patterns of behavior are being used, and initiation of talk about terminating the treatment.

OVERVIEW AND RESULTS

The shared techniques of all the brief psychotherapies described above outdistance their differences. They share the therapeutic alliance or dynamic interaction between therapist and patient, the use of transference, the active interpretation of a therapeutic focus or central issue, the repetitive links between parental and transference issues, and the early termination of therapy.

The outcomes of these brief treatments have been investigated extensively. Contrary to prevailing ideas that the therapeutic factors in psychotherapy are nonspecific, controlled studies and other assessment methods (e.g., interviews with unbiased evaluators, patients' self-evaluations) point to the importance of the specific techniques used. The capacity for genuine recovery in certain patients is far greater than was thought. A certain type of patient receiving brief psychotherapy can benefit greatly from a practical working through of his or her nuclear conflict in the transference. Such patients can be recognized in advance through a process of dynamic interaction, because they are responsive, motivated, and able to face disturbing feelings and because a circumscribed focus can be formulated for them. The more radical the technique in terms of transference, depth of interpretation, and the link to childhood, the more radical the therapeutic effects will be. For some disturbed patients, a carefully chosen partial focus can be therapeutically effective.

28.3 Group Psychotherapy, Combined Individual and Group Psychotherapy, and Psychodrama

Group psychotherapy is a modality that employs a professionally trained leader who selects, composes, organizes, and leads a collection of members to work together toward the maximal attainment of the goals for each individual in the group and for the group itself. Certain properties present in groups, such as mutual support, can be harnessed in the service of providing relief from psychological suffering and supply peer support to counter isolation experienced by many who seek psychiatric help. Similarly, homogeneously composed small groups are ideal settings for the dissemination of accurate information about a condition shared by group members. Medical illness, substance abuse, and chronic and persistent severe psychiatric conditions, including schizophrenia and major affective disorders, are cases in point.

A widely accepted psychiatric treatment modality, group psychotherapy uses therapeutic forces within the group, constructive interactions among members, and interventions of a trained leader to change the maladaptive behaviors, thoughts, and feelings of emotionally distressed individuals. In an era of increasingly stringent financial constraints, decreasing emphasis on individual psychotherapies, and expanding use of psychopharmacological approaches, more patients have been treated with group psychotherapy than with any other form of verbal therapy. Group therapy is applicable to inpatient and outpatient settings, institutional work, partial hospitalization units, halfway houses, community settings, and private practice. Group psychotherapy is also widely used by those who are not mental health professionals in the adjuvant treatment of physical disorders. The principles of group psychotherapy have also been applied with success in the fields of business and education in the form of training, sensitivity, and role-playing.

Group psychotherapy is a treatment in which carefully selected persons who are emotionally ill meet in a group guided by a trained therapist and help one another effect personality change. By using a variety of technical maneuvers and theoretical constructs, the leader directs group members' interactions to bring about changes.

CLASSIFICATION

Group therapy at present has many approaches. Some clinicians work within a psychoanalytic frame of reference. Others use therapy techniques, such as transactional group therapy, which was devised by Eric Berne and emphasizes the here-and-now interactions among group members; behavioral group therapy, which relies on conditioning techniques based on learning theory; Gestalt group therapy, which was created from the theories of Frederick Perls, enables patients to abreact and express themselves fully; and client-centered group psychotherapy, which was developed by Carl Rogers and is based on the nonjudgmental expression of feelings among group members. [Table 28.3-1](#) outlines the major group psychotherapy approaches.

 **Table 28.3-1**
Comparison of Types of Group Psychotherapy

Parameters	Supportive Group Therapy	Analytically Oriented Group Therapy	Psychoanalysis of Groups	Transactional Group Therapy	Behavioral Group Therapy
Frequency	Once a week	One to three times a week	One to five times a week	One to three times a week	One to three times a week
Duration	Up to 6 months	1 to 3+ years	1 to 3+ years	1 to 3 years	Up to 6 months
Primary indications	Psychotic and anxiety disorders	Anxiety disorders, borderline states, personality disorders	Anxiety disorders, personality disorders	Anxiety and psychotic disorders	Phobias, passivity, sexual problems
Individual screening interview	Usually	Always	Always	Usually	Usually
Communication content	Primarily environmental factors	Present and past life situations, intragroup and extragroup relationships	Primarily past life experiences, intragroup relationships	Primarily intragroup relationships; rarely, history; here and now stressed	Specific symptoms without focus on causality
Transference	Positive transference encouraged to promote improved functioning	Positive and negative transference evoked and analyzed	Transference neurosis evoked and analyzed	Positive relationships fostered, negative feelings analyzed	Positive relationships fostered, no examination of transference
Dreams	Not analyzed	Analyzed frequently	Always analyzed and encouraged	Analyzed rarely	Not used
Dependence	Intragroup dependence encouraged; members rely on leader to great extent	Intragroup dependence encouraged; dependence on leader variable	Intragroup dependence not encouraged; dependence on leader variable	Intragroup dependence encouraged; dependence on leader not encouraged	Intragroup dependence not encouraged; reliance on leader is high
Therapist activity	Strengthen existing defenses, active, give advice	Challenge defenses, active, give advice or personal response	Challenge defense, passive, give no advice or personal response	Challenge defenses, active, give personal response, rather than advice	Create new defenses, active and directive
Interpretation	No interpretation of unconscious conflict	Interpretation of unconscious conflict	Interpretation of unconscious conflict extensive	Interpretation of current behavioral patterns in the here and now	Not used
Major group processes	Universalization, reality testing	Cohesion, transference, reality testing	Transference, ventilation, catharsis, reality testing	Abreaction, reality testing	Cohesion, reinforcement, conditioning
Socialization outside of group	Encouraged	Generally discouraged	Discouraged	Variable	Discouraged
Goals	Improved adaptation to environment	Moderate reconstruction of personality dynamics	Extensive reconstruction of personality dynamics	Alteration of behavior through mechanism of conscious control	Relief of specific psychiatric symptoms

PATIENT SELECTION

To determine a patient's suitability for group psychotherapy, a therapist needs a great deal of information, which is gathered in a screening interview. The psychiatrist should take a psychiatric history and perform a mental status examination to obtain certain dynamic, behavioral, and diagnostic information. Table 28.3-2 outlines the general criteria for the selection of patients for group therapy.

Table 28.3-2
Therapist's Role in Group Therapy

1. Size of group
2. Frequency of sessions
3. Patient composition
4. Confidentiality
5. Goals
6. Preparation of patients
7. Determine group processes

Authority Anxiety

Those patients whose primary problem is their relationship to authority and who are extremely anxious in the presence of authority figures may do well in group therapy because they are more comfortable in a group and more likely to do better in a group than in a dyadic (one-to-one) setting. Patients with a great deal of authority anxiety may be blocked, anxious, resistant, and unwilling to verbalize thoughts and feelings in an individual setting, generally for fear of the therapist's censure or disapproval. Thus, they may welcome the suggestion of group psychotherapy to avoid the scrutiny of the dyadic situation. Conversely, if a patient reacts negatively to the suggestion of group psychotherapy or openly resists the idea, the therapist should consider the possibility that the patient has high peer anxiety.

Peer Anxiety

Patients with conditions such as borderline and schizoid personality disorders who have destructive relationships with their peer groups or who have been extremely isolated from peer group contact generally react negatively or anxiously when placed in a group setting. When such patients can work through their anxiety, however, group therapy can be beneficial.

Robert entered therapy seeking to understand why he was unable to maintain close or lasting relationships. A handsome and successful businessman, he had made a painful and courageous transition away from self-centered, dysfunctional parents early in his life. Although he made good initial impressions in his jobs, he was always puzzled and disappointed when his superiors gradually lost interest in him and his colleagues avoided him. In one-on-one therapy, he was charming and entertaining, but was easily injured by perceived narcissistic slights and would become angry and attacking. Group psychotherapy was suggested when his transference feelings remained intense and therapy was at a seeming impasse. Initially, Robert charmed the group and strove to be the center of attention. Visibly annoyed whenever he felt the group leader was paying more attention to other members, Robert was especially critical and hostile toward older people in the group and displayed little empathy for others. After repeated and forceful confrontations from the group about his antagonistic

behavior, he gradually realized that he was repeating childhood patterns in his family of desperately seeking the attention of unloving parents and then entering violent rages when they lost interest. (Courtesy of Normund Wong, M.D.)

Diagnosis

The diagnosis of patients' disorders is important in determining the best therapeutic approach and in evaluating patients' motivations for treatment, capacities for change, and personality structure strengths and weaknesses. Few contraindications exist to group therapy. Antisocial patients generally do poorly in a heterogeneous group setting because they cannot adhere to group standards; but if the group is composed of other antisocial patients, they may respond better to peers than to perceived authority figures. Depressed patients profit from group therapy after they have established a trusting relationship with the therapist. Patients who are actively suicidal or severely depressed should not be treated solely in a group setting. Patients who are manic are disruptive but, once under pharmacological control, do well in the group setting. Patients who are delusional and who may incorporate the group into their delusional system should be excluded, as should patients who pose a physical threat to other members because of uncontrollable aggressive outbursts.

PREPARATION

Patients prepared by a therapist for a group experience tend to continue in treatment longer and report less initial anxiety than those who are not prepared. The preparation consists of having a therapist explain the procedure in as much detail as possible and answer the patient's questions before the first session.

STRUCTURAL ORGANIZATION

Table 28.3-2 summarizes some of the critical tasks that a group therapist must face when organizing a group.

Size

Group therapy has been successful with as few as 3 members and as many as 15, but most therapists consider 8 to 10 members the optimal size. Interaction may be insufficient with fewer members unless they are especially verbal, and with more than 10 members, the interaction may be too great for the members or the therapist to follow.

Frequency and Length of Sessions

Most group psychotherapists conduct group sessions once a week. Maintaining continuity in sessions is important. When there are alternate sessions, the group meets twice a week, once with and once without the therapist. Group sessions generally last anywhere from 1 to 2 hours, but the time limit should be constant.

Marathon groups were most popular in the 1970s but are much less common today. In time-extended therapy (marathon group therapy), the group meets continuously for 12 to 72 hours. Enforced interactional proximity and, during the longest time-extended sessions, sleep deprivation break down certain ego defenses, release affective processes, and theoretically promote open communication. Time-extended sessions, however, can be dangerous for patients with weak ego structures, such as persons with schizophrenia or borderline personality disorder.

Homogeneous versus Heterogeneous Groups

Most therapists believe that groups should be as heterogeneous as possible to ensure maximal interaction. Members with different diagnostic categories and varied behavioral patterns; from all races, social levels, and educational backgrounds; and of varying ages and both sexes should be brought together. Patients between the ages of 20 and 65 years can be included effectively in the same group. Age differences help in developing parent-child and brother-sister models, and patients have the opportunity to relive and rectify interpersonal difficulties that may have appeared insurmountable.

Both children and adolescents are best treated in groups comprising mostly persons in their own age groups. Some adolescent patients are capable of assimilating the material of an adult group, regardless of content, but they should not be deprived of a constructive peer experience that they might otherwise not have.

Open versus Closed Groups

Closed groups have a set number and composition of patients. If members leave, no new members are accepted. In open groups, membership is more fluid, and new members are taken on whenever old members leave.

MECHANISMS

Group Formation

Each patient approaches group therapy differently and, in this sense, groups are microcosms. Patients use typical adaptive abilities, defense mechanisms, and ways of relating, and when these tactics are ultimately reflected back to them by the group, they learn to be introspective about their personality functioning. A process inherent in group formation requires that patients suspend their previous ways of coping. In entering the group, they allow their executive ego functions—reality testing, adaptation to and mastery of the environment, and perception—to be assumed, to some degree, by the collective assessment provided by the total membership, including the leader.

Therapeutic Factors

Table 28.3-3 outlines 20 significant therapeutic factors that account for change in group psychotherapy.

Table 28.3-3
Twenty Therapeutic Factors in Group Psychotherapy

Factor	Definition
Abreaction	A process by which repressed material, particularly a painful experience or conflict, is brought back to consciousness. In the process, the person not only recalls but relives the material, which is accompanied by the appropriate emotional response; insight usually results from the experience.
Acceptance	The feeling of being accepted by other members of the group; differences of opinion are tolerated, and there is an absence of censure.
Altruism	The act of one member helping another; putting another person's need before one's own and learning that there is value in giving to others. The term was originated by Auguste Comte (1798–1857), and Sigmund Freud believed it was a major factor in establishing group cohesion and community feeling.
Catharsis	The expression of ideas, thoughts, and suppressed material that is accompanied by an emotional response that produces a state of relief in the patient.
Cohesion	The sense that the group is working together toward a common goal; also referred to as a sense of "we-ness"; believed to be the most important factor related to positive therapeutic effects.
Consensual validation	Confirmation of reality by comparing one's own conceptualizations with those of other group members; interpersonal distortions are thereby corrected. The term was introduced by Harry Stack Sullivan; Trigant Burrow had used the phrase "consensual observation" to refer to the same phenomenon.
Contagion	The process in which the expression of emotion by one member stimulates the awareness of a similar emotion in another member.
Corrective familial experience	The group re-creates the family of origin for some members who can work through original conflicts psychologically through group interaction (e.g., sibling rivalry, anger toward parents).
Empathy	The capacity of a group member to put himself or herself into the psychological frame of reference of another group member and thereby understand his or her thinking, feeling, or behavior.
Identification	An unconscious defense mechanism in which the person incorporates the characteristics and the qualities of another person or object into his or her ego system.
Imitation	The conscious emulation or modeling of one's behavior after that of another (also called <i>role modeling</i>); also known as spectator therapy, as one patient learns from another.
Insight	Conscious awareness and understanding of one's own psychodynamics and symptoms of maladaptive behavior. Most therapists distinguish two types: (1) intellectual insight—knowledge and awareness without any changes in maladaptive behavior; (2) emotional insight—awareness and understanding leading to positive changes in personality and behavior.
Inspiration	The process of imparting a sense of optimism to group members; the ability to recognize that one has the capacity to overcome problem; also known as instillation of hope.
Interaction	The free and open exchange of ideas and feelings among group members; effective interaction is emotionally charged.
Interpretation	The process during which the group leader formulates the meaning or significance of a patient's resistance, defenses, and symbols; the result is that the patient has a cognitive framework within which to understand his or her behavior.
Learning	Patients acquire knowledge about new areas, such as social skills and sexual behavior; they receive advice, obtain guidance, and attempt to influence and are influenced by other group members.
Reality testing	Ability of the person to evaluate objectively the world outside the self; includes the capacity to perceive oneself and other group members accurately. See also Consensual validation.
Transference	Projection of feelings, thoughts, and wishes onto the therapist, who has come to represent an object from the patient's past. Such reactions, while perhaps appropriate for the condition prevailing in the patient's earlier life, are inappropriate and anachronistic when applied to the therapist in the present. Patients in the group may also direct such feelings toward one another, a process called <i>multiple transferences</i> .
Universalization	The awareness of the patient that he or she is not alone in having problems; others share similar complaints or difficulties in learning; the patient is not unique.
Ventilation	The expression of suppressed feelings, ideas, or events to other group members; the sharing of personal secrets that ameliorate a sense of sin or guilt (also referred to as <i>self-disclosure</i>).

ROLE OF THE THERAPIST

Although opinions differ about how active or passive a group therapist should be, the consensus is that the therapist's role is primarily facilitative. Ideally, the group members themselves are the primary source of cure and change. The climate produced by the therapist's personality is a potent agent of change. The therapist is more than an expert applying techniques; he or she exerts a personal influence that taps such variables as empathy, warmth, and respect.

INPATIENT GROUP PSYCHOTHERAPY

Group therapy is an important part of hospitalized patients' therapeutic experiences. Groups can be organized in many ways on a ward. In a community meeting, an entire inpatient unit meets with all the staff members (e.g., psychiatrists, psychologists, and nurses). In team meetings, 15 to 20 patients and staff members meet; a regular or small group comprising eight to ten patients may meet with one or two therapists, as in traditional group therapy. Although the goals of each group vary, they all have common purposes: to increase patients' awareness of themselves through their interactions with the other group members, who provide feedback about their behavior; to provide patients with improved interpersonal and social skills; to help the members adapt to an inpatient setting; and to improve communication between patients and staff. In addition, one type of group meeting is attended only by inpatient hospital staff and is meant to improve communication among the staff members and to provide mutual support and encouragement in their day-to-day work with patients. Community meetings and team meetings are more helpful for dealing with patient treatment problems than they are for providing insight-oriented therapy, which is the province of the small-group therapy meeting.

Group Composition

Two key factors of inpatient groups common to all short-term therapies are the heterogeneity of the members and the rapid turnover of patients. Outside the hospital, therapists have large caseloads from which to select patients for group therapy. On the ward, therapists have a limited number of patients to choose from and are further restricted to those patients who are both willing to participate and suitable for a small-group experience. In certain settings, group participation may be mandatory (e.g., in substance abuse and alcohol dependence units), but mandatory attendance does not usually apply in a general psychiatry unit. In fact, most group experiences are more productive when the patients themselves choose to enter them.

More sessions are preferable to fewer. During patients' hospital stays, groups may meet daily to allow interactional continuity and the carryover of themes from one session to the next. A new member of a group can be brought up to date quickly, either by the therapist in an orientation meeting or by one of the members. A newly admitted patient has often learned many details about the small-group program from another patient before actually attending the first session. The less frequently the group sessions are held, the greater the need for a therapist to structure the group and be active in it.

Inpatient versus Outpatient Groups

Although the therapeutic factors that account for change in small inpatient groups are similar to those in the outpatient settings, there are qualitative differences. For example, the relatively high turnover of patients in inpatient groups complicates the process of cohesion. But the fact that all the group members are together in the hospital aids cohesion, as do the therapists' efforts to foster the process. Sharing of information, universalization, and catharsis are the main therapeutic factors at work in inpatient groups. Although insight more likely occurs

in outpatient groups because of their long-term nature, some patients can obtain a new understanding of their psychological makeup within the confines of a single group session. A unique quality of inpatient groups is the patients' extragroup contacts, which are extensive because they live together on the same ward. Verbalizing their thoughts and feelings about such contacts in the therapy sessions encourages interpersonal learning. In addition, conflicts between patients or between patients and staff members can be anticipated and resolved.

Twelve former psychiatric inpatients who attended the monthly medication clinic would meet for 1 hour before their individual appointments with the psychiatrist to review their current social situation and medications. All had been treated by the same ward doctor and had known one another while on the inpatient service. The psychiatrist who performed the medication reviews also served as the group leader. Periodically, he was assisted by a staff member who was also familiar with the patients. Coffee was available, and the patients often brought pastries from home. The patients socialized with one another during the hour and frequently exchanged helpful ideas and tips about job opportunities. Those without cars shared rides with other members. The group was open ended and well attended. Most of the patients were single and had a long history of psychotic illness. For most, this meeting was their only opportunity to socialize and be among peers. Frequently, on learning that a member had been rehospitalized, many in the group would visit their colleague on the ward. (Courtesy of Normund Wong, M.D.)

SELF-HELP GROUPS

Self-help groups comprise persons who are trying to cope with a specific problem or life crisis and are usually organized with a particular task in mind. Such groups do not attempt to explore individual psychodynamics in great depth or to change personality functioning significantly, but self-help groups have improved the emotional health and well-being of many persons.

A distinguishing characteristic of the self-help groups is their homogeneity. The members have the same disorders and share their experiences—good and bad, successful and unsuccessful—with one another. By so doing, they educate one another, provide mutual support, and alleviate the sense of alienation usually felt by persons drawn to this kind of group.

Self-help groups emphasize cohesion, which is exceptionally strong in these groups. Because the group members have similar problems and symptoms, they develop a strong emotional bond. Each group may have its unique characteristics, to which the members can attribute magical qualities of healing. Examples of self-help groups are Alcoholics Anonymous (AA), Gamblers Anonymous (GA), and Overeaters Anonymous (OA).

The self-help group movement is presently in ascendancy. These groups meet their members' needs by providing acceptance, mutual support, and help in overcoming maladaptive patterns of behavior or states of feeling that traditional mental health and medical professionals have not generally dealt with successfully. Self-help groups and therapy groups have begun to converge. Self-help groups have enabled their members to give up patterns of unwanted behavior; therapy groups have helped their members understand why and how they got to be the way they were or are.

COMBINED INDIVIDUAL AND GROUP PSYCHOTHERAPY

In combined individual and group psychotherapy, patients see a therapist individually and also take part in group sessions. The therapist for the group and individual sessions is usually the same person. Groups can vary in size from 3 to 15 members, but the most helpful size is 8 to 10. Patients must attend all group sessions. Attendance at individual sessions is also important, and failure to attend either group or individual sessions should be examined as part of the therapeutic process.

Combined therapy is a particular treatment modality, not a system by which individual therapy is augmented by an occasional group session or a group therapy in which a participant meets alone with a therapist from time to time. Rather, it is an ongoing plan in which meaningful integration of the group experience with the individual sessions yields reciprocal feedback to help form an integrated therapeutic experience. Although the one-to-one doctor-patient relationship makes a deep examination of the transference reaction possible for some patients, it may not provide other patients with the corrective emotional experiences necessary for therapeutic change. The group gives patients a variety of persons with whom they can have transference reactions. In the microcosm of the group, patients can relive and work through familial and other important influences.

Techniques

Differing techniques based on varying theoretical frameworks have been used in the combined therapy format. Some clinicians increase the frequency of individual sessions to encourage the emergence of the transference neurosis. In the behavioral model, individual sessions are scheduled regularly, but they tend to be less frequent than in other approaches. Whether patients use a couch or a chair during individual sessions depends on a therapist's orientation. Techniques such as alternate meetings or "after-sessions" without the therapist present may be used. A combined therapy approach called *structured interactional group psychotherapy* has a different group member as the focus of each weekly group session who is discussed in depth by the other members.

Results

Most workers in the field believe that combined therapy has the advantages of both dyadic and group settings, without sacrificing the qualities of either. Generally, the dropout rate in combined therapy is lower than that in group therapy alone. In many cases, combined therapy appears to bring problems to the surface and to resolve them more quickly than might be possible with either method alone.

PSYCHODRAMA

Psychodrama is a method of group psychotherapy originated by the Viennese-born psychiatrist Jacob Moreno in which personality makeup, interpersonal relationships, conflicts, and emotional problems are explored by means of special dramatic methods. Therapeutic dramatization of emotional problems includes the protagonist or patient, the person who acts out problems with the help of auxiliary egos, persons who enact varying aspects of the patient, and the director, psychodramatist, or therapist, the person who guides those in the drama toward the acquisition of insight.

Roles

Director. The director is the leader or therapist and so must be an active participant. He or she has a catalytic function by encouraging the members of the group to be spontaneous. The director must also be available to meet the group's needs without superimposing his or her values. Of all the group psychotherapies, psychodrama requires the most participation from the therapist.

Protagonist. The protagonist is the patient in conflict. The patient chooses the situation to portray in the dramatic scene, or the therapist chooses it if the patient so desires.

Auxiliary Ego. An auxiliary ego is another group member who represents something or someone in the protagonist's experience. The auxiliary egos help account for the great range of therapeutic effects available in psychodrama.

Group. The members of the psychodrama and the audience make up the group. Some are participants, and others are observers, but all benefit from the experience to the extent that they can identify with the ongoing events. The concept of spontaneity in psychodrama refers to the ability of each member of the group, especially the protagonist, to experience the thoughts and feelings of the moment and to communicate emotion as authentically as possible.

Techniques

The psychodrama can focus on any special area of functioning (a dream, a family, or a community situation), a symbolic role, an unconscious attitude, or an imagined future situation. Such symptoms as delusions and hallucinations can also be acted out in the group. Techniques to advance the therapeutic process and to increase productivity and creativity include the soliloquy (a recital of overt and hidden thoughts and feelings), role reversal (the exchange of the patient's role for the role of a significant person), the double (an auxiliary ego acting as the patient), the multiple double (several egos acting as the patient did on varying occasions), and the mirror technique (an ego imitating the patient and speaking for him or her). Other techniques include the use of hypnosis and psychoactive drugs to modify the acting behavior in various ways.

ETHICAL AND LEGAL ISSUES

Confidentiality

Except where disclosure is required by law, the group therapist legally and ethically gives information about the group members to others only after obtaining appropriate patient consent. The therapist is obligated to take appropriate steps to be responsible to society, as well as to patients, when patients pose a danger to themselves or to others. The guidelines for ethics of the American Group Psychotherapy Association state that therapists must obtain specific permission to confer with the referring therapist or with the individual therapist when the patient is in conjoint therapy.

Although the group members, as well as the therapist, should protect the identity of the members and maintain confidentiality, the group members are not legally bound to do so. During the preparation of patients for group psychotherapy, therapists should routinely instruct the prospective members to keep all material discussed in the group confidential. Theoretically, in a legal case, one member of a group can be asked to testify against another, but such a situation has not yet occurred.

A therapist must exercise clinical judgment and caution in placing a patient in a group if he or she thinks that the burdens of maintaining secrets will be too great for some potential members or if a prospective group patient harbors a secret of such magnitude or notoriety that membership in a group would not be wise.

Violence and Aggression

Although reports of violence and aggression are rare, the potential exists that a group member may physically attack another patient or a therapist. The attack may occur within the group or outside the group. The likelihood of such an event can be diminished through the careful selection of group members. Patients with a demonstrated history of assaultive behavior and psychotic patients who pose a potential for violence should not be placed in a group. In institutional settings, in which group therapy is commonly practiced, sufficient safeguards must be in place to discourage any physical danger to others—for example, guards or attendants can act as observers.

Sexual Behavior

For therapists, sexual intercourse with a patient or a former patient is unethical; in many states, such behavior is considered a criminal act. The issue is complicated in group psychotherapy, however, because members may engage in sexual activities with one another. The issues of pregnancy, rape, and the transmission of acquired immunodeficiency syndrome (AIDS) by group members are open questions. If a patient is injured as a result of sexual activity by group members, the therapist could be held accountable for not preventing such behavior. The therapist should advise prospective group members that each patient is responsible for reporting any sexual contact between members. The therapist cannot anticipate every group sexual encounter or prevent sexual relationships from developing, but he or she is obligated to provide patients with guidelines of acceptable behavior. The therapist should identify sexual, vulnerable, or exploitive patients in the selection and preparation of patients for the group. Sociopathic patients who sexually exploit others should be informed that such behavior is explicitly not acceptable in the group and that such behavior should be verbalized rather than acted out. The group must be conducted in such a way that the therapist does not encourage or tacitly allow sexual activity. Patients with AIDS are encouraged to reveal that they harbor the virus. To protect members if sexual relationships occur, some therapists do not accept patients with AIDS into a group unless they agree to reveal their condition. In those situations, the therapist discusses the issue of AIDS with the patient and the group into which the patient is to be placed.

28.4 Family Therapy and Couples Therapy

FAMILY THERAPY

The family is the foundation on which most societies are built. The study of families in different cultures has been a subject of fascination and scientific interest from viewpoints as diverse as sociology, group dynamics, anthropology, ethnicity, race, evolutionary biology, and, of course, the mental health field. The confluence of information gleaned from family studies has set the backdrop against which the contemporary practice of family therapy has evolved.

Family therapy can be defined as any psychotherapeutic endeavor that explicitly focuses on altering the interactions between or among family members and seeks to improve the functioning of the family as a unit, or its subsystems, and the functioning of individual members of the family. Both family therapy and couple therapy aim at some change in relational functioning. In most cases, they also aim at some other change, typically in the functioning of specific individuals in the family. Family therapy meant to heal a rift between parents and their adult children is an example of the use of family therapy centered on relationship goals. Family therapy aimed at increasing the family's coping with schizophrenia and at reducing the family's expressed emotion is an example of family therapy aimed at individual goals (in this case, the functioning of the person with schizophrenia), as well as family goals. In the early years of family therapy, change in the family system was seen as being sufficient to produce individual change. More recent treatments aimed at change in individuals, as well as in the family system, tend to supplement the interventions that focus on interpersonal relationships with specific strategies that focus on individual behavior.

Indications

The presence of a relational difficulty is a clear indication for family and couple therapy. Couples and family therapies are the only treatments that have been shown to be efficacious for such problems as marital maladjustment, and other methods, such as individual therapy, have been shown to often have deleterious effects in these situations. Couples and family therapy has also been demonstrated to have a clear and important role in the treatment of numerous specific psychiatric disorders, often as a component within a multimethod treatment.

Of course, as with any therapy, the indications for family and couple therapy are broad and vary from case to case. Family therapy is a therapeutic collage of ideas regarding the underpinnings of family and individual stability and change, psychopathology, and problems in living, as well as relational ethics. Family therapy might better be called *systemically sensitive therapy* and, in this sense, reflects a basic worldview as much as a clinical treatment methodology. For therapists thus inclined, then, all clinical problems involve salient interactional components; thus, some kind of family (or other functionally significant other's) involvement in therapy is always called for, even in treatment that emphasizes individual problems.

An impressive array now exists of common clinical disorders and problems, including child, adolescent, and adult disorders, for which research has demonstrated family or couple treatment methods to be effective. In a few instances, couple and family interventions are probably even the treatment of choice, and for several disorders, the research argues for family intervention to be an essential part of treatment.

Techniques

Initial Consultation. Family therapy is familiar enough to the general public for families with a high level of conflict to request it specifically. When the initial complaint is about an individual family member, however, pretreatment work may be needed. Underlying resistance to a family approach typically includes fears by parents that they will be blamed for their child's difficulties, that the entire family will be pronounced sick, that a spouse will object, and that open discussion of one child's misbehavior will have a negative influence on siblings. Refusal by an adolescent or young adult patient to participate in family therapy is frequently a disguised collusion with the fears of one or both parents.

Interview Technique. The special quality of a family interview springs from two important facts. A family comes to treatment with its history and dynamics firmly in place. To a family therapist, the established nature of the group, more than the symptoms, constitutes the clinical problem. Family members usually live together and, at some level, depend on one another for their physical and emotional well-being. Whatever transpires in the therapy session is known to all. Central principles of technique also derive from these facts. For example, the therapist must carefully channel the catharsis of anger by one family member toward another. The person who is the object of the anger will react to the attack, and the anger may escalate into violence and fracture relationships, with one or more member withdrawing from therapy. For another example, free association is inappropriate in family therapy because it can encourage one person to dominate a session. Thus, therapists must always control and direct the family interview.

Table 28.4-1 summarizes the principles in which the history of the family is examined in an effort to understand how that history informs the current familial interactions.

Table 28.4-1
Rationale for Family-Life Chronology

The family therapist enters a session knowing little or nothing about the family.

The therapist may know who the identified patient is and what symptoms the patient manifests, but that is usually all. So the therapist must get clues about the meaning of the symptom.

The therapist may know that pain exists in the marital relationship, but needs to get clues about how the pain shows itself.

The therapist needs to know how the mates have tried to cope with their problems.

The therapist may know that the mates both operate from models (from what they saw going on between their own parents), but needs to find out how those models have influenced each mate's expectations about how to be a mate and how to be a parent.

The family therapist enters a session knowing that the family, in fact, has had a history, but that is usually all.

Every family, as a group, has gone through or jointly experienced many events. Certain events (e.g., deaths, childbirth, sickness, geographical moves, and job changes) occur in almost all families.

Certain events primarily affect the mates and only indirectly the children. (Maybe the children were not born yet or were too young to fully comprehend the nature of an event as it affected their parents. They may have only sensed periods of parental remoteness, distraction, anxiety, or annoyance.)

The therapist can profit from answers to just about every question asked.

Family members enter therapy with a great deal of fear.

Therapist structuring helps decrease the threats. It says, "I am in charge of what will happen here. I will see to it that nothing catastrophic happens here."

All members are covertly feeling to blame that nothing seems to have turned out right (even though they may overtly blame the identified patient or the other mate).

Parents, especially, need to feel that they did the best they could as parents. They need to tell the therapist, "This is why I did what I did. This is what happened to me."

A family-life chronology that deals with such facts as names, dates, labeled relationships, and moves, seems to appeal to the family. It asks questions that members can answer, questions that are relatively nonthreatening. It deals with life as the family understands it.

Family members enter therapy with a great deal of despair.

Therapist structuring helps stimulate hope.

As far as family members are concerned, past events are part of them. They now can tell the therapist, "I existed." And they can also say, "I am not just a big blob of pathology. I succeeded in overcoming many handicaps."

If the family knew what questions needed asking, they would not need to be in therapy. So the therapist does not say, "Tell me what you want to tell me." Family members will simply tell the therapist what they have been telling themselves for years. The therapist's questions say, "I know what to ask. I take responsibility for understanding you. We are going to go somewhere."

The family therapist also knows that, to some degree, the family has focused on the identified patient to relieve marital pain. The therapist also knows that, to some degree, the family will resist any effort to change that focus. A family-life chronology is an effective, nonthreatening way to change from an emphasis on the "sick" or "bad" family member to an emphasis on the marital relationship.

The family-life chronology serves other useful therapy purposes, such as providing the framework within which a reeducation process can take place. The therapist serves as a model in checking out information or correcting communication techniques and placing questions and eliciting answers to begin the process. In addition, when taking the chronology, the therapist can introduce in a relatively nonfrightening way some of the crucial concepts to induce change.

(Adapted from Satir V. *Conjoint Family Therapy*. Palo Alto, CA: Science and Behavior; 1967:57, with permission.)

Frequency and Length of Treatment. Unless an emergency arises, sessions are usually held no more than once a week. Each session, however, may require as much as 2 hours. Long sessions can include an intermission to give the therapist time to organize the material and plan a response. A flexible schedule is necessary when geography or personal circumstances make it physically difficult for the family to get together. The length of treatment depends both on the nature of the problem and on the therapeutic model. Therapists who use problem-solving models exclusively may accomplish their goals in a few sessions, whereas therapists using growth-oriented models may work with a family for years and may schedule sessions at long intervals. Table 28.4-2 summarizes one model for treatment termination.

 **Table 28.4-2**
Criteria for Treatment Termination

Treatment is completed:

- When family members can complete transactions, check, ask
- When they can interpret hostility
- When they can see how others see them
- When they can see how they see themselves
- When one member can tell others how they manifest themselves
- When one member can tell others what is hoped, feared, and expected from them
- When they can disagree
- When they can make choices
- When they can learn through practice
- When they can free themselves from the harmful effects of past models
- When they can give clear messages—that is, be congruent in their behavior—with a minimum of difference between feelings and communication and with a minimum of hidden messages.

(Adapted from Satir V. *Conjoint Family Therapy*. Palo Alto, CA: Science and Behavior; 1967:133, with permission.)

Models of Intervention

Many models of family therapy exist, none of which is superior to the others. The particular model used depends on the training received, the context in which therapy occurs, and the personality of the therapist.

Psychodynamic-Experiential Models. Psychodynamic-experiential models emphasize individual maturation in the context of the family system and are free from unconscious patterns of anxiety and projection rooted in the past. Therapists seek to establish an intimate bond with each family member, and sessions alternate between the therapist's exchanges with the members and the members' exchanges with one another. Clarity of communication and honestly admitted feelings are given high priority. Toward this end, family members may be encouraged to change their seats, to touch each other, and to make direct eye contact. Their use of metaphor, body language, and parapraxes helps reveal the unconscious pattern of family relationships. The therapist may also use family sculpting, in which family members physically arrange one another in tableaux depicting their personal view of relationships, past or present. The therapist both interprets the living sculpture and modifies it in a way to suggest new relationships. In addition, the therapist's subjective responses to the family are given great importance. At appropriate moments, the therapist expresses these responses to the family to form yet another feedback loop of self-observation and change.

Bowen Model. Murray Bowen called his model *family systems*, but in the family therapy field it rightfully carries the name of its originator. The hallmark of the Bowen model is persons' differentiation from their family of origin, their ability to be their true selves in the face of familial or other pressures that threaten the loss of love or social position. Problem families are assessed on two levels: the degree of their enmeshment versus the degree of their ability to differentiate and the analysis of emotional triangles in the problem for which they seek help.

An emotional triangle is defined as a three-party system (and many of these can exist within a family) arranged so that the closeness of two members expressed as either love or repetitive conflict tends to exclude a third. When the excluded third person attempts to join with one of the other two or when one of the involved parties shifts in the direction of the excluded one, emotional cross-currents are activated. The therapist's role is, first, to stabilize or shift the "hot" triangle—the one producing the presenting symptoms—and, second, to work with the most psychologically available family members, individually if necessary, to achieve sufficient personal differentiation so that the hot triangle does not recur. To preserve his or her neutrality in the family's triangles, the therapist minimizes emotional contact with family members.

Bowen also originated the *genogram*, a theoretical tool that is a historical survey of the family, going back several generations.

Structural Model. In a structural model, families are viewed as single, interrelated systems assessed in terms of significant alliances and splits among family members, hierarchy of power (parents in charge of children), clarity and firmness of boundaries between the generations, and family tolerance for one another. The structural model uses concurrent individual and family therapy.

General Systems Model. Based on general systems theory, a general systems model holds that families are systems and that every action in a family produces a reaction in one or more of its members. Families have external boundaries and internal rules. Every member is presumed to play a role (e.g., spokesperson, persecutor, victim, rescuer, symptom bearer, nurturer), which is relatively stable, but which member fills each role may change. Some families try to scapegoat one member by blaming him or her for the family's problems (the identified patient). If the identified patient improves, another family member may become the scapegoat. The general systems model overlaps with some of the other models presented, particularly the Bowen and structural models.

Modifications of Techniques

Family Group Therapy. Family group therapy combines several families into a single group. Families share mutual problems and compare their interactions with those of the other families in the group. Treatment of schizophrenia has been effective in multiple family groups. Parents of disturbed children may also meet together to share their situations.

Social Network Therapy. In social network therapy, the social community or network of a disturbed patient meets in group sessions with the patient. The network includes those with whom the patient comes into contact in daily life, not only the immediate family but also relatives, friends, tradespersons, teachers, and coworkers.

Paradoxical Therapy. With the paradoxical therapy approach, which evolved from the work of Gregory Bateson, a therapist suggests that the patient intentionally engage in the unwanted behavior (called the paradoxical injunction) and, for example, avoid a phobic object or perform a compulsive ritual. Although paradoxical therapy and the use of paradoxical injunctions seem to be counterintuitive, the therapy can create new insights for some patients. It is used in individual therapy as well as in family therapy.

Reframing. Reframing, also known as *positive connotation*, is a relabeling of all negatively expressed feelings or behavior as positive. When the therapist attempts to get family members to view behavior from a new frame of reference, "This child is impossible" becomes "This child is desperately trying to distract and protect you from what he or she perceives as an unhappy marriage." Reframing is an important process that allows family members to view themselves in new ways that can produce change.

Goals

Family therapy has several goals: to resolve or reduce pathogenic conflict and anxiety within the matrix of interpersonal relationships; to enhance the perception and fulfillment by family members of one another's emotional needs; to promote appropriate role relationships between the sexes and generations; to strengthen the capacity of individual members and the family as a whole to cope with destructive forces inside and outside the surrounding environment; and to influence family identity and values so that members are oriented toward health and growth. The therapy ultimately aims to integrate families into the large systems of society, extended family, and community groups and social systems, such as schools, medical facilities, and social, recreational, and welfare agencies.

COUPLES (MARITAL) THERAPY

Couples or marital therapy is a form of psychotherapy designed to psychologically modify the interaction of two persons who are in conflict with each other over one parameter or a variety of parameters—social, emotional, sexual, or economic. In couples therapy, a trained person establishes a therapeutic contract with a patient-couple and, through definite types of communication, attempts to alleviate the disturbance, to reverse or change maladaptive patterns of behavior, and to encourage personality growth and development.

Marriage counseling may be considered more limited in scope than marriage therapy: Only a particular familial conflict is discussed, and the counseling is primarily task oriented, geared to solving a specific problem, such as child rearing. Marriage therapy, by contrast, emphasizes restructuring a couple's interaction and sometimes explores the psychodynamics of each partner. Both therapy and counseling stress helping marital partners cope effectively with their problems. Most important is the definition of appropriate and realistic goals, which may involve extensive reconstruction of the union or problem-solving approaches or a combination of both.

Types of Therapies

Individual Therapy. In individual therapy, the partners may consult different therapists, who do not necessarily communicate with each other and indeed may not even know each other. The goal of treatment is to strengthen each partner's adaptive capacities. At times, only one of the partners is in treatment; and, in such cases, it is often helpful for the person who is not in treatment to visit the therapist. The visiting partner may give the therapist data about the patient that may otherwise be overlooked; overt or covert anxiety in the visiting partner as a result of change in the patient can be identified and dealt with; irrational beliefs about treatment events can be corrected; and conscious or unconscious attempts by the partner to sabotage the patient's treatment can be examined.

Individual Couples Therapy. In individual couples therapy, each partner is in therapy, which is either concurrent, with the same therapist, or collaborative, with each partner seeing a different therapist.

Conjoint Therapy. In conjoint therapy, the most common treatment method in couples therapy, either one or two therapists treat the partners in joint sessions. Cotherapy with therapists of both sexes prevents a particular patient from feeling ganged up on when confronted by two members of the opposite sex.

Four-Way Session. In a four-way session, each partner is seen by a different therapist, with regular joint sessions in which all four persons participate. A variation of the four-way session is the roundtable interview, developed by William Masters and Virginia Johnson for the rapid treatment of sexually dysfunctional couples. Two patients and two opposite-sex therapists meet regularly.

Group Psychotherapy. Group therapy for couples allows a variety of group dynamics to affect the participants. Groups usually consist of three to four couples and one or two therapists. The couples identify with one another and recognize that others have similar problems; each gains support and empathy from fellow group members of the same or opposite sex. They explore sexual attitudes and have an opportunity to gain new information from their peer groups, and each receives specific feedback about his or her behavior, either negative or positive, which may have more meaning and be better assimilated coming from a neutral, nonspouse member, for example, than from the spouse or the therapist.

During the middle phase of a couples group comprising four couples, the theme of whether to have children arose. One couple had just come from a visit to the gynecologist, who informed them that they were running out of time because of the wife's age. The woman in the couple did not want to have children, but her husband did. His complaint about the marriage was that his wife never was demonstrative in showing her loving feelings for him. He felt her to be detached, distant, and sexually inhibited.

The prevailing sentiment among the other couples who had children was that children only added additional stress to an already stressed relationship. One other couple, however, voiced their different view by describing how their children had enriched their lives.

As the talk about going forward and getting pregnant progressed, the group leader noted the nonverbal communication between the ambivalent couple. Whenever the tone of the group leaned toward having children, the wife would reach out and grasp the hand of her husband in a tender way. This invariably had the effect of stopping him from pursuing the topic for fear of the withdrawal of the affection he hungered for. All this occurred without words. Once identified, this repetitive nonverbal pattern was available for examination in the group, and the supportive elements provided by other members and the leader encouraged a frank, direct, and open conversation between the partners, who eventually chose to go forward and attempt to have a child. (Courtesy of H. I. Spitz, M.D., and S. Spitz, ACSW.)

Combined Therapy. Combined therapy refers to all or any of the preceding techniques used concurrently or in combination. Thus, a particular patient-couple may begin treatment with one or both partners in individual psychotherapy, continue in conjoint therapy with the partner, and terminate therapy after a course of treatment in a married couples' group. The rationale for combined therapy is that no single approach to marital problems has been shown to be superior to another. A familiarity with a variety of approaches thus allows therapists a flexibility that provides maximal benefit for couples in distress.

Indications

Whatever the specific therapeutic technique, initiation of couples therapy is indicated when individual therapy has failed to resolve the relationship difficulties, when the onset of distress in one or both partners is clearly a relational problem, and when couples therapy is requested by a couple in conflict. Problems in communication between partners are a prime indication for couples therapy. In such instances, one spouse may be intimidated by the other, may become anxious when attempting to tell the other about thoughts or feelings, or may project unconscious expectations onto the other. The therapy is geared toward enabling each partner to see the other realistically.

Conflicts in one or several areas, such as the partners' sexual life, are also indications for treatment. Similarly, difficulty in establishing satisfactory social, economic, parental, or emotional roles implies that a couple needs help. Clinicians should evaluate all aspects of the marital relationship before attempting to treat only one problem, which could be a symptom of a pervasive marital disorder.

Contraindications

Contraindications for couples therapy include patients with severe forms of psychosis, particularly patients with paranoid elements and those in whom the marriage's homeostatic mechanism is a protection against psychosis, marriages in which one or both partners really want to divorce, and marriages in which one spouse refuses to participate because of anxiety or fear.

Goals

Nathan Ackerman defined the aims of couples therapy as follows: The goals of therapy for partner relational problems are to alleviate emotional distress and disability and to promote the levels of well-being of both partners together and of each as an individual. Ideally, therapists move toward these goals by strengthening the shared resources for problem solving, by encouraging the substitution of adequate controls and defenses for pathogenic ones, by enhancing both the immunity against the disintegrative effects of emotional upset and the complementarity of the relationship, and by promoting the growth of the relationship and of each partner.

Part of a therapist's task is to persuade each partner in the relationship to take responsibility in understanding the psychodynamic makeup of personality. Each person's accountability for the effects of behavior on his or her own life, the life of the partner, and the lives of others in the environment is emphasized, and the result is often a deep understanding of the problems that created the marital discord.

Couples therapy does not ensure the maintenance of any marriage or relationship. Indeed, in certain instances, it may show the partners that they are in a nonviable union that should be dissolved. In these cases, couples may continue to meet with therapists to work through the difficulties of separating and obtaining a divorce, a process that has been called *divorce therapy*.

28.5 Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) is the psychosocial treatment that has received the most empirical support for patients with borderline

personality disorder. Put simply, the overarching goal of DBT is to help create a life worth living for patients who often suffer tremendously from chronic and pervasive problems across many areas of their lives. DBT is a type of psychotherapy that was originally developed for chronically self-injurious patients with borderline personality disorder and parasuicidal behavior. In recent years, its use has extended to other forms of mental illness. The method is eclectic, drawing on concepts derived from supportive, cognitive, and behavioral therapies. Some elements can be traced to Franz Alexander's view of therapy as a corrective emotional experience and other elements from certain Eastern philosophical schools (e.g., Zen).

Patients are seen weekly, with the goal of improving interpersonal skills and decreasing self-destructive behavior using techniques involving advice, metaphor, storytelling, and confrontation, among others. Patients with borderline personality disorder especially are helped to deal with the ambivalent feelings that are characteristic of the disorder. Marsha Linehan, Ph.D., developed the treatment method, based on her theory that such patients cannot identify emotional experiences and cannot tolerate frustration or rejection. As with other behavioral approaches, DBT assumes all behavior (including thoughts and feelings) is learned and that patients with borderline personality disorder behave in ways that reinforce or even reward their behavior, regardless of how maladaptive it is.

FUNCTIONS OF DBT

As described by its originator, there are five essential "functions" in treatment: (1) to enhance and expand the patient's repertoire of skillful behavioral patterns; (2) to improve patient motivation to change by reducing reinforcement of maladaptive behavior, including dysfunctional cognition and emotion; (3) to ensure that new behavioral patterns generalize from the therapeutic to the natural environment; (4) to structure the environment so that effective behaviors, rather than dysfunctional behaviors, are reinforced; and (5) to enhance the motivation and capabilities of the therapist so that effective treatment is rendered. Figure 28.5-1 illustrates how DBT breaks the cycle of problem behavior being used to avoid emotional distress.

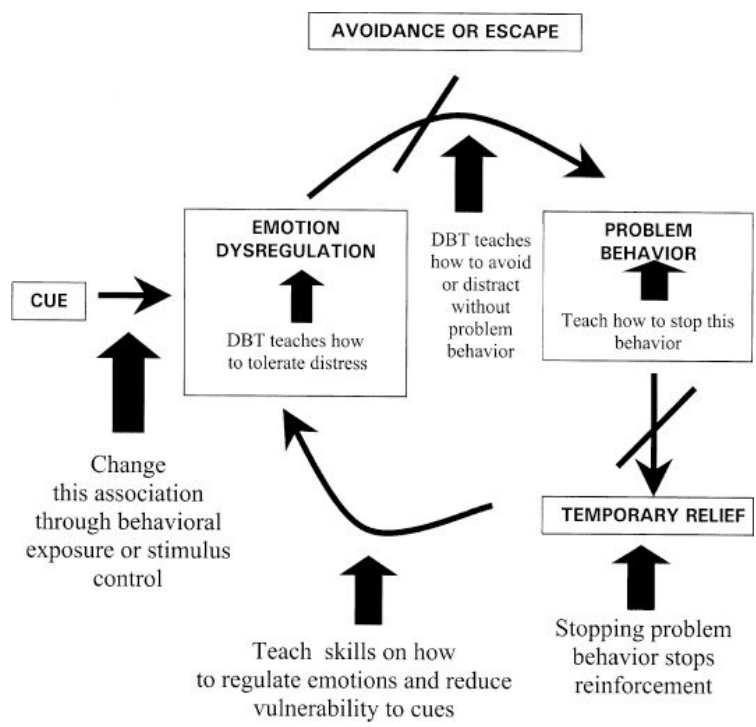

FIGURE 28.5-1
How dialectical behavior therapy (DBT) works.

The four modes of treatment in DBT are as follows: (1) group skills training, (2) individual therapy, (3) phone consultations, and (4) consultation team. These are described below. Other ancillary treatments used are pharmacotherapy and hospitalization, when needed.

Group Skills Training

In group format, patients learn specific behavioral, emotional, cognitive, and interpersonal skills. Unlike traditional group therapy, observations about others in the group are discouraged. Rather, a didactic approach, using specific exercises taken from a skills training manual, is used, many of which are geared toward control emotional dysregulation and impulsive behavior.

Individual Therapy

Sessions in DBT are held weekly, generally for 50 to 60 minutes, in which skills learned during group training are reviewed and life events from the previous week are examined. Particular attention is paid to episodes of pathological behavioral patterns that could have been corrected if learned skills had been put into effect. Patients are encouraged to record their thoughts, feelings, and behaviors on diary cards, which are analyzed in the session.

Telephone Consultation

Therapists are available for phone consultation 24 hours per day. Patients are encouraged to call when they feel themselves heading toward some crisis that might lead to injurious behavior to themselves or others. Calls are intended to be brief and usually last about 10 minutes.

Consultation Team

Therapists meet in weekly meetings to review their work with their patients. By doing so, they provide support for one another and maintain motivation in their work. The meetings enable them to compare techniques used and to validate those that are most effective (Table 28.5-1).

Table 28.5-1
Consultation Team Agreements in Dialectical Behavior Therapy

Meet weekly for 1 to 2 hours
Discuss cases according to the treatment hierarchy (i.e., self-injurious/life-threatening behavior, behaviors that interfere with treatment or quality of life).
Accept a dialectical philosophy.
Consult with the patient on how to interact with other therapists, but do not tell other therapists how to interact with the patient.
Consistency of therapists with one another (even across the same patient) is not expected.
All therapists observe their own limits without fear of judgmental reactions from other consultation group members.
Search for nonpejorative empathic interpretation of the patient's behavior.
All therapists are fallible.

RESULTS

Several studies evaluating the effect of DBT for patients with borderline personality disorder found that such therapy was positive. Patients had a low dropout rate from treatment; the incidence of parasuicidal behaviors declined; self-report of angry affect decreased; and social adjustment and work performance improved. The method is now being applied to other disorders, including substance abuse, eating disorders, schizophrenia, and posttraumatic stress disorder.

28.6 Biofeedback

Biofeedback involves the recording and display of small changes in the physiological levels of the feedback parameter. The display can be visual, such as a big meter or a bar of lights, or auditory. Patients are instructed to change the levels of the parameter, using the feedback from the display as a guide. Biofeedback is based on the idea that the autonomic nervous system can come under voluntary control through operant conditioning. Biofeedback can be used by itself or in combination with relaxation. For example, patients with urinary incontinence use biofeedback alone to regain control over the pelvic musculature. Biofeedback is also used in the rehabilitation of neurological disorders. The benefits of biofeedback may be augmented by the relaxation that patients are trained to facilitate.

THEORY

Neal Miller demonstrated the medical potential of biofeedback by showing that the normally involuntary autonomic nervous system can be operantly conditioned by use of appropriate feedback. By means of instruments, patients acquire information about the status of involuntary biological functions, such as skin temperature and electrical conductivity, muscle tension, blood pressure, heart rate, and brain wave activity. Patients then learn to regulate one or more of these biological states that affect symptoms. For example, a person can learn to raise the temperature of his or her hands to reduce the frequency of migraines, palpitations, or angina pectoris. Presumably, patients lower the sympathetic activation and voluntarily self-regulate arterial smooth muscle vasoconstrictive tendencies.

METHODS

Instrumentation

The feedback instrument used depends on the patient and the specific problem. The most effective instruments are the electromyogram (EMG), which measures the electrical potentials of muscle fibers; the electroencephalogram (EEG), which measures alpha waves that occur in relaxed states; the galvanic skin response (GSR) gauge, which shows decreased skin conductivity during a relaxed state; and the thermistor, which measures skin temperature (which drops during tension because of peripheral vasoconstriction). Patients are attached to one of the instruments that measures a physiological function and translates the measurement into an audible or visual signal that patients use to gauge their responses. For example, in the treatment of bruxism, an EMG is attached to the masseter muscle. The EMG emits a high tone when the muscle is contracted and a low tone when at rest. Patients can learn to alter the tone to indicate relaxation. Patients receive feedback about the masseter muscle, the tone reinforces the learning, and the condition ameliorates—all of these events interacting synergistically.

Many less-specific clinical applications (e.g., treating insomnia, dysmenorrhea, and speech problems; improving athletic performance; treating volitional disorders; achieving altered states of consciousness; managing stress; and supplementing psychotherapy for treating anxiety associated with somatic symptom and related disorders) use a model in which frontalis muscle EMG biofeedback is combined with thermal biofeedback and verbal instructions in progressive relaxation. [Table 28.6-1](#) outlines some important clinical applications of biofeedback and shows that a wide variety of biofeedback modalities have been used to treat numerous conditions.

 **Table 28.6-1**
Biofeedback Applications

Condition	Effects
Asthma	Both frontal electromyogram (EMG) and airway resistance biofeedback have been reported as producing relaxation from the panic associated with asthma, as well as improving air flow rate.
Cardiac arrhythmias	Specific biofeedback of the electrocardiogram has permitted patients to lower the frequency of premature ventricular contractions.
Fecal incontinence and enuresis	The timing sequence of internal and external anal sphincters has been measured, using triple lumen rectal catheters providing feedback to incontinent patients to allow them to reestablish normal bowel habits in a relatively small number of biofeedback sessions. An actual precursor of biofeedback dating to 1938 was a buzzer sounding for sleeping enuretic children at the first sign of moisture (the pad and bell).
Grand mal epilepsy	A number of electroencephalogram (EEG) biofeedback procedures have been used experimentally to suppress seizure activity prophylactically in patients not responsive to anticonvulsant medication. The procedures permit patients to enhance the sensorimotor brain wave rhythm or to normalize brain activity as computed in real-time power spectrum displays.
Hyperactivity	EEG biofeedback procedures have been used with children with attention-deficit/hyperactivity disorder to train them to reduce their motor restlessness.
Idiopathic hypertension and orthostatic hypotension	A variety of specific (direct) and nonspecific biofeedback procedures—including blood pressure feedback, galvanic skin response, and foot-hand thermal feedback combined with relaxation procedures—have been used to teach patients to increase or decrease their blood pressure. Some follow-up data indicate that the changes may persist for years and often permit the reduction or elimination of antihypertensive medications.
Migraine	The most common biofeedback strategy with classic or common vascular headaches has been thermal biofeedback from a digit accompanied by autogenic self-suggestive phrases encouraging hand warming and head cooling. The mechanism is thought to help prevent excessive cerebral artery vasoconstriction, often accompanied by an ischemic prodromal symptom, such as scintillating scotomata, followed by rebound engorgement of arteries and stretching of vessel wall pain receptors.
Myofacial and temporomandibular joint (TMJ) pain	High levels of EMG activity over the powerful muscles associated with bilateral TMJs have been decreased, using biofeedback in patients who are jaw clencher or have bruxism.
Neuromuscular rehabilitation	Mechanical devices or an EMG measurement of muscle activity displayed to a patient increases the effectiveness of traditional therapies, as documented by relatively long clinical histories in peripheral nerve-muscle damage, spasmodic torticollis, selected cases of tardive dyskinesia, cerebral palsy, and upper motor neuron hemiplegias.
Raynaud's syndrome	Cold hands and cold feet are frequent concomitants of anxiety and also occur in Raynaud's syndrome, caused by vasospasm of arterial smooth muscle. A number of studies report that thermal feedback from the hand, an inexpensive and benign procedure compared with surgical sympathectomy, is effective in about 70 percent of cases of Raynaud's syndrome.
Tension headaches	Muscle contraction headaches are most frequently treated with two large active electrodes spaced on the forehead to provide visual or auditory information about the levels of muscle tension. The frontal electrode placement is sensitive to EMG activity regarding the frontalis and occipital muscles, which the patient learns to relax.

Relaxation Therapy

Muscle relaxation is used as a component of treatment programs (e.g., systematic desensitization) or as treatment in its own right (relaxation therapy). Relaxation is characterized by (1) immobility of the body, (2) control over the focus of attention, (3) low muscle tone, and (4) cultivation of a specific frame of mind, described as contemplative, nonjudgmental, detached, or mindful.

Progressive relaxation was developed by Edmund Jacobson in 1929. Jacobson observed that when an individual lies “relaxed,” in the ordinary sense, the following clinical signs reveal the presence of residual tension: respiration is slightly irregular in time or force; the pulse rate, although often normal, is in some instances moderately increased as compared with later tests; voluntary or local reflex activities are revealed in such slight marks as wrinkling of the forehead, frowning, movements of the eyeballs frequent or rapid winking, restless shifting of the head, a limb, or even a finger; and finally, the mind continues to be active, and once started, worry or oppressive emotion will persist. It is amazing that a faint degree of tension can be responsible for all of this.

Learning relaxation, therefore, involves cultivating a muscle sense. To develop the muscle sense further, patients are taught to isolate and contract specific muscles or muscle groups, one at a time. For example, patients flex the forearm while the therapist holds it back to observe tenseness in the biceps muscle. (Jacobson used the word “tenseness” rather than “tension” to emphasize the patient’s role in tensing the muscles.) Once this sensation is reported, Jacobson would say, “This is your doing! What we wish is the reverse of this—simply not doing.” Patients are repeatedly reminded that relaxation involves no effort. In fact “making an effort is being tense and therefore is not to relax.” As the session progresses, patients are instructed to let go further and further, even past the point when the body part seems perfectly relaxed.

Patients would work in this fashion with different muscle groups, often over more than 50 sessions. For example, an entire session might be devoted to relaxing the biceps muscle. Another feature of Jacobson’s method was that instructions were given tersely so they would not interfere with a patient’s focus on muscle sensations; suggestions commonly used today (e.g., “*Your arm is becoming limp*”) were avoided. Patients were also frequently left alone, while the therapist attended to other patients.

In psychiatry, relaxation therapy is mainly used as a component of multifaceted broad-spectrum programs. Its use in desensitization was mentioned previously. Relaxing breathing exercises are often helpful for patients with panic disorder, especially when considered to be related to hyperventilation. In the treatment of patients with anxiety disorders, relaxation can serve as an occasion-setting stimulus (i.e., as a context of safety in which other specific intervention can be confidently tried).

Later Adaptation of Progressive Muscular Relaxation

Joseph Wolpe chose progressive relaxation as a response incompatible with anxiety when designing his systematic desensitization treatment (discussed below). For this purpose, Jacobson’s original method was too lengthy to be practical. Wolpe abbreviated the program to 20 minutes during the first six sessions (devoting the remainder of these sessions to other things, such as behavioral analysis). In a later modification of progressive relaxation, patients completed work with all the principal muscle groups in one session. The specific muscle groups and instructions for this type of progressive relaxation are listed in [Table 28.6-2](#). Once patients have mastered this procedure (typically after three sessions), these groups are combined into larger groups. Finally, patients practice relaxation by recall (i.e., without tensing the muscles).

Table 28.6-2
Outline of Initial Progressive Relaxation Session, All Muscle Groups

Muscle Group	Instruction
Dominant hand and forearm	Make a tight fist, now
Dominant biceps, triceps	Make your upper arm tense by counter-posing muscles
Nondominant arm, forearm	Make a tight fist, now
Nondominant biceps	Make your upper arm tense by counter-posing muscles
Forehead	Lift eyebrows
Orbital and nose muscles	Squint and wrinkle your nose
Lower cheeks and jaws	Bite your teeth together and pull the corners of your mouth back
Neck and throat	Pull your chin toward your chest, but prevent it from happening by counter-posing muscles in front and back
Chest, shoulders, upper back	Take a deep breath, hold it, and pull the shoulder blades upward (if sitting) or backward (if supine)
Abdominal or stomach region	Make your stomach hard, as if you were going to hit yourself
Dominant thigh	Counter-pose extensors and flexors
Dominant lower leg	Dorsiflex foot
Dominant foot	Curl toes upward (not down to avoid cramps)
Nondominant thigh	Counter-pose extensors and flexors
Nondominant calf	Dorsiflex foot
Nondominant foot	Curl toes upward (not down, to avoid cramps)

(Adapted from Bernstein DA, Borkovec TD. *Progressive Relaxation Training: A Manual for the Helping Professions*. Champaign, IL: Research Press; 1973, with permission.)

Autogenic Training

Autogenic training is a method of self-suggestion that originated in Germany. It involves the patients directing their attention to specific bodily areas and hearing themselves think certain phrases reflecting a relaxed state. In the original German version, patients progressed through six themes over many sessions. The six areas are listed in [Table 28.6-3](#) along with representative autogenic phrases. Autogenic relaxation is an American modification of autogenic training, in which all six areas are covered in one session.

 **Table 28.6-3**
Sample Autogenic Phrases

Theme	Examples of Self-Statements
Heaviness	"My left arm is heavy."
Warmth	"My left arm is warm."
Cardiac regulation	"My heartbeat is calm and regular."
Breathing adjustment	"It breathes me."
Solar plexus	"My solar plexus is warm."
Forehead	"My forehead is cool."

Applied Tension

Applied tension is a technique that is the opposite of relaxation; applied tension can be used to counteract the fainting response. The treatment extends over four sessions. In the first session, patients learn to tense the muscles of the arms, legs, and torso for 10 to 15 seconds (as if they were bodybuilders). The tension is maintained long enough for a sensation of warmth to develop in the face. The patients then release the tension, but do not progress to a state of relaxation. The maneuver is repeated five times at half-minute intervals. This method can be augmented with feedback of the patient's blood pressure during the muscle contraction; increased blood pressure suggests that appropriate muscle tension was achieved. The patients continue to practice the technique five times a day. An adverse effect of treatment that sometimes develops is headache. In this case, the intensity of the muscle contraction and the frequency of treatment are reduced.

Patients with blood and injury phobia show a unique, biphasic response when exposed to a phobic stimulus. The first phase is associated with increased heart rate and blood pressure. In the second phase, however, blood pressure suddenly falls and the patient faints. To treat the problem, patients are shown a series of slides that are provocative (e.g., mutilated bodies). They are coached in identifying early warning signs of fainting, such as queasiness, cold sweats, or dizziness, and in applying the learned muscle tension response quickly, contingent on these warning signs. Patients can also perform applied tension while donating blood or watching a surgical operation. The technique of isometric tension raises blood pressure, which prevents fainting.

Applied Relaxation

Applied relaxation involves eliciting a relaxation response in the stressful situation itself. The previous discussion showed that this is not advisable right away because of the possible ironic effects of relaxation. Therefore, patients should first practice relaxation in nonstressful circumstances. The method developed by Lars-Göran Öst and coworkers in Sweden has been proven efficacious for panic disorder and generalized anxiety disorder. Establishing the relaxation response in the patient's natural environment consists of seven phases of one to two sessions each: progressive relaxation, release-only relaxation, cue-controlled relaxation, differential relaxation, rapid relaxation, application training, and maintenance. Details are provided in [Table 28.6-4](#).

 **Table 28.6-4**
Steps in Applied Relaxation

Technique	Instructions
Progressive relaxation	Session 1: hands, arms, face, neck, and shoulders Session 2: back, chest, stomach, breathing, hips, legs, and feet
Release-only relaxation	As with progressive relaxation, except that the tension phase is omitted; when release-only relaxation is mastered, the patient can relax within 5 to 7 minutes
Cue-controlled relaxation	A stimulus—the word <i>relax</i> —is presented just before exhalation; patients focus on their breathing while already in a relaxed state; the therapist says the word <i>inhale</i> just before each inhalation and the word <i>relax</i> just before each exhalation; after approximately five cycles, the patient mentally says these words (optionally dropping the <i>inhale</i>)
Differential relaxation	Patients can remain relaxed and move at the same time by differentially keeping muscles unrelated to the movement in a relaxed state; after achieving a relaxed state, patients lift an arm or a leg or look around in the room, while keeping movements and tension in other body parts at a minimum; patients also perform differential relaxation in other settings, including sitting in different chairs, sitting at a desk while writing, talking on the phone, and walking.
Rapid relaxation	Patients relax by taking one to three breaths with slow exhalations, thinking the word <i>relax</i> before each exhalation and scanning their bodies for areas of tension; with this practice, relaxation is shortened to 20 to 30 seconds; patients are instructed to relax in this manner 15 to 20 times per day at certain predetermined events in their natural environment (e.g., when they look at a watch or make a telephone call. As a reminder, colored dots might be taped on the watch or phone. After some time, the dots are changed to a different color to keep their reminding power fresh).
Application training	Patients relax just before entering the target situation; they stay in the situation for 10 to 15 minutes, using their relaxation skills as a coping technique; patients may initially be accompanied by the therapist; alternatively, if the patient's problem is panic attacks or generalized anxiety, imagery or physical exercise is used to induce fearful sensations, which then are used for application training.

RESULTS

Biofeedback, progressive relaxation, and applied tension have been shown to be effective treatment methods for a broad range of disorders. They form one basis of behavioral medicine in which the patient changes (or learns how to change) behavior that contributes to illness. They form a basis on which many complementary and alternative medical procedures are effective (e.g., yoga and Reiki) in which relaxation is an important component. Relaxation also informs more mainstream treatments, such as hypnosis.

28.7 Cognitive Therapy

A central feature of the cognitive theory of emotional disorders is its emphasis on the psychological significance of people's beliefs about themselves, their personal world (including the people in their lives), and their future—the “cognitive triad.” When people experience excessive, maladaptive emotional distress, it is linked to their problematic, stereotypic, biased interpretations pertinent to this cognitive triad of self, world, and future. For example, clinically depressed patients may be prone to believe that they are incapable and helpless and to

view others as being judgmental and critical and the future as being bleak and unrewarding. Similarly, patients with anxiety disorders may be apt to see themselves as highly vulnerable, others as more capable, and the future as likely to be characterized by personal disasters.

Although the patient's viewpoints are flawed and dysfunctional, they nonetheless tend to be perpetuated by cognitive processes that maintain them. Cognitive therapy is a short-term, structured therapy that uses active collaboration between patient and therapist to achieve its therapeutic goals, which are oriented toward current problems and their resolution. Cognitive therapy is used with depression, panic disorder, obsessive-compulsive disorder, personality disorders, and somatoform disorders. Therapy is usually conducted on an individual basis, although group methods are sometimes helpful. A therapist may also prescribe drugs in conjunction with therapy.

The treatment of depression can serve as a paradigm of the cognitive approach. Cognitive therapy assumes that perception and experiencing, in general, are active processes that involve both inspective and introspective data. The patient's cognitions represent a synthesis of internal and external stimuli. The way persons appraise a situation is generally evident in their cognitions (thoughts and visual images). Those cognitions constitute their stream of consciousness or phenomenal field, which reflects their configuration of themselves, their world, their past, and their future.

Alterations in the content of their underlying cognitive structures affect their affective state and behavioral pattern. Through psychological therapy, patients can become aware of their cognitive distortions. Correction of faulty dysfunctional constructs can lead to clinical improvement.

COGNITIVE THEORY OF DEPRESSION

According to the cognitive theory of depression, cognitive dysfunctions are the core of depression, and affective and physical changes and other associated features of depression are consequences of cognitive dysfunctions. For example, apathy and low energy result from a person's expectation of failure in all areas. Similarly, paralysis of will stems from a person's pessimism and feelings of hopelessness. From a cognitive perspective, depression can be explained by the cognitive triad, which explains that negative thoughts are about the self, the world, and the future.

The goal of therapy is to alleviate depression and to prevent its recurrence by helping patients to identify and test negative cognitions, to develop alternative and more flexible schemas, and to rehearse both new cognitive and behavioral responses. Changing the way a person thinks can alleviate the psychiatric disorder.

STRATEGIES AND TECHNIQUES

Therapy is relatively short and lasts about 25 weeks. If a patient does not improve in this time, the diagnosis should be reevaluated. Maintenance therapy can be carried out over years. As with other psychotherapies, therapists' attributes are important to successful therapy. Therapists must exude warmth, understand the life experience of each patient, and be genuine and honest with themselves and with their patients. They must be able to relate skillfully and interactively with their patients. Cognitive therapists set the agenda at the beginning of each session, assign homework to be performed between sessions, and teach new skills. Therapist and patient collaborate actively (Table 28.7-1). The three components of cognitive therapy are didactic aspects, cognitive techniques, and behavioral techniques.

 **Table 28.7-1**
Cognitive Psychotherapy

Goal	Identify and alter cognitive distortions that maintain symptoms
Selection criteria	Primarily used in dysthymic disorder Nonendogenous depressive disorders Symptoms not sustained by pathological family
Duration	Time-limited, usually 15 to 25 weeks, once-weekly meetings
Techniques	Collaborative empiricism Structured and directive Assigned readings Homework and behavioral techniques Identification of irrational beliefs and automatic thoughts Identification of attitudes and assumptions underlying negatively biased thoughts

(Reprinted from Ursano RJ, Silberman EK. Individual psychotherapies. In: Talbott JA, Hales RE, Yudofsky SC, eds. *The American Psychiatric Press Textbook of Psychiatry*. Washington, DC: American Psychiatric Press; 1988:872, with permission.)

Didactic Aspects

The therapy's didactic aspects include explaining to patients the cognitive triad, schemas, and faulty logic. Therapists must tell patients that they will formulate hypotheses together and test them over the course of the treatment. Cognitive therapy requires a full explanation of the relation between depression and thinking, affect, and behavior, as well as the rationale for all aspects of treatment. This explanation contrasts with psychoanalytically oriented therapies, which require little explanation.

Cognitive Techniques

The therapy's cognitive approach includes four processes: eliciting automatic thoughts, testing automatic thoughts, identifying maladaptive underlying assumptions, and testing the validity of maladaptive assumptions.

Eliciting Automatic Thoughts. Automatic thoughts, also called *cognitive distortions*, are cognitions that intervene between external events and a person's emotional reaction to the event. For example, the belief that "people will laugh at me when they see how badly I bowl!" is an automatic thought that occurs to someone who has been asked to go bowling and responds negatively. Another example is the thought "She doesn't like me" when someone passes in the hall without saying "Hello." Every psychopathological disorder has its own specific cognitive profile of distorted thought, which, if known, provides a framework for specific cognitive interventions (Table 28.7-2).

 **Table 28.7-2**
Cognitive Profile of Psychiatric Disorders

Disorder	Core Belief
Depressive disorder	Negative view of self, experience, and future
Hypomanic episode	Inflated view of self, experience, and future
Anxiety disorders	Fear of physical or psychological danger
Panic disorder	Catastrophic misinterpretation of bodily and mental experiences
Phobias	Danger in specific, avoidable situations
Paranoid personality disorder	Negative bias, interference, and so forth by others
Conversion disorder	Concept of motor or sensory abnormality
Obsessive-compulsive disorder	Repeated warning or doubting about safety and repetitive acts to ward off threat
Suicidal behavior	Hopelessness and deficit in problem solving
Anorexia nervosa	Fear of being fat or unshapely
Hypochondriasis	Attribution of serious medical disorder

(Courtesy of Aaron Beck, M.D., and A. John Rush, M.D.)

Testing Automatic Thoughts. Acting as a teacher, a therapist helps a patient test the validity of automatic thoughts. The goal is to encourage the patient to reject inaccurate or exaggerated automatic thoughts after careful examination. Patients often blame themselves when things that are outside their control go awry. The therapist reviews the entire situation with the patient and helps reassign the blame or cause of the unpleasant events. Generating alternative explanations for events is another way of undermining inaccurate and distorted automatic thoughts.

Identifying Maladaptive Assumptions. As the patient and therapist continue to identify automatic thoughts, patterns usually become apparent. The patterns represent rules or maladaptive general assumptions that guide a patient's life. Samples of such rules are "In order to be happy, I must be perfect" and "If anyone doesn't like me, I'm not lovable." Such rules inevitably lead to disappointments and failure and, ultimately, to depression (Fig. 28.7-1).

Testing the Validity of Maladaptive Assumptions. Testing the accuracy of maladaptive assumptions is similar to testing the validity of automatic thoughts. In a particularly effective test, therapists ask patients to defend the validity of their assumptions. For example, patients may state that they should always work up to their potential, and a therapist may ask "Why is that so important to you?" Table 28.7-3 gives examples of some interventions designed to elicit, identify, test, and correct the cognitive distortions that lead to depressive and other painful affects.

Table 28.7-3
Cognitive Errors Derived from Assumptions

Cognitive Error	Assumption	Intervention
Overgeneralizing	If it's true in one case, it applies to any case that is even slightly similar.	Exposure of faulty logic. Establish criteria of which cases are similar to what degree.
Selective abstraction	The only events that matter are failures, deprivation, etc. Should measure self by errors, weaknesses, etc.	Use log to identify successes patient forgot.
Excessive responsibility (assuming personal causality)	I am responsible for all bad things, failures, etc.	Disattribution technique.
Assuming temporal causality (predicting without sufficient evidence)	If it has been true in the past, it's always going to be true.	Expose faulty logic. Specify factors that could influence outcome other than past events.
Self-references	I am the center of everyone's attention—especially my bad performances. I am the cause of misfortunes.	Establish criteria to determine when patient is the focus of attention and also the probable facts that cause bad experiences.
Catastrophizing	Always think of the worst. It's almost likely to happen to you.	Calculate real probabilities. Focus on evidence that the worst did not happen.
Dichotomous thinking	Everything is either one extreme or another (black or white, good or bad).	Demonstrate that events may be evaluated on a continuum.

(From Beck AT, Rush AJ, Shaw BF, Emery G. *Cognitive Therapy of Depression*. New York: Guilford; 1979:48, with permission.)

A woman presented for therapy with anger control problems. She had sent a slew of hostile voicemail and e-mail messages to a colleague, had alienated her neighbors with her complaints about noise, and had been asked to leave her bowling league after two physical altercations with members of other teams. A careful review of the patient's thoughts and beliefs surrounding these situations revealed a common denominator of a sense of *mistrust* and *entitlement*. In each situation, she believed that the persons who were the objects of her anger had gone out of their way to mistreat her. Furthermore, she had an exaggerated sense of self-importance represented by beliefs such as, "Nobody has the right to treat me that way," "I shouldn't have to deal with these people and their stupidity," and "I have to show them they can't ever push me around." To this patient, her anger was justified, as she was trying to defend herself from the misbehavior of others. However, to the outside observer, the patient was a "loose cannon" who took offense at the drop of a hat and whose behavior was outrageous and indefensible. In therapy, the patient at first was not open to viewing her anger problem in the manner just described. However, as she learned to recognize the activation of her schemas of *mistrust* and *entitlement*, she became more willing to consider ways in which she could modify her viewpoints and behaviors. This positive change was facilitated by the therapist's empathic responses to the patient's more credible stories of mistreatment she had received from her family, whose abusive behavior gave her the message that she should never trust anyone and that she should never put up with being mistreated again. (Courtesy of C. F. Newman, Ph.D., and A. T. Beck, M.D.)

AUTOMATIC THOUGHT RECORD

Directions: When you notice your mood getting worse, ask yourself, "What's going through my mind right now?" and as soon as possible jot down the thought or mental image in the Automatic Thoughts column.

DATE/ TIME	SITUATION	AUTOMATIC THOUGHT(S)	EMOTION(S)	ALTERNATIVE RESPONSE	OUTCOME
	1. What event, dysfunction, or recollection led to the unpleasant emotion? 2. What (if any) distressing physical sensations did you have?	1. What thought(s) and/or image(s) went through your mind? 2. How much do you believe each one at the time?	1. What emotion(s) (sad, anxious, angry, etc.) did you feel at the time? 2. How intense (0-100%) was the emotion?	1. (optional) What cognitive distortion did you make? (e.g., all-or-nothing thinking, mind-reading, catastrophizing) 2. Use questions at bottom to compose a response to the automatic thought(s). 3. How much do you believe each response?	1. How much do you now believe each automatic thought? 2. What emotion(s) do you feel now? How intense (0-100%) is the emotion? 3. What will or did you do?
Friday 7:30 PM	I called Sally to go out, as we talked about. I got her answering machine. Felt a sinking sensation.	1) They have all gone out and forgotten about me, because I'm not important to them anymore. (90% believable) 2) I'm left out again. (90% believable) 3) I'm going to have to spend another Friday night alone. (100% believable) 4) I just don't fit in anywhere in this world. (70% believable)	1) Angry (60% intensity) 2) Lonely (95% intensity) 3) Depressed (95% intensity)	I'm engaging in arbitrary inference, overgeneralization, personalization, and catastrophization. 1) It could all be an innocent misunderstanding. (40% believable) 2) I have spent a lot of time with Sally and the others and I know they like me. (60% believable) 3) Being at home alone is not the end of the world. (50% believable)	1) 30% 2) 10% 3) 50% 4) 0% Angry (5%) Lonely (40%) Depressed (20%) Calm (70%) I will call back in an hour if I don't hear from Sally.

Questions to help compose an alternative response: (1) What is the evidence that the automatic thought is true? Not true? (2) Is there an alternative explanation? (3) What's the worst that could happen? Could I live through it? What's the best that could happen? What's the most realistic outcome? (4) What's the effect of my believing the automatic thought? What could be the effect of changing my thinking? (5) What should I do about it? (6) If _____ (friend's name) was in the situation and had this thought, what would I tell him/her?

Sample automatic thought record.

Behavioral Techniques

Behavioral and cognitive techniques go hand in hand; behavioral techniques test and change maladaptive and inaccurate cognitions. The overall purposes of such techniques are to help patients understand the inaccuracy of their cognitive assumptions and learn new strategies and ways of dealing with issues.

Among the behavioral techniques in cognitive therapy are scheduling activities, mastery and pleasure, graded task assignments, cognitive rehearsal, self-reliance training, role playing, and diversion techniques. One of the first things done in therapy is to schedule activities on an hourly basis. Patients keep records of the activities and review them with the therapist. In addition to scheduling activities, patients are asked to rate the amount of mastery and pleasure their activities bring them. Patients are often surprised to learn that they have much more mastery of activities and enjoy them more than they had thought.

To simplify the situation and allow miniaccomplishments, therapists often break tasks into subtasks, as in graded task assignments, to show patients that they can succeed. In cognitive rehearsal, patients imagine and rehearse the various steps in meeting and mastering a challenge.

Patients (especially inpatients) are encouraged to become self-reliant by doing such simple things as making their own beds, doing their own shopping, and preparing their own meals. This process is called self-reliance training. Role playing is a particularly powerful and useful technique to elicit automatic thoughts and to learn new behaviors. Diversion techniques are useful in helping patients get through difficult times and include physical activity, social contact, work, play, and visual imagery.

Imagery or thought stoppage can treat impulsive or obsessive behavior. For instance, patients imagine a stop sign with a police officer nearby or another image that evokes inhibition at the same time that they recognize an impulse or obsession that is alien to the ego. Similarly, obesity can be treated by having patients visualize themselves as thin, athletic, trim, and well muscled, and then training them to evoke this image whenever they have an urge to eat. Hypnosis or autogenic training can enhance such imagery. In a technique called guided imagery, therapists encourage patients to have fantasies that can be interpreted as wish fulfillments or attempts to master disturbing affects or impulses.

EFFICACY

Cognitive therapy can be used alone in the treatment of mild to moderate depressive disorders or in conjunction with antidepressant medication for major depressive disorder. Studies have clearly shown that cognitive therapy is effective and in some cases is superior or equal to medication alone. It is one of the most useful psychotherapeutic interventions currently available for depressive disorders, and it shows promise in the treatment of other disorders.

Cognitive therapy has also been studied as a way of increasing compliance with lithium (Eskalith) prescription by patients with bipolar I disorder and as an adjunct in treating withdrawal from heroin. Table 28.7-4 outlines Beck's criteria for determining when cognitive therapy is indicated.

Table 28.7-4
Indications for Cognitive Therapy

Criteria that justify the administration of cognitive therapy alone:

- Failure to respond to adequate trials of two antidepressants
- Partial response to adequate dosages of antidepressants
- Failure to respond or only a partial response to other psychotherapies
- Diagnosis of dysthymic disorder
- Variable mood reactive to environmental events
- Variable mood that correlates with negative cognitions
- Mild somatoform disorders (sleep, appetite, weight, libidinal)
- Adequate reality testing (i.e., no hallucinations or delusions), span of concentration, and memory function
- Inability to tolerate medication effects or evidence that excessive risk is associated with pharmacotherapy

Features that suggest cognitive therapy alone is not indicated:

- Evidence of coexisting schizophrenia, dementia, substance-related disorders, mental retardation
- Patient has medical illness or is taking medication that is likely to cause depression
- Obvious memory impairment or poor reality testing (hallucinations, delusions)
- History of manic episode (bipolar I disorder)
- History of family member who responded to antidepressant
- History of family member with bipolar I disorder
- Absence of precipitating or exacerbating environmental stresses
- Little evidence of cognitive distortions
- Presence of severe somatoform disorders (e.g., pain disorder)

Indications for combined therapies (medication plus cognitive therapy):

- Partial or no response to trial of cognitive therapy alone
- Partial but incomplete response to adequate pharmacotherapy alone
- Poor compliance with medication regimen
- Historical evidence of chronic maladaptive functioning with depressive syndrome on intermittent basis
- Presence of severe somatoform disorders and marked cognitive distortions (e.g., hopelessness)
- Impaired memory and concentration and marked psychomotor difficulty
- Major depressive disorder with suicidal danger
- History of first-degree relative who responded to antidepressants
- History of manic episode in relative or patient

28.8 Behavior Therapy

The term *behavior* in *behavior therapy* refers to a person's observable actions and responses. Behavior therapy involves changing the behavior of patients to reduce dysfunction and to improve quality of life. Behavior therapy includes a methodology, referred to as *behavior analysis*, for the strategic selection of behaviors to change, and a technology to bring about behavior change, such as modifying antecedents or consequences or giving instructions. Behavior therapy has not only influenced mental health care, but, under the rubric of behavioral medicine, it has also made inroads into other medical specialties.

Behavior therapy represents clinical applications of the principles developed in learning theory. Behavioral psychology, or behaviorism, arose in the early 20th century in reaction to the method of introspection that dominated psychology at the time. John B. Watson, the father of behaviorism, had initially studied animal psychology. This background made it a small conceptual leap to argue that psychology should concern itself only with publicly observable phenomena (i.e., overt behavior). According to behavioristic thinking, because mental content is not publicly observable, it cannot be subjected to rigorous scientific inquiry. Consequently, behaviorists developed a focus on overt behaviors and their environmental influences.

Today, different behavioral schools continue to share a focus on verifiable behavior. Behavioral views differ from cognitive views in holding that physical, rather than mental, events control behavior. According to behaviorism, mental phenomena or speculations about them are of little or no scientific interest.

HISTORY

As early as the 1920s, scattered reports about the application of learning principles to the treatment of behavioral disorders began to appear, but they had little effect on the mainstream of psychiatry and clinical psychology. Not until the 1960s did behavior therapy emerge as a systematic and comprehensive approach to psychiatric (behavioral) disorders; at that time, it arose independently on three continents.

Joseph Wolpe and his colleagues in Johannesburg, South Africa, used Pavlovian techniques to produce and eliminate experimental neuroses in cats. From this research, Wolpe developed systematic desensitization, the prototype of many current behavioral procedures for the treatment of maladaptive anxiety produced by identifiable stimuli in the environment. At about the same time, a group at the Institute of Psychiatry of the University of London, particularly Hans Jurgen Eysenck and M. B. Shapiro, stressed the importance of an empirical, experimental approach to understanding and treating individual patients, using controlled, single-case experimental paradigms and modern learning theory. The third origin of behavior therapy was work inspired by the research of Harvard psychologist B. F. Skinner. Skinner's students began to apply his operant-conditioning technology, developed in animal-conditioning laboratories, to human beings in clinical settings.

SYSTEMATIC DESENSITIZATION

Developed by Wolpe, systematic desensitization is based on the behavioral principle of counterconditioning, whereby a person overcomes maladaptive anxiety elicited by a situation or an object by approaching the feared situation gradually, in a psychophysiological state that inhibits anxiety. In systematic desensitization, patients attain a state of complete relaxation and are then exposed to the stimulus that elicits the anxiety response. The negative reaction of anxiety is inhibited by the relaxed state, a process called *reciprocal inhibition*. Rather than using actual situations or objects that elicit fear, patients and therapists prepare a graded list or hierarchy of anxiety-provoking scenes associated with a patient's fears. The learned relaxation state and the anxiety-provoking scenes are systematically paired in treatment. Thus, systematic desensitization consists of three steps: relaxation training, hierarchy construction, and desensitization of the stimulus.

Relaxation Training

Relaxation produces physiological effects opposite to those of anxiety: slow heart rate, increased peripheral blood flow, and neuromuscular stability. A variety of relaxation methods have been developed. Some, such as yoga and Zen, have been known for centuries. Most methods use so-called progressive relaxation, developed by the psychiatrist Edmund Jacobson. Patients relax major muscle groups in a fixed order, beginning with the small muscle groups of the feet and working cephalad or vice versa. Some clinicians use hypnosis to facilitate relaxation or use tape-recorded exercise to allow patients to practice relaxation on their own. Mental imagery is a relaxation method in which patients are instructed to imagine themselves in a place associated with pleasant, relaxed memories. Such images allow patients to enter a relaxed state or experience (as Herbert Benson termed it) the *relaxation response*.

The physiological changes that take place during relaxation are the opposite of those induced by the adrenergic stress responses that are part of many emotions. Muscle tension, respiration rate, heart rate, blood pressure, and skin conductance decrease. Finger temperature and blood flow to the finger usually increase. Relaxation increases respiratory heart rate variability, an index of parasympathetic tone.

Hierarchy Construction

When constructing a hierarchy, clinicians determine all the conditions that elicit anxiety, and then patients create a hierarchy list of 10 to 12 scenes in order of increasing anxiety. For example, an acrophobic hierarchy may begin with a patient's imagining standing near a window on the second floor and end with being on the roof of a 20-story building, leaning on a guard rail and looking straight down. Table 28.8-1 provides an example of a hierarchy construction for fear of water and heights.

 **Table 28.8-1**
Hierarchy Construction (Least Anxious to Most Anxious): Fear of Water and Heights

- | | |
|---|--|
| 1. Taking a bath at home. | 22. Several jumps at 6 feet and 7 feet, alternating them, and then remaining at the 7-foot depth. |
| 2. Taking a shower at home. | 23. Going onto the first diving board and jumping into the water. |
| 3. Going into the shallow end of the swimming pool. | 24. Jumping off the first diving board, then diving from the first board. |
| 4. Starting to swim at the shallow end of the swimming pool, breaststroke only. | 25. Diving off the first board. |
| 5. Swimming at the shallow end, doing the crawl. | 26. Jumping from the first diving board, jumping from the second diving board, then diving from the first diving board. |
| 6. Jumping into the swimming pool at the shallow end. | 27. Jumping off the first, second, and third diving boards, then diving from the first diving board. |
| 7. Jumping into the pool and then doing the crawl. | 28. Jumping off the first, second, and third diving boards, then diving from the first and then the second diving board. |
| 8. Swimming at the shallow end, first breaststroke, then the crawl. | 29. Jumping off the fourth diving board, then diving off the second diving board. |
| 9. Pushing away from the bars and causing a splash. | 30. Jumping off the fifth diving board, then diving off the third diving board. |
| 10. Swimming in the middle of the pool at a depth of 5 feet 3 inches. | 31. Jumping off the fifth diving board, then diving off the fourth diving board. |
| 11. Swimming at the shallow end and then at the deep end (10 feet 3 inches). | 32. Jumping off the top board, then diving off the fourth diving board. |
| 12. Going into the deep end of the swimming pool. | 33. Jumping off the top board, then diving off the fifth diving board. |
| 13. Watching people jump from the diving boards. | 34. Diving off the top diving board. |
| 14. Standing on a step at the deep end of the pool and making a little jump into the water. | 35. Random stimuli. |
| 15. Backstroke at the shallow end of the pool. | 36. Looking around before jumping off the third diving board. |
| 16. Jumping into the water at the shallow end of the pool (belly-flop dive). | 37. Looking around before jumping off the fourth diving board. |
| 17. Belly-flop dive at the deep end of the pool. | 38. Looking around before jumping off the fifth diving board. |
| 18. Racing dive at the shallow end of the pool. | 39. Diving from the fifth diving board and looking around before diving. |
| 19. Racing dive at the deep end of the pool. | 40. Diving from the top board and looking around before diving. |
| 20. Swimming three times across the deep end of the pool without stopping: | |
| a. breaststroke | |
| b. crawl | |
| c. backstroke | |
| 21. Jumping into the pool at a depth of: | |
| a. 5 feet 3 inches | |
| b. 6 feet | |
| c. 7 feet | |

(From Kraft T. The use of behavior therapy in a psychotherapeutic context. In: Lazarus AA, ed. *Clinical Behavior Therapy*. New York: Brunner/Mazel; 1972:222, with permission.)

Desensitization of the Stimulus

In the final step, called *desensitization*, patients proceed systematically through the list from the least to the most anxiety-provoking scene while in a deeply relaxed state. The rate at which patients progress through the list is determined by their responses to the stimuli. When patients can vividly imagine the most anxiety-provoking scene of the hierarchy with equanimity, they experience little anxiety in the corresponding real-life situation.

Adjunctive Use of Drugs. Clinicians have used various drugs to hasten relaxation, but drugs should be used cautiously and only by clinicians trained and experienced in potential adverse effects. Either the ultrarapidly acting barbiturate sodium methohexital (Brevital) or

diazepam (Valium) is given intravenously in subanesthetic doses. If the procedural details are followed carefully, almost all patients find the procedure pleasant, with few unpleasant side effects. The advantages of pharmacological desensitization are that preliminary training in relaxation can be shortened, almost all patients can relax adequately, and the treatment itself seems to proceed more rapidly than without the drugs.

Indications. Systematic desensitization works best in cases of a clearly identifiable anxiety-provoking stimulus. Phobias, obsessions, compulsions, and certain sexual disorders have been treated successfully with this technique.

THERAPEUTIC-GRADED EXPOSURE

Therapeutic-graded exposure is similar to systematic desensitization, except that relaxation training is not involved and treatment is usually carried out in a real-life context. This means that the individual must be brought in contact with (i.e., be exposed to) the warning stimulus to learn firsthand that no dangerous consequences will ensue. Exposure is graded according to a hierarchy. Patients afraid of cats, for example, might progress from looking at a picture of a cat to holding one.

FLOODING

Flooding (sometimes called *implosion*) is similar to graded exposure in that it involves exposing the patient to the feared object in vivo; however, there is no hierarchy. Flooding is based on the premise that escaping from an anxiety-provoking experience reinforces the anxiety through conditioning. Thus, clinicians can extinguish the anxiety and prevent the conditioned avoidance behavior by not allowing patients to escape the situation. Clinicians encourage patients to confront feared situations directly, without a gradual buildup, as in systematic desensitization or graded exposure. No relaxation exercises are used, as in systematic desensitization. Patients experience fear, which gradually subsides after a time. The success of the procedure depends on having patients remain in the fear-generating situation until they are calm and feel a sense of mastery. Prematurely withdrawing from the situation or prematurely terminating the fantasized scene is equivalent to an escape, which then reinforces both the conditioned anxiety and the avoidance behavior and produces the opposite of the desired effect. In a variant, called *imaginal flooding*, the feared object or situation is confronted only in the imagination, not in real life. Many patients refuse flooding because of the psychological discomfort involved. It is also contraindicated when intense anxiety would be hazardous to a patient (e.g., those with heart disease or fragile psychological adaptation). The technique works best with specific phobias. An example of in vivo flooding is presented in the case study.

The patient was a 33-year-old woman with social fears of eating in public. In particular, she was afraid of being observed by others when chewing and swallowing, particularly at dinner parties. A contrived situation was arranged in which the patient came to the session with a prepared meal and drink. She entered a conference room in which five persons in professional attire were already seated along a table. The patient was instructed to eat her meal in front of these individuals. Between bites, she was instructed to look at them often, and they had been instructed to avoid staring contests. She was not to distract herself from her anxiety symptoms. She was to eat her meal slowly, paying attention to the behavior of the observers and to her anxiety symptoms (e.g., dry mouth or difficulty swallowing). No conversation between the patient and observers was permitted. The observers would look at her and observe her chewing and swallowing behaviors, at times writing comments in a notebook. Occasionally, observers would communicate by whispering to each other, exchanging written notes, or giving knowing glances and smiles.

The only other communication occurred between the patient and therapist, and this was limited to the patient providing her subjective units of distress rating. The session lasted 90 minutes. Note: this situation may seem quite traumatizing. Because the exposure session is long and continues until ratings decline, the patient becomes desensitized. (Courtesy of Rolf G. Jacob, M.D., and William H. Pelham, M.D.)

PARTICIPANT MODELING

In participant modeling, patients learn a new behavior by imitation, primarily by observation, without having to perform the behavior until they feel ready. Just as irrational fears can be acquired by learning, they can be unlearned by observing a fearless model confront the feared object. The technique has been useful with phobic children who are placed with other children of their own age and sex who approach the feared object or situation. With adults, a therapist may describe the feared activity in a calm manner that a patient can identify. Or, the therapist may act out the process of mastering the feared activity with a patient. Sometimes a hierarchy of activities is established, with the least anxiety-provoking activity being dealt with first. The participant-modeling technique has been used successfully with agoraphobia by having a therapist accompany a patient into the feared situation. In a variant of the procedure, called *behavior rehearsal*, real-life problems are acted out under a therapist's observation or direction.

The following is a self-report by a patient with a contamination phobia, who is afraid to touch objects for fear of being infected or contaminated. She describes her reactions.

[The therapist] started touching everything very slowly. I was told to follow behind and touch everything she touched. It was like we were spreading the contamination. She touched doorknobs, light switches, walls, pictures, and woodwork. She opened drawers in each bedroom and touched the contents. She opened closets and touched clothes hanging on the rods. She touched the towels and sheets in the linen closet. She went through the children's rooms, touching dolls, stuffed animals, models, Star Wars figures, Transformers, and books.

[The therapist] kept talking to me quietly and calmly all the time we went along. I had been anxious when we started, but as we continued, my anxiety level decreased. At one point, when I had begun to think the worst was over, she pointed to the attic door and said we were going inside. I said, "No, that's where the mice were." She told me I didn't want to have a place in my home that was off limits. I agreed but became very anxious. It was very hard for me to go inside. I began touching the boxes too, but I was very upset. Then, she put her hands down on the floor and wanted me to do the same. I said, "I can't. I just can't." [The therapist] said, "Yes you can."

[The therapist] spent several hours with me that day. Before she left, she made a list of things for me to do by myself. Twice a day I was to go through the house touching everything the way she had done with me. I was to invite a friend of mine who had a pet to come and visit and also friends of my children who had pets. (Courtesy of Rolf G. Jacobs, M.D., and William H. Pelham, M.D.)

EXPOSURE TO STIMULI PRESENTED IN VIRTUAL REALITY

Advances in computer technology have made it possible to present environmental cues in virtual reality for exposure treatment. Beneficial effects have been reported with virtual reality exposure of patients with height phobia, fear of flying, spider phobia, and claustrophobia. Much experimental work is being done in the field. One model uses an avatar of the patient walking through a crowded supermarket filled with other avatars (including one of the therapists) as a way of conquering agoraphobia.

ASSERTIVENESS TRAINING

Assertiveness is defined as assertive behavior that enables a person to act in his or her own best interest, to stand up for herself or himself without undue anxiety, to express honest feelings comfortably, and to exercise personal rights without denying the rights of others.

Two types of situations frequently call for assertive behaviors: (1) setting limits on pushy friends or relatives and (2) commercial situations, such as countering a sales pitch or being persistent when returning defective merchandise. Early assertiveness training programs tended to define specific behaviors as assertive or nonassertive. For example, individuals were encouraged to assert themselves if somebody got in front of them in a supermarket checkout line. Increasing attention is now given to context, that is, what would be assertive behavior in this situation depends on circumstances.

SOCIAL SKILLS TRAINING

The negative symptoms in patients with schizophrenia constitute behavioral deficits that go beyond difficulties with assertiveness. These patients have inadequate expressive behaviors and inappropriate stimulus control of their social behaviors (i.e., they do not pick up social cues). Similarly, patients with depression often experience a lack of social reinforcement because of a lack of social skills, and social skills training has been found to be efficacious for depression. Patients with social phobia similarly often have not acquired adolescents' social skills. In fact, their social defensive behaviors (e.g., avoiding eye contact, making brief statements, and minimizing self-disclosure) increase the probability of the rejection that they fear.

Social skills training programs for patients with schizophrenia cover skills in the following areas: conversation, conflict management, assertiveness, community living, friendship and dating, work and vocation, and medication management. Each of these skills has several components. For example, assertiveness skills include making requests, refusing requests, making complaints, responding to complaints, expressing unpleasant feelings, asking for information, making apologies, expressing fear, and refusing alcohol and street drugs. Each component involves specific steps. For example, conflict management includes skills in negotiating, compromising, tactful disagreeing, responding to untrue accusations, and leaving overly stressful situations. A situation in which conflict management skills might be used is when the patient and a friend decide to go to a movie and their choice of movie differs.

Negotiating and compromising, for example, involves the following steps:

1. Explain one's viewpoint briefly.
2. Listen to the other person's viewpoint.
3. Repeat the other person's viewpoint.
4. Suggest a compromise.

At his initial appointment, Phillip described very serious symptoms of obsessive-compulsive disorder (OCD). He was 23 years old and living at home because he was no longer able to work or go to school. His days were consumed with behaviors related to checking, repeating, and hoarding. Phillip was unable to throw away anything—he saved junk mail, used tissues and napkins, old papers and magazines, and any kind of receipt for fear that he might lose something important. Phillip spent many hours checking his trash, his car, and his home to be sure that he had not thrown away anything important. He also checked everything he wrote (e.g., checks, school exams and papers, letters and e-mails) to be sure that he had not made a mistake, and he read and reread books, magazines, and articles to be sure he understood the written material adequately. Phillip worried constantly that he had done something wrong and would disappoint his parents. He was also depressed because he was unable to function well in life, and he had tremendous social anxiety that had plagued him for many years, making it difficult to make and keep friends.

By the end of Phillip's second session, his therapist was beginning to get a good idea of the general nature and severity of his symptoms and some of the maintaining factors. However, to plan the treatment in more detail and to get a better idea of how the symptoms occurred during his daily life, she asked Phillip to keep daily records over the next week using a form that she had prepared for him. The form had a place for recording the amount of time he spent doing rituals each morning, afternoon, and evening, as well as another place to record more details about at least one episode of rituals each day (e.g., what was happening before, during, and after the rituals; see Table 28.8-2).

Table 28.8-2
Daily Monitoring of Rituals

Each day, record the amount of time spent doing rituals in the morning, afternoon, and evening.							
	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday	Monday
Morning	2 hrs	1.5 hrs					
Afternoon	3 hrs	2 hrs					
Evening	1.5 hrs	3 hrs					
Once a day, record the following details about an episode of rituals:							
Day	Time	Situation	Feelings	Thoughts (Obsessions)	Type of Ritual	Feelings After Rituals	
Saturday	8 a.m.	Finished breakfast	Afraid	Shouldn't have thrown away my napkin	Checking through trash	Better	
			Scared	Might have left something under my plate	Looking under plate	For now, I think I have not lost anything	
			Worried	What if I lost something important?	Staring to see if I lost something		
Sunday	2 p.m.	At the store; signed a check	Worried	Did I sign my name correctly?	Staring at the check	Anxious because I couldn't finish checking	
			Anxious	Did I write the correct amount?	Tracing the lines I wrote		
				What if I give them the check and it is wrong?	Standing there		

(Courtesy of M. A. Stanley, Ph.D., and D. C. Beidel, Ph.D.)

Phillip's therapist determined that his difficulties with obsessions, rituals, depression, and social fears reflected a core fear of negative evaluation. Phillip was overly concerned with making mistakes, being imperfect, and disappointing others. Even as a child, Phillip was concerned about not doing well enough, and he had difficulty making friends for fear that others would not like him. His parents, who were highly anxious, provided much adulation when Phillip did things well (e.g., learned to ride a bike, got good grades in school), and they spent much time instructing him about how to improve his performance when an activity or grade was not perfect. As Phillip took on more responsibility at school and with part-time work, he became more concerned about doing things right. He learned that going back and checking his work relieved his anxiety. He also learned that saving his papers for future checking reassured him that he would be able to fix any unrecognized mistakes at a later time. His parents helped him to reduce his anxiety when he was uncertain about his work by reassuring him that he was doing okay. As Phillip progressed from elementary school to junior high school to high school, his workload and anxiety gradually increased, but he was able to manage things with some moderate checking and saving. When he

began attending college, however, the workload increased extensively, and he found himself doing even more checking and hoarding to reduce his fears about making mistakes. Phillip began to feel that these behaviors were getting out of control, but he could not stop them. He had to check and recheck to be sure that he was not making mistakes. The cycle of anxiety S ritual S reduced anxiety was so powerfully reinforcing that he could not stop. He needed help to break this cycle and to address his persistent fear of negative evaluation.

Phillip's therapist decided to begin treatment with a course of exposure and response prevention (ERP) to get his obsessions and rituals under control and begin to address his core fear of making mistakes and being evaluated negatively. Given that Phillip's depression had grown from the disability associated with his OCD, the therapist expected that a successful course of ERP might also help to reduce his depressive symptoms. ERP for Phillip began with a home visit, where the therapist helped him to complete common daily activities with adherence to his RP plan, which included the following:

- ▶ No more checking: After eating, leave the table immediately without inspecting your plate and the surrounding areas (including under the table and chair) for lost items. Leave the restroom immediately after using it, without checking the toilet, trash, and sink for lost items. When leaving the car, no more checking of seats, floors, and windows. Write everything (papers, checks, etc.) only once; no checking to be sure that letters and words are correct.

- ▶ No more repeating: No more rereading books. No staring repeatedly at items to ensure that nothing is lost.

- ▶ No more saving. Throw tissues away immediately after using. Discard trash and junk mail immediately. Do not look into the trash can for lost items.

Phillip's parents also were asked to stop reassuring him and to discontinue doing rituals for him. This was a very difficult session for Phillip and his family, but they understood the logic of ERP, and they were willing to try anything.

For the next 3 weeks, Phillip and his therapist met three times a week to conduct in vivo exposure sessions that helped him to face his core fears. For many of these sessions, Phillip was asked to bring hoarded items from home and to discard all unnecessary items during the therapy session. At first, this created tremendous anxiety, but over time, Phillip was able to throw things away with less fear of losing something important. He also developed the ability to conduct self-directed exposure at home. Other exposure sessions involved writing letters and mailing them without checking, reading passages from magazines and books only once, and sorting through junk mail to make quick decisions about what to save or discard. As Phillip was able to take on more responsibility for home-based exposure, session frequency decreased to two times per week, and then to once per week. After 3 months of treatment, Phillip's scores on the YBOCS (Yale-Brown Obsessive-Compulsive Scale) and BDI (Beck Depression Inventory) had decreased to 20 and 19, respectively, demonstrating significant improvement in obsessive-compulsive symptoms and depression. His SPAI (Social Phobia and Anxiety Inventory) score, however, remained relatively unchanged, suggesting that he was still experiencing significant social anxiety.

Next, while Phillip worked on maintaining the gains he had made following ERP, he and his therapist conducted some role plays to evaluate his social skills. It was apparent that Phillip had extreme difficulty with initiating and maintaining conversations. His eye contact also was quite poor in social interactions. Thus, the therapist devised a plan for teaching and practicing new skills, which also involved additional exposure to Phillip's core fears as he was asked to resume contact with old friends and identify activities where he could meet new people. He practiced new behaviors first in session with his therapist and then developed a hierarchy of feared social situations in which he could practice his new behaviors. These practice exercises also involved a form of exposure as Phillip was asked to make social contact, which produced fears of negative evaluation. After another 3 months of treatment focused on social skills training (and associated exposure), Phillip's scores on the YBOCS and BDI had decreased further (YBOCS = 15; BDI = 13), and his SPAI score had decreased to 100. Phillip had gone back to school to take one class, he was spending small amounts of time with old friends, and he was volunteering a few hours each week at his church. (Courtesy of M. A. Stanley, Ph.D., and D. C. Beidel, Ph.D.)

AVERSION THERAPY

When a noxious stimulus (punishment) is presented immediately after a specific behavioral response, theoretically, the response is eventually inhibited and extinguished. Many types of noxious stimuli are used: electric shocks, substances that induce vomiting, corporal punishment, and social disapproval. The negative stimulus is paired with the behavior, which is thereby suppressed. The unwanted behavior may disappear after a series of such sequences. Aversion therapy has been used for alcohol abuse, paraphilias, and other behaviors with impulsive or compulsive qualities, but this therapy is controversial for many reasons. For example, punishment does not always lead to the expected decreased response and can sometimes be positively reinforcing. Aversion therapy has been used with good effect in some cultures in the treatment of opioid addicts (Fig. 28.8-1).

FIGURE 28.8-1

Treatment of addicts at Tham Krabok Monastery in Thailand results in a 70 percent success rate, according to its records. The 10-day free treatment begins with a vow to Buddha never to use narcotics again. Then, patients are given an herbal medicine that makes them vomit immediately. (From White PT, Raymer S. The poppy—for good and evil. *National Geographic*. 1985;167:187, with permission.)

EYE MOVEMENT DESENSITIZATION AND REPROCESSING

Saccadic eye movements are rapid oscillations of the eyes that occur when a person tracks an object that is moved back and forth across the line of vision. A few studies have demonstrated that inducing saccades while a person is imagining or thinking about an anxiety-producing event can yield a positive thought or image that results in decreased anxiety. Eye movement desensitization and reprocessing has been used in posttraumatic stress disorders and phobias.

POSITIVE REINFORCEMENT

When a behavioral response is followed by a generally rewarding event, such as food, avoidance of pain, or praise, it tends to be strengthened and to occur more frequently than before the reward. This principle has been applied in a variety of situations. On inpatient hospital wards, patients with mental disorders receive a reward for performing a desired behavior, such as tokens that they can use to purchase luxury items or certain privileges. The process, known as *token economy*, has successfully altered behavior. Table 28.8-3 gives a summary of some clinical applications of behavior therapy.

 **Table 28.8-3**
Some Common Clinical Applications of Behavior Therapy

Disorder	Comments
Agoraphobia	Graded exposure and flooding can reduce the fear of being in crowded places. About 60% of patients so treated improve. In some cases, the spouse can serve as the model while accompanying the patient into the fear situation; however, the patient cannot get a secondary gain by keeping the spouse nearby and displaying symptoms.
Alcohol dependence	Aversion therapy in which the alcohol-dependent patient is made to vomit (by adding an emetic to the alcohol) every time a drink is ingested is effective in treating alcohol dependence. Disulfiram (Antabuse) can be given to alcohol-dependent patients when they are alcohol free. Such patients are warned of the severe physiological consequences of drinking (e.g., nausea, vomiting, hypotension, collapse) with disulfiram in the system.
Anorexia nervosa	Observe eating behavior; contingency management; record weight
Bulimia nervosa	Record bulimic episodes; log moods
Hyperventilation	Hyperventilation test; controlled breathing; direct observation
Other phobias	Systematic desensitization has been effective in treating phobias, such as fears of heights, animals, and flying. Social skills training has also been used for shyness and fear of other people.
Paraphilias	Electric shocks or other noxious stimuli can be applied at the time of a paraphilic impulse, and eventually the impulse subsides. Shocks can be administered by either the therapist or the patient. The results are satisfactory but must be reinforced at regular intervals.
Schizophrenia	The token economy procedure, in which tokens are awarded for desirable behavior and can be used to buy ward privileges, has been useful in treating inpatients with schizophrenia. Social skills training teaches patients with schizophrenia how to interact with others in a socially acceptable way so that negative feedback is eliminated. In addition, the aggressive behavior of some patients with schizophrenia can be diminished through those methods.
Sexual dysfunctions	Sex therapy, developed by William Masters and Virginia Johnson, is a behavior therapy technique used for various sexual dysfunctions, especially male erectile disorder, orgasm disorders, and premature ejaculation. It uses relaxation, desensitization, and graded exposure as the primary techniques.
Shy bladder	Inability to void in a public bathroom; relaxation exercises
Type A behavior	Physiological assessment, muscle relaxation, biofeedback (on electromyogram [EMG])

Charles was a 70-year-old retired business executive. Throughout his life, his work consumed him. Although he married and had a family, his job was his primary focus. He went to the office early and came home late. He enjoyed what he did—it was stimulating and made him feel important and useful. But as he got older, his performance was not what it used to be, and he decided it was time to retire. However, his mood was pretty low when he no longer had a job. He did not have the energy to get more involved in his church or to develop other hobbies, so he sat around all day, without any social contacts. His wife and best friend encouraged him to go talk to someone. The therapist suggested that they try behavioral activation. Charles was somewhat skeptical, as it seemed too simple, but he needed to do something. The therapist spent some time with Charles talking about the kinds of activities that used to make him feel good and some of the things he used to enjoy. They then put together a list of things he might be able to do—even if he did not feel much like it—just to see what would happen. The list included looking for volunteer work where he could use his job skills, spending more time with his wife in some of the activities they once had enjoyed (e.g., watching movies, taking walks), and rejuvenating an old hobby from his college days—fishing. Charles initially agreed to do some easy activities—go to one movie a week, take one walk a week, and contact his church activity leader about possible volunteer activities. He was surprised to find that even these “baby steps” helped him feel better. He had the chance to talk with other people and began to see that even in retirement, he could find useful and fun things to do. (Courtesy of M. A. Stanley, Ph.D., and D. C. Beidel, Ph.D.)

RESULTS

Behavior therapy has been used successfully for a variety of disorders (Table 28.8-3) and can be easily taught (Table 28.8-4). It requires less time than other therapies and is less expensive to administer. Although useful for circumscribed behavioral symptoms, the method cannot be used to treat global areas of dysfunction (e.g., neurotic conflicts, personality disorders). Controversy continues between behaviorists and psychoanalysts, which is epitomized by Eysenck’s statement: “Learning theory regards neurotic symptoms as simply learned habits; there is no neurosis underlying the symptoms, but merely the symptom itself. Get rid of the symptom and you have eliminated the neurosis.” Analytically oriented theorists have criticized behavior therapy by noting that simple symptom removal can lead to symptom substitution: When symptoms are not viewed as consequences of inner conflicts and the core cause of the symptoms is not addressed or altered, the result is the production of new symptoms. Whether this occurs remains open to question, however.

 **Table 28.8-4**
Social Skills Competence Checklist of Therapist-Trainer Behaviors

1. Actively helps the patient set and elicit specific interpersonal goals.
2. Promotes favorable expectations, a therapeutic orientation, and motivation before role playing begins.
3. Assists the patient in building possible scenes in terms of "What emotion or communication?" "Who is the interpersonal target?" "Where and when?"
4. Structures the role playing by setting the scene and assigning roles to the patient and surrogates.
5. Engages the patient in behavioral rehearsal—getting the patient to role play with others.
6. Uses self or other group members in modeling appropriate alternatives for the patient.
7. Prompts and cues the patient during the role playing.
8. Uses an active style of training through coaching, shadowing, being physically out of a seat, and closely monitoring and supporting the patient.
9. Gives the patient positive feedback for specific verbal and nonverbal behavioral skills.
10. Identifies the patient's specific verbal and nonverbal behavioral deficits or excesses and suggests constructive alternatives.
11. Ignores or suppresses inappropriate and interfering behavior.
12. Shapes behavioral improvements in small, attainable increments.
13. Solicits from the patient or suggests an alternative behavior for a problem situation that can be used and practiced during the behavioral rehearsal or role playing.
14. Evaluates deficits in social perception and problem solving and remedies them.
15. Gives specific attainable and functional homework assignments.

BEHAVIORAL MEDICINE

Behavioral medicine uses the concepts and methods described above to treat a variety of physical diseases. Emphasis is placed on the role of stress and its influence on the body, particularly on the endocrine system. Attempts to relieve stress are made with the expectation that either the disease state will lessen or the patient's ability to tolerate the disease state will strengthen.

One study measured the effects of a behavioral medicine program on symptoms of acquired immunodeficiency syndrome (AIDS). The treatment group received training in biofeedback, guided imagery, and hypnosis. Results included significant decreases in fever, fatigue, pain, headache, nausea, and insomnia and increased vigor and hardiness.

Another study of immunological and psychological outcomes of a stress reduction program was conducted with patients with malignant melanoma. Results included significant increases in large granular lymphocytes (defined as CD57 with Leu-7) and natural killer (NK) cells (defined as CD16 with Leu-II and CD56 with NKHI), along with indications of increased NK cytotoxic activity. Also noted were significantly lower levels of psychological distress and higher levels of positive coping methods in comparison with patients who were not part of the group.

Many other applications of behavior therapy are used in medical care. In general, most patients feel they benefit from such interventions, especially in their ability to cope with chronic illness.

28.9 Hypnosis

The concept of hypnosis conjures up myriad perceptions among clinicians and the lay public. Even the term *hypnosis* can be misleading, coming as it does from the Greek root *hypnos* (meaning "sleep"). In reality, hypnosis is not sleep. It is more likely a complex process that requires alert focused and receptive attention. Hypnosis is a powerful means of directing innate capabilities of imagination, imagery, and attention. Many also believe the myth that the clinician projects the hypnotic trance onto the patient or has the power to influence the patient. In reality it is the patient who has the hypnotic gift, and the clinician's role is to assess the patient's capacity to capitalize on this asset and to help the patient discover and use it effectively. Patient motivation, personality style, and biological predisposition may contribute to the manifestation of this talent.

During the hypnotic trance, focal attention and imagination are enhanced and simultaneously peripheral awareness is decreased. This trance may be induced by a hypnotist through formalized induction procedures, but it can also occur spontaneously. The capacity to be hypnotized and, relatedly, the occurrence of spontaneous trance states is a trait that varies among individuals but is relatively stable throughout a person's life cycle.

HISTORY

Descriptions of trance states, ecstatic states, and spontaneous dissociative states abound in the Eastern and Western religious, literary, and philosophical traditions. Anton Franz Anton Mesmer (1734–1815) first formally described hypnosis as a therapeutic modality in the 18th century and believed it to be the result of a magnetic energy or an invisible fluid that the therapist channels into the patient to correct imbalances, restoring health. James Braid (1795–1860), an English physician and surgeon, used eye fixation and closure to induce trance states. Later, Jean Martin Charcot (1825–1893) theorized the hypnotic state to be a neurophysiologic phenomenon that was a sign of mental illness. Contemporaneously, Hippolyte Bernheim (1840–1919) believed it to be a function of the normal brain.

Early in his career, Sigmund Freud (1856–1939) used hypnosis as part of his psychoanalysis and noticed that patients in a trance could relieve traumatic events, a process called *abreaction*. Later, Freud switched from hypnosis to free association because he wanted to minimize the transference that sometimes accompanies the trance state. Importantly, the switch did not eliminate the occurrence of spontaneous trance during the analysis.

World War I produced many shell-shocked soldiers and Ernst Simmel (1882–1947), a German psychoanalyst, developed a technique for accessing repressed material that he named *hypnoanalysis*. During World War II, hypnosis played a prominent role in the treatment of pain, combat fatigue, and neurosis. Formal recognition of hypnosis as a therapeutic modality did not occur, however, until the 1950s. The British Medical Society recommended its teaching in medical schools in 1955 and the American Medical Association and American Psychiatric Association officially stated its safety and efficacy in 1958.

DEFINITION

Hypnosis is currently understood as a normal activity of a normal mind through which attention is more focused, critical judgment is partially suspended, and peripheral awareness is diminished. The trance state, being a function of the subject's mind, cannot be forcibly projected by an outside person. The hypnotist, however, may aid in the achievement of the state and use its uncritical, intense focus to facilitate the acceptance of new thoughts and feelings, thereby accelerating therapeutic change. For the subject, hypnosis is typified by a feeling of involuntariness and movements seem automatic.

TRAIT OF HYPNOTIZABILITY

A person's degree of hypnotizability is a trait that is relatively stable throughout the life cycle and is measurable. The process of hypnosis takes the hypnotizability trait and transforms it into the hypnotized state. Experiencing the hypnotic concentration state requires a convergence of three essential components: absorption, dissociation, and suggestibility.

Absorption is an ability to reduce peripheral awareness that results in a greater focal attention. It can be metaphorically described as a psychological zoom lens that increases attention to the given thought or emotion to the increasing exclusion of all context, even including orientation to time and space.

Dissociation is the separating out from consciousness elements of the patient's identity, perception, memory, or motor response as the hypnotic experience deepens. The result is that components of self-awareness, time, perception, and physical activity can occur without being known to the patient's consciousness and so may seem involuntary.

Suggestibility is the tendency of the hypnotized patient to accept signals and information with a relative suspension of normal critical judgment; it is controversial whether critical judgment can be completely suspended. This trait will vary from an almost compulsive response to input in the highly hypnotizable to a sense of automaticity in the less hypnotizable individual. [Table 28.9-1](#) lists the indicators of trance development.

 **Table 28.9-1**
Indicators of Trance Development

Autonomous ideation
Balanced tonicity (catalepsy)
Changed voice quality
Comfort, relaxation
Economy of movement
Eye changes/closure
Facial features ironed out
Feeling distant
Feeling good after trance
Lack of body movement
Lack of startle response
Literalism
Objective and impersonal ideation
Pupillary changes
Response attentiveness
Retardation of reflexes:
Swallowing
Blinking
Sensory, muscular, and body changes
Slowing pulse
Slowing and loss of blink reflex
Slowing respiration
Spontaneous hypnotic phenomena:
Amnesia
Anesthesia
Catalepsy
Regression
Time distortion
Time lag in motor and conceptual behavior

(From Erickson M, Rossi EL, Rossi SL. *Hypnotic Realities: The Induction of Clinical Hypnosis and Forms of Indirect Suggestion*. New York: Irvington; 1976:98, with permission.)

QUANTIFICATION OF HYPNOTIZABILITY

Quantifying a patient's degree of hypnotizability is useful in a clinical setting because it predicts the effectiveness of hypnosis as a therapeutic modality. Quantification also provides useful information about the way patients relate to themselves and the social environment. Highly hypnotizable patients have an increased incidence of spontaneous trance-like states and so may be unduly influenced by ideas and emotions that are not being appropriately self-critiqued.

NEUROPHYSIOLOGICAL CORRELATES OF HYPNOSIS

Neurological testing of individuals in the hypnotized state and those with a high degree of hypnotizability has led to some interesting findings, but no set of changes has been shown to be sensitive or specific for the trance state or hypnotizability trait.

Electroencephalographic (EEG) studies have shown that hypnotized persons exhibit electrical patterns that are similar to those of fully awake and attentive persons and not like those found during sleep. Increased alpha activity and theta power in the left frontal region has been reported in highly hypnotizable patients as compared with those who are less hypnotizable; these differences exist in the trance and nontrance states.

Positron emission tomography (PET) studies that compare regional blood flow in the brain in both hypnotized and nonhypnotized subjects lend further evidence to the hypothesis that hypnosis exerts some of its effects at lower-level modalities of the brain. Hypnotic suggestions to add color to a visual image result in increased blood flow to the lingual and fusiform gyri, the color vision processing centers of the brain; suggestions to remove color have the opposite effect. Similarly, the intensity and noxiousness of pain are believed to be processed by different regions of the brain, because different areas of reduced blood flow result when each is minimized through hypnosis.

The role of the anterior brain regions, such as the frontal lobes, in hypnosis has been shown physiologically by the positive correlation between homovanillic acid concentrations in the cerebrospinal fluid and degree of hypnotizability. The frontal cortex and basal ganglia have a large number of neurons that use dopamine, of which the metabolite is homovanillic acid. This may explain why pharmacological enhancement of hypnotizability, although difficult, is primarily accomplished with dopaminergic agents, such as amphetamine. The increased activation of the basal ganglia may relate to the increased automaticity of hypnotic motor behavior.

CLINICAL ASSESSMENT OF HYPNOTIC CAPACITY

Two major procedures exist to clinically evaluate hypnotic capacity: the Stanford Hypnotic Susceptibility Scale and the Hypnotic Induction Profile (HIP) (Table 28.9-2). The Stanford Hypnotic Susceptibility Scale is a long laboratory-based test that has been modified for clinical evaluation and requires approximately 20 minutes to perform. It primarily measures behavioral compliance and suggestibility. The HIP is a shorter test that uses the eye-roll sign as a biological indicator and measures cognitive flow, which differentiates those with no hypnotic capacity because of mental pathology from those mentally normal patients with any inherent hypnotic capacity (Fig. 28.9-1).

FIGURE 28.9-1

Administration of the Hypnotic Induction Profile can be a routine part of the initial visit and evaluation. The test begins with the eye-roll sign, a presumptive measure of biological ability to experience dissociation. In the test procedure for eye-roll sign measurement, the patient is told “Hold your head looking straight forward; while holding your head in that position, look upward, toward your eyebrows—now toward the top of your head [up-gaze]. While continuing to look upward, close your eyelids slowly [roll].” The up-gaze and roll are scored on a 0 to 4 scale by observing the amount of sclera visible between the lower eyelid and the lower edge of the cornea. If an internal squint occurs, the degree is scored on a 1 to 3 scale. The squint score is added to the roll score. This procedure takes about 5 seconds. The eye-roll is a part of the hypnotic induction, which is also scored as an initial indicator of the potential for hypnotic experience. (Courtesy of Herbert Spiegel, M.D., Marcia Greenleaf, Ph.D., and Davig Spiegel, M.D.)

Table 28.9-2 **Hypnotic Induction Profile–Derived Method of Self-Hypnosis**

One, look up toward your eyebrows, all the way up; two, close your eyelids slowly and take a deep breath; count to three, exhale, let your eyes relax, and let your body float.

As you feel yourself floating, you permit one hand or the other to feel like a buoyant balloon and allow it to float upward. As it does, your elbow bends, and your forearm floats into an upright position. When your hand reaches this upright position, it becomes a signal for you to enter a state of meditation and to increase your receptivity to new thoughts and feelings.

In this state of meditation, you concentrate on this feeling of imaginary floating and, at the same time, concentrate on the following critical points (e.g., the three critical points to stop smoking in the following discussion).

Reflect on the implications of these critical points, and then bring yourself out of this state of concentration called self-hypnosis by counting backward in this manner: Three, get ready; two, with your eyelids closed, roll up your eyes (do it now); and, one, let your eyelids open slowly. Then, when your eyes are back in focus, slowly make a fist with the hand that is up; and, as you open your fist slowly, your usual sensation and control returns. Let your hand float down. That is the end of the exercise, but you can retain a general overall feeling of floating.

By doing this exercise ten different times each day, you can float into this state of buoyant repose. Give yourself this island of time, 20 seconds, ten times a day, in which to use this extra receptivity to reimprint these critical points. Reflect on them, then float back to your usual state of awareness, and then continue with what you ordinarily do.

(Courtesy of Herbert Spiegel, M.D., Marcia Greenleaf, Ph.D., and David Spiegel, M.D.)

INDUCTION

Many different induction protocols follow the same basic principles and pattern, but may be better suited to the patients with different levels of hypnotizability.

Doctor: Take a long, deep breath—inhalation and exhalation; now close your eyes and relax. Pay particular attention to the muscles in and about your eyes—relax them to the point that they just won't work. Are you trying to do that? Good. If you really have them relaxed, right at this very moment, no matter how hard you try, they just won't open. Test them. The harder you try, the faster they stick together, just as if they were glued together. That's fine!

Now you can open your eyes; that's good. When I tell you to and not before, open and close your eyes once more, and, when you close them this time, you will be ten times as relaxed as you are right now. Go ahead, open and close, and feel that surge of relaxation go through your whole body, from the top of your head to the tip of your toes. Very good!

Now once again, open and close your eyes, and this time, when you close them, you will double the relaxation that you now have. Fine.

If you have followed my suggestions, right at this very moment, when I lift your hand and let it drop into your lap, it will drop like a wet cloth, heavy and limp. That's very, very good.

You now have good physical relaxation, but medical relaxation consists of two phases: physical, which you now have, and mental, which I will now show you how to achieve.

When I ask you to and not before, I want you to start counting backward from 100. I know you can count; that is not what we're after. I just want you to relax mentally. As you say each number, pause momentarily until you feel a wave of relaxation cover your whole body, from the top of your head to the tip of your toes. When you feel this wave of relaxation, then say the next number, and each time you say a number, you will double the relaxation you had before you said the number. If you do this properly, an interesting thing will happen—as you say the numbers and relax, the succeeding numbers will start to disappear and vanish from your mind. Command your mind to dispel these numbers. Now, aloud and slowly, start counting backward from 100.

Patient: One hundred.

Doctor: Very good.

Patient: Ninety-nine.

Doctor: Make them start to disappear now.

Patient: Ninety-eight.

Doctor: Now they're fading away, and after the next number they'll all be gone. Make them disappear. Let the numbers go.

Patient: Ninety-seven.

Doctor: And now they're all gone. Are they gone? Fine. If there are any numbers still lurking in your mind, when I lift your hand and drop it, they will all disappear. (Courtesy of William Holt, M.D.)

INDICATIONS

A patient's degree of hypnotizability and the technique of hypnosis are clinically useful in diagnosis and in treatment, respectively.

The existence of spontaneous, trance-like states in everyday life and the potential of individuals to uncritically accept emotions and information in these states make a person's degree of hypnotizability a factor in the way the world is viewed and processed. A relation is seen between various conditions and hypnotizability. For example, patients with paranoid personality disorder are low and patients who are histrionic are higher on the hypnotizability spectrum. Patients with dissociative identity disorder are highly hypnotizable. Patients with eating disorders are difficult to hypnotize.

A 32-year-old man presented to the emergency department with a severe headache. He was a chronic migraine sufferer and had been unable to control the pain on this occasion with his propranolol (Inderal). The emergency department recognized that he had high hypnotic capacity. The imagery of an icepack being placed on his forehead was suggested. Initially some real ice was placed on his forehead to help. The patient was able to control his pain completely with this imagery. He did not require narcotics, as he had on previous visits. On follow-up several weeks later the patient reported being able to use this strategy to control, as well as prevent, migraine attacks, and he no longer had to rely on frequent emergency department visits for pain relief. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 22-year-old male patient was brought to the emergency room with bilateral blindness. Following an evaluation by ophthalmology, it was determined that the blindness was psychogenic. After initial evaluation by psychiatry, a therapeutic alliance was developed, and hypnosis was used to take the patient to a safe place and then back to the time immediately prior to the blindness. After two sessions the patient was able to describe seeing his wife in an adulterous relationship. At that moment the patient vocalized a desire to harm his wife and her suitor. Immediately after this vocalization, he became amnesic for the event and blind. On describing this under hypnosis, he was given a suggestion that when he became alert "He would only remember what he felt comfortable remembering." Subsequent to the patient becoming alert, he had no idea what had occurred, and each day after the hypnotic intervention was initiated the patient's anger was reframed. When the patient felt comfortable he then confronted his wife. The patient became aware that the amnesia was being used to prevent him from acting out. Use of a psychodynamic, cognitive reframing approach with a hypnotic milieu helped this patient to gain control and understanding of his symptoms. The patient and his wife were then referred for marital counseling. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

Therapeutically, hypnosis's effectiveness in facilitating acceptance of new thoughts and feelings makes it useful in treating habitual problems and also with symptom management. Smoking, overeating, phobias, anxiety, conversion symptoms, and chronic pain are all indications for hypnosis. They can often be treated in a single session, in which a patient is taught to perform self-hypnosis. Hypnosis can also aid in psychotherapy, notably for posttraumatic stress disorder, and it has been used for memory retrieval.

A 29-year-old woman was referred for evaluation and treatment of ongoing facial pain that was not responding to traditional methods of intervention. Neurological evaluation showed no objective physical correlations. Her high midrange performance on the HIP added support to the potential of a psychological mechanism for the pain. Initially the pain was controlled by a hypnotic intervention, but it returned 24 hours later. Her self-hypnotic technique ceased to be effective. A decision was made to explore more completely the meaning of the pain. Age regression under hypnosis was used, and the patient was regressed to a time prior to the pain. She related that her brother had been injured by a car while he was running in the street. The patient was babysitting at the time, and her father was so angered that he hit her. Recently her friend's dog ran away, and she felt responsible. As she began to recognize her need to punish herself because of her guilt over what had occurred, she was able to understand her feelings and reframe her thoughts in a more productive

manner. An “affect bridge” was also used, and the patient was asked to go back to a previous time when she felt guilty and was punished. She then was able to describe her feelings of being hit by her alcoholic, abusive father. She continued to gain insight and mastery over the past and was able to ablate her pain. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 42-year-old married mother of three children had been kidnapped and locked in a large packing trunk. After she had freed herself and broken out, her abductors had stabbed her multiple times, tied her up, put her back in the trunk, and thrown her down a cliff. She had eventually managed to break out and crawl to safety. Eventually she had been picked up by a passerby. She reported that others had seen her lying on the road and appeared frightened to approach her. Eventually 911 had been called and she had been transported to a hospital. Following medical stabilization she had been discharged and found herself developing nightmares, reexperiencing avoidance, and having hyperarousal symptoms. She was referred by her internist for treatment and was initially started on 25 mg of sertraline (Zoloft), which was increased to 50 mg 4 days later. She was evaluated on the HIP and determined to be a mid- to high-range hypnotic subject. She was taught to go to a safe place and to use a split-screen technique. She was also given permission to describe her nightmares, reexperiences, and overwhelming anxieties and fears that she faced while being captive, as well as her feelings of abandonment while lying on the road. She was reinforced for her ingenuity in breaking out of the trunk. Her feeling of blame for her capture was reframed while she was under hypnosis. She was taught to calm herself and to reframe her negative feelings about her helplessness. Hypnotic age regression was used to help her master her experiences and facilitate their becoming like a bad movie. Initially her startle response was used as a signal for her to go to her comfort zone. Age progression was used to help her to rehearse the future. The treatment used the milieu of hypnosis along with exposure, cognitive reframing, psychodynamic approaches, and pharmacology. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

CONTRAINDICATIONS

No intrinsic dangers to the hypnotic process exist. Because of the increased dependence that the hypnotized patient has toward the therapist, a strong transference may occur, however, in which the patient exhibits feelings for the therapist that are inappropriate in regards to their relationship. Strong attachments may occur, and it is important that these are respected and properly interpreted. Negative emotions may also be brought out in the patient, especially those who are emotionally fragile or who have poor reality testing. To minimize the likelihood of this negative transference, caution should be taken when choosing patients who have problems with basic trust, such as those who are paranoid or who require high levels of control. The hypnotized patient also has a reduced ability to critically evaluate hypnotic suggestions and, thus, the hypnotist must have a strong ethical value system. Controversy exists about whether patients can perform acts during a trance state that they would otherwise find repugnant or that run contrary to their moral system.

▲ 28.10 Interpersonal Therapy

Interpersonal psychotherapy (ITP), a time-limited treatment for major depressive disorder, was developed in the 1970s, defined in a manual, and tested in randomized clinical trials by Gerald L. Klerman and Myrna Weissman. ITP was initially formulated as an attempt to represent the current practice of psychotherapy for depression. It assumes that the development and maintenance of some psychiatric illnesses occur in a social and interpersonal context and that the onset, response to treatment, and outcomes are influenced by the interpersonal relations between the patient and significant others. The overall goal of ITP is to reduce or eliminate psychiatric symptoms by improving the quality of the patient's current interpersonal relations and social functioning.

The typical course of ITP lasts 12 to 20 sessions over a 4-month to 5-month period. ITP moves through three defined phases: (1) The initial phase is dedicated to identifying the problem area that will be the target for treatment; (2) the intermediate phase is devoted to working on the target problem area(s); and (3) the termination phase is focused on consolidating gains made during treatment and preparing the patients for future work on their own (Table 28.10-1).

▲ **Table 28.10-1**
Phases of Interpersonal Psychotherapy

Initial phase: sessions 1–5

- Give the syndrome a name; provide information about prevalence and characteristics of the disorder
- Describe the rationale and nature of interpersonal psychotherapy
- Conduct the interpersonal inventory to identify the current interpersonal problem area(s) associated with the onset or maintenance of the psychiatric symptoms
- Review significant relationships, past and present
- Identify interpersonal precipitants of episodes of psychiatric symptoms
- Select and reach consensus about the interpersonal psychotherapy problem area(s) and treatment plan with patient

Intermediate phase: sessions 6–15

- Implement strategies specific to the identified problem area(s)
- Encourage and review work on goals specific to the problem area
- Illuminate connections between symptoms and interpersonal events during the week
- Work with the patient to identify and manage negative or painful affects associated with his or her interpersonal problem area
- Relate issues about psychiatric symptoms to the interpersonal problem area

Termination phase: sessions 16–20

- Discuss termination explicitly
- Educate patient about the end of treatment as a potential time of grieving; encourage patient to identify associated emotions
- Review progress to foster feelings of accomplishment and competence
- Outline goals for remaining work; identify areas and warning signs of anticipated future difficulty
- Formulate specific plans for continued work after termination of treatment

TECHNIQUES

Individual Interpersonal Psychotherapy

Initial Phase. Sessions 1 through 5 typically constitute the initial phase of ITP. After assessing the patient’s current psychiatric symptoms and obtaining a history of these symptoms, the therapist gives the patient a formal diagnosis. Therapist and patient then discuss the diagnosis, as well as what might be expected from treatment. Assignment of the sick role during this phase serves the dual function of granting the patient both the permission to recover and the responsibility to recover. The therapist explains the rationale of ITP, underscoring that therapy will focus on identifying and altering dysfunctional interpersonal patterns related to psychiatric symptomatology. To determine the precise focus of treatment, the therapist conducts an interpersonal inventory with the patient and develops an interpersonal formulation based on this. In the interpersonal formulation, the therapist links the patient’s psychiatric symptomatology to one of the four interpersonal problem areas—grief, interpersonal deficits, interpersonal role disputes, or role transitions. The patient’s concurrence with the therapist’s identification of the problem area and agreement to work on this area are essential before beginning the intermediate treatment phase.

Intermediate Phase. The intermediate phase—typically sessions 6 to 15—constitutes the “work” of the therapy. An essential task throughout the intermediate phase is to strengthen the connections the patient makes between the changes he or she is making in his or her interpersonal life and the changes in his or her psychiatric symptoms. During the intermediate phase, the therapist implements the treatment strategies specific to the identified problem area as specified in Table 28.10-2.

 **Table 28.10-2**
Treatment of Interpersonal Problem Areas

Problem Area	Description	Goals	Strategies
Grief and loss	Depression after the death of a loved one	Help patient through the mourning process Reestablish interest in new relationships	Explore relationship of patient with the deceased; explore negative and positive feelings associated with the loss
Role transitions	Life-phase transitions such as adolescence, childbirth, aging; or social/economic changes such as getting married, change in career, diagnosis of a medical illness	Deal with the loss of the old role Affirm positive and negative aspects of new roles Develop self-esteem and mastery	Examine all aspects of old and new roles; examine feelings about what is lost; explore social support system and develop new skills
Interpersonal role disputes	Conflict between the patient and someone else	Identify and modify expectations and faulty communication	Examine how role expectations relate to conflict; examine ways to bring about change in the relationship
Interpersonal deficits	A history of inadequate or unsustaining interpersonal relationships	Enhance quality of existing relationships; encourage the formation of new relationships	Discuss negative and positive feelings regarding the therapist; examine parallel interpersonal relations in patient’s life

Based on Treasure J, Schmidt U, van Furth E. *Handbook of Eating Disorders*. 2nd ed. Hoboken, NJ: John Wiley & Sons; 2003:258.

Termination Phase. In the termination phase (usually, sessions 16 through 20), the therapist discusses termination explicitly with the patient and assists him or her in understanding that the end of treatment is a potential time of grief. During this phase, patients are encouraged to describe specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s). The therapist also assists the patient in evaluating and consolidating gains, detailing plans for maintaining improvements in the identified interpersonal problem area(s), and outlining remaining work for the patient to continue on his or her own. Patients are also encouraged to identify early warning signs of symptom recurrence and to identify plans of action.

Ms. G is a 51-year-old woman who presented for treatment of binge eating disorder. She is college educated, has her own business, and is a divorced mother of one adult son in his early 20s. Before treatment, she had a body mass index (BMI) of 42 and had been binge eating approximately 10 to 15 days per month for the past 8 years. Along with her current diagnosis of binge eating disorder, Ms. G struggled with recurrent major depression.

During the initial phase, Ms. G and her therapist began to review her history and the interpersonal events that were associated with her binge eating. Ms. G shared that she began overeating and gaining weight at age 14. When she was 18 years of age, she moved to a foreign country with her parents. Soon after the move, Ms. G's father left her and her mother to return to the United States. Ms. G was enraged at her father for leaving them and still gets very tearful and angry when discussing the separation. She and her mother decided to stay abroad because she had started university and her mother was working. Both had developed strong social ties and felt comfortable in their new home. During this time, Ms. G continued to gain weight and started dieting. Shortly after graduating from university, Ms. G met and married a foreign national and, at the age of 28, delivered their only son. Two years later, she and her husband went through a very bitter divorce. Although Ms. G described this as a terrible time in her life, she maintained close ties with her friends and her mother. During this time, she began to diet and reached her lowest adult weight. At the age of 35, when her mother died of a heart condition, Ms. G had her first episode of major depression, which was treated and resolved with antidepressants and a brief course of psychotherapy. Although she had previous cycles of weight loss and weight regain, she did not evidence any sign of eating disturbance at this point. She continued to maintain close social ties and enjoyed her close relationship with her son. When Ms. G was in her early 40s, an economic downturn in her adopted country forced her to return to the United States. Having lost all of her savings, she struggled financially while she looked for work. During this time, she started binge eating and gaining weight. Within 1 year of this move, Ms. G's son decided to return to live with his father (who was very wealthy). Ms. G felt angry and betrayed. Yet, when her son would visit, she would assume a subservient role with him, because she was afraid of losing his affection. He, in turn, became quite demanding and critical of her. Before seeking treatment, her heightened feelings of isolation and loneliness were leading to increased binge eating, depression, and weight gain.

By session 3 of the initial phase, Ms. G's therapist began to consider which problem area would be the focus of the remainder of treatment. Ms. G had a history of important relationship losses and subsequent grief—the loss of her father, her husband, her mother, and, most recently, her son. However, none of these losses was associated with the development of binge eating problems (although her dieting was clearly linked to her feelings of anger after the divorce from her husband and her depression was intimately linked with her mother's death). Ms. G's anger at her son for returning to live with the enemy was clearly a role dispute, yet her binge eating had begun 2 years before his departure (although it clearly worsened after he left). Because neither of these problem areas was directly linked to the onset of the eating disorder, Ms. G's therapist decided that the focus of treatment would be to assist her in managing her role transition. Her move back to the United States, with the subsequent loss of her support and friendship networks, was clearly associated with the onset and continued maintenance of her binge eating. During session 4 of the initial phase, Ms. G's therapist shared her formulation of the problem area with her: "From what you have described, your binge eating really began after you returned to the United States. After that transition, you were more isolated and alone than you have ever been. It seems that binge eating was a way for you to manage that transition and the subsequent feelings of isolation and loneliness. Your transition has also had a negative impact on your relationship with your son. Even though you are a very social person and enjoy the company of others, you have yet to develop the kind of support that you had before you moved. Although you have struggled with some very significant issues over the course of your life—your father leaving, the pain of the divorce, and the death of your mother—your friends and support systems sustained you. If we work together to help you find and develop more intimate and supportive relationships here, I believe you will be much less likely to turn to food and binge eating as a source of support or comfort."

Ms. G agreed with the formulation and worked with her therapist to establish some treatment goals to help her resolve the problem area. First, she was encouraged to become more aware of her feelings (especially isolation and loneliness) when she was binge eating and of how binge eating seemed to be the way she managed those feelings. A second goal was for her to take steps to increase her social contacts and develop more friendships. The third goal, which was identified as a secondary problem area, centered on helping Ms. G resolve the role dispute with her son. Specifically, the therapist developed a goal with her to help her establish a clearer parental role with her son.

During the intermediate phase, the therapist helped Ms. G grieve the loss of her previous role and the extensive support that she once had. Ms. G and her therapist worked to identify several sources of support and friendships of which she had not been aware. Soon after, Ms. G reported significant progress in initiating and establishing relationships with others. This change appeared to help give her confidence in her new roles. In fact, she had begun to receive a few social invitations. She was more attuned to the ways that she would rely on food, especially when she felt lonely or felt that she was not receiving enough time from others. The connection between the lack of supportive contacts and binge eating was becoming very clear to her in these intermediate sessions. During this phase, the therapist also assisted her in setting appropriate limits in her relationship with her adult son and in recognizing his adult-like responses in return. By the termination phase, Ms. G reported that she no longer felt so lonely and isolated and that her binge eating had all but disappeared. She remarked how the quality of her relationship with her son had changed dramatically. He was more supportive and respectful, visited more frequently, and stayed with her for longer periods of time. In the final sessions, she talked about her need to let go of the past and move on with her life as it is now, assuming her new roles more fully. She worked closely with her therapist to develop a plan to maintain the gains that she had made in treatment and used the final session to review the important work that she had accomplished. Interpersonal Psychotherapy Delivered in a Group Format

A recent approach in the ongoing development of ITP has been its use in a group format. ITP delivered in a group format has many potential benefits in comparison with individual treatment. For example, a group format in which membership is based on diagnostic similarity (e.g., depression, social phobia, eating disorders) can help alleviate patients' concerns that they are the only one with a particular psychiatric disorder, while offering a social environment for patients who have become isolated, withdrawn, or disconnected from others. Given the number and different types of interpersonal interactions in a group setting, the interpersonal skills that are developed may be more readily transferable to the patient's outside social life than are the relationship patterns that are addressed in a one-on-one setting. Moreover, a group modality has therapeutic features not present in individual psychotherapy (e.g., interpersonal learning). The group format also facilitates the identification of problems common to many patients and provides a cost-effective alternative to individual treatment. [Table 28.10-3](#) links the phases of ITP to the stages of group development.

Table 28.10-3
Stages of Group Development in Interpersonal Psychotherapy (ITP)

ITP Phases	Group Stages	Group Process	Group Technique
Initial: sessions 1–5; identify interpersonal problem areas	Engagement: sessions 1–2	Members deal with anxiety and sharing of problems; need for leadership emerges	Therapist should encourage self-disclosure and sharing of experience
	Differentiation: sessions 3–5	As interpersonal differences emerge in the group, members work to manage negative feelings	Members share their feelings in the context of interpersonal activities outside the group
Middle: sessions 6–15; work on goals	Work: sessions 6–15	Members strive toward common goals and work out differences.	Connections among members increase as they share common experiences. Therapist encourages the practice of newly acquired interpersonal skills
Final: sessions 16–20; consolidate treatment	Termination: sessions 16–20	Members deal with loss and separation as group disbands	Set goals after leaving group; deal with feelings of loss and grieving

Based on Wilfley DE, MacKenzie KR, Welch RR, et al. *Interpersonal Psychotherapy for Group*. New York: Basic Books; 2000:20.

Timeline and Structure of Treatment. The typical course of group ITP lasts 20 sessions over a 5-month period. It is recommended that group size range from six to nine members, with one or two group leaders, depending on resources and training needs. The three individual meetings (pregroup, midgroup, and postgroup), sequenced to correspond with critical time points in the three phases of ITP, in combination with other techniques, were designed to maintain the exclusive and strategic focus on individual patients' interpersonal problem areas—the hallmark of ITP.

Pregroup Meeting. The pretreatment meeting is crucial for facilitating a patient's individualized work in the first phase of group ITP. The focus of the 2-hour pretreatment meeting is to identify interpersonal problem areas, establish an explicit treatment contract to work on problem areas, and prepare patients for group treatment. After identifying a patient's interpersonal problem(s) (i.e., interpersonal deficits, role disputes, role transitions, or grief), the therapist works collaboratively with the patient to formulate concrete prescriptions for change, in addition to the specific steps the patient will take to improve social relationships and patterns of relating. These goals of treatment are expressed in language that is as specific and personally meaningful to the patient as possible. Before the start of the group, each group member is given a written summary of his or her goals and told that these goals will guide his or her work in the group.

Another important element of the pregroup meeting involves adequately preparing patients for group treatment. That is, patients are encouraged to think of the group as an "interpersonal laboratory" in which they can experiment with new approaches to handle challenging interpersonal situations. In this regard, patients are informed about the important interpersonal skills that are learned while participating in a group (e.g., interpersonal confrontation, honest communication, expression of feelings) and are encouraged to learn from others as they see changes occur. The therapist stresses to patients the importance of keeping their work in the group focused on changing their current interpersonal situations or intensifying important existing relationships and not using the group as a substitute social network.

Initial Phase. The first five sessions of the group treatment comprise the initial phase in group ITP. During this phase, the therapist works to cultivate positive group norms and group cohesion, while emphasizing the commonality of symptoms among members and how they will be addressed in the group context. During this phase, group members are encouraged to review their goals with the group and begin to make some initial changes in their respective interpersonal problem areas. As members begin to experiment with the changes outlined in their goals, the therapist works collaboratively with each group member to refine and make any alterations in the target areas before the beginning of the intermediate phase.

Intermediate Phase. During the intermediate "work" phase of group ITP (sessions 6 through 15), the therapist works to facilitate connections among members as they share the work on their goals with one another. In contrast to other interactive group approaches, the group interpersonal psychotherapist is much less likely to focus on intragroup processes and relationships unless they are specific to the work on a member's interpersonal problem area (e.g., interpersonal deficits). The therapist, however, consistently and continuously encourages group members to practice newly acquired interpersonal skills both inside and, most importantly, outside the group. As is the case with individual ITP, an essential task throughout the intermediate phase is to strengthen the connections the group members make between difficulties in their interpersonal lives and their psychiatric problems.

MIDTREATMENT MEETING. The midtreatment meeting is held midway (usually between sessions 10 and 11) through the intermediate phase. This meeting provides an opportunity to conduct a detailed review of each group member's progress on his or her individual problems and to refine interpersonal goals. The therapist(s) recontracts with group members during this meeting as a means of outlining and emphasizing the work that remains, both inside and outside of the group, before the conclusion of treatment.

Termination Phase. In the termination phase (sessions 16 through 20), the therapist discusses termination explicitly with the group members and begins to help them recognize that the end of treatment is a time of possible grief and loss. The therapist helps members recognize their own progress and the progress made by other group members. During this phase, group members are encouraged to describe the specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s) and relationships. Although it is common for group members to want to keep meeting on their own or to have frequent reunions, group members are encouraged to use this phase of the group to formally say goodbye to one another and to the therapist(s). The therapist(s) also uses this time to encourage members to detail their plans for maintaining improvements in their identified interpersonal problem area(s) and to outline their remaining work.

POSTTREATMENT MEETING. The posttreatment meeting is scheduled within 1 week after the final group session. The therapist(s) uses this final individual meeting to develop an individualized plan for each group member's continued work on his or her interpersonal goals. The therapist(s) reviews the group experience and the changes the patient has made in his or her interpersonal problem area and significant relationships.

28.11 Narrative Psychotherapy

More than anything else psychiatrists do, they listen to stories. These stories so saturate the clinical encounter that it would be impossible to imagine a clinical encounter without them. In the very first meeting between psychiatrist and patient, the psychiatrist begins with an open-ended invitation to a story: “*What brings you here?*” or “*What seems to be the problem?*” Patients respond to these questions by telling psychiatrists about their lives, their troubles, when the troubles began, what seems to have caused them, how they create difficulty, and what kinds of problem solving they have tried. Such stories may be rudimentary, they may be only partially worked out, and they may even be baffled and confused. The patient may even be perplexed enough to answer “I don’t know why I came” or “I’m not really sure what’s wrong, my family sent me.” Nonetheless, the patient’s response to the psychiatrist’s initial questions always involves a story.

Narrative psychotherapy emerges out of this increased interest in clinical stories. The two main tributaries that lead to narrative psychotherapy come from the two different sides of psychiatry: narrative medicine and narrative psychotherapy. Narrative psychiatrists are psychiatrists who combine the wisdom of these two domains. Following the lead of narrative medicine, narrative psychiatrists recognize that psychiatric patients, like medical patients, come to clinics with intense stories to tell. Contemporary narrative medicine has developed from 30 years of work in bioethics and medical humanities devoted to humanizing the clinical encounter through a better understanding of patient stories. The term *narrative medicine* comes from Rita Charon, an internist and literary scholar, who used it to describe an approach to medicine that uses narrative approaches to augment scientific understandings of illness. Narrative medicine brings together insights from human-centered medical models, such as George Engel’s biopsychosocial model and Eric Cassel’s person-centered model, with research and insights from phenomenology, the humanities, and interpretive social sciences.

Narrative medicine uses these resources to better understand the illness experience, “to recognize, absorb, interpret, and be moved by the stories of illness.” As Charon argued, when clinicians possess narrative competency, they can enter the clinical setting with a nuanced capacity for “attentive listening. . . , adopting alien perspectives, following the narrative thread of the story of another, being curious about other people’s motives and experiences, and tolerating the uncertainty of stories.” She further argued that doctors “*need rigorous and disciplined training*” in narrative reading and writing not just for their own sake (helping them to deal with the strains and traumas of clinical work), but also “*for the sake of their practice.*” Without such narrative competency, clinicians lack the ability to fully understand their client’s experience of illness. For Charon and others in narrative medicine, narrative study is not a mere adornment to a doctor’s medical training; it is a crucial and basic science that must be mastered for medical practice.

A major task of narrative medicine, and therefore narrative psychotherapy, is to be a good listener and to connect empathically with the patient’s story. A narrative psychiatrist, like a narrative physician, seeks to understand the patient first and foremost. This understanding brings patient and clinician together into a shared experience of the patient’s world. This narrative understanding is much more than a causal explanation of problem A or problem B that the patient might have. It does not simply abstract from the person’s situation a categorical label that groups problems under a well-known abstract grid. Instead, narrative understanding tunes in to the uniqueness of the individual and the unrepeatability of the person’s experience and difficulties. Narrative understanding, in short, is a deep appreciation of the person as a whole—what it feels like for this person, in this particular context, going through these particular problems.

In addition to following the lead of narrative medicine colleagues, narrative psychiatrists also follow the lead of contemporary colleagues in narrative psychotherapy. The history of narrative psychotherapy goes back to Sigmund Freud’s early work at the inception of psychoanalysis. At that time, Freud lamented about how his case histories sounded more like narrative fictions than hard science.

Contemporary narrative psychotherapy’s motivation for returning to the role of narrative comes partly from the broader turn to narrative in humanities, psychology, and social science and partly from the history of psychotherapy since Freud. The past century of psychotherapy has been a century of strife, with one faction after another splitting off from psychoanalysis. Leading alternatives to psychoanalysis included behavioral, humanistic, family, cognitive, feminist, and interpersonal, just to name some. All of these splits are characterized by further splits within splits, which has fragmented the field of psychotherapy to the point that there are now more than 400 active approaches to psychotherapy. Narrative approaches emerge at this particular moment as part of an important trend away from further fragmentation and toward psychotherapy reintegration. Narrative approaches are invaluable for psychotherapy integration because they provide a metatheoretical orientation from which to understand and practice psychotherapy.

METAPHOR

Metaphor performs this function by allowing us to understand and experience one thing in terms of something else. The metaphor selects, accentuates, and backgrounds aspects of two systems of ideas so that they come to be seen as similar: “Men are seen to be more like wolves after the wolf metaphor is used, and wolves seem to be more human.”

Understanding metaphor in this way connects to broader work in continental linguistic philosophy, and that work, as a whole, shifts standard ideas about truth and objectivity. It allows us to sidestep the usual binary traps between relativism (anything goes) and realism (there is only one correct or true way to describe the world). When the role of language is understood as a mediator between our concepts and the world, it no longer makes sense to think in these highly modernist either/or terms. Rather than using the rigid binary distinction between true and false, it becomes possible to think instead in a postmodern language of semiotic realism and pluridimensional consequences.

PLOT

Plot works like metaphor in that it also orders experiences and provides form for narratives. Plot, or the process of emplotment, adds to metaphor two key dimensions: (1) it brings together what would otherwise be separate and heterogeneous elements, and (2) it organizes understanding and experience or time, or what could be called temporal perception.

The critical function of plot for narrative is that plot creates a narrative synthesis between multiple individual events and brings them together into a single story. It allows an intelligible connection to be made between them. Remarkably, plot can create a synthesis between events and elements that are surprisingly incongruous or heterogeneous—events that do not seem to fit together.

Plot also configures these multiple elements into a temporal order. This temporal order is of two sorts. First, each plot is comprised of a discrete series of incidents, of theoretically infinite *nows*. Second, each plot takes these infinite *nows*, proceeding one after another in succession, and organizes them into a humanly manageable experience.

CHARACTER

In narrative theory, the concept of character connects directly to contemporary controversy surrounding the related and, some may argue, more basic concept of identity. The controversy around identity may be understood as a tension between essentialist and nonessentialist approaches. Essentialist notions of identity tell us that each person has a fixed personality, perhaps biologically stamped, that authentically belongs to that person and that is at the core of that person’s being. This “true self” or “core self” may be distorted or covered over, but it is nonetheless there for the discovery if individuals apply themselves patiently and persistently to the task. Nonessentialist critiques, however, have deconstructed this ideal of identity and its notion of an integral, originary, and unified self. One of the most productive ways to navigate the tension between essentialist and nonessentialist understandings of identity is to draw a comparison between identity (in life)

and character (in fiction). Rather than adopting a linear logic that understands identity as a more fundamental concept to character, this approach uses a circular logic to argue that people understand themselves in the same way they understand characters.

Narrative approaches to identity allow people to navigate the tension between essentialist and nonessentialist identities because narrative identity allows for a kind of continuity over time, a relative stability of self, without implying a substantial or essentialist core to this stability. People's interpretations of themselves use the cultural stories with which they are surrounded to tell a story of self that escapes the two poles of random change and absolute identity. In this way, a narrative identity is also a cultural identification. A person's identification may seem original, but he or she narrates them with the resources of history, language, and culture.

NARRATIVE PSYCHOTHERAPY

With this brief introduction into narrative medicine, narrative psychotherapy, and narrative theory, it is possible to draw out further the meaning of narrative for psychiatry.

Fortunately, one of the most helpful aspects of narrative theory for psychiatry is that it provides an overarching, or metatheoretical, rationale for understanding how these many psychotherapies work. From a narrative perspective, all therapies involve a process of story telling and story retelling. No matter which style of psychotherapy one uses, the process of therapy involves an initial presentation of problems that the client is unable to resolve. The client and therapist work together to bring additional perspectives to these problems, allowing the client to understand them in a new way. These additional perspectives vary greatly depending on which style of psychotherapy is used. It matters, in other words, whether the therapy is psychodynamic, cognitive, humanistic, feminist, spiritual, or expressive. From the vantage point of narrative theory, however, what these different approaches all have in common is that they rework, or "re-author," the patient's initial story into a new story. This new story allows new degrees of flexibility for understanding the past and provides new strategies for moving into the future.

FUTURE DIRECTIONS

Recent work in narrative medicine, narrative psychotherapy, and narrative theory has opened the door for the development of narrative psychiatry. This development provides a critical corrective to contemporary psychiatric practice that helps to bring psychiatry back from its current obsessions with science and scientific method. This corrective is not a return to psychoanalysis nor does it demolish the progress of scientific psychiatry. When psychiatrists take a narrative turn, they do not throw out their other skills and knowledge. The shift to narrative is, as much as anything else, an attitude shift and an opening out to additional sources of information. It starts by bringing to the foreground that the clinical encounter is a human encounter, and it follows by opening out to colleagues in the humanities, interpretive social sciences, and the arts to help to better understand this human encounter.

Most of all, narrative psychotherapy joins with other contemporary efforts in psychiatry—such as the recovery movement—to make clinical encounters much more client focused and collaborative. Narrative psychotherapy, at its core, recognizes that there are many ways to tell the story of one's life. The choice among these different options is a key way in which people create their identity. These choices should not be reduced to expert choices or scientific choices because they are always also personal and ethical choices. In the end, they are choices about what kind of life one wants to live.

Furthermore, clinicians must come to understand the value of biography, autobiography, and literature for developing a repertoire of narrative frames and options. In the end, narrative competency in psychiatry means a tremendous familiarity with the many possible stories of psychic pain and psychic difference. The more stories clinicians know, the more likely they are to help their clients to find a narrative frame that works for them.

For patients and potential service users, a narrative understanding means that there is a range of possible therapists and healing solutions that might be helpful. An approach that is right for one person may not be right for another. There must be a fit between the person and the approach, and people should feel empowered to take seriously their intuitions and feelings. If the person getting help does not feel this fit, he or she is likely right. There may well be another approach that would work better with the person's proclivities. Like everything else, however, judgment is critical. Therapeutic experiences of all kinds can be frustrating, slow, and uncertain. How, for example, does one know when an approach misses his or her needs and when it is something that will take time, patience, and perseverance to be helpful? From a narrative perspective, there can be no gold standard or simple answers. Only judgment, wisdom, and trial and error can decide.

28.12 Psychiatric Rehabilitation

Psychiatric rehabilitation denotes a wide range of interventions designed to help people with disabilities caused by mental illness improve their functioning and quality of life by enabling them to acquire the skills and supports needed to be successful in usual adult roles and in the environments of their choice. Normative adult roles include living independently, attending school, working in competitive jobs, relating to family, having friends, and having intimate relationships. Psychiatric rehabilitation emphasizes independence rather than reliance on professionals, community integration rather than isolation in segregated settings for persons with disabilities, and patient preferences rather than professional goals.

VOCATIONAL REHABILITATION

Impairment of vocational role performance is a common complication related to schizophrenia. Studies across the United States show that less than 15 percent of patients with severe mental illnesses, such as schizophrenia, are employed. Nevertheless, studies also show that competitive employment is a primary goal for 50 to 75 percent of patients with schizophrenia. Because of patient interests and historical factors, vocational rehabilitation has always been a centerpiece of psychiatric rehabilitation.

Antonio is a 45-year-old man who has been a client of a mental health agency for more than 10 years. He attended the rehabilitative day treatment program until it was converted to a supported employment program. His case manager encouraged him to think about the possibility of working part time. Antonio told his case manager that he could not work because of his schizophrenia and because he was helping to raise his two kids and needed to be home at 3 P.M., when they returned from school every day. The case manager explained to Antonio that getting a job does not necessarily mean working 40 hours a week and that lots of people in the agency's supported employment program were working in part-time jobs, even jobs that only require a few hours a week.

Antonio agreed to meet one of the employment specialists to discuss the possibility of work. Over the next couple of weeks, the employment specialist met with Antonio several times, read his clinical record, and talked with his case manager and psychiatrist. The employment specialist learned that Antonio loved to drive his car. He also learned that Antonio had attendance problems in past jobs because he felt unappreciated. The employment specialist found Antonio to be a sociable and likable person.

Antonio told the employment specialist that he was willing to do any job. He did not have one specific job in mind. After discussing options with Antonio and with the team, the employment specialist suggested a job at Meals on Wheels as a driver for the lunch delivery. Antonio was hired and loved it right from the start. Absenteeism was never a problem, because he liked driving around and knew that people were counting on him for their meals. The hours were perfect (10 A.M. to 2 P.M.), so he could be at home when his kids returned from school. He became good friends with the other workers. He told his case manager that it was wonderful to be bringing home a paycheck again. And best of all, he said, was that his kids saw him going to work just like their friends' dads. (Courtesy of Robert E. Drake, M.D., Ph.D., and Alan S. Bellack, Ph.D.)

SOCIAL SKILLS REHABILITATION

Social dysfunction is a defining characteristic of schizophrenia. People with the illness have difficulty fulfilling social roles, such as worker, spouse, and friend, and have difficulty meeting their needs when social interaction is required (e.g., negotiating with merchants, requesting assistance to solve problems). Social dysfunction is semi-independent of symptomatology and plays an important role in the course and outcome of the illness. As shown in Table 28.12-1, social competence is based on three component skills: (1) social perception, or receiving skills; (2) social cognition, or processing skills; and (3) behavioral response, or expressive skills. Social perception is the ability to read or decode social inputs accurately. This includes accurate detection of affect cues, such as facial expressions and nuances of voice, gesture, and body posture, as well as verbal content and contextual information. Social cognition involves effective analysis of the social stimulus, integration of current information with historical information, and planning an effective response. This domain is also referred to as *social problem solving*.

 **Table 28.12-1**
Components of Social Skill

Expressive behaviors
Speech content
Paralinguistic features
Voice volume
Speech rate
Pitch
Intonation
Nonverbal behaviors
Eye contact (gaze)
Posture
Facial expression
Proxemics
Kinesics
Receptive skills (social perception)
Attention to and interpretation of relevant cues
Emotion recognition
Processing skills
Analysis of the situation demands
Incorporation of relevant contextual information
Social problem solving
Interactive behaviors
Response timing
Use of social reinforcers
Turn taking
Situational factors
Social "intelligence" (knowledge of social mores and the demands of the specific situation)

Methods

The primary modality of social skills training is role play of simulated conversations. The trainer first provides instructions on how to perform the skill and then models the behavior to demonstrate how it is performed. After identifying a relevant social situation in which the skill might be used, the patient engages in role play with the trainer. The trainer next provides feedback and positive reinforcement, which are followed by suggestions for how the response can be improved. The sequence of role play followed by feedback and reinforcement is repeated until the patient can perform the response adequately. Training is typically conducted in small groups (six to eight patients), in which case patients each practice role playing for three to four trials and provide feedback and reinforcement to one another. Teaching is tailored to the individual—for example, a highly impaired group member might simply practice saying “no” to a simple request, whereas a less cognitively impaired peer might learn to negotiate and compromise.

Richard was a single white man first diagnosed with schizophrenia at age 22, when he was a freshman at college. He was hospitalized briefly but was unable to return to school and moved back home with his parents. He attended a day treatment program intermittently over the next 6 years, before he was referred for help with getting a job and dating.

Richard had missed out on a critical period of adult development and had never learned dating skills or the social skills needed to get or maintain a job. He was appropriately groomed and did not present himself as a patient, but he seemed quite uncomfortable in social interactions. He scarcely made eye contact, staring at the floor when he spoke, and did not initiate conversation, responding to questions with brief answers.

Richard was invited to participate in a social skills training group for 3 months with six other patients. The focus of the group was employment skills. Patients were taught critical social skills for getting and maintaining a job, such as how to participate in job interviews; how to approach a supervisor to understand how to do a job or for help with work-related problems; how and when to make requests or explain problems, such as getting to work late because of traffic or needing to leave early to go to a doctor's appointment; and socializing with coworkers. Simultaneously, Richard was enrolled in a supported employment program and worked with a case manager to find a job as a computer support person. He found a 24-hour-per-week job at a small company and continued to attend the skills group, using the sessions to work on interpersonal issues at work, including engaging in casual conversation with coworkers and dealing with unreasonable requests from people.

When the vocational skills group ended, Richard was scheduled for a dating group with seven other male and female patients who had similar interests. This group focused on finding someone to date, dating etiquette, asking someone out (or being asked out), appropriate conversation for dates, sexual interactions, and safe sex practices. In addition to role play and discussion, the group shared ideas on how to meet people and what to do on dates.

Richard responded well to treatment. He had maintained the computer job at follow-up, 6 months after he concluded the dating skills group. His case manager also reported that he had a girlfriend, a woman whom he had met at his church group. He had also expressed an interest in enrolling in college classes at night. He was still living at home with his parents, but, for the first time, was seriously considering what he would need to do to move out. (Courtesy of Robert E. Drake, M.D., Ph.D., and Alan S. Bellack, Ph.D.)

Goals

In a treatment setting, there are four major goals of social skills training: (1) improved social skills in specific situations, (2) moderate generalization of acquired skills to similar situations, (3) acquisition or relearning of social and conversational skills, and (4) decreased social anxiety. Learning, however, is tedious or almost nonexistent when patients are floridly ill with positive symptoms and high levels of distractibility.

Some findings limit the applicability of social skills training. It is more difficult to teach complex conversational skills than to teach briefer, more discrete verbal and nonverbal responses in social situations. Because complex behaviors are more critical for generating social support in the community, methods have been developed to improve the learning and durability of conversational skills. These training methods, focusing on training in social skills and information-processing skills, are discussed below.

Training in Social Perception Skills

Recently, efforts have been made to develop strategies for training patients in affect and social cue recognition. Patients with chronic psychotic disorders, such as schizophrenia, often have difficulty perceiving and interpreting the subtle affective and cognitive cues that are critical elements of communication. Social perception abilities are considered the first step in effective interpersonal problem solving; difficulties in this area are likely to lead to a cascade of deficits in social behavior. Training skills in social perception address these deficits and help provide a foundation for developing more specific social and coping skills.

Despite attending several social gatherings, Matt felt apart from the rest of the group. He reported that these events seemed like "a jumble of sights and sounds." His therapist, recognizing Matt's difficulty with social perception, gave him a series of questions designed to help him organize and give meaning to the social stimuli he encountered. For example, when Matt was confused about a conversation someone was having with him, he would ask himself, "What is this person's short-term goal? At what level of disclosure should I be? Should I be talking now or listening?" Identifying the rules and goals of a particular social interaction provided a template for Matt to recognize, and react to, a greater variety of social cues, thus enhancing his behavioral repertoire. (Courtesy of Robert Paul Liberman, M.D., Alex Kopelowicz, M.D., and Thomas E. Smith, M.D.)

Information-Processing Model of Training. Methods of training that follow a cognitive perspective teach patients to use a set of generative rules that can be adapted for use in various situations. For example, a six-step problem-solving strategy has developed as an outline for helping patients overcome interpersonal dilemmas: (1) adopt a problem-solving attitude, (2) identify the problem, (3) brainstorm alternative solutions, (4) evaluate solutions and pick one to implement, (5) plan the implementation and carry it out, and (6) evaluate the efficacy of the effort and, if ineffective, choose another alternative. Although the step-wise, structured, linear process of problem solving occurs intuitively, without conscious awareness in normal persons, it can be a useful interpersonal crutch to help cognitively impaired mental patients cope with the information needed to fill their social and personal needs.

MILIEU THERAPY

The locus of milieu is a living, learning, or working environment. The defining characteristics of treatment are the use of a team to provide treatment and the time the patient spends in the environment. Recent adaptations of milieu therapy include 24-hour-a-day programs situated in community locales frequented by patients, which provide in vivo support, case management, and training in living skills.

Most milieu therapy programs emphasize group and social interaction; rules and expectations are mediated by peer pressure for normalization of adaptation. When patients are viewed as responsible human beings, the patient role becomes blurred. Milieu therapy stresses a patient's rights to goals and to have freedom of movement and informal relationship with staff; it also emphasizes interdisciplinary participation and goal-oriented, clear communication.

Token Economy

The use of tokens, points, or credits as secondary or generalized reinforcers can be seen as normalizing a mental hospital or day hospital environment with a program mimicking society's use of money to meet instrumental needs. Token economies establish the rules and culture of a hospital inpatient unit or partial hospitalization program, offering coherence and consistency to the interdisciplinary team as it struggles to promote therapeutic progress in difficult patients. These programs are challenging to establish, however, and their widespread dissemination has suffered because of the organizational prerequisites and the additional resources and rewards needed to create a truly positively reinforcing environment. [Table 28.12-2](#) lists behaviors that can be reinforced by tokens.

Table 28.12-2

Contingencies of Reinforcement in the Token Economy Used at the Camarillo-UCLA Clinical Research Unit^a

Token earnings	
Morning rising from bed and getting dressed on time	3
Satisfactory completion of morning activities of daily living	3
Satisfactory participation in a social skills training group or recreational therapy activity	10
Satisfactory participation in individual behavioral therapy session	10
Satisfactory participation in leisure time activities (per activity)	5
Meets criteria for dress and grooming checks during day (per check)	3
Showers satisfactorily	3
Completes assigned jobs or tasks on unit (per job or task)	4
Participates in off-unit vocational rehabilitation or adult education activity (per half-day)	10
Token fines	
Smoking rule violation	5
Lying on floor	5
Stealing	10
Forgery of token credit card	10
Assault or property destruction	20
Late return from grounds privileges	20
Reinforcers available for tokens	
Cigarettes	4
Drinks (coffee, tea, sodas, hot chocolate)	10
Snacks (potato chips, pretzels, ice cream, candy)	10
Grounds privileges (per half-hour)	4
Music time (per half-hour)	4
Private room time (per half-hour)	4
Nintendo, Walkman stereo, private TV (per half-hour)	4

^aThis token economy uses a card that can be punched with holes to document token earnings and purchases. The token economy has three levels, which differ in the immediacy and type of reinforcement and privileges. At the highest level of performance, the patient carries a "credit card" and has full access to all unit privileges and rewards without having to pay with tokens.

(Courtesy of Robert Paul Liberman, M.D.)

COGNITIVE REHABILITATION

Increased recognition of the prevalence and importance of neurocognitive deficits over the past decade has stimulated increasing interest in remediation strategies. Much of the work in this area has focused on psychopharmacological approaches, especially on the new-generation antipsychotics. New-generation medications appear to have a positive effect on neurocognitive test performance, but the effect size for any of the medications is small to medium, and little evidence indicates that these medications have a clinically meaningful impact on neurocognitive functioning in the community. As a result, a parallel interest has arisen in the potential for *rehabilitation* or *cognitive remediation*. This body of work is distinguished from cognitive-behavioral therapy and cognitive therapy, which focus on reducing psychotic symptoms.

A study at the National Institutes of Health (NIH) found that patients with schizophrenia were unable to benefit from explicit instructions and practice on the Wisconsin Card Sorting Test (WCST), a widely used test of executive functioning. The study was linked to data demonstrating that patients had diminished prefrontal blood flow in dorsolateral prefrontal cortex while responding to the WCST, implying that schizophrenia was marked by an unmodifiable abnormality of the dorsolateral prefrontal cortex. The NIH work stimulated a series of mostly successful laboratory demonstrations that WCST performance deficits, albeit widespread, are neither endemic to the illness nor immutable. For example, one study demonstrated that WCST performance could be enhanced by financial reinforcement and specific instructions. Other laboratories have since produced comparable and enduring effects using similar training strategies and extended practice alone.

ETHICAL ISSUES

The ethics of conducting rehabilitation strategies are generally the same as for conducting other psychotherapies. Two issues come up regularly, however: avoiding infantilization and maintaining confidentiality. The first concerns the risk of viewing the patient as unable to make adult choices, such as whether to participate in rehabilitation, where to live, whether or not to work, and whether or not to use drugs and alcohol. Although it may be more of a value than an ethical standard, psychiatric rehabilitation is based on the assumption that the practitioner and the patient are in a partnership to facilitate recovery and improve quality of life. The basic model involves collaboration and shared decision making and does not portray the practitioner as an authority or parental figure. When patients make what appear to be bad choices, the practitioner must consider the patient's right to choose and whether the choice is dangerous versus simply not the choice the practitioner would make. If the choice, in fact, is potentially harmful, a collaborative process of considering alternatives is more likely to produce good choices than an authoritative, admonitory approach.

Failure to consider the patient as a partner also leads to violations of confidentiality. Practitioners sometimes assume that they are the primary arbiters of what information to share with parents, other clinicians, and other agencies. In fact, in most circumstances that do not involve the safety of patients or others, the patient should be the arbiter of what information is shared with whom. For example, in supported employment, the patients always determine whether to disclose information about their illnesses to employers.

▲ 28.13 Combined Psychotherapy and Pharmacotherapy

The use of psychotropic drugs in combination with psychotherapy has become widespread. In fact, it has become the standard of care for many patients seen by psychiatrists. In this therapeutic approach, psychotherapy is augmented by the use of pharmacological agents. It should not be a system in which the therapist meets with the patient on an occasional or irregular basis to monitor the effects of medication or to make notations on a rating scale to assess progress or side effects; rather, it should be a system in which both therapies are integrated and synergistic. In many cases, it has been demonstrated that the results of combined therapy are superior to either type of therapy used alone. The term *pharmacotherapy-oriented psychotherapy* is used by some practitioners to refer to the combined approach. The methods of psychotherapy used can vary immensely, and all can be combined with pharmacotherapy when indicated.

INDICATIONS FOR COMBINED THERAPY

A major indication for using medication when conducting psychotherapy, particularly for those patients with major mental disorders such as schizophrenia or bipolar disorder, is that psychotropics reduce anxiety and hostility. This improves the patient's capacity to communicate and to participate in the psychotherapeutic process. Another indication for combined therapy is to relieve distress when the signs and the symptoms of the patient's disorder are so prominent that they require more rapid amelioration than psychotherapy alone may be able to offer. In addition, each technique may facilitate the other; psychotherapy may enable the patient to accept a much needed pharmacological agent, and the psychoactive drug may enable the patient to overcome resistance to entering or continuing psychotherapy (Table 28.13-1).

▲ Table 28.13-1
Benefits of Combined Therapy

Improved medication compliance
Better monitoring of clinical status
Decreased number and length of hospitalizations
Decreased risk of relapse
Improved social and occupational functioning

The reduction of symptoms, especially anxiety, does not decrease the patient's motivation for psychoanalysis or other insight-oriented psychotherapy. In practice, drug-induced symptom reduction improves communication and motivation. All therapies have a cognitive base, and anxiety generally interferes with the patient's ability to gain cognitive understanding of the illness. Drugs that decrease anxiety facilitate cognitive understanding. They can improve attention, concentration, memory, and learning in patients who suffer from anxiety disorders.

NUMBER OF TREATING CLINICIANS

Any number of clinicians can be involved in treatment of a psychiatric disorder. In *one-person therapy*, the psychiatrist provides individual psychotherapy and medication treatment. Multiperson therapy is a form of treatment in which one therapist (who may be a psychiatrist, psychologist, or a social worker) conducts psychotherapy while the other therapist (always a psychiatrist) prescribes medications. Other therapists may oversee marriage or family therapy or group therapy. The terms *cotherapy* or *triangular therapy* are sometimes used to describe permutations of multiperson therapy.

COMMUNICATION AMONG THERAPISTS

Whenever more than one clinician is involved in treatment, there should be regular exchanges of information. Some patients split the transference between the two; one therapist may be seen as giving and nurturing, and the other may be seen as withholding and aloof. Similarly, countertransference issues, such as one therapist's identifying with the patient's idealized or devalued image of the other therapist, can interfere with therapy. Those issues must be worked out, and the cotherapists must be compatible and respectful of each other's orientation, so that the therapy program can succeed.

A therapist may have some concerns about the quality of the psychopharmacology or that the existing regimen needs to be reconsidered. For example, a patient may not be doing well on medication, experiencing significant side effects, or showing lack of sufficient improvement. Some patients may also be taking many different medications. When and if it is deemed in the patient's interest to question the medication regimen or the prescriber's skill, these misgivings should not be shared with the patient without first conferring with the prescribing physician.

If the therapist or pharmacologist, after a good-faith effort to understand the methods and course of treatment, still has misgivings about treatment, he or she should inform his or her counterpart that a second opinion would be useful. This should then be suggested to the patient without necessarily raising undue alarm. Communication between treating clinicians should take place as frequently as needed. No standard exists for how frequent that should be.

ORIENTATIONS OF TREATING CLINICIANS

The orientation of the treating psychiatrist or other clinician can influence the therapeutic process during combination treatment. Clinicians invariably bring a theoretical bias to the treatment setting. Some, for example, are oriented, by preference and training, to practice a specific form of psychotherapy, such as psychoanalysis, cognitive-behavioral therapy (CBT), or group therapy. To these clinicians, psychotherapy is seen as the primary treatment modality, with pharmacological agents being used as an adjunct. Conversely, to a psychopharmacologically oriented psychiatrist, psychotherapy is seen as augmenting the use of medication. Although disagreement may arise on which approach represents the most active ingredient in clinical response, the optimal use of both modalities should complement each other.

In addition to having extensive training in one or more psychoanalytic or psychotherapeutic techniques, the psychiatrist who practices pharmacotherapy-oriented psychotherapy must have a comprehensive knowledge of psychopharmacology. That knowledge must include a thorough understanding of the indications for the use of each drug, the contraindications, the pharmacokinetics and pharmacodynamics, the drug-drug interactions (with all pharmacological agents, not only the psychoactive agents), and the adverse effects of medications. The psychiatrist must be able both to identify adverse effects and to treat them.

Nonpsychiatric physicians often use psychoactive agents inaccurately (too small or too large a dose for too short or too long a course), because they lack the requisite psychopharmacological knowledge, training, and experience. Psychotherapists who work with primary care physicians instead of psychiatrists should understand the limitations in depth of knowledge that these practitioners have and should seek a consultation with a psychiatrist if a patient is not responding to, or tolerating, medication. In some situations, it is preferable for psychotherapy and pharmacotherapy to be carried out by the same clinician; however, this is often not possible for a variety of reasons, including therapist availability, time limitations, and economic restraints, among others (Table 28.13-2).

▲ Table 28.13-2
Clinical Situations in Which It Is Advantageous for One Psychiatrist to Provide Medication and Psychotherapy

Patients with schizophrenia and other psychotic disorders who are not compliant with prescribed medication
Patients with bipolar I disorder who deny illness and do not cooperate with the treatment plan
Patients with serious or unstable medical conditions
Patients with severe borderline personality disorders
Impulsive and severely suicidal patients who are likely to require hospitalization
Patients with eating disorders who present complicated management problems
Patients who present a clinical picture in which the need for medication is unclear, thus requiring ongoing assessment

Therapist Attitudes

Psychiatrists trained primarily as psychotherapists may prescribe medication more reluctantly than those who are more oriented toward biological psychiatry. Conversely, those who view medication as the preferred intervention for most psychiatric disorders may be reluctant to refer patients for psychotherapy. Therapists who are pessimistic about the value of psychotherapy or who misjudge the patient's motivation may prescribe medications because of their own beliefs; others may withhold medication if they overvalue psychotherapy or undervalue pharmacological treatments. When a patient is in psychotherapy with someone other than the clinician prescribing medication, it is important to recognize treatment bias and to avoid contentious turf battles that put the patient in the middle of such conflict.

Linkage Phenomenon

At some point, patients may view the improvement being made in therapy as the result of a conscious or unconscious linkage between the psychopharmacological agent and the therapist. In fact, after being weaned from medication, patients often carry a pill with them for reassurance. In that sense, the pill acts as a transitional object between the patient and the therapist. Some patients with anxiety disorders, for example, may carry a single benzodiazepine tablet, which they take when they think they are about to have an anxiety attack. Then, the patient may report that the attack was aborted—before the medication could even have been absorbed into the bloodstream. In other cases, the pill is never taken, because the patient knows that the pill is available and gains reassurance from that fact. The linkage phenomenon is usually not seen unless the patient is in a positive transference to the therapist. Indeed, the therapist may use this phenomenon to his or her advantage by suggesting that the patient carry medication to use as needed. Eventually, the behavior has to be analyzed, and it is often found that the patient has attributed magical properties to the therapist that are then transferred to the medication. Some clinicians believe the effect to be the result of conditioning. After repeated trials, the sight of the medicine can decrease anxiety. The positive transference may also cause *transference cure* or *flight into health*, in which the patient feels better in an unconscious attempt to meet the presumed expectations of the prescribing physician. Therapists should consider this phenomenon if the patient reports rapid improvement well before a particular medication may reach its therapeutic level.

Rachel, a 25-year-old white woman, presented with depressive symptoms and abdominal pain. After an extensive psychiatric and medical evaluation, she was diagnosed with major depression of moderate severity and irritable bowel disorder. She began a course of CBT targeting her negative attributional style and low self-esteem, and she was taught relaxation and distraction techniques for her pain. After a 12-week trial, she experienced only partial remission of her symptoms and was offered an antidepressant, citalopram (Celexa) at 20 mg per day. Her depressive symptoms remitted within 1 month, and she was able to function better at work but socially remained hesitant to engage with her peers. Her abdominal pain persisted, and she began to exhibit a pattern of disordered eating, severely restricting her intake to 500 calories per day due to the “pain.” She experienced a 15-pound weight loss over the next several months. An intensive behavioral plan to target eating was begun, as well as continued probing of her negative cognitions relating to eating, pain, and newly emerging concerns that she would regain the weight too quickly and would become “fat.” She did not meet weight loss criteria for anorexia nervosa, although her cognitive distortions about her body image were extreme. These new concerns resulted in a relapse of her depressive symptoms, including suicidal ideation, and her citalopram was increased to 40 mg per day. She reported severe akathisia on this dose and refused to take any more medication, including an antidepressant of another class. Rachel did agree to intensify her therapy to twice weekly, and this allowed her to explore some of her conflicts, feelings, and thoughts that fostered her treatment-refractory illness. A combination of psychotherapy and hypnosis was used for this work. Over the next 6 months, Rachel revealed that she had been sexually abused as a child and this made her feel that she did not “deserve” to live or to eat and that the pain served to “punish” her for being bad. She also admitted that she resisted the medication “psychologically” because she felt that she did not deserve to get well. Her newly found insight, as well as the coping skills she developed in therapy, resulted in a reduction of her depressive symptoms, marked improvement in her eating habits with normalization of her weight, and decreased abdominal pain. She maintained these gains over the next year, including normalization of her daily functioning, a promotion at work, and the ability to tolerate the intimacy of a boyfriend. (Courtesy of E. M. Szigethy, M.D., Ph.D., and E. S. Friedman, M.D.)

COMPLIANCE AND PATIENT EDUCATION

Compliance

Compliance is the degree to which a patient carries out the recommendations of the treating physician. Compliance is fostered when the doctor–patient relationship is a positive one, and the patient's refusal to take medication may provide insight into a negative transference situation. In some cases, the patient acts out hostilities by noncompliance, rather than by becoming aware of, and ventilating, such negative feelings toward the doctor. Medication noncompliance may provide the psychiatrist with the first clue that a negative transference is present in an otherwise compliant patient who had appeared to be agreeable and cooperative.

Education

Patients should know the target signs and symptoms that the drug is supposed to reduce, the length of time they will be taking the drug, the expected and unexpected adverse effects, and the treatment plan to be followed if the current drug is unsuccessful. Although some psychiatric disorders interfere with patients' abilities to comprehend that information, the psychiatrist should relay as much of the information as possible. The clear presentation of such material is often less frightening than are patients' fantasies about drug treatment. The psychiatrist should tell patients when they may expect to begin to receive benefits from the drug. That information is most critical when the patient has a mood disorder and may not observe any therapeutic effects for 3 to 4 weeks.

Some patients' ambivalent attitudes toward drugs often reflect the confusion about drug treatment that exists in the field of psychiatry. Patients often believe that taking a psychotherapeutic drug means they are not in control of their lives or they may become addicted to the drug and have to take it forever. Psychiatrists should explain the difference between drugs of abuse that affect the normal brain and psychiatric drugs that are used to treat emotional disorders. They should also point out to patients that antipsychotics, antidepressants, and

antimanic drugs are not addictive in the way in which, for example, heroin is addictive. The psychiatrist's clear and honest explanation of how long the patient should take the drug helps the patient adjust to the idea of chronic maintenance medication if that is the treatment plan. In some cases, the psychiatrist may appropriately give the patient increasing responsibility for adjusting the medications as the treatment progresses. Doing so often helps the patient feel less controlled by the drug and supports a collaborative role with the therapist.

ATTRIBUTION THEORY

Attribution theory is concerned with how persons perceive the causes of behavior. According to attribution theory, persons are likely to attribute changes in their own behavior to external events, but are likely to attribute another's behavior to internal dispositions, such as that person's personality traits. Research on drug effects by attribution theorists has shown that, when patients take medication and their behaviors change, they attribute it to the drug and not to any changes that occur within themselves. Accordingly, it may be unwise to describe a drug as extremely strong or effective, because if it does have the desired effect, the patient may believe that is the only reason he or she got better; if the drug does not work, the patient may assume his or her condition is incurable. Therapists do best by presenting the use of drugs and psychotherapy as complementary or adjunctive, as neither standing alone and both being needed for improvements or cure to occur.

MENTAL DISORDERS

Depressive Disorders

Some patients and clinicians fear that medication covers over the depression and that psychotherapy is impeded. Instead, medication should be viewed as a facilitator in overcoming the anergia that can inhibit the communication process between doctor and patient. The psychiatrist should explain to the patient that depression interferes with interpersonal activity in a variety of ways. For instance, depression produces withdrawal and irritability, which alienate significant others who may otherwise gratify the strong dependency needs that make up much of depressive psychodynamics.

If medication is stopped, the psychiatrist should be alert for signs and symptoms of a recurrent major depressive episode. Medication may have to be reinstated. Before doing so, however, carefully review any stress, especially rejections, that could have precipitated recurrent major depressive disorder. A new episode of depression may occur because the patient is in a stage of negative transference, and the psychiatrist must try to elicit negative feelings. In many cases, the ventilation of angry feelings toward the therapist without an angry response can serve as a corrective emotional experience, and a major depressive episode necessitating medication can thereby be forestalled. Depressed patients are generally maintained on their medication for 6 months or longer after clinical improvement. The cessation of pharmacotherapy before that time is likely to result in a relapse.

Combined treatment has been shown to be superior to either therapy used alone in the treatment of major depression. It is associated with improved social and occupational functioning and improved quality of life compared with either therapy alone.

Bipolar I Disorder

Patients taking lithium (Eskalith) or other treatments for bipolar I disorder are usually medicated for an indefinite period of time to prevent episodes of mania or depression. Most psychotherapists insist that patients with bipolar I disorder be medicated before starting any insight-oriented therapy. Without such premedication, most patients with bipolar I disorder are unable to make the necessary therapeutic alliance. When those patients are depressed, their abulia seriously disrupts their flow of thoughts, and the sessions are nonproductive. When they are manic, their flow of associations can be rapid, and their speech can be so pressured that the therapist could be flooded with material and may be unable to make appropriate interpretations or to assimilate the material into the patient's disrupted cognitive framework.

The practice guideline of the American Psychiatric Association (APA) for bipolar disorder recommends combined therapy as the best approach. It increases compliance, decreases relapse, and reduces the need for hospitalization.

Substance Abuse

Patients who abuse alcohol or drugs present the most difficult challenge in combined therapy. They are often impulsive, and, although they may promise not to abuse a substance, they may do so repeatedly. In addition, they frequently withhold information from the psychiatrist about episodes of abuse. For that reason, some psychiatrists do not prescribe any medication to such patients, especially not those substances with a high abuse potential, such as benzodiazepines, barbiturates, and amphetamines. Drugs with no abuse potential, such as amitriptyline (Elavil) and fluoxetine (Prozac), have an important role in treating the anxiety or depression that almost always accompanies substance-related disorders. The psychiatrist conducting psychotherapy with such patients should have no reservations about sending the patient to a laboratory for random urine toxicological tests.

Anxiety Disorders

Anxiety disorders encompass obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), generalized anxiety disorder, phobic disorders, and panic disorder with or without agoraphobia. Many drugs are effective in managing distressing signs and symptoms. As the symptoms are controlled by medication, patients are reassured and develop confidence that they will not be incapacitated by the disorder. That effect is particularly strong in panic disorder, which is often associated with anticipatory anxiety about the attack. Depression can also complicate the symptom picture in patients with anxiety disorders and has to be addressed pharmacologically and psychotherapeutically. Studies have shown that patients with anxiety disorders who receive ongoing psychotherapy are less likely to experience relapse compared with patients who receive medication alone.

Schizophrenia and Other Psychotic Disorders

Included in the group of schizophrenia and other disorders are schizophrenia, delusional disorder, schizoaffective disorder, schizophreniform disorder, and brief psychotic disorder. Drug treatment for those disorders is always indicated, and hospitalization is often necessary for diagnostic purposes, to stabilize medication, to prevent danger to self or others, and to establish a psychosocial treatment program that may include individual psychotherapy. In attempting individual psychotherapy, the therapist must establish a treatment relationship and a therapeutic alliance with the patient. The patient with schizophrenia defends against closeness and trust and often becomes suspicious, anxious, hostile, or regressed in therapy. Before the advent of psychotropics, many psychiatrists were fearful for their own safety when working with such patients. Indeed, many assaults occurred.

Individual psychotherapy for schizophrenia is labor intensive, expensive, and not often attempted. The recognition that combined psychotherapy and pharmacotherapy have a greater chance of success than either type of therapy alone may reverse that situation. The psychiatrist who conducts such combined therapy must be especially empathic and must be able to tolerate the bizarre manifestations of the illness. The patient with schizophrenia is exquisitely sensitive to rejection, and individual psychotherapy should never be started unless the therapist is willing to make a total commitment to the process.

OTHER ISSUES

Evidence suggests that therapy can induce physical changes in the nervous system. Eric Kandel has provided elegant proof, winning the Nobel Prize for demonstrating that environmental stimuli produce lasting changes in the synaptic architecture of living organisms. Imaging studies have begun to show that patients who show clinical improvement from psychotherapy show changes in brain metabolism that are similar to that seen in patients successfully treated with medications.

Still, some patients do well on only one form of treatment. Even with identical diagnoses, not all patients respond to the same treatment regimens. Success may be as dependent on the knowledge and quality of the clinician as on the potential benefit of a particular drug.

A real dilemma when combining treatment is the additional direct costs of two treatments. Although successful treatment results in reduced costs to society, the cost of treatment is usually narrowly defined by the patient as out-of-pocket expenses and by insurance and managed care companies as payments to the physician or hospital. Restrictions placed on the frequency and cost of visits to mental health professionals by managed care organizations, however, encourage the use of medication rather than psychotherapy.

28.14 Genetic Counseling

Medical geneticists and specially trained and qualified genetic counselors have traditionally provided genetic counseling to patients in need of such help. Many psychiatrists, however, are also well placed to provide genetic education and counseling because they often have knowledge of their clients' needs and family histories and have ongoing therapeutic relationships. The ideal approach for providing psychiatric genetic counseling is through a multidisciplinary team approach, with collaboration between genetics and mental health professionals. Genetic professionals often seek collaboration with a psychiatrist for those with difficult psychiatric medical or family histories. Genetic professionals also seek collaboration or referral for persons with a psychiatric disorder; those who are having difficulty adapting to a genetic-related diagnosis; those dealing with the death of a family member; or those who are experiencing persistent difficulty with decision making regarding prenatal diagnosis or genetic testing. In turn, genetic professionals can be available for professional consultation regarding risk assessment, the collection and construction of complicated family medical histories, and the availability and limitations of genetic or genomic testing.

DEFINITIONS

Genetic counseling is the process of helping people to understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. According to the National Society of Genetic Counseling, it integrates three factors: (1) interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; (2) education about inheritance, testing, management, prevention, resources, and research; and (3) counseling to promote informed choices and adaptation to the risk or condition. The process aims to minimize distress and facilitate adaptation, to increase one's feeling of personal control, and to facilitate informed decision making and life planning.

Genetic counseling is not limited to considerations of the genetic contributions of disease. Genetic counseling also considers *environmental* components of the presenting disease along with *genetic* ones. [Table 28.14-1](#) lists common terminology used in the field of genetic counseling. [Figure 28.14-1](#) illustrates a complex family medical history presented in the form of a pedigree.

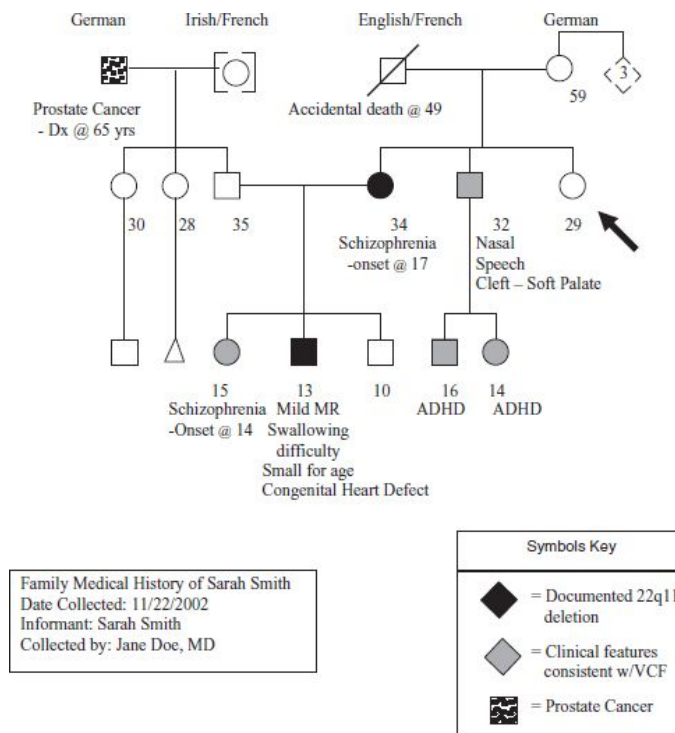

FIGURE 28.14-1

Pedigree of a family with velocardiofacial (VCF) syndrome. ADHD, attention-deficit/hyperactivity disorder; Dx, diagnosed; MR, mental retardation. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins, 2009, with permission.)

Table 28.14-1
Genetic Terminology

Absolute risk	One's risk of developing a disease over a specified time period (e.g., the empirical risk for autism in a sibling of an individual with idiopathic autism is about 6%–8%; related term: relative risk)
Allele	One of the variant forms of a gene at a particular locus, or location, on a chromosome
Assortative mating	Nonrandom mating in which individuals preferentially mate with others with similar traits
Consultand	Person seeking genetic counseling
Complex (or multifactorial)	Traits, diseases, or disorders resulting from the interactions of genetic and environmental factors
Familial	Disorder recurring in a family that may result from a combination of shared genotype and environment
First-degree relatives	Biological relatives sharing 50% of their genetic makeup (e.g., parents, siblings, children)
Gene of major effect	As found in true dominant and recessive genetic disorders, a gene that is able independently to cause a phenotype, with little influence from the environment or other genetic contributions
Genome	All of the DNA (deoxyribonucleic acid) within a cell or organism; nuclear and mitochondrial
Genotype	Genetic makeup; most often referring to the allelic contribution at a particular locus
Heritability	Proportion of phenotypic variance attributable to genetic variance
Morbid or lifetime risk	The probability that subjects under study will develop an illness if they live long enough; takes into consideration that a susceptible subject may not have onset at the time of examination or may die of another cause before onset
Phenotype	Clinical presentation of the disorder
Polygenic	Traits resulting from the interaction of multiple genes
Presymptomatic	Unaffected individual known to carry a mutation that is very likely to result in the expression of the disorder
Proband	The affected person bringing the family to medical attention
Recurrence risk	Probability that a disorder will recur in other family members
Relative risk	One's risk of developing a disease when compared with a referent group (e.g., if the probability of developing idiopathic autism among siblings of an affected person is 6%–8% compared with the risk in the general population of 0.1%, then the relative risk of autism in siblings of an affected individual is about 70; related term: absolute risk)
Second-degree relative	Biological relatives sharing 25% of their genetic makeup (e.g., grandparents, grandchildren, nephews, nieces)
Susceptibility	Increased risk, owing to the presence of deleterious allele, of developing a disease or disorder compared with the general population
Spectrum disorders	Disease or disorders in which the phenotypic expression is characterized by a broad range of variance (e.g., autism spectrum disorders)

GENETICS AND MENTAL HEALTH

Disorders can recur in families for many reasons, including the functioning of genes (single genes vs. polygenic) (Table 28.14-2), shared environmental exposures, a combination of genetic and environmental factors (multifactorial), and cultural transmission. *Single gene disorders* are caused by defects in one particular gene, and they often have simple and predictable inheritance patterns. By contrast, most psychiatric disorders are *multifactorial* in etiology, influenced by multiple genes as well as environmental factors, making them more difficult to predict.

Table 28.14-2
Examples of Psychiatric Disorders Recognized as Having a Genetic Component to Their Etiology

Psychotic disorders: Schizophrenia, schizoaffective disorder
Mood disorders: Bipolar disorder, recurrent unipolar depression
Personality disorders: Antisocial personality disorder, schizotypal disorder
Anxiety disorders: Generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, phobia
Substance-related disorders: Substance dependence and abuse
Eating disorders: Anorexia nervosa, bulimia
Childhood disorders: Attention-deficit/hyperactivity disorder, autism, chronic tic disorders, including Tourette's disorder
Memory disorders: Alzheimer's disease

Two phenomena that further complicate genetic counseling include penetrance and expressivity. *Penetrance* refers to the portion of individuals with a specific genotype who also manifest that genotype at the phenotype level. If all individuals who carry the dominant gene show any phenotype of the gene, the gene is said to be *completely penetrant*. Currently, only rare examples exist of known genes for mental disorders that demonstrate complete penetrance of symptoms in the presence of a single gene. One such example is early-onset familial Alzheimer's disease resulting from mutations in the amyloid precursor protein (APP) located on the long arm of chromosome 21. In contrast, *expressivity* refers to the extent to which a genotype is expressed. In the case of variable expressivity, the trait can vary in expression from mild to severe, but is never completely unexpressed in individuals who have the gene. The genes that result in most mental disorders are believed to regulate a wide spectrum of traits demonstrating variability of expression (spectrum disorders).

COMPONENTS OF THE GENETIC COUNSELING PROCESS

Requests for genetic counseling are often initiated by the client's or relatives' questions about the disorder that is present in the family. In the case of mental illness, the questions are often posed to the treating psychiatrist. The client's questions are most effectively addressed through an interactive process that provides the client, as well as the professional, with information pertinent to the next step in the communication process. The basic components of genetic counseling are outlined in [Table 28.14-3](#).

Table 28.14-3 **Steps and Process of Genetic Counseling**

Solicit and clarify the client's presenting questions and goals for genetic counseling.
Collect and review medical and family medical history.
Identify support systems.
Verify diagnoses in proband and other affected family members when possible.
Address issues and concerns identified through the genetic counseling process.
Assess the client's emotional and intellectual capacity before proceeding to determine the approach to the provision of education and counseling.
Provide information at cognitively appropriate levels.
Note that the processing of emotional reactions is intertwined with the provision of information.
Assess the personal meaning of the information and the client's willingness to negotiate various risks and burdens.
When applicable, assist the client in arriving at a decision by discussing available options; discuss benefits and limitations of each alternative.
Assist the client with adapting to the risk status in the family.
Assist in formulating a plan that the client is able to carry out.
Provide follow-up counseling and support. Continue to assess the client's and family's understanding of the information and the effect of the information, risks, or decisions.

Contracting

Contracting is a vital portion of the psychiatric genetic counseling session. Often the goals of the session will vary based on the consultant's histories and reason(s) for concern. The provider should work with the consultant at the beginning of the session to define mutual goals.

Documentation of Diagnosis, Collection, and Review of Family Medical History

A family medical history (FMH) is collected, and at least a three-generation pedigree is constructed. The collection of FMH begins with the individual seeking information. The *consultant* (or client) is the individual seeking information. *Proband* is the term used to identify the affected person within the family who first brought the family to medical attention. The FMH should be comprehensive and include the following information: ages (or dates of birth) of each family member, the age at which the diagnosis was made for individuals with the disorder, pregnancy losses (including the gestational length along with the recognized cause, if known), the recognized cause and age of any deceased family members, and ethnic backgrounds ([Table 28.14-4](#)).

Table 28.14-4 **Topics Included in the Family Medical History**

- A. Any psychiatric diagnosis, whether childhood, adult, postpartum, or geriatric
 1. Age of symptom onset and at diagnosis
 2. Subjective assessment of illness severity and treatment response
 3. Potentially important environmental exposures (e.g., birth trauma, cannabis use, head injury)
 - B. Symptomatic, undiagnosed individuals
 1. Suggest a psychiatric evaluation
 - C. Undiagnosed individuals treated with psychiatric medications
 - D. Developmental history (e.g., has the individual achieved normal milestones for age, such as independent living and employment for adults?)
 - E. Social history
 - F. Substance abuse
 - G. Suicide
 - H. Birth defects, mental retardation or learning disabilities, and unusual medical conditions
 - I. The age and sex of at-risk family members (which may play a role in risk assessment)
-

Confirmation or clarification of the diagnosis is essential to the provision of valid information within the session. This usually requires obtaining medical records to clarify or to confirm the suspected diagnosis in the relatives. Depending on the situation, genetic testing may be available for at-risk members in families with single-gene disorders; but because DNA (deoxyribonucleic acid) testing for most mental disorders is not yet an option, risk assessment is based solely on analysis of the pedigree.

The collection and review of the FMH with the patient might elicit or recall intense feelings of sadness, guilt, anxiety, or anger. Furthermore, the graphic presentation of the family history may bring to light a more concrete realization of an individual's risks; therefore, attention to the patient's affect is important throughout the process. Specific issues that may hinder an accurate psychiatric family history and may increase consultant affect related to family history are listed in Table 28.14-5.

Table 28.14-5
Issues that Can Hinder an Accurate Psychiatric Family History

- ▶ Stigma and shame may limit what a consultant is willing to share.
- ▶ Stigma and shame may limit what family history has been shared with the consultant by other family members.
- ▶ Many affected individuals have not been diagnosed.
- ▶ Diagnoses change over time for reasons including patients' evolving illness course, changes in diagnostic criteria, and interprofessional variation in diagnosis.
- ▶ Highly symptomatic individuals may not be able to provide a comprehensive and accurate family history.

Communication of Risk and Decision Making

Individuals vary in their level of understanding risks. The provision of risk information is best approached in a balanced and accurate manner that is tailored to the patient as much as possible. There is the temptation to use nonnumeric phrases of probability (e.g., often, rarely, most likely); however, the meaning of these nonnumeric phrases is highly subjective and their use in the genetic counseling session introduces the potential for bias.

Ideally, risks should be presented in several different ways, taking clues from interactions with the client that inform the approach. Some examples of approaches to assist the client's understanding of risks include stating numeric risks as percentages (25 percent) and as fractional risks (one-in-four chance). It is important to frame risks from the perspective of a negative and a positive outcome; for example, there is a 1 percent chance that the test will result in a complication and a 99 percent chance that there will be no complication.

Owing to the high rate of co-occurring disorders and the wide phenotypic range of psychiatric disorders, patients should be informed of potential risks for disorders other than those that brought them to genetic counseling. An example of this is the risk to first-degree relatives of an individual diagnosed with bipolar disorder. In this situation, the risk for bipolar disorder is increased for first-degree relatives, as are the risks for unipolar disorder, schizoaffective disorder, and cyclothymia.

It should be made clear that the risks are determined from populations and not derived from individuals and, therefore, are estimates at best. Table 28.14-6 provides a compilation of recurrence risks from various referenced sources in the literature.

Table 28.14-6
Empirical Risks for Selected Mental Disorders

	Schizophrenia	Bipolar Disorder	Unipolar Major Depressive Disorder		Schizoaffective Disorder	Obsessive-Compulsive Disorder	Panic Disorder	Generalized Anxiety Disorder	Alcohol Dependence		Anorexia Nervosa	ADHD

PSYCHOSOCIAL COUNSELING AND SUPPORT

Setting the stage for the inclusion of psychological and emotional issues can occur early in the process by verbalizing the intent to provide factual information, as well as fostering a discussion of the client's reaction to the information. Insight into the client's perspective and experiences with the disorder, values, beliefs, and family dynamics can begin to be obtained through asking what brings the client to the genetic counseling session. Eliciting this personal information provides a relational context from which the provider can assess concerns and emotional issues. Collection of the FMH can also provide a backdrop of the client's and family's experiences with the disorder. The exchange of information that occurs during the collection of the FMH can identify underlying risk and perceptions, family beliefs or myths regarding the disorder, and existing support system within the family.

A couple in their mid-30s with a 10-year history of infertility had been trying to adopt a child for a number of years. Recently, the adoption agency they were working with told them of a baby who was being placed for adoption because the biological mother was affected with bipolar disorder and did not feel that she could provide adequate care for the baby. The FMH collected on the newborn baby did not identify others in his family with mental disorders. The recurrence risk for bipolar disorder to the newborn was, therefore, estimated to be between 5 and 20 percent, with additional risks for other mental disorders. The couple individually reacted quite disparately to the estimated risks. In attempting to help them clarify the factors contributing to their feelings regarding the risks, the husband shared his experience with a childhood neighbor who had "some kind of mental illness" and detailed the "torment and agony" that the child brought to the family. Retorting, the woman shared the fact that her coworker also had bipolar disorder and did "just fine" at work with the help of medication. She therefore did not feel that the risks for mental disorders were of concern. The psychiatrist facilitated the couple's discussion of the spectrum and meaning of mental illness, along with recurrence risks in the context of a genetic education and counseling session. Although the couple did not come to agreement at that meeting over the potential for adopting the child, they did feel that the information and sharing of experiences and perspectives about mental disorders were beneficial. They agreed to return in 1 week after further considering the issues in an effort to reach a decision regarding the adoption. (Courtesy of Holly L. Peay, M.S., and Donald W. Hadley, M.S.)

CHALLENGES POSED BY PRESYMPTOMATIC AND SUSCEPTIBILITY GENETIC TESTING

Psychiatrists will be on the front line for receiving requests for genetic counseling and testing because of their established relationship between patients and families with mental disorders. The identification of these risks will most likely occur before the discovery or availability of preventative options. The option of knowing risks without preventative options raises concerns regarding the impact of such knowledge on the individual's mood, anxiety, distress, self-image, reproductive decisions, career decisions, family relationships, insurability, employment, and, potentially, other areas.

A model for the provision of presymptomatic genetic testing is provided through the protocol developed for Huntington's disease (see the Hereditary Disease Foundation web site at www.hdfoundation.org). This model recommends conducting education, counseling, and evaluative sessions over an extended period of time (3 to 4 months), during which time information is provided, questions are addressed, and counseling is initiated, thus maximizing informed decision making. The process is most appropriately undertaken in the absence of other stressful events (e.g., death of a family member, diagnosis of the disease in another family member, job loss, and divorce).

Studies suggest that most individuals receiving information of their increased risk for the disease in their family experience significantly more anxiety, depression, and psychological distress and have poorer perception of their health over the short term (within 1 month after receiving test results) compared with their baseline levels, but no difference over the long term (as long as 1 year after the receipt of results) compared with pretest levels. Consideration should also be given to the impact of such information on the spouse, because initial studies have suggested that the spouse may experience higher levels of depression related to the presymptomatic diagnosis than the client. Furthermore, partners of gene-positive individuals may experience increased levels of intrusive thoughts, avoidance, and hopelessness over the short and long term compared with baseline levels.

ETHICAL, LEGAL, AND SOCIAL CONSIDERATIONS

Certain individuals and families may experience significant levels of stigma associated with the identification of a genetic disorder, a situation already familiar to individuals and families with mental illness. The added knowledge of a hereditary component may heighten stigmatization. Conversely, having an identified, biological basis may supplant current public perceptions that mental illness is somehow a personal or family failure in moral, spiritual, or attitudinal perspectives.

Questions frequently arise about the privacy of an individual's genetic information, the ability of employers or insurers to access such information, and the potential of using the information against them by denying insurance, raising rates to unreasonable levels, or denying jobs, and a host of other possible concerns. Currently, no overarching federal laws comprehensively protect citizens of the United States from the potential of these abuses, although significant efforts are continuing in this regard. The status of existing and proposed state and federal laws can be reviewed through the web site of the National Human Genome Research Institute (www.genome.gov).

28.15 Mentalization-Based Therapy and Mindfulness

Mentalization is a relatively new term that has been defined as the process of thinking and feeling about oneself and others. Mindfulness is somewhat similar except that it applies only to oneself. In both modalities the person attempts to stay aware of thoughts, feelings, affects, moods, and somatic sensations; but in mentalization that exercise extends to another person as well. It is an interpersonal transaction. The origins of mentalization-based therapy (MBT) have been attributed to two psychologists, Jon Allen and Peter Fonagy, and one psychiatrist, Anthony Bateman, who described the process in their book *Mentalizing in Clinical Practice*, much of which formed the basis for this section.

From a theoretical perspective, MBT is eclectic in that it combines theories from a number of analytic and nonanalytic schools of thought: Sigmund Freud and psychoanalysis; John Bowlby and attachment theory; Aaron Beck and cognitive therapy; Carl Rogers and client-centered therapy; and Gerald Klerman and interpersonal therapy. The amalgam of these techniques developed into the unique method of treatment known as mentalization.

Mindfulness has its origins in Buddhist philosophy and the term was used in the 19th century to refer to a meditative technique in which the person stayed in the moment focusing on innermost feelings and states of mind. Mindfulness and mentalization rely on the same process; the person focuses on being in the “here and now.” Some have described the differences between MBT and mindfulness by stating that in MBT one is “mindful of mindfulness.”

The novel focus of a mindfulness approach is on present-moment, nonjudgmental awareness of consciousness, that is, noticing one's thoughts and feelings in the moment and accepting them without judging or trying to change them. In many ways, mindfulness is a variation of self-monitoring in which patients attend to and increase awareness of thoughts, feelings, and behaviors. However, increased awareness of these phenomena from a mindfulness perspective does not involve analyzing them to determine how best to modify them. Instead, patients might be asked to imagine their thoughts and feelings as if they were written on cards carried by marchers in a parade or as if they were pieces of luggage on a conveyor belt. They are asked to observe internal phenomena without reaction.

THERAPEUTIC APPROACHES

Freud believed that all action was preceded by thought (conscious or unconscious), and in mentalization the therapist helps the patient “capture” the thought so that actions are understood more fully. Bowlby saw attachment of the infant to the mother or to the primary caregiver as the basis for a sense of security later in life. In mentalization, the therapist relies on a secure attachment with the patient to enable him or her to explore the inner world of emotions and the outer world of action, both of which elicit anxiety. Beck proposed that cognitive distortions of the self (e.g., “She doesn't like me”) could be reversed by positive cognitions (e.g., “I don't know if she likes me; many people do”). The mentalization therapist corrects distortions through interpretation and helps the patient test the validity of negative thoughts. The patient is encouraged to use the mechanism of empathy to step into the shoes of the other and to experience what that person may be thinking or feeling. It is the antithesis of self-centeredness. Klerman emphasized transference distortions—a Freudian concept—that interfere with interpersonal relationships. The mentalization therapist attempts to strengthen the patient's capacity to see the other as he or she really is by not “mind reading” or fantasizing about what the other person thinks. Rogers emphasized the autonomy of the patient vis-à-vis the therapist who was not to be seen as all knowing and omnipotent. The mentalization therapist relies on a certain degree of self-disclosure to reinforce that concept. In that sense, the therapist serves as a role model for coping with the anxieties of daily living and the vicissitudes of life. The task of the therapist is neither to judge nor advise. He or she takes a “mentalizing stance,” which is neutral and allows the patient to resolve conflict using innate resources that were previously unrecognized. MBT also allows the patient to mentalize the future by anticipating events and his or her reactions to them. In MBT emotion is experienced in a controlled and modulated manner, which can be a valuable therapeutic experience for persons whose affect is restricted because of fear. Fonagy has described what he calls the *mentalizing stance* as “an attitude of openness, inquisitiveness and curiosity about what's going on in the others' mind and in your own.” In that sense, the use and development of empathy is a core component of the process.

Mindfulness is the practice of paying attention in a particular way—on purpose, in the present moment, and without judgment. Mindfulness skills include the ability to observe, describe, and participate fully in one's actions in a nonjudgmental, mindful, and effective manner. Some of the work in mindfulness-based approaches centers on decreasing what is known as *experiential avoidance* or the unwillingness to experience negative feelings, thoughts, and sensations. Persons who are skilled and well practiced in mindfulness are more adept at taking their automatic thoughts “with a grain of salt.” Upset by a series of interpersonal disappointments, a person may think “I am never going to let myself care about people ever again.” However, as he or she takes stock of this thought, the individual quickly concludes that this self-statement is neither realistic nor constructive. Instead, the person recognizes that the emotional pain of the moment is tied up in biased thinking, and that the solution to recovering from negative life events requires learning from the difficult situations and moving on.

Mindfulness approaches are aimed at improving patients' abilities to regulate their emotions and tolerating distress may then be considered, in effect, exposure exercises. Although techniques that increase patients' nonjudgmental awareness of internal sensations may be

considered at odds with attempts to change thoughts in a way that is typical within cognitive therapy, the techniques may be considered comparable to exposure-based procedures that help patients to reduce anxiety and distress associated with certain types of thoughts and images through repeated exposure to those thoughts and images. The overlap between cognitive-behavioral treatments and mindfulness-based approaches continues to be hotly debated.

INDICATIONS

Mentalization has been applied to a number of clinical disorders, one of which is autism. In autism, both child and adult are impaired socially because they are less sensitive to emotional cues given by others. They have difficulty empathizing, which makes their social interactions awkward and stilted. Mentalization focuses on teaching empathy and improving social engagement with others.

Patients with antisocial personality disorder may also benefit from MBT. Such patients are manipulative, give no thought to the results of their actions, lack the capacity for loyalty, and are unable or unwilling to empathize with others. MBT focuses on the core issues of their psychopathology. If a secure attachment can be made between patient and therapist the basic trust that is lacking in the antisocial person may be developed for the first time. MBT has also been of use in patients with borderline personality disorder.

Mindfulness-based treatments have been demonstrated to be effective for a wide range of psychological problems, including borderline personality disorder, anxiety, chronic pain, depression, and stress. The approaches also have been used to reduce dysfunction in patients with medical conditions (e.g., cancer, multiple sclerosis) and to increase general well-being. Patients also learn to develop a greater tolerance for feelings of anxiety or depression and recognize that those states are often transitory, which may enable them to deal with conflict with greater confidence.

Psychopharmacological Treatment

29.1 General Principles of Psychopharmacology

Psychopharmacologic advances continue to dramatically expand the parameters of psychiatric treatments. Greater understanding of how the brain functions has led to more effective, less toxic, better-tolerated, and more specifically targeted therapeutic agents. With the ever-increasing sophistication and array of treatment options, clinicians, however, must remain aware of potential adverse effects, drug–drug (and drug–food or drug–supplement) interactions, and how to manage the emergence of unwanted or unintended consequences. Newer drugs could ultimately lead to side effects that are not recognized initially. Keeping up with the latest research findings is increasingly important as these findings proliferate. A thorough understanding of the management of medication-induced side effects (either through treating the effect with another agent or substituting another primary agent) is necessary.

CLASSIFICATION

Medications used to treat psychiatric disorders are referred to as *psychotropic drugs*. These drugs are commonly described by their major clinical application, for example, *antidepressants*, *antipsychotics*, *mood stabilizers*, *anxiolytics*, *hypnotics*, *cognitive enhancers*, and *stimulants*. A problem with this approach is that, in many instances, drugs have multiple indications. For example, drugs such as the selective serotonin reuptake inhibitors (SSRIs) are both antidepressants and anxiolytics, and the serotonin-dopamine antagonists (SDAs) are both antipsychotics and mood stabilizers.

Psychotropic drugs have also been organized according to structure (e.g., tricyclic), mechanism (e.g., monoamine oxidase inhibitor [MAOI]), history (e.g., first generation, traditional), uniqueness (e.g., atypical), or indication (e.g., antidepressant). A further problem is that many drugs used to treat medical and neurological conditions are routinely used to treat psychiatric disorders.

In addition, psychotropic drug terminology can be confusing. The first pharmaceutical agents used to treat schizophrenia were termed *tranquilizers*. When newer drugs emerged as therapies for anxiety, a distinction was drawn between *major* and *minor tranquilizers*. At first, antidepressants were tricyclic antidepressants (TCAs) or MAOIs. In the 1970s and 1980s, as newer antidepressant drugs emerged, they were labeled as *second- or third-generation antidepressants*. More recently, older agents used as treatments for psychosis became known as *typical, conventional, or traditional neuroleptics*. Newer ones became *atypical neuroleptics*. In order to eliminate much of this confusion, in this section, drugs are presented according to shared mechanism of action or by similarity of structure to provide consistency, ease of reference, and comprehensiveness.

PHARMACOLOGICAL ACTIONS

Both genetic and environmental factors influence individual response to, and tolerability of, psychotropic agents. Thus, a drug that may not prove effective in many patients with a disorder can dramatically improve symptoms in others. In these cases, identification of characteristics that might predict potential candidates for that drug becomes important, but often remains elusive.

Drugs, even within the same class, are distinguished from one another by often subtle differences in molecular structure, types of interactions with neurotransmitter systems, differences in pharmacokinetics, the presence or absence of active metabolites, and protein binding. These differences, combined with the biochemistry of the patient, account for the profile of efficacy, tolerability, and safety and the risk-to-benefit ratio for the individual. These multiple variables, some poorly understood, make it difficult to predict a drug's effect with certainty. Nevertheless, knowledge of the nature of each property increases the likelihood of successful treatment. The clinical effects of drugs are best understood in terms of pharmacokinetics, which describes *what the body does to a drug*, and pharmacodynamics, which describes *what the drug does to the body*.

Pharmacokinetics and pharmacodynamics need to be seen in the context of the underlying variability among patients with respect to how drug effects are expressed clinically. Patients differ in their therapeutic response to a drug and the experience of side effects. It is increasingly clear that these differences have a strong genetic basis. Pharmacogenetics research is attempting to identify the role of genetics in drug response.

DRUG SELECTION

Although all U.S. Food and Drug Administration (FDA)-approved psychotropics are similar in overall effectiveness for their indicated disorder, they differ considerably in their pharmacology and in their efficacy and adverse effects on individual patients. The ability of a drug to prove effective, thus, is only partially predictable and is dependent on poorly understood patient variables. Nevertheless, it is possible that some drugs have a niche in which they can be uniquely helpful for a subgroup of patients, without demonstrating any overall superiority in efficacy. No drug is universally effective, and no evidence indicates the unambiguous superiority of any single agent as a treatment for any major psychiatric disorders. The only exception, clozapine (Clozaril), has been approved by the FDA as a treatment for cases of treatment-refractory schizophrenia.

Decisions about drug selection and use are made on a case-by-case basis, relying on the individual judgment by the physician. Other factors in drug selection are the characteristics of the drug and the nature of the patient's illness. Each of these components affects the probability of a successful outcome.

DRUG FACTORS

Pharmacodynamics

The time course and intensity of a drug's effects are referred to as its *pharmacodynamics*. Major pharmacodynamic considerations include receptor mechanisms, the dose–response curve, the therapeutic index, and the development of tolerance, dependence, and withdrawal phenomena. Drug mechanism of action is subsumed under pharmacodynamics. The clinical response to a drug, including adverse reactions, results from an interaction between that drug and a patient's susceptibility to those actions. Pharmacogenetic studies are beginning to identify genetic polymorphisms linked to individual differences in treatment response and sensitivity to side effects.

Mechanisms

The mechanisms through which most psychotropic drugs produce their therapeutic effects remain poorly understood. Standard explanations focus on ways that drugs alter synaptic concentrations of dopamine, serotonin, norepinephrine, histamine, γ -aminobutyric acid (GABA), or acetylcholine. These changes are said to result from receptor antagonists or agonists, interference with neurotransmitter reuptake, enhancement of neurotransmitter release, or inhibition of enzymes. Specific drugs are associated with permutations or combinations of these actions. For example, a drug can be an agonist for a receptor, thus stimulating the specific biological activity of the receptor, or an

antagonist, thus inhibiting the biological activity. Some drugs are partial agonists, because they are not capable of fully activating a specific receptor. Some psychotropic drugs also produce clinical effects through mechanisms other than receptor interactions. For example, lithium (Eskalith) can act by directly inhibiting the enzyme inositol-1-phosphatase. Some effects are closely linked to a specific synaptic effect. For example, most medications that treat psychosis share the ability to block the dopamine type 2 (D₂) receptor. Similarly, benzodiazepine agonists bind a receptor complex that contains benzodiazepine and GABA receptors.

Further illustrating the fact that the mechanisms of action of psychotropic drugs remain only partially understood are observations that medications that do not directly target monoamine neurotransmitters can be remarkably effective in treating some psychiatric disorders. For example, ketamine (Ketalar), an anesthetic agent that targets glutamate, can rapidly and dramatically alleviate symptoms of depression when given as a slow infusion. Another example involves the antibiotic minocycline (Solodyn), which has been shown to have antidepressant effects. Along with other findings, this suggests that the immune system and inflammatory responses may underlie some mood disorders.

Accounts of so-called mechanisms of action should nevertheless be kept in perspective. Explanations of how psychotropic drugs actually work that focus on synaptic elements represent an oversimplification of a complex series of events. If merely raising or lowering levels of neurotransmitter activity is associated with the clinical effects of a drug, then all drugs that cause these changes should produce equivalent benefits. This is not the case. Multiple obscure actions, several steps removed from events at neuronal receptor sites, are probably responsible for the therapeutic effects of psychotropic drugs. These *downstream* elements are postulated to represent the actual reasons that these drugs produce clinical improvement. A glossary of terms related to receptor drug interactions is given in Table 29.1-1.

 **Table 29.1-1**
Glossary of Receptor Drug Interactions

Receptor Interaction	Definition	Examples and Comments
Agonist (full agonist)	A drug or medication that binds to a specific receptor producing an effect identical to that usually produced by the neurotransmitter affecting that receptor. Drugs are often designed as receptor agonists to treat a variety of diseases and disorders in which the original neurotransmitter is missing or diminished.	Full agonists include opioids such as morphine, methadone, oxycodone, hydrocodone, heroin, codeine, meperidine, propoxyphene, and fentanyl. Benzodiazepines act as agonists at the GABA receptor complex.
Antagonist	A compound that binds to a receptor that blocks or reduces the action of another substance (agonist) at the receptor site involved. Antagonists that compete with an agonist for a receptor are <i>competitive antagonists</i> . Those that antagonize by other means are <i>noncompetitive antagonists</i> .	Flumazenil is a competitive benzodiazepine receptor antagonist. It competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. It is the purest antagonist synthesized. Drugs used in the treatment of schizophrenia block dopamine 2 receptors. Examples of opioid antagonists include naltrexone and naloxone.
Partial agonist (mixed agonist)	A compound that (even when fully occupying a receptor) possesses affinity for a receptor, but elicits a partial pharmacological response at the receptor involved. Partial agonists are often structural analogs of agonist molecules. If neurotransmitter concentrations are low, partial agonists may behave as an agonist. This is why these medications are sometimes called mixed agonists.	Buprenorphine is a partial agonist that produces typical opioid agonist effects and side effects, such as euphoria and respiratory depression, but its maximal effects are less than those of full agonists like heroin and methadone. When used at low doses buprenorphine produces sufficient agonist effect to enable opioid-addicted individuals to discontinue the drugs with fewer withdrawal symptoms.
Inverse agonist	An inverse agonist is an agent that binds to the same receptor as an agonist for that receptor but produces the opposite pharmacological effect.	Several inverse agonists are currently in clinical development. One particular example is R015-4513, which is the inverse agonist of the benzodiazepine class of drugs. R015-4513 and the benzodiazepines both utilize the same GABA binding site on neurons, yet R015-4513 has the opposite effect, producing severe anxiety rather than the sedative and anxiolytic effects associated with benzodiazepines. Cannabinoid inverse agonists have been found to reduce appetite, the opposite of the craving effect associated with cannabis.

GABA, γ -aminobutyric acid.
(Table by Norman Sussman, M.D.)

SIDE EFFECTS

Side effects are an unavoidable risk of medication treatment. Although it is impossible to have an encyclopedic knowledge of all possible adverse drug effects, prescribing clinicians should be familiar with the more common adverse effects, as well as those with serious medical consequences. No single text or document, including the product information, contains a complete list of possible treatment-emergent events.

Side effect considerations include the probability of its occurrence, its impact on a patient's quality of life, its time course, and its cause. Just as no one drug is certain to produce clinical improvement in all patients, no side effect, no matter how common, occurs in every patient. When concurrent medical disorders or a history of a similar adverse reaction puts a patient at increased risk for a side effect, it is logical to consider prescribing a compound not typically associated with that adverse reaction.

Side effects can result from the same pharmacological action that is responsible for a drug's therapeutic activity or from an unrelated property. In examples of the latter, some of the most common adverse effects of the TCAs are caused by blockade of muscarinic acetylcholine receptors or histamine 2 receptors. If a patient is sensitive to these effects, alternative agents without these properties should be prescribed. When side effects are manifestations of the drug's presumed mechanism of action, side effects may be unavoidable. Thus, blockade of serotonin reuptake by SSRIs can cause nausea and sexual dysfunction. The D₂ blockade of drugs used to treat psychosis can cause extrapyramidal side effects. Agonist action of benzodiazepine receptors can cause ataxia and daytime sleepiness. In these cases, additional medications are frequently used to make the primary agent better tolerated.

Time Course

Adverse effects differ in terms of their onset and duration. Some side effects appear at the outset of treatment and then rapidly diminish. Nausea occurring with SSRIs or venlafaxine (Effexor) and sedation occurring with mirtazapine (Remeron) are good examples of early, time-limited side effects. Early-onset, but persistent, side effects include dry mouth that is associated with noradrenergic reuptake inhibition or antimuscarinic activity. Some side effects appear later in treatment (*late-appearing side effects*) and, sometimes, may be just the opposite of adverse events early in treatment. For example, patients may typically lose weight during early treatment with SSRIs, only to find, over time, a reversal occurs, so that they gain weight. Similarly, early activation or agitation may be followed by constant fatigue or apathy. Because most data about new drugs come from short-term studies, generally 8 weeks in duration, early-onset side effects are overrepresented in

product information and descriptions of newly marketed information. It is essential that clinicians follow the letters to the editor sections of journals and other sources of information to update their understanding of the true side effect profile of a drug.

Adverse effects differ in their impact on compliance and potential to cause harm. Depending on a patient's threshold of tolerance for a side effect and the impact on quality of life, side effects can lead to drug discontinuation. Examples of serious side effects include agranulocytosis (clozapine), Stevens-Johnson syndrome (lamotrigine [Lamictal]), hepatic failure (nefazodone [Serzone]), stroke (phenelzine [Nardil]), and heart block (thioridazine [Mellaril]). Overall, the risk of life-threatening side effects with psychotropics is low. Drugs that carry such a risk should be monitored more closely, and the prescribing physician should take into account whether the potential clinical benefits justify the additional risk. Any drug with a serious risk, as reflected in a black box warning, is generally used less extensively than would otherwise be the case.

In the case of haloperidol (Haldol) and other dopamine receptor antagonists, long-term complications, such as tardive dyskinesia, have been well documented. Emerging evidence also suggests that the use of dopamine antagonists is associated with a small increase in the risk of breast cancer and that this is related to larger cumulative doses. In cases in which serious risk is associated with a drug, closer medical monitoring of medication treatment is warranted. Because the most widely used psychotropics, such as the SSRIs and serotonin-dopamine antagonists, have only been in use since the 1980s or 1990s, there is less certainty about long-term effects, but no evidence indicates that side effects are not merely extensions of those already evident during initial therapy. It should also be kept in mind that most drugs used in the treatment of chronic medical disorders have not been in use sufficiently long to provide assurances about unintended long-term adverse effects.

Suicidal Ideation and Antidepressant Treatment

The issue of antidepressant-associated suicide has become front-page news, the result of an analysis suggesting a link between medication use and suicidal ideation among children, adolescents, and adults up to age 24 in short-term (4 to 16 weeks), placebo-controlled trials of nine newer antidepressant drugs. The data from trials involving more than 4,400 patients suggested that the average risk of suicidal thinking or behavior (suicidality) during the first few months of treatment in those receiving antidepressants was 4 percent, twice the placebo risk of 2 percent. No suicides occurred in these trials. The analysis also showed no increase in suicide risk among the 25 to 65 age group. Antidepressants reduced suicidality among those over age 65.

Following public hearings on the subject, in October 2004, the FDA requested the addition of black box warnings—the most serious warning placed on the labeling of a prescription medication—to all antidepressant drugs, old and new. This action raised alarm among parents and physicians and prompted an explosion of advertisements by malpractice attorneys. Most important, antidepressant prescriptions written for adolescents declined, whereas those for adults flattened, after years of growth.

A large study of real world patients published in the January 2006 issue of the *American Journal of Psychiatry* raised serious doubt about true antidepressants and suicidality and about the wisdom of the FDA's decision to change the labeling. The study examined suicides and hospitalizations for suicide attempts in the medical records of 65,103 members of a nonprofit insurer in the Pacific Northwest that covers about 500,000 people who received antidepressants from 1992 to 2003. It found that (1) newer antidepressants were associated with a more rapid and greater reduction in risk than older types of antidepressants and (2) patients were significantly more likely to attempt or commit suicide in the month before they began drug therapy than in the 6 months after starting it.

This is not the first time credible evidence has contradicted a significant link between antidepressant use and increased risk of suicide. At the hearings that led to the black box warning, John Mann of Columbia University presented population data showing that since 1987, the year before fluoxetine (Prozac) became the first marketed SSRI, suicide rates in the United States began dropping, and that areas in the United States with the highest SSRI prescription rates had the biggest decline in suicides. For every 10 percent increase in prescription rates, the US suicide rate declined 3 percent.

Another study, a review of 588 case files of patients aged 10 to 19, found that a 1 percent increase in antidepressant use was associated with a decrease of 0.23 suicides per 100,000 adolescents per year.

A more important question, given how slight the risk may be, if indeed it exists, is whether as a result of the FDA's ill-considered actions, some depressed patients are not getting potentially life-saving treatment. Epidemiological findings from several countries, including the United States, have shown that decreased prescribing of antidepressants for depressed children and adolescents resulted in an increase in suicide rates in those populations.

Side Effects Associated with Newer Medications

All medications are associated with side effects. The clinician should be aware of these, be able to recognize them, and take appropriate measures to treat them.

Somnolence. Sedation is often an intended effect of many psychotropic drugs, especially when used to treat insomnia, anxiety, or agitation. Daytime sleepiness, or somnolence, is also an unwanted adverse event, however. It is important for the clinician to alert patients to the possibility of sedation and to document that the person was advised to exercise caution when operating any type of vehicle or mechanical equipment. Some somnolence results from a carryover of nighttime use of drugs as hypnotics. Even with drugs, such as the SSRIs, which are activating to many patients, somnolence can be problematic. In some instances, it results from impairment of sleep quality. Chronic use of SSRIs can cause some patients to experience a subjective sense of fatigue, exhaustion, or yawning, even with adequate amounts of sleep. Management of unwanted somnolence includes adjustment of dose or timing of administration, switching to alternative medications, addition of small doses of stimulants, or the addition of modafinil (Provigil).

Gastrointestinal Disturbances. The major gastrointestinal (GI) side effects of the older antidepressant and antipsychotic drugs consisted primarily of constipation and dry mouth, a consequence of their antimuscarinic activity. Most of the newer drugs have little antimuscarinic activity, but do have effects on the serotonin system. Most of the body's serotonin is in the GI tract, and serotonergic drugs often cause varying degrees of stomach pain, nausea, flatulence, and diarrhea. In most cases, these side effects are transient, but some persons never accommodate and must switch to another class of drugs. Initial use of lower doses or use of delayed release preparations are the most effective strategies for minimizing GI side effects.

Movement Disorders. The introduction of serotonin-dopamine antagonists has greatly reduced the incidence of medication-induced movement disorders, but varying degrees of dose-related parkinsonism, akathisia, and dystonia still occur. Risperidone (Risperdal) most closely resembles the older agents in terms of these side effects. Olanzapine (Zyprexa) also causes more extrapyramidal effects than clinical trials suggested. Aripiprazole (Abilify) causes severe akathisia. There have been rare reports of SSRI-induced movement disorders, ranging from akathisia to tardive dyskinesia.

Sexual Dysfunction. The use of psychiatric drugs can be associated with sexual dysfunction—decreased libido, impaired ejaculation and erection, and inhibition of female orgasm. In clinical trials with the SSRIs, the extent of sexual side effects was grossly underestimated, because data were based on spontaneous reports by patients. The rate of sexual dysfunction in the original fluoxetine product information, for example, was less than 5 percent. In subsequent studies in which information about sexual side effects was elicited by specific questions,

the rate of SSRI-associated sexual dysfunction was found to be between 35 and 75 percent. In clinical practice, patients are not likely to report sexual dysfunction spontaneously to the physician, so it is important to ask about this side effect. Also, some sexual dysfunctions may be related to the primary psychiatric disorder. Nevertheless, if sexual dysfunction emerges after pharmacotherapy has begun and the primary response to treatment has been positive, it may be worthwhile to attempt to treat the symptoms. Long lists of possible antidotes to these side effects have evolved, but few interventions are consistently effective, and few have more than anecdotal evidence to support their use. The clinician and patient should consider the possibility of sexual side effects with a patient when selecting a drug and switching treatment to another drug that is less or not at all associated with sexual dysfunction if this adverse effect is not acceptable to the patient.

Weight Gain. Weight gain accompanies the use of many psychotropic drugs as a result of retained fluid, increased caloric intake, decreased exercise, or altered metabolism. Weight gain can also occur as a symptom of disorder, as in bulimia or atypical depression, or as a sign of recovery from an episode of illness. Treatment-emergent increase in body weight is a common reason for noncompliance with a drug regimen. No specific mechanisms have been identified as causing weight gain, and it appears that the histamine and serotonin systems mediate changes in weight associated with many drugs used to treat depression and psychosis. Metformin (Glucophage) has been reported to facilitate weight loss among patients whose weight gain is attributed to use of serotonin-dopamine reuptake inhibitors and valproic acid (Depakene). Valproate (Depacon), as well as olanzapine, has been linked to the development of insulin resistance, which could induce appetite increase, with subsequent weight increase. Weight gain is a noteworthy side effect of clozapine (Clozaril) and olanzapine. Genetic factors that regulate body weight, as well as the related problem of diabetes mellitus, seem to involve the 5-HT_{2C} receptor. There is a genetic polymorphism of the promoter region of this receptor, with significantly less weight gain in patients with the variant allele than in those without this allele. Drugs with a strong 5-HT_{2C} affinity would be expected to have a greater impact on body weight of patients with a polymorphism of the 5-HT_{2C} receptor promoter region.

Weight Loss. Initial weight loss is associated with SSRI treatment but is usually transient, with most weight being regained within the first few months. Bupropion (Wellbutrin) has been shown to cause modest weight loss that is sustained. When combined with diet and lifestyle changes, bupropion can facilitate more significant weight loss. Topiramate (Topamax) and zonisamide (Zonegran), marketed as treatments for epilepsy, sometimes produce substantial, sustained loss of weight.

Glucose Changes. Increased risk of glucose abnormalities, including diabetes mellitus, is associated with weight increase during psychotropic drug therapy. Clozapine and olanzapine are associated with a greater risk than other serotonin-dopamine antagonists of abnormalities in fasting glucose levels, as well as hyperosmolar diabetes and ketoacidosis. This dysregulation of glucose homeostasis appears to be drug induced and increases glucagon.

Hyponatremia. Hyponatremia is associated with oxcarbazepine (Trileptal) and SSRI treatment, especially in elderly patients. Confusion, agitation, and lethargy are common symptoms.

Cognitive Impairment. Cognitive impairment means a disturbance in the capacity to think. Some agents, such as the benzodiazepine agonists, are recognized as causes of cognitive impairment. Other widely used psychotropics, such as the SSRIs, lamotrigine (Lamictal), gabapentin (Neurontin), lithium, TCAs, and bupropion, however, are also associated with varying degrees of memory impairment and word-finding difficulties. In contrast to the benzodiazepine-induced anterograde amnesia, these agents cause a more subtle type of absent-mindedness. Drugs with anticholinergic properties are likely to worsen memory performance.

Sweating. Severe perspiration unrelated to ambient temperature is associated with TCAs, SSRIs, and venlafaxine. This side effect is often socially disabling. Attempts can be made to treat this side effect with alpha agents, such as terazosin (Hytrin) and oxybutynin (Ditropan).

Cardiovascular Disturbances. Newer agents are less likely to have direct cardiac effects. Many older agents, such as TCAs and phenothiazines, affected blood pressure and cardiac conduction. Thioridazine (Mellaril), which has been in use for decades, has been shown to prolong the QTc interval in a dose-related manner and may increase the risk of sudden death by delaying ventricular repolarization and causing torsades de pointes. Newer drugs are now routinely scrutinized for evidence of cardiac effects. A promising treatment for psychosis, sertindole (Serlect), was not marketed because the FDA would have required a black box warning. Slight QTc effects noted with ziprasidone (Geodon) delayed the marketing of that drug. Clozapine can cause myocarditis in rare cases of which the clinician should be aware.

Rash. Any medication is a potential source of a drug rash. Some psychotropics, such as carbamazepine (Equetro, Tegretol) and lamotrigine, have been linked to an increased risk of serious exfoliative dermatitis. Commonly referred to as Stevens-Johnson syndrome, this condition is a systemic, immune-mediated reaction that can prove fatal or result in permanent scarring or blindness. All patients should be informed about the potential seriousness of lesions that are widespread, that occur above the neck, that involve the mucous membranes, and that may be associated with fever and lymphadenopathy. If such symptoms manifest, a patient should be instructed at the time that the medication is prescribed to go immediately to an emergency department.

Idiosyncratic and Paradoxical Drug Responses

Idiosyncratic reactions occur in a very small percentage of patients taking a drug. The reactions are not related to the known pharmacologic properties, and most likely represent a genetically based abnormal sensitivity to a drug. A paradoxical response represents the manifestation of a clinical effect the opposite of what is expected. In March 2007, the FDA reported dissociative-like states associated with certain sedative hypnotics. These included behaviors such as sleepwalking, binge eating, aggressive outbursts, and night driving of which the patient was unaware. Table 29.1-2 lists the drugs required to have warning labels for that effect.

Table 29.1-2
Sedative Hypnotics Cited by the U.S. Food and Drug Administration

Drug	Manufacturer
Zolpidem (Ambien/Ambien CR)	Sanofi Aventis
Butabarbital (Butisol Sodium)	MedPointe Pharmaceuticals
Pentobarbital and carbromal (Carbrital)	Parke-Davis
Flurazepam (Dalmane)	Valeant Pharmaceuticals
Quazepam (Doral)	Questcor Pharmaceuticals
Triazolam (Halcion)	Pfizer
Eszopiclone (Lunesta)	Sepracor
Ethchlorvynol (Placidyl)	Abbott
Estazolam (Prosom)	Abbott
Temazepam (Restoril)	Tyco Healthcare
Ramelteon (Rozerem)	Takeda
Secobarbital (Seconal)	Lilly
Zaleplon (Sonata)	King Pharmaceuticals

Therapeutic Index

Therapeutic index is a relative measure of the toxicity or safety of a drug and is defined as the ratio of the median toxic dose to the median effective dose. The median toxic dose is the dose at which 50 percent of patients experience a specific toxic effect, and the median effective dose is the dose at which 50 percent of patients have a specified therapeutic effect. When the therapeutic index is high, as it is for haloperidol, it is reflected by the wide range of dosages in which that drug is prescribed. Conversely, the therapeutic index for lithium is quite low, thus requiring careful monitoring of serum lithium levels in patients for whom the drug is prescribed.

Overdose

Safety in overdose is always a consideration in drug selection. Almost all of the newer agents, however, have a wide margin of safety when taken in overdose. By contrast, a 1-month supply of TCAs could be fatal. The depressed patients they were used to treat are the group most at risk to attempt suicide. Because even the safest drugs can sometimes produce severe medical complications, especially when combined with other agents, clinicians must recognize that the prescribed medication can be used in an attempt to commit suicide. Although it is prudent to write nonrefillable prescriptions for small quantities, this practice passes along increased copay costs to the patient. In fact, many pharmacy benefit management programs encourage the prescribing of a 3-month supply of medication.

In cases in which suicide is a major concern, an attempt should be made to verify that the medication is not being hoarded for a later overdose attempt. Random pill counts or asking a family member to dispense daily doses may be helpful. Some patients attempt suicide just as they are beginning to recover. Large quantities of medications with a low therapeutic index should be prescribed judiciously. Another reason to limit the number of pills prescribed is the possibility of accidental ingestion of medications by children in the household. Psychotherapeutic medications should be kept in a safe place.

Physicians who work in emergency rooms should know which drugs can be hemodialyzed. The issues involved are complex and are not based on any single chemical property of the drug. For example, it is generally presumed that drugs with low protein binding are good candidates for dialysis. Venlafaxine, however, is only 27 percent protein bound and is too large as a molecule dialyzed. Hemodialysis is effective for treating overdose of valproic acid.

Pharmacokinetics

Pharmacokinetic drug interactions are the effects of drugs on the plasma concentrations of each other, and *pharmacodynamic drug interactions* are the effects of drugs on the biological activities of each other. Pharmacokinetic concepts are used to describe and predict the time course of drug concentrations in different parts of the body, such as plasma, adipose tissue, and the central nervous system (CNS). From a clinical perspective, pharmacokinetic methods help explain or predict the onset and duration of drug activity and interactions between drugs that alter their metabolism or excretion.

Pharmacogenetic research focuses on finding variant alleles that alter drug pharmacokinetics and pharmacodynamics. Researchers are attempting to identify genetic differences in how enzymes metabolize psychotropics, as well as CNS proteins directly involved in drug action. Likely, identification of patient genotypes will facilitate prediction of clinical response to different types of drugs.

Most clinicians need to consult charts or computer programs to determine when potential interactions may occur and, if so, how clinically relevant they may be. Whenever possible, it is preferable to use a medication that produces minimal risk of drug interactions. Also, it is recommended that prescribers know the interaction profiles of the drugs they most commonly prescribe.

Examples of pharmacokinetic interactions include one drug increasing or decreasing the concentrations of a coadministered compound. These types of interactions can also lead to altered concentrations of metabolites. In some cases, there may also be interference with the conversion of a drug to its active metabolite. Enormous variability exists among patients with respect to pharmacokinetic parameters, such as drug absorption and metabolism. Another type of interaction is represented by interactions involving the kidney. Commonly used medications, such as angiotensin-converting enzyme (ACE) inhibitors, nonsteroidal anti-inflammatory drugs (NSAIDs), and thiazides, decrease renal clearance of lithium, increasing the likelihood of severe elevations of lithium. Drug interactions can occur pharmacokinetically or pharmacodynamically.

Pharmacogenetics is being used to study why patients differ in the way they metabolize drugs. In patients who are ultrarapid or extensive metabolizers, the concentrations of a drug may be lower than expected.

PATIENT-RELATED FACTORS

Response to medication and sensitivity to side effects are influenced by factors related to the patient. This is why there is no one-size-fits-all approach to pharmacological treatment. Patient-related variables include diagnosis, genetic factors, lifestyle, overall medical status, concurrent disorders, and history of drug response. A patient's attitude toward medication in general, aversion to certain types of side effects, and preference for a specific agent also need to be considered.

Diagnosis

Failure to correctly diagnose a disorder diminishes the likelihood of optimal drug selection. Misdiagnosis not only can result in a missed opportunity, but it also can, at times, produce worsening of symptoms. Inadvertently diagnosing a patient in the depressed phase of bipolar disorder as having unipolar depression can induce mania or rapid cycling. Treatment failure or exacerbation of symptoms should prompt a reassessment of the working diagnosis.

Past Treatment Response

A specific drug should be selected according to the patient's history of drug response (compliance, therapeutic response, adverse effects), the patient's family history of drug response, the profile of adverse effects for that drug with regard to the particular patient, and the prescribing

clinician's usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again. For reasons that are not understood, however, some patients fail to respond to a previously effective agent when challenged again. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug.

It is helpful if patients can recall the details of past psychotropic drug treatment: the drugs prescribed, in what dosages, for how long, and in what combinations. Because of their mental disorders, many patients, however, are poor historians. If possible, patients' medical records should be obtained to confirm their reports. Family members are a good source of collateral information.

Response in Family Members

It is widely held that drug responses cluster in families. Thus, response to a drug in a relative is an indicator of whether a patient might also benefit from that medication. Although no conclusive evidence supports this as a consideration in drug selection, existing studies do confirm that a history of positive response to treatment with a drug should be considered in making treatment decisions.

Concurrent Medical or Psychiatric Disorders

Initial assessment should elicit information about coexisting medical disorders. In some cases, a medical disorder may be responsible for the symptoms. Patients with thyroid disease who are not adequately treated may appear depressed. Sleep apnea produces depression and cognitive impairment. Rare conditions, such as Kleine-Levin syndrome, can mimic bipolar disorder. A drug should be selected that minimally exacerbates any preexisting medical problems that a particular patient may have.

Recreational drug use, excessive consumption of alcohol, and frequent ingestion of caffeine-containing beverages can complicate and even undermine psychotropic drug treatment. These compounds possess significant psychoactive properties and, in some cases, may represent the source of the patient's symptoms. It is reasonable to ask patients to abstain from use of these substances, at least until the benefits of psychotropic drug treatment have been unequivocally established. Gradual reintroduction of moderate amounts of alcohol, tea, and coffee can then take place. Patients can then observe for themselves whether there are any untoward effects on their clinical status.

INFORMED CONSENT AND PATIENT EDUCATION

Establishing trust and providing motivation to comply with the medication regimen are essential components of successful treatment. Patients should be informed about treatment options and the probable side effects and unique benefits of each treatment. Patient preference should be respected, unless a compelling advantage exists involving efficacy, tolerability, or safety with an alternative agent. If a particular medication is being recommended, the reasons for this recommendation should be explained. Patients are more likely to continue taking their medication if they fully understand the reasons why it is being prescribed.

A strong therapeutic alliance between a clinician and a patient is always helpful. Given the unpredictability of medication response, the frequent occurrence of side effects, and underlying ambivalence about, or fear of taking, medication, a positive, trusting relationship serves to improve patient compliance. Repeated failed trials may be needed before a response is seen. A patient's confidence in the physician's knowledge and judgment enables medication trials and more complex regimens, such as the use of multiple medications.

Discussions about drug selection should be documented in notes, but a signed informed consent is not needed. Surprisingly, patients who are informed of potential adverse effects report a higher incidence of side effects but do not have higher rates of premature discontinuation.

How the patient and family are engaged in the treatment plan can determine the success of treatment. The psychodynamic meaning of pharmacotherapy to the patient and family and environmental influences, psychosocial stressors, and support should be explored. Some patients may view drug treatment as a panacea, and others may view it as the enemy. With the patient's consent, relatives and other clinicians should be instructed about the reasons for the drug treatment, as well as the expected benefits and potential risks.

DOSING, DURATION, AND MONITORING

Dosing

The clinically effective dose for treatment depends on the characteristics of the drug and patient factors, such as inherited sensitivity and ability to metabolize a drug, concurrent medical disorders, use of concurrent medications, and history of exposure to previous medications.

Plasma concentrations of many psychotropics can vary up to tenfold. Thus, to some extent, the optimal dose for an individual is ultimately determined by trial and error, guided by the empirical evidence of the usual dose range for that drug. In some cases, it may prove helpful to test patients for genetic polymorphisms involving hepatic enzymes. Patients who are ultrarapid metabolizers of certain drugs may require higher than normal dosing. Slow metabolizers might demonstrate side effects and even toxicity at very low doses.

Some drugs demonstrate a clear relationship between increases in dose and clinical response. This dose-response curve plots the drug concentration against the effects of the drug.

The *potency* of a drug refers to the relative dose required to achieve certain effects, not to its efficacy. Haloperidol, for example, is more potent than chlorpromazine (Thorazine), because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. These drugs, however, are equal in their clinical efficacy—that is, the maximal clinical response achievable by administration of a drug.

Drugs must be used in effective dosages for sufficient periods. Although drug tolerability and safety are always considerations, subtherapeutic doses and incomplete therapeutic trials should be avoided. The use of inadequate doses merely exposes the patient to the risk of side effects, without providing the probability of therapeutic benefit. In view of the wide margin of safety associated with most currently prescribed medications, more risk exists in underdosing than in overshooting the recommended dose range.

Time of dosing is usually based on the plasma half-life of a drug and its side effect profile. Sedating drugs are given all at night or with disproportionate daily doses at night. The opposite is true with activating drugs. The frequency of dosing is less clear-cut. Most dosing regimens of psychotropic drugs, such as once-a-day versus divided doses, are based on measurements of plasma concentrations rather than receptor occupancy in the brain. Evidence suggests a significant dissociation exists between brain and plasma kinetics. Reliance on plasma kinetics as the basis for dosing regimens leads to misunderstanding of necessary schedules.

As a rule, psychotropic drugs should be used continuously. Exceptions are the use of drugs for insomnia, acute agitation, and severe situational anxiety. A common mistake is the use of high-potency benzodiazepines, such as alprazolam (Xanax) and clonazepam (Klonopin), only after an attack has begun. These drugs should be used as part of a regular schedule to prevent attacks.

Some patients who experience sexual dysfunction while being treated with SSRIs take a drug holiday, that is, they skip a daily dose from time to time to facilitate sexual performance.

Intermittent dosing regimens of SSRIs have been found to be effective as a treatment for premenstrual dysphoric disorder. The drugs are taken daily during the 2-week luteal phase of the menstrual cycle.

Duration of Treatment

A common question from a patient is "How long do I need to take the medication?" The answer depends on multiple variables, including the nature of the disorder, the duration of symptoms, the family history, and the extent to which the patient tolerates and benefits from the medication. Patients can be given a reasonable explanation of the probabilities but should be told that it is first best to see if the medication

works for him or her and whether any side effects are acceptable. Any more definitive discussion of treatment duration can be held once the degree of success is clear. Even patients with a philosophical aversion to the use of psychotropic drugs may elect to stay on medication indefinitely if the magnitude of improvement is great. Most psychiatric disorders have high rates of chronicity and relapse. Because of this, long-term treatment is often needed to prevent recurrence. Nevertheless, the fact remains that psychotropic drugs are not said to cure the disorders they treat but rather to help control the symptoms.

Treatment is conceptually broken down into three phases: the initial therapeutic trial, the continuation, and the maintenance phase. The initial period of treatment should last at least several weeks because of the delay in therapeutic effects that characterizes most classes of psychotropic drugs. The required duration of a *therapeutic trial* of a drug should be discussed at the outset of treatment, so that the patient does not have unrealistic expectations of an immediate improvement in symptoms. Patients are more likely to experience side effects early in the course of pharmacotherapy than any relief from their disorder. In some cases, medication may even exacerbate some symptoms. Patients should be counseled that a poor initial reaction to medication is not an indicator of the ultimate outcome of treatment. For instance, many patients with panic disorder develop jitteriness or an increase in panic attacks after starting on tricyclic or SSRI treatment. Benzodiazepine agonists are an exception to the rule that clinical onset is delayed. In most cases, their hypnotic and anti-anxiety effects are evident immediately.

Ongoing use of medication, however, does not provide absolute protection against relapse. Continuation therapy provides clinically and statistically significant protective effects against relapse. The optimal duration of continuation or maintenance therapy is variable and dependent on the clinical history of the patient. Early-onset chronic major depression, for example, has a more severe course and greater comorbidity than late-onset chronic major depression. In addition to early onset, a history of multiple past episodes and severity and length of a current episode would make longer, even indefinite, treatment appropriate.

Frequency of Visits

Until an unequivocal response to treatment occurs, patients should be seen as frequently as circumstances warrant. The frequency of follow-up or monitoring visits is determined by clinical judgment. In severely ill patients, this might mean several times a week. Patients on maintenance therapy, even when stable, need monitoring, but no consensus exists on the frequency of follow-up therapy. Three months is a reasonable interval between visits, but 6 months may be adequate after long-standing treatment.

LABORATORY TESTS AND THERAPEUTIC BLOOD MONITORING

Laboratory testing and therapeutic blood monitoring should be based on clinical circumstances and the drugs being used. For most commonly used psychotropic drugs, routine testing is not required. No currently available laboratory test can confirm the diagnosis of a mental disorder.

Pretreatment tests are routine as part of a workup to establish baseline values and to rule out underlying medical problems that may be causing the psychiatric symptoms or that might complicate treatment with drugs. Results of recently performed tests should be obtained. With agents known to cause cardiac conduction changes, a pretreatment electrocardiogram (ECG) should be obtained before initiating treatment. With lithium and clozapine, the possibility of serious changes in thyroid, renal, hepatic, or hematological functions requires pretreatment and ongoing monitoring with appropriate laboratory tests.

As a result of both anecdotal and research findings of sometimes severe glucose dysregulation during treatment primarily with SDAs, the FDA has suggested that patients being treated with any atypical antipsychotic be monitored for the emergence of diabetes.

Certain circumstances present in which it is necessary or useful to use plasma concentrations to monitor a patient's condition. These include the monitoring of drugs with narrow therapeutic indexes, such as lithium; drugs with a therapeutic window, the optimal dose range for a therapeutic response; drug combinations that can lead to interactions that raise drug concentrations of medications or their metabolites, which can cause toxicity; unexplained toxicity at normal therapeutic doses; and failure to respond in a patient who may be noncompliant. A clinician should have no reservations about requesting random urine toxicological tests in a patient who abuses substances.

TREATMENT OUTCOMES

The goal of psychotropic treatment is to eliminate all manifestations of a disorder, thus enabling the patient to regain the ability to function as well and to enjoy life as fully as before he or she became ill. This degree of improvement to below the syndromal threshold is defined as *remission*.

Response and Remission

Remission is the preferred outcome of treatment, not only because of the immediate impact on functioning and state of mind, but also because emerging evidence suggests that patients in remission are less likely to experience relapse and recurrence of their disorder.

Patients who improve but do not experience a full resolution are considered to be responders. They may exhibit significant improvement but continue to experience symptoms. In depression studies, *response* is usually defined as a 50 percent or greater decrease from baseline on a standard rating scale, such as the Hamilton Depression (HAM-D) Scale or the Montgomery-Asberg Depression Rating Scale (MADRS). *Remission* is defined as an absolute score of 7 or less on the HAM-D or 10 or less on the MADRS. Expectations about the likely degree of improvement should be based on what is known about the responsiveness of specific disorders to medication therapy. Obsessive-compulsive disorder (OCD) and schizophrenia, for example, are more likely to be associated with residual manifestations of illness than major depression or panic disorder. The probability of full remission from OCD with SSRI treatment alone over a 2-year period is less than 12 percent, and the probability of partial remission is approximately 47 percent.

Treatment Failure

The initial treatment plan should anticipate the possibility that the medication may be ineffective. A next-step strategy should be in place at the initiation of treatment. Repeated drug failures should prompt reassessment of the patient. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of an undiagnosed medical condition or recreational drug use as the cause of the psychiatric symptoms.

Second, are the observed symptoms related to the original disorder, or are they actually adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Long-term use of SSRIs can produce emotional blunting, which can mimic depression.

Intolerance of side effects may be the most common reason for treatment failure. Third, was the drug administered at an appropriate dosage for a sufficient length of time? Because absorption and metabolism of drugs can vary greatly in patients, the clinician may need to measure plasma levels of a drug to ensure a sufficient dose of the drug.

Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug that the patient was taking reduce the efficacy of the newly prescribed drug?

Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dosage), adverse effects (especially if unnoticed by the clinician), and poor

patient education about the drug treatment plan. Patients may discontinue medication when they recover, thinking that they are cured and no longer benefiting from the medication.

Treatment Resistance

Some patients fail to respond to repeated trials of medication. No single factor can explain the ineffectiveness of the various interventions in these cases. Strategies in these cases include the use of drug combinations, high-dose therapy, and use of unconventional drugs. Limited evidence is available on the comparative success rates associated with any given strategy.

Tolerance

The development of tolerance is marked by a need, over time, to use increased doses of a drug for it to maintain a clinical effect. This decreased responsiveness to a drug occurs after repeated doses. Tolerance also describes decreased sensitivity to adverse effects of the drug, such as nausea. This phenomenon is used as the basis for starting some drugs at subtherapeutic doses, with the plan to adjust the schedule once the patient can tolerate higher doses. Clinical tolerance appears to represent changes in the CNS, such as altered receptor configuration or density. Drugs with similar pharmacological actions often exhibit cross-tolerance.

Sensitization

Clinically manifested as the reverse of tolerance, sensitization is said to occur when sensitivity to a drug effect increases over time. In these cases, the same dose typically produces more pronounced effects as treatment progresses.

Withdrawal

The development of physiological adaptation to a drug, with a subsequent risk of withdrawal symptoms, has been reported for many classes of psychotropic drugs. Technically, withdrawal should be considered a side effect. The probability and severity of these reactions are remote with most drugs and more common with others. As a general rule, the more abruptly a drug is stopped and the shorter its elimination half-life, the more likely it is that clinically significant withdrawal symptoms will occur. When using some short-acting drugs, withdrawal reactions can result from missed doses and during daily intervals between doses. Gradual tapering of medications after prolonged use is recommended whenever possible. Although this reduces the risk of withdrawal reactions, it does not ensure they will not occur. So-called sedative hypnotics and opiates are the agents most often associated with mentally and physically distressing discontinuation reactions. In some cases, such as barbiturate use, withdrawal can be fatal.

Marked differences are found among agents, even within a given class, with respect to the probability and severity of discontinuation effects. For example, among the benzodiazepines, alprazolam and triazolam (Halcion) commonly produce more immediate and intense withdrawal symptoms than other compounds. Among the SSRIs, there is a well-described withdrawal syndrome that appears to be more frequent and severe with paroxetine (Paxil). It can, however, occur with any SSRI. Even fluoxetine can be associated with discontinuation symptoms, but the symptoms may be delayed and attenuated because of the long elimination half-life of its active metabolite. These manifestations are subtle and are delayed for weeks after the last dose. Venlafaxine also produces a severe SSRI-like withdrawal syndrome.

In addition to half-life, many variables can influence the likelihood and degree of discontinuation symptoms. Changes in the rate of drug metabolism, as an example, can play a role. Paroxetine is primarily metabolized by the cytochrome P450 (CYP) 2D6 isoenzyme, however, it is also a potent inhibitor of CYP 2D6. This results in *autoinhibition*, a dose-dependent inhibition of its own metabolism, with a subsequent increase in plasma concentrations of paroxetine. If the dose of paroxetine is decreased or the drug is stopped, the decline in its plasma concentrations can be steep, causing withdrawal to occur. Withdrawal can occur in rare cases in which the dose of a drug is not decreased, but a second agent, which had been inhibiting its metabolism, was stopped. For example, alprazolam is metabolized via the CYP 3A3/4 enzyme system. Nefazodone inhibits that enzyme. If a patient taking both agents for several weeks discontinues the nefazodone, it could result in a rapid increase in the rate of alprazolam metabolism and a consequent drop in plasma concentrations.

The development of sustained-release versions of drugs, such as alprazolam, paroxetine, and venlafaxine, has not reduced the severity of their withdrawal reactions. The prolonged half-life of those agents results from delayed absorption rather than prolongation of the elimination phase. The frequency of drug dosing is reduced but not the rate of falloff in plasma concentrations.

Poor bioavailability with a generic agent may account for unexpected loss of clinical effect in emergence of withdrawal symptoms. The occurrence of these events soon after refilling a prescription should prompt examination of the new medication. It should be confirmed whether the dispensed medication and dose are both correct. It is difficult to ascertain whether generic medications are truly equivalent, so the possibility exists that differences in potency may underlie adverse changes in clinical status.

Withdrawal symptoms invariably occur hours or days after dose reduction or discontinuation. Symptoms resolve within a few weeks, so the persistence of symptoms argues against withdrawal. Although depletion studies have been shown to provoke rapid return of symptoms, in clinical practice, psychotic and mood symptoms do not usually reappear abruptly after long-term treatment.

COMBINATION OF DRUGS

According to the American Psychiatric Association Practice Guidelines for the Treatment of Psychiatric Disorders, “the use of multiple agents should be avoided if possible” in the treatment of psychiatric disorders. Although *monotherapy* represents the ideal, *polypharmacy*, the simultaneous use of psychotropic medications, has been commonplace since chlorpromazine was combined with reserpine (Diupres) in the early 1950s. The practice of combining drugs and the merits of various *augmentation* or *combination* strategies are routinely discussed in the literature and at scientific meetings. The mean number of simultaneously prescribed medications has increased in recent decades. Among psychiatric inpatients, the mean number of psychotropics prescribed is approximately three. Fixed combinations—drugs that contain more than one active ingredient—have been successfully marketed in the past, and research on new combinations is ongoing. A fluoxetine-olanzapine fixed combination has been approved as a treatment for bipolar disorder. The use of such drugs may increase the patients’ compliance by simplifying the drug regimen. A problem with combination drugs, however, is that the clinician has less flexibility in adjusting the dosage of one of the components; that is, the use of combination drugs can cause two drugs to be administered when only one drug continues to be necessary for therapeutic efficacy (Table 29.1-3).

Table 29.1-3

Combination Drugs Used in Psychiatry

Ingredients	Preparation	Amount of Each	Recommended Dosage	Indications
Perphenazine and amitriptyline	—	Tablet: 2:25, 4:25, 4:50, 2:10, 4:10	Initial therapy: tablet of 2:25 or 4:25 qid Maintenance therapy: tablet 2:25 or 4:25 bid or qid.	Depression and associated anxiety
Dextroamphetamine and amphetamine	Adderall	Tablet: 5, 7.5, 10.0, 12.5, 15.0, 20.0, 30.0 mg	3 to 5 yrs: 2.5 mg/day; 6 yrs and older: 5 mg/day	Attention deficit/hyperactivity disorder
	Adderall XR	Capsule: 5, 10, 15, 20, 25, 30 mg	—	—
Chlordiazepoxide and clidinium bromide	—	Capsule: 5:25	One or two capsules tid or qid before meals and at bedtime	Peptic ulcer, gastritis, duodenitis, irritable bowel syndrome, spastic colitis, and mild ulcerative colitis
Chlordiazepoxide and amitriptyline	—	Tablet: 5.0:12.5, 10:25	Tablet of 5:12.5 tid or qid; tablet of 10:25 tid or qid, initially, then may increase to six tablets daily as required	Depression and associated anxiety
Olanzapine and fluoxetine	Symbyax	Capsule: 6:25, 6:50, 12:25, 12:50	Once daily in the evening in a dose range of olanzapine 6 to 12 mg and fluoxetine 25 to 50 mg	Depressive episodes associated with bipolar I disorder

qid, four times daily; bid, twice daily; tid, three times daily.

Sometimes distinctions are made between augmentation and combination therapy. When two psychotropics with the same approved indications are used concurrently, this is termed *combination therapy*. Adding a drug with another indication is termed *augmentation*. Augmentation often entails use of a drug that is not primarily considered a psychotropic. For example, in treating depression, it is not common to add thyroid hormone to an approved antidepressant.

Almost all patients with bipolar disorder are taking more than one psychotropic agent. Combination treatment with drugs that treat depression and dopamine receptor antagonist or serotonin-dopamine antagonist has long been held as preferable in patients with psychotic depression. Similarly, SSRIs typically produce partial improvement in patients with OCD, so the addition of a serotonin-dopamine antagonist may be helpful.

Medications also can be combined to counteract side effects, to treat specific symptoms, and as a temporary measure to transition from one drug to another. It is common practice to add a new medication without the discontinuation of a prior drug, particularly when the first drug has provided partial benefit. This can be done as part of a plan to transition from an agent that is not producing a satisfactory response or as an attempt to maintain the patient on combined therapy.

Advantages of combining drugs include building on existing response, which may be less demoralizing, and the possibility that combinations produce new mechanisms that no single agent can provide. One limitation is that noncompliance and adverse effects increase, and the clinician may not be able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect. Combining drugs can create a broad spectrum effect and also changes the ratio of metabolites.

COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY

Many psychiatrists believe that patients are best treated with a combination of medication and psychotherapy. Studies have demonstrated that the results of combined therapy are superior to those of either type of therapy alone. When pharmacotherapy and psychotherapy are used together, the approach should be coordinated, integrated, and synergistic. If the psychotherapy and the pharmacotherapy are directed by two separate clinicians, the clinicians must communicate with each other clearly and often.

SPECIAL POPULATIONS

Although every patient brings a unique combination of demographic and clinical variables to the clinical setting, certain patient populations require special consideration. When treating the young, the elderly, those with medical disorders, and women who want to conceive, are pregnant, or are nursing, awareness of risks associated with medication assumes increased importance. Data derived from clinical trials are of limited value in guiding many decisions, because populations in these studies consisted of healthy young adults and, until recently, excluded many women of child-bearing age. Studies of children and adolescents have become more common, so understanding of treatment effects in this population has grown.

Children

Understanding of the safety and efficacy of most psychotropic drugs when used to treat children is based more on clinical experience than on evidence from large clinical trial data. Other than attention-deficit/hyperactivity disorder (ADHD) and OCD, commonly used psychotropic drugs have no labeling for pediatric use, so results from adult studies are extrapolated to children. This is not necessarily appropriate because of developmental differences in pharmacokinetics and pharmacodynamics. Dosing is another special consideration in drug use with children. Although the small volume of distribution suggests the use of lower doses than those used in adults, a child's higher rate of metabolism suggests that a higher ratio of milligrams of drug to kilograms of body weight should be used. In practice, it is best to begin with a small dose and to increase it until clinical effects are observed. The clinician should not hesitate, however, to use adult dosages in children if these dosages are effective and the adverse effects are acceptable.

The paucity of research data is a legacy of many years in which manufacturers avoided conducting trials in children because of liability concerns, small market share, and, hence, limited profit potential represented by this population. To correct this problem, the FDA Modernization Act (FDAMA) of 1997 provided for special encouragement and incentives to study drugs for pediatric use.

Pregnant and Nursing Women

No definitive assurances exist that any drug is completely without risk during pregnancy and lactation. No psychotropic medication is absolutely contraindicated during pregnancy, although drugs with known risks of birth defects, premature birth, or neonatal complications should be avoided if acceptable alternatives are available.

Women who are pregnant or lactating are excluded from clinical trials, and it is only recently that women of child-bearing age have been able to participate in these studies. As a result, there are large gaps in knowledge of the effects of psychotropic agents on the developing fetus and on the neonate. Most of what is known is the result of anecdotal reports or data from registries. The basic rule is to avoid administering any drug to a woman who is pregnant (particularly during the first trimester) or who is breast-feeding a child, unless the mother's psychiatric disorder is severe and it is determined that the therapeutic value of the drug outweighs the theoretical adverse effects on the fetus or newborn. A woman may elect to continue on medication, because she does not want to chance a possible recurrence of painful or disabling symptoms.

Among the newer antidepressants, paroxetine is the only one to carry a warning from the FDA, the result of an increased risk of cardiac malformation. The agents with the most well-documented risk of specific birth defects are lithium, carbamazepine, and valproate. Lithium

administration during pregnancy is associated with Ebstein's anomaly, a serious abnormality in cardiac development, although recent evidence suggests that the risk is not as great as previously believed. Carbamazepine and valproic acid are associated with neural tube defects, which can be prevented by use of folate during pregnancy. Lamotrigine may cause oral clefts when used during the first trimester. Some experts advise that all women of child-bearing age who are treated with psychotropics take supplemental folate.

The administration of psychotherapeutic drugs at or near delivery can cause the baby to be overly sedated at delivery, thus requiring a respirator, or to be physically dependent on the drug, requiring detoxification and the treatment of a withdrawal syndrome. Reports exist of a neonatal withdrawal syndrome associated with third trimester use of SSRIs in pregnant women. They have also been implicated in producing pulmonary hypertension in newborns.

Virtually all psychiatric drugs are secreted in the milk of a nursing mother; therefore, mothers on those agents should be advised not to breast-feed their infants.

Elderly Patients

The two major concerns when treating geriatric patients with psychotherapeutic drugs are that elderly persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly, thus requiring lower dosages of medication. In practice, clinicians should begin treating geriatric patients with a small dose, usually approximately half of the usual starting dose. The dose should be raised in small increments, more slowly than for middle-aged adults, until a clinical benefit is achieved or unacceptable adverse effects appear. Although many geriatric patients require a small dose of medication, many others require a full therapeutic dose.

Elderly patients account for approximately one third of all prescription drug use and a substantial percentage of over-the-counter preparations as well. Even more significant is the incidence of polypharmacy. Recent surveys have found that elderly patients in the community are taking between three and five medications, and that hospitalized elderly patients are treated with an average of ten drugs. Nearly half of all patients in long-term care facilities are prescribed one or more psychotropic agents. In view of these statistics, clinicians need to consider potential types and likelihood of drug interactions when selecting medications.

Psychotropic drugs have been shown to be causally related to falls in the elderly. Discontinuation of psychotropic drugs results in an estimated 40 percent risk reduction for falls. This association between psychotropics and falls and hip fractures may weaken as newer agents become widely used. As a rule, new-generation compounds produce less unwanted sedation, dizziness, parkinsonism, and postural hypotension.

Age-related changes in renal clearance and hepatic metabolism make it more important to be conservative with the starting doses of medication as well as the rate of dose titration. Within any class of psychotropic agents, those with potentially serious consequences, such as hypotension, cardiac conduction abnormalities, anticholinergic activity, and respiratory depression, are not suitable choices. Drugs that cause cognitive impairment, such as benzodiazepines and anticholinergics, can mimic or exacerbate symptoms of dementia. Similarly, dopamine receptor antagonists can worsen or induce Parkinson's disease, another age-related disorder. Some side effects, such as SSRI-associated syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and oxcarbazepine-associated hyponatremia, occur more commonly in older patients.

A common ethical dilemma with the medically ill elderly or those with dementia is the question of their capacity to give informed consent before treatment with psychotropic drugs or electroconvulsive therapy (ECT).

Medically Ill Patients

There are special considerations, diagnostic and therapeutic, when administering psychiatric drugs to medically ill patients. The medical disorder should be ruled out as a cause of the psychiatric symptoms. For example, patients with neurological or endocrine disorders or those infected with human immunodeficiency virus (HIV) may experience disturbances of mood and cognition. Common medications, such as corticosteroids and L-dopa, are associated with induction of mania.

A patient with diabetes mellitus is better treated with an agent without the risk of weight gain or glucose dysregulation. Depending on the diagnosis, drugs that might treat the primary psychiatric disorder and also cause weight loss, drugs such as bupropion, topiramate, and zonisamide, should be prescribed for these patients. Patients with obstructive pulmonary disease should not be given sedating drugs, which raise the arousal threshold and suppress respiration. Patients with medical disorders are also taking other medications, which can result in pharmacodynamic and pharmacokinetic interactions. Combined treatment with an inducer of multiple CYP enzymes and a drug that is a substrate for those enzymes could result in subtherapeutic levels, leading to inadequate symptom control. Use of the tuberculosis treatment rifampicin (Rifadin) with carbamazepine is an example of this. Use of drugs that inhibit CYP 2D6, agents such as paroxetine and fluoxetine, can prevent the conversion of hydrocodone (Robidone) and other opiates into an active analgesic form. NSAIDs are also a rare cause of perceptual disturbances and psychotic symptoms.

Other issues include a potentially increased sensitivity to adverse effects, including increased or decreased metabolism and excretion of the drug, and interactions with other medications. Drug interactions are an obvious concern when drugs with a narrow therapeutic range are being used. Any change in the rate of metabolism or interference with the formation and elimination of metabolites can profoundly influence the activity of that drug. Similarly, interactions that interfere with drug metabolism can produce an increase in side effects and toxicity.

As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dosage, to increase it slowly, and to watch for clinical benefit and adverse effects. Determining the plasma drug concentrations may be helpful for such patients, but therapeutic blood concentrations for most psychotropic drugs are neither necessary nor routinely available.

Substance Abuse

Many patients who seek or need treatment for a psychiatric disorder engage in chronic use of illicit substances or drink excessive amounts of alcohol. Marijuana is the most commonly used illicit (in most states) drug in the United States.

Discontinuation of chronic drug or alcohol use can result not only in craving, but also in clinically significant psychiatric and physiological withdrawal symptoms. For many patients, successful treatment of their underlying psychiatric disorder may not be possible in the presence of ongoing marijuana, cocaine, and alcohol use. If several trials of medications fail, hospitalization for detoxification may be necessary. Little research and no consensus exist about how to use psychotropic agents in patients who are regular users of cocaine, marijuana, or other recreational drugs.

REGULATORY ISSUES

The FDA has the authority to approve a drug for clinical use and to ensure that product labeling is truthful and contains all information pertinent to the safe and effective use of that drug.

Product information that is FDA approved for marketed drugs appears as a package insert that lists potential side effects, drug interactions, the need for special monitoring, and restrictions for use. In some cases, these adverse reactions and potential safety hazards warrant a special warning label called a black box label. The FDA typically negotiates final labeling language with the company; however, in cases where a company refuses to satisfy the FDA, the agency may initiate proceedings to remove the drug from clinical use. In recent years, warning labels have been applied to entire classes of psychotropic drugs, including the serotonin dopamine antagonists and

antidepressants such as the SSRIs.

The product information may also contain a “Contraindications” heading. This section describes instances in which the drug should not be used because the risk of using it clearly outweighs the benefit. If no contraindications are known, this section of the labeling will state “None known.”

A precautions section may contain precautions for most individuals taking the drug, as well as for specific groups, such as pregnant women, nursing mothers, or children. In this section, one will find recommendations for patients to ensure safe and effective use of the drug. For example, there may be precautions about driving when taking the medication or using substances such as other drugs, food, or alcohol that may have harmful effects if taken while using the medication. The Precautions section also provides information about laboratory tests needed to track responses or to identify adverse reactions to the drug or about known interactions with other drugs, foods, or ingredients.

Every product label has an Adverse Reaction section that lists the frequency of undesirable effects that may be associated with use of a drug. Causes of adverse reactions can include medication errors, such as overdosage, or interactions between different drugs or between drugs and certain foods.

NONAPPROVED DOSAGES AND USES

It is now common practice to treat psychiatric disorders with drugs that are approved for nonpsychiatric conditions. Some examples include propranolol (Inderal) for social anxiety and treatment of lithium-induced tremor; verapamil (Calan, Isoptin) for mania and treatment of MAOI-induced hypertensive crisis; levothyroxine (Levoxy) for antidepressant augmentation; clonidine (Catapres) and guanfacine (Tenex) for ADHD and posttraumatic stress disorder (PTSD); dextroamphetamine (Dexedrine) for antidepressant augmentation; and riluzole (Rilutek) for self-injurious behavior. Off-label use of a drug is not a violation of law or a departure from good medical practice. The FDA does not limit the manner in which a physician may use an approved drug. Medications can be prescribed for any reason shown to be medically indicated for the welfare of the patient. Once a drug is approved for commercial use, a physician can, as part of the practice of medicine, lawfully prescribe a different dosage for a patient or may otherwise vary the conditions of use from what is approved in the package labeling without notifying the FDA or obtaining its approval.

Failure to follow the information on the drug label does not in itself impose liability and should not preclude a physician from using good clinical judgment in the service of the patient. Physicians are permitted to use a drug for indications not included on the drug’s official labeling without violating the FDA rules. This fact, however, does not absolve the physician of responsibility for an untoward result from treatment. Patients can still sue for possible medical malpractice with the reasoning that the failure to follow the FDA-approved label can be interpreted as deviating from the prevailing standard of care.

When using a drug for an unapproved indication or in a dose outside the usual range, good clinical practice is to explain to the patient and to document in the chart why a drug is being used instead of an approved agent. In cases of doubt about a plan to use a drug off label, a consultation with a colleague should be obtained.

In some cases, a drug has obtained a limited approval for an indication. Divalproex (Depakote), quetiapine (Seroquel), and risperidone, for example, are approved by the FDA for the acute, but not long-term, treatment of mania. Nevertheless, these drugs are routinely used for long-term prevention of recurrences of mania and bipolar disorder. In the case of lamotrigine, it was accepted as a first-choice agent for the treatment of bipolar disorder long before the FDA granted approval for that indication.

PLACEBOS

Pharmacologically inactive substances have long been known to sometimes produce significant clinical benefits. A patient who believes that a compound is helpful may often derive considerable benefit from taking that substance, whether it is known to be pharmacologically active or not. For many psychiatric disorders, including mild to moderate depression and some anxiety disorders, well over 30 percent of patients can exhibit significant improvement or remission of symptoms on a placebo. For other conditions, such as schizophrenia, manic episodes, and psychotic depression, the placebo response rate is very low. Whereas suggestion is undoubtedly important in the efficacy of placebos (and active drugs), placebos can produce biological effects. For example, placebo-induced analgesia may sometimes be blocked by naloxone (Narcan), which suggests that endorphins may mediate the analgesia derived from taking a placebo. It is conceivable that placebos may also stimulate endogenous anxiolytic and antidepressant factors, resulting in clinical improvement in patients with depression and anxiety disorders.

Just as placebos can produce benefit, they can also have adverse effects. In many studies, some adverse effects are likely to be more common with placebos than with the active drug. Some patients will not tolerate placebos despite the fact that they are supposedly inert, and they exhibit adverse effects (called the *nocebo phenomenon*). It is easy to discount such patients as overly suggestible; however, if beneficial endogenous factors can be stimulated by placebos, perhaps toxic endogenous factors can also be produced.

Prudence is needed in contemplating the use of a placebo in clinical practice. Treating a patient with a placebo without consent can seriously undermine a patient’s confidence in the physician if, and when, it is discovered.

29.2 Medication-Induced Movement Disorders

Medication-induced movement disorders are commonly associated with the use of psychotropic drugs. Although most frequently associated with drugs that block dopamine type 2 (D₂) receptors, abnormal motor activity may occur with other types of medications as well. Sometimes it can be difficult to determine if abnormal motor movements are an adverse event or a symptom of an underlying disorder. For example, anxiety can resemble akathisia, and alcohol or benzodiazepine withdrawal can cause tremor. The American Psychiatric Association has decided to retain the term *neuroleptic* when discussing side effects associated with drugs used to treat psychosis—the dopamine receptor antagonists (DRAs) and second-generation antipsychotics (SGAs). The rationale for continued use of the term is that it was originally used to describe the tendency of these drugs to cause abnormal movements.

The most common neuroleptic-related movement disorders are parkinsonism, acute dystonia, and acute akathisia. Neuroleptic malignant syndrome is a life-threatening and often misdiagnosed condition. Neuroleptic-induced tardive dyskinesia is a late-appearing adverse effect of neuroleptic drugs and can be irreversible; recent data, however, indicate that the syndrome, although still serious and potentially disabling, is less pernicious than was previously thought in patients taking DRAs. The newer antipsychotics, the serotonin-dopamine antagonists (SDAs), block binding to dopamine receptors to a much lesser degree and thereby are presumed to be less likely to produce such movement disorders. Nevertheless, this risk remains and vigilance is still required when these drugs are prescribed.

Table 29.2-1 lists the selected medications associated with movement disorders and their impact on relevant neuroreceptors.

Table 29.2-1
Selected Medications Associated with Movement Disorders: Impact on Relevant Neuroreceptors

Type (Subtype)	Name (Brand)	D ₂ Blockade	5-HT ₂ Blockade	mACh Blockade
Antipsychotics				
Phenothiazine (Aliphatic)	Chlorpromazine (Thorazine)	Low	High	High
Phenothiazine (Piperidines)	Thioridazine (Mellaril)	Low	Med	High
	Mesoridazine (Serentil)	Low	Med	High
	Trifluoperazine (Stelazine)	Med	Med	Med
Phenothiazine (Piperazines)	Fluphenazine (Prolixin)	High	Low	Low
	Perphenazine (Trilafon)	High	Med	Low
	Thioxanthenes	Thiothixene (Navane)	High	Med
Thioxanthenes	Chlorprothivene (Taractan)	Med	High	Med

NEUROLEPTIC-INDUCED PARKINSONISM AND OTHER MEDICATION-INDUCED PARKINSONISM

Diagnosis, Signs, and Symptoms

Symptoms of neuroleptic-induced parkinsonism and other medication-induced parkinsonism include muscle stiffness (lead pipe rigidity), cogwheel rigidity, shuffling gait, stooped posture, and drooling. The pill-rolling tremor of idiopathic parkinsonism is rare, but a regular, coarse tremor similar to essential tremor may be present. The so-called *rabbit syndrome*, a tremor affecting the lips and perioral muscles, is another parkinsonian effect seen with antipsychotics, although perioral tremor is more likely than other tremors to occur late in the course of treatment.

Epidemiology

Parkinsonian adverse effects typically occur within 5 to 90 days of the initiation of treatment. Patients who are elderly and female are at the highest risk for neuroleptic-induced parkinsonism, although the disorder can occur at all ages.

Etiology

Neuroleptic-induced parkinsonism is caused by the blockade of D₂ receptors in the caudate at the termination of the nigrostriatal dopamine neurons. All antipsychotics can cause the symptoms, especially high-potency drugs with low levels of anticholinergic activity, most notably haloperidol (Haldol).

Differential Diagnosis

Included in the differential diagnosis are idiopathic parkinsonism, other organic causes of parkinsonism, and depression, which can also be associated with parkinsonian symptoms. Decreased psychomotor activity and blunted facial expression are symptoms of depression and idiopathic parkinsonism.

Treatment

Parkinsonism can be treated with anticholinergic agents, benzotropine (Cogentin), amantadine (Symmetrel), or diphenhydramine (Benadryl) (Table 29.2-2). Anticholinergics should be withdrawn after 4 to 6 weeks to assess whether tolerance to the parkinsonian effects has developed; about half of patients with neuroleptic-induced parkinsonism require continued treatment. Even after the antipsychotics are withdrawn, parkinsonian symptoms can last up to 2 weeks and even up to 3 months in elderly patients. With such patients, the clinician may continue the anticholinergic drug after the antipsychotic has been stopped until the parkinsonian symptoms resolve completely.

Table 29.2-2
Drug Treatment of Extrapyrarnidal Disorders

Generic Name	Trade Name	Usual Daily Dosage	Indications
Anticholinergics			
Benzotropine	Cogentin	PO 0.5 to 2 mg tid; IM or IV 1 to 2 mg	Acute dystonia, parkinsonism, akinesia, akathisia
Biperiden	Akineton	PO 2 to 6 mg tid; IM or IV 2 mg	
Procyclidine	Kemadrin	PO 2.5 to 5 mg bid-qid	
Trihexyphenidyl	Artane, Tremin	PO 2 to 5 mg tid	
Orphenadrine	Norflex, Disipal	PO 50 to 100 mg bid-qid; IV 60 mg	Rabbit syndrome
Antihistamine			
Diphenhydramine	Benadryl	PO 25 mg qid; IM or IV 25 mg	Acute dystonia, parkinsonism, akinesia, rabbit syndrome
Amantadine	Symmetrel	PO 100 to 200 mg bid	Parkinsonism, akinesia, rabbit syndrome
β-Adrenergic antagonist			
Propranolol	Inderal	PO 20 to 40 mg tid	Akathisia, tremor
α-Adrenergic antagonist			
Clonidine	Catapres	PO 0.1 mg tid	Akathisia
Benzodiazepines			
Clonazepam	Klonopin	PO 1 mg bid	Akathisia, acute dystonia
Lorazepam	Ativan	PO 1 mg tid	
Buspirone	BuSpar	PO 20 to 40 mg qid	Tardive dyskinesia
Vitamin E	—	PO 1,200 to 1,600 IU/day	Tardive dyskinesia

PO, orally; IM, intramuscularly; IV, intravenously; qd, per day; bid, twice a day; tid, three times a day; qid, four times a day.

NEUROLEPTIC MALIGNANT SYNDROME

Diagnosis, Signs, and Symptoms

Neuroleptic malignant syndrome is a life-threatening complication that can occur anytime during the course of antipsychotic treatment. The motor and behavioral symptoms include muscular rigidity and dystonia, akinesia, mutism, obtundation, and agitation. The autonomic symptoms include hyperthermia, diaphoresis, and increased pulse and blood pressure. Laboratory findings include an increased white blood cell count and increased levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure.

Epidemiology

About 0.01 to 0.02 percent of patients treated with antipsychotics develop neuroleptic malignant syndrome. Men are affected more frequently than women, and young patients are affected more commonly than elderly patients. The mortality rate can reach 10 to 20 percent or even higher when depot antipsychotic medications are involved.

Course and Prognosis

The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect an exacerbation of the psychosis.

Treatment

In addition to supportive medical treatment, the most commonly used medications for the condition are dantrolene (Dantrium) and bromocriptine (Parlodel), although amantadine (Symmetrel) is sometimes used (Table 29.2-3). Bromocriptine and amantadine pose direct DRA effects and may serve to overcome the antipsychotic-induced dopamine receptor blockade. The lowest effective dosage of the antipsychotic drug should be used to reduce the chance of neuroleptic malignant syndrome. High-potency drugs, such as haloperidol, pose the greatest risk. Antipsychotic drugs with anticholinergic effects seem less likely to cause neuroleptic malignant syndrome. Electroconvulsive therapy (ECT) has been used.

Table 29.2-3
Treatment of Neuroleptic Malignant Syndrome

Intervention	Dosing	Effectiveness
Amantadine	200 to 400 mg PO/day in divided doses	Beneficial as monotherapy or in combination; decrease in death rate
Bromocriptine	2.5 mg PO bid or tid, may increase to a total of 45 mg/day	Mortality reduced as a single or combined agent
Levodopa/carbidopa	Levodopa 50 to 100 mg/day IV as continuous infusion	Case reports of dramatic improvement
Electroconvulsive therapy	Reports of good outcome with both unilateral and bilateral treatments; response may occur in as few as three treatments	Effective when medications have failed; also may treat underlying psychiatric disorder
Dantrolene	1 mg/kg/day for 8 days, then continue as PO for 7 additional days	Benefits may occur in minutes or hours as a single agent or in combination
Benzodiazepines	1 to 2 mg IM as test dose; if effective, switch to PO; consider use if underlying disorder has catatonic symptoms	Has been reported effective when other agents have failed
Supportive measures	IV hydration, cooling blankets, ice packs, ice-water enema, oxygenation, antipyretics	Often effective as initial approach early in the episode

PO, orally; bid, twice a day; tid, three times a day; IV, intravenously; IM, intramuscularly.

MEDICATION-INDUCED ACUTE DYSTONIA

Diagnosis, Signs, and Symptoms

Dystonias are brief or prolonged contractions of muscles that result in obviously abnormal movements or postures, including oculogyric crises, tongue protrusion, trismus, torticollis, laryngeal–pharyngeal dystonias, and dystonic postures of the limbs and trunk. Other dystonias include blepharospasm and glossopharyngeal dystonia; the latter results in dysarthria, dysphagia, and even difficulty in breathing, which can cause cyanosis. Children are particularly likely to evidence opisthotonos, scoliosis, lordosis, and writhing movements. Dystonia can be painful and frightening and often results in noncompliance with future drug treatment regimens.

Epidemiology

The development of acute dystonic symptoms is characterized by their early onset during the course of treatment with neuroleptics. There is a higher incidence of acute dystonia in men, in patients younger than age 30 years, and in patients given high dosages of high-potency medications.

Etiology

Although it is most common with intramuscular doses of high-potency antipsychotics, dystonia can occur with any antipsychotic. The mechanism of action is thought to be dopaminergic hyperactivity in the basal ganglia that occurs when central nervous system (CNS) levels of the antipsychotic drug begin to fall between doses.

Differential Diagnosis

The differential diagnosis includes seizures and tardive dyskinesia.

Course and Prognosis

Dystonia can fluctuate spontaneously and respond to reassurance, so the clinician gets the false impression that the movement is hysterical or completely under conscious control.

Treatment

Prophylaxis with anticholinergics or related drugs (outlined in [Table 29.2-2](#)) usually prevents dystonia, although the risks of prophylactic treatment weigh against that benefit. Treatment with intramuscular anticholinergics or intravenous or intramuscular diphenhydramine (Benadryl) (50 mg) almost always relieves the symptoms. Diazepam (Valium) (10 mg intravenously), amobarbital (Amytal), caffeine sodium benzoate, and hypnosis have also been reported to be effective. Although tolerance for the adverse effects usually develops, it is prudent to change the antipsychotic if the patient is particularly concerned that the reaction may recur.

MEDICATION-INDUCED ACUTE AKATHISIA

Diagnosis, Signs, and Symptoms

Akathisia is subjective feelings of restlessness, objective signs of restlessness, or both. Examples include a sense of anxiety, inability to relax, jitteriness, pacing, rocking motions while sitting, and rapid alternation of sitting and standing. Akathisia has been associated with the use of a wide range of psychiatric drugs, including antipsychotics, antidepressants, and sympathomimetics. Once akathisia is recognized and diagnosed, the antipsychotic dose should be reduced to the minimal effective level. Akathisia may be associated with a poor treatment outcome.

Epidemiology

Middle-aged women are at increased risk of akathisia, and the time course is similar to that for neuroleptic-induced parkinsonism.

Treatment

Three basic steps in the treatment of akathisia are reducing medication dosage, attempting treatment with appropriate drugs, and considering changing the neuroleptic. The most efficacious drugs are β -adrenergic receptor antagonists, although anticholinergic drugs, benzodiazepines, and cyproheptadine (Periactin) may benefit some patients. In some cases of akathisia, no treatment seems to be effective.

TARDIVE DYSKINESIA

Diagnosis, Signs, and Symptoms

Tardive dyskinesia is a delayed effect of antipsychotics; it rarely occurs until after 6 months of treatment. The disorder consists of abnormal, involuntary, irregular choreoathetoid movements of the muscles of the head, limbs, and trunk. The severity of the movements ranges from minimal—often missed by patients and their families—to grossly incapacitating. Perioral movements are the most common and include darting, twisting, and protruding movements of the tongue; chewing and lateral jaw movements; lip puckering; and facial grimacing. Finger movements and hand clenching are also common. Torticollis, retrocollis, trunk twisting, and pelvic thrusting occur in severe cases. In the most serious cases, patients may have breathing and swallowing irregularities that result in aerophagia, belching, and grunting. Respiratory dyskinesia has also been reported. Dyskinesia is exacerbated by stress and disappears during sleep.

Epidemiology

Tardive dyskinesia develops in about 10 to 20 percent of patients who are treated for more than a year. About 20 to 40 percent of patients who require long-term hospitalization have tardive dyskinesia. Women are more likely to be affected than men. Children, patients who are more than 50 years of age, and patients with brain damage or mood disorders are also at high risk.

Course and Prognosis

Between 5 and 40 percent of all cases of tardive dyskinesia eventually remit, and between 50 and 90 percent of all mild cases remit. Tardive dyskinesia is less likely to remit in elderly patients than in young patients, however.

Treatment

The three basic approaches to tardive dyskinesia are prevention, diagnosis, and management. Prevention is best achieved by using antipsychotic medications only when clearly indicated and in the lowest effective doses. The atypical antipsychotics are associated with less tardive dyskinesia than the older antipsychotics. Clozapine (Clozaril) is the only antipsychotic to have minimal risk of tardive dyskinesia and can even help improve preexisting symptoms of tardive dyskinesia. This has been attributed to its low affinity for D_2 receptors and high affinity for 5-hydroxytryptamine (5-HT) receptor antagonism. Patients who are receiving antipsychotics should be examined regularly for the appearance of abnormal movements, preferably with the use of a standardized rating scale ([Table 29.2-4](#)). Patients frequently experience an exacerbation of their symptoms when the DRA is withheld, whereas substitution of an SDA may limit the abnormal movements without worsening the progression of the dyskinesia.

Table 29.2-4

Abnormal Involuntary Movement Scale (AIMS) Examination Procedure

Rated by

Either before or after completing the examination procedure, observe the patient unobtrusively at rest (e.g., in waiting room).

The chair to be used in this examination should be a hard, firm one without arms.

After observing the patient, rate him or her on a scale of 0 (none), 1 (minimal), 2 (mild), 3 (moderate), and 4 (severe), according to the severity of the symptoms.

Ask patient whether there is anything in his or her mouth (e.g., gum, candy) and, if so, to remove it.

Ask patient about the current condition of his or her teeth. Ask patient if he or she wears dentures. Do teeth or dentures bother patient now?

Ask patient whether he or she notices movement in mouth, face, hands, or feet. If yes, ask patient to describe and indicate to what extent movements currently bother patient or interfere with his or her activities.

0 1 2 3 4 Have patient sit in chair with hands on knees, legs slightly apart, and feet flat on floor. (Look at entire body for movement while in this position.)

0 1 2 3 4 Ask patient to sit with hands hanging unsupported—If male, between legs; if female and wearing a dress, hanging over knees. (Observe hands and other body areas.)

0 1 2 3 4 Ask patient to open mouth. (Observe tongue at rest within mouth.) Do this twice.

0 1 2 3 4 Ask patient to protrude tongue. (Observe abnormalities of tongue movement.) Do this twice.

0 1 2 3 4 Ask patient to tap thumb, with each finger, as rapidly as possible for 10 to 15 seconds; separately with right hand, then with left hand. (Observe facial and leg movements.)

0 1 2 3 4 Flex and extend patient's left and right arms. (One at a time.)

0 1 2 3 4 Ask patient to stand up. (Observe in profile. Observe all body areas again, hips included.)

0 1 2 3 4 ^aAsk patient to extend both arms outstretched in front with palms down. (Observe trunk, legs, and mouth.)

0 1 2 3 4 ^aHave patient walk a few paces, turn, and walk back to chair. (Observe hands and gait.)

Do this twice.

^aActivated movements.

Once tardive dyskinesia is recognized, the clinician should consider reducing the dose of the antipsychotic or even stopping the medication altogether. Alternatively, the clinician may switch the patient to clozapine or to one of the new SDAs. In patients who cannot continue taking any antipsychotic medication, lithium (Eskalith), carbamazepine (Tegretol), or benzodiazepines may effectively reduce the symptoms of both the movement disorder and the psychosis.

TARDIVE DYSTONIA AND TARDIVE AKATHISIA

On occasion, dystonia and akathisia emerge late in the course of treatment. These symptoms may persist for months or years despite drug discontinuation or dose reduction.

MEDICATION-INDUCED POSTURAL TREMOR

Diagnosis, Signs, and Symptoms

Tremor is a rhythmic alteration in movement that is usually faster than one beat per second. Fine tremor (8 to 12 Hz) is most common.

Epidemiology

Typically, tremors decrease during periods of relaxation and sleep and increase with stress or anxiety.

Etiology

Whereas all the above diagnoses specifically include an association with a neuroleptic, a range of psychiatric medications can produce tremor—most notably, lithium, stimulants, antidepressants, caffeine, and valproate (Depakene).

Treatment

The treatment involves four principles:

1. The lowest possible dose of the psychiatric drug should be taken.
2. Patients should minimize caffeine consumption.
3. The psychiatric drug should be taken at bedtime to minimize the amount of daytime tremor.
4. β -adrenergic receptor antagonists (e.g., propranolol [Inderal]) can be given to treat drug-induced tremors.

OTHER MEDICATION-INDUCED MOVEMENT DISORDERS

Nocturnal Myoclonus

Nocturnal myoclonus consists of highly stereotyped, abrupt contractions of certain leg muscles during sleep. Patients lack any subjective awareness of the leg jerks. The condition may be present in about 40 percent of persons over 65 years of age. The cause is unknown, but it is a rare side effect of selective serotonin reuptake inhibitors (SSRIs).

The repetitive leg movements occur every 20 to 60 seconds, with extensions of the large toe and flexion of the ankle, the knee, and the hips. Frequent awakenings, unrefreshing sleep, and daytime sleepiness are major symptoms. No treatment for nocturnal myoclonus is universally effective. Treatments that may be useful include benzodiazepines, levodopa (Larodopa), quinine, and, in rare cases, opioids.

Restless Leg Syndrome

In *restless leg syndrome*, persons feel deep sensations of creeping inside the calves whenever sitting or lying down. The dysesthesias are rarely painful but are agonizingly relentless and cause an almost irresistible urge to move the legs; thus, this syndrome interferes with sleep and with falling asleep. It peaks in middle age and occurs in 5 percent of the population. The cause is unknown, but it is a rare side effect of SSRIs.

Symptoms are relieved by movement and by leg massage. The dopamine receptor agonists ropinirole (Requip) and pramipexole (Mirapex) are effective in treating this syndrome. Other treatments include the benzodiazepines, levodopa, quinine, opioids, propranolol, valproate, and carbamazepine.

HYPERTHERMIC SYNDROMES

All the medication-induced movement disorders may be associated with hyperthermia. [Table 29.2-5](#) lists the various conditions associated with hyperthermia.

Table 29.2-5
Drug-Induced Central Hyperthermic Syndromes^a

Condition (and Mechanism)	Common Drug Causes	Frequent Symptoms	Possible Treatment ^b	Clinical Course
Hyperthermia (↓ heat dissipation) (↑ heat production)	Atropine, lidocaine, meperidine NSAID toxicity, pheochromocytoma, thyrotoxicosis	Hyperthermia, diaphoresis, malaise	Acetaminophen per rectum (325 mg every 4 hrs), diazepam oral or per rectum (5 mg every 8 hrs) for febrile seizures	Benign, febrile seizures in children
Malignant hyperthermia (↑ heat production)	NMJ blockers (succinylcholine), halothane	Hyperthermia muscle rigidity, arrhythmias, ischemia, ^c hypotension, rhabdomyolysis; disseminated intravascular coagulation	Dantrolene sodium (1–2 mg/kg/min IV infusion) ^d	Familial, 10% mortality if untreated
Tricyclic overdose (↑ heat production)	Tricyclic antidepressants, cocaine	Hyperthermia, confusion, visual hallucinations, agitation, hyperreflexia, muscle relaxation, anticholinergic effects (dry skin, pupil dilation), arrhythmias	Sodium bicarbonate (1 mEq/kg IV bolus) if arrhythmia is present, physostigmine (1–3 mg IV) with cardiac monitoring	Fatalities have occurred if untreated
Autonomic hyperreflexia (↑ heat production)	CNS stimulants (amphetamines)	Hyperthermia excitement, hyperreflexia	Trimethaphan (0.3–7 mg/min IV infusion)	Reversible
Lethal catatonia (↓ heat dissipation)	Lead poisoning	Hyperthermia, intense anxiety, destructive behavior, psychosis	Lorazepam (1–2 mg IV every 4 hrs), antipsychotics may be contraindicated	High mortality if untreated
Neuroleptic malignant syndrome (mixed; hypothalamic, ↓ heat dissipation, ↑ heat production)	Antipsychotics (neuroleptics), methyl dopa, reserpine	Hyperthermia, muscle rigidity, diaphoresis (60%), leukocytosis, delirium, rhabdomyolysis, elevated CPK, autonomic deregulation, extrapyramidal symptoms	Bromocriptine (2–10 mg every 8 hrs orally or nasogastric tube), lysuride (0.02–0.1 mg/hr IV infusion), carbidopa-levodopa (Sinemet) (25/100 PO every 8 hrs), dantrolene sodium (0.3–1 mg/kg IV every 6 hrs)	Rapid onset, 20% mortality if untreated

NSAID, nonsteroidal anti-inflammatory drug; MAOI, monoamine oxidase inhibitor; NMJ, neuromuscular junction; CNS, central nervous system; CPK, creatine phosphokinase; PO, orally; IV, intravenously.

^aBoldface indicates features that may be used to distinguish one syndrome from another.

^bGastric lavage and supportive measures, including cooling, are required in most cases.

^cOxygen consumption increases by 7% for every 1°F increase in body temperature.

^dHas been associated with idiosyncratic hepatocellular injury, as well as severe hypotension in one case.

29.3 α₂-Adrenergic Receptor Agonists, α₁-Adrenergic Receptor Antagonists: Clonidine, Guanfacine, Prazosin, and Yohimbine

Clonidine (Catapres) was developed initially as an antihypertensive medication because of its noradrenergic effects. It is an α_2 -adrenergic receptor agonist and reduces plasma norepinephrine. It has been studied in many neurologic and psychiatric conditions, including attention-deficit/hyperactivity disorder (ADHD), tic disorders, opiates and alcohol withdrawal, and posttraumatic stress disorder (PTSD). Its use has been somewhat limited by sedation and hypotension, which are common, and in children, its use is limited by its cardiac effects. Guanfacine (Tenex), another α_2 -adrenergic receptor agonist, has been preferentially used because of its differential affinity for certain α_2 -adrenergic receptor subtypes, resulting in less sedation and hypotension. However, there have been fewer clinical studies of guanfacine than of clonidine.

Prazosin (Minipress) is an α_1 -postsynaptic antagonist. It reduces blood pressure (BP) through vasodilation. Prazosin has shown benefits in treating sleep disorders associated with PTSD.

CLONIDINE AND GUANFACINE

Pharmacologic Actions

Guanfacine is an agonist on presynaptic α_2 -receptors. It inhibits sympathetic outflow and causes vasodilation of blood vessels. It is marketed as a treatment for high BP. It is more selective and less potent than clonidine, the other widely used α_2 -agonist. Clonidine and guanfacine are well absorbed from the gastrointestinal tract and reach peak plasma levels 1 to 3 hours after oral administration. The half-life of clonidine is 6 to 20 hours and that of guanfacine is 10 to 30 hours.

The agonist effects of clonidine and guanfacine on presynaptic α_2 -adrenergic receptors in the sympathetic nuclei of the brain result in a decrease in the amount of norepinephrine released from the presynaptic nerve terminals. This serves generally to reset the body's sympathetic tone at a lower level and decrease arousal.

Therapeutic Indications

There is considerably more experience in clinical psychiatry with clonidine than with guanfacine. There is recent interest in the use of guanfacine for the same indications that respond to clonidine due to guanfacine's longer half-life and relative lack of sedative effects.

Withdrawal from Opioids, Alcohol, Benzodiazepines, or Nicotine. Clonidine and guanfacine are effective in reducing the autonomic symptoms of rapid opioid withdrawal (e.g., hypertension, tachycardia, dilated pupils, sweating, lacrimation, and rhinorrhea) but not the associated subjective sensations. Clonidine administration (0.1 to 0.2 mg two to four times a day) is initiated before detoxification and is then tapered off over 1 to 2 weeks (Table 29.3-1).

Table 29.3-1
Oral Clonidine Protocols for Opioid Detoxification

Clonidine 0.1–0.2 mg PO four times a day; hold if systolic BP <90 mm Hg or bradycardia; stabilize for 2–3 days, then taper over 5–10 days

OR

Clonidine 0.1–0.2 mg PO q4–6h as needed for withdrawal signs or symptoms; stabilize for 2–3 days, then taper over 5–10 days

OR

Test dose with clonidine 0.1–0.2 mg PO or SL (for patients weighing over 200 lbs); check BP after 1 hr. If diastolic BP >70 mm Hg and no symptoms of hypotension, begin treatment as follows:

Weight (lb)	Number of Clonidine Patches
<110	1 patch
110–160	2 patches
160–200	2 patches
>200	2 patches

OR

Test dose of oral clonidine 0.1 mg; check BP after 1 hr (if systolic BP <90 mm Hg, do not give patch)

Place two TTS-2 clonidine patches (or three patches if patient weighs >150 lbs) on hairless area of upper body; then

For first 23 hrs after patch application, give oral clonidine 0.2 mg q6h; then

For next 24 hrs, give oral clonidine 0.1 mg q6h

Change patches weekly

After 2 weeks of two patches, switch to one patch (or two patches if patient weighs >150 lb)

After 1 week of one patch, discontinue patches

BP, blood pressure; PO, oral; q, every; SL, sublingual; TTS, through the skin.
(From American Society of Addiction Medicine. Detoxification: Principle and protocols. In: *The Principles Update Series: Topics in Addiction Medicine*, section 11. American Society of Addiction, 1997, with permission.)

Clonidine and guanfacine can reduce symptoms of alcohol and benzodiazepine withdrawal, including anxiety, diarrhea, and tachycardia. They can reduce craving, anxiety, and the irritability symptoms of nicotine withdrawal. The transdermal patch formulation of clonidine is associated with better long-term compliance for purposes of detoxification than is the tablet formulation.

Tourette's Disorder. Clonidine and guanfacine are effective drugs for the treatment of Tourette's disorder. Most clinicians begin treatment for Tourette's disorder with the standard dopamine receptor antagonists haloperidol (Haldol) and pimozide (Orap) and the serotonin-dopamine antagonists risperidone (Risperdal) and olanzapine (Zyprexa). However, if concerned about the adverse effects of these drugs, the clinician may begin treatment with clonidine or guanfacine. The starting dose of clonidine for children is 0.05 mg a day; it can be increased to 0.3 mg a day in divided doses. Up to 3 months are needed before the beneficial effects of clonidine can be seen in patients with Tourette's disorder. The response rate has been reported to be up to 70 percent.

Other Tic Disorders. Clonidine and guanfacine reduce the frequency and severity of tics in persons with tic disorder with or without comorbid ADHD.

Hyperactivity and Aggression in Children. Clonidine and guanfacine can be useful alternatives for the treatment of ADHD. They

are used in place of sympathomimetics and antidepressants, which may produce paradoxical worsening of hyperactivity in some children with intellectual disability, aggression, or features on the spectrum of autism. Clonidine and guanfacine can improve mood, reduce activity level, and improve social adaptation. Some impaired children may respond favorably to clonidine, but others may simply become sedated. The starting dose is 0.05 mg a day; it can be raised to 0.3 mg a day in divided doses. The efficacy of clonidine and guanfacine for control of hyperactivity and aggression often diminishes over several months of use.

Clonidine and guanfacine can be combined with methylphenidate (Ritalin) or dextroamphetamine (Dexedrine) to treat hyperactivity and inattentiveness, respectively. A small number of cases have been reported of sudden death of children taking clonidine together with methylphenidate; however, it has not been conclusively demonstrated that these medications contributed to these deaths. The clinician should explain to the family that the efficacy and safety of this combination have not been investigated in controlled trials. Periodic cardiovascular assessments, including vital signs and electrocardiograms, are warranted if this combination is used.

Posttraumatic Stress Disorder. Acute exacerbations of PTSD may be associated with hyperadrenergic symptoms such as hyperarousal, exaggerated startle response, insomnia, vivid nightmares, tachycardia, agitation, hypertension, and perspiration. Preliminary reports suggested that these symptoms may respond to the use of clonidine or, especially for overnight benefit, to the use of guanfacine. More recent studies have failed to demonstrate that guanfacine produces an improvement in PTSD symptoms.

Other Disorders. Other potential indications for clonidine include other anxiety disorders (panic disorder, phobias, obsessive-compulsive disorder, and generalized anxiety disorder) and mania, in which it may be synergistic with lithium (Eskalith) or carbamazepine (Tegretol). Anecdotal reports have noted the efficacy of clonidine in schizophrenia and tardive dyskinesia. A clonidine patch can reduce the hypersalivation and dysphagia caused by clozapine. Low-dose use has been reported effective in hallucinogen-persisting perceptual disorders.

Precautions and Adverse Reactions

The most common adverse effects associated with clonidine are dry mouth and eyes, fatigue, sedation, dizziness, nausea, hypotension, and constipation, which result in discontinuation of therapy by about 10 percent of all persons taking the drug. Some persons also experience sexual dysfunction. Tolerance may develop to these adverse effects. A similar but milder adverse profile is seen with guanfacine, especially in doses of 3 mg or more per day. Clonidine and guanfacine should not be taken by adults with BP below 90/60 mm Hg or with cardiac arrhythmias, especially bradycardia. Development of bradycardia warrants gradual, tapered discontinuation of the drug. Clonidine in particular is associated with sedation, and tolerance does not usually develop to this adverse effect. Uncommon central nervous system (CNS) adverse effects of clonidine include insomnia, anxiety, and depression; rare CNS adverse effects include vivid dreams, nightmares, and hallucinations. Fluid retention associated with clonidine treatment can be treated with diuretics.

The transdermal patch formulation of clonidine may cause local skin irritation, which can be minimized by rotating the sites of application.

Overdose. Persons who take an overdose of clonidine may present with coma and constricted pupils, symptoms similar to those of an opioid overdose. Other symptoms of overdose are decreased BP, pulse, and respiratory rate. Guanfacine overdose produces a milder version of these symptoms. Clonidine and guanfacine should be avoided during pregnancy and by nursing mothers. Elderly persons are more sensitive to the drug than are younger adults. Children are susceptible to the same adverse effects as are adults.

Withdrawal. Abrupt discontinuation of clonidine can cause anxiety, restlessness, perspiration, tremor, abdominal pain, palpitations, headache, and a dramatic increase in BP. These symptoms may appear about 20 hours after the last dose of clonidine, and these may also be seen if one or two doses are skipped. A similar set of symptoms occasionally occurs 2 to 4 days after discontinuation of guanfacine, but the usual course is gradual return to baseline BP over 2 to 4 days. Because of the possibility of discontinuation symptoms, doses of clonidine and guanfacine should be tapered slowly.

Drug Interactions

Clonidine and guanfacine cause sedation, especially early in therapy, and when administered with other centrally active depressants, such as barbiturates, alcohol, and benzodiazepines, the potential for additive sedative effects should be considered. Dose reduction may be required in patients receiving agents that interfere with atrioventricular (AV) node and sinus node conduction such as β -blockers, calcium channel blockers, and digitalis. This combination increases the risk of AV block and bradycardia. Clonidine should not be given with tricyclic antidepressants, which can inhibit the hypotensive effects of clonidine.

Laboratory Interferences

No known laboratory interferences are associated with the use of clonidine or guanfacine.

Dosage and Clinical Guidelines

Clonidine is available in 0.1-, 0.2-, and 0.3-mg tablets. The usual starting dosage is 0.1 mg orally twice a day; the dosage can be raised by 0.1 mg a day to an appropriate level (up to 1.2 mg per day). Clonidine must always be tapered when it is discontinued to avoid rebound hypertension, which may occur about 20 hours after the last clonidine dose. A weekly transdermal formulation of clonidine is available at doses of 0.1, 0.2, and 0.3 mg per day. The usual starting dosage is the 0.1-mg-a-day patch, which is changed each week for adults and every 5 days for children; the dose can be increased, as needed, every 1 to 2 weeks. Transition from the oral to the transdermal formulations should be accomplished gradually by overlapping them for 3 to 4 days.

Guanfacine is available in 1- and 2-mg tablets. The usual starting dosage is 1 mg before sleep, and this can be increased to 2 mg before sleep after 3 to 4 weeks, if necessary. Regardless of the indication for which clonidine or guanfacine is being used, the drug should be withheld if a person becomes hypotensive (BP below 90/60 mm Hg).

An extended-release preparation of guanfacine (Intuniv) is also available. Extended-release guanfacine should be dosed once daily. Tablets should not be crushed, chewed, or broken before swallowing because this will increase the rate of guanfacine release. It should not be administered with high fat meals due to increased exposure. The extended-release formulation should not be substituted for immediate-release guanfacine tablets on a milligram-per-milligram basis because of differing pharmacokinetic profiles. If switching from immediate-release guanfacine, discontinue that treatment, and titrate with extended-release guanfacine according to the following recommended schedule:

1. Begin at a dose of 1 mg/day, and adjust in increments of no more than 1 mg/week, for both monotherapy and adjunctive therapy to a psychostimulant.
2. Maintain the dose within the range of 1 to 4 mg once daily, depending on clinical response and tolerability, for both monotherapy and adjunctive therapy to a psychostimulant. In clinical trials, patients were randomized or dose optimized to doses of 1 mg, 2 mg, 3 mg, or 4 mg and received extended-release guanfacine once daily in the morning in monotherapy trials and once daily in the morning or the

evening in the adjunctive therapy trial.

3. In monotherapy trials, clinically relevant improvements were observed beginning at doses in the range 0.05 to 0.08 mg/kg once daily. Efficacy increased with increasing weight-adjusted dose (mg/kg). If well tolerated, doses up to 0.12 mg/kg once daily may provide additional benefit. Doses above 4 mg/day have not been systematically studied in controlled clinical trials.
4. In the adjunctive trial, the majority of subjects reached optimal doses in the 0.05 to 0.12 mg/kg/day range.

In clinical trials, there were dose-related and exposure-related risks for several clinically significant adverse reactions (e.g., hypotension, bradycardia, sedative events). Thus, consideration should be given to dosing an extended-release preparation of guanfacine on a milligram-per-kilogram basis in order to balance the exposure-related potential benefits and risks of treatment.

YOHIMBINE

Yohimbine (Yocon) is an α_2 -adrenergic receptor antagonist that is used as a treatment for both idiopathic and medication-induced erectile disorder. Currently, sildenafil (Viagra) and its congeners and alprostadil (Impulse, Edex) are considered more efficacious for this indication than yohimbine. Yohimbine is derived from an alkaloid found in *Rubaceae* and related trees and in the *Rauwolfia serpentina* plant.

Pharmacologic Actions

Yohimbine is erratically absorbed after oral administration, with bioavailability ranging from 7 to 87 percent. There is extensive hepatic first-pass metabolism. Yohimbine affects the sympathomimetic autonomic nervous system by increasing plasma concentrations of norepinephrine. The half-life of yohimbine is 0.5 to 2 hours. Clinically, yohimbine produces increased parasympathetic (cholinergic) tone.

Therapeutic Indications

Yohimbine has been used to treat erectile dysfunction. Penile erection has been linked to cholinergic activity and to α_2 -adrenergic blockade, which theoretically results in increased penile inflow of blood, decreased penile outflow of blood, or both. Yohimbine is reported to help counteract the loss of sexual desire and the orgasmic inhibition caused by some serotonergic antidepressants (e.g., selective serotonin reuptake inhibitors). It has not been found useful in women for these indications.

Precautions

The side effects of yohimbine include anxiety, elevated BP and heart rate, increased psychomotor activity, irritability, tremor, headache, skin flushing, dizziness, urinary frequency, nausea, vomiting, and sweating. Patients with panic disorder show heightened sensitivity to yohimbine and experience increased anxiety, increased BP, and increased plasma 3-methoxy-4-hydroxyphenylglycol (MHPG).

Yohimbine should be used with caution in female patients and should not be used in patients with renal disease, cardiac disease, glaucoma, or a history of gastric or duodenal ulcer.

Drug Interactions

Yohimbine blocks the effects of clonidine, guanfacine, and other α_2 -receptor agonists.

Laboratory Interferences

No known laboratory interferences are associated with yohimbine use.

Dosage and Clinical Guidelines

Yohimbine is available in 5.4-mg tablets. The dosage of yohimbine in the treatment of erectile disorder is approximately 16 mg a day given in doses that range from 2.7 to 5.4 mg three times a day. In the event of significant adverse effects, dose should first be reduced and then gradually increased again. Yohimbine should be used judiciously in psychiatric patients because it may have an adverse effect on their mental status. Because yohimbine has no consistent effect on erectile dysfunction, its use remains controversial. Phosphodiesterase-5 (PDE-5) inhibitors are the preferred medication for this disorder.

PRAZOSIN

Prazosin (Minipress) is a quinazoline derivative and one of a new chemical class of antihypertensives. It is an α_1 -adrenergic receptor antagonist as opposed to the drugs mentioned above, which are α_2 -blockers.

Pharmacologic Actions

The exact mechanism of the hypotensive action of prazosin is unknown, particularly as it effects nightmare suppression. Prazosin causes a decrease in total peripheral resistance that is related to its action as an α_1 -adrenergic receptor antagonist. BP is lowered in both the supine and standing positions. This effect is most pronounced on the diastolic BP. After oral administration, human plasma concentrations reach a peak at about 3 hours with a plasma half-life of 2 to 3 hours. The drug is highly bound to plasma protein. Tolerance has not been observed to develop with long-term therapy.

Therapeutic Action

Prazosin is used in psychiatry to suppress nightmares, particularly those associated with PTSD.

Precautions and Adverse Reactions

During clinical trials and subsequent marketing experience, the most frequent reactions were dizziness (10.3 percent); headache (7.8 percent); drowsiness (7.6 percent); lack of energy (6.9 percent); weakness (6.5 percent); palpitations (5.3 percent); and nausea (4.9 percent). In most instances, side effects disappeared with continued therapy or have been tolerated with no decrease in dose of drug. Prazosin should not be used in nursing mothers or during pregnancy.

Drug Interactions

No adverse drug interactions have been reported.

Laboratory Interferences

No laboratory interferences have been reported.

Dosage and Clinical Guidelines

The drug is supplied in 1-, 2-, and 5-mg capsules and a nasal spray. The therapeutic dosages most commonly used have ranged from 6 to 15 mg daily given in divided doses. Doses higher than 20 mg do not increase efficacy. When adding a diuretic or other antihypertensive agent, the dose should be reduced to 1 or 2 mg three times a day and retitration then carried out. Concomitant use with a PDE-5 inhibitor can result in additive BP lowering effects and symptomatic hypotension; therefore, PDE-5 inhibitor therapy should be initiated at the lowest dose in patients taking prazosin.

Table 29.3-2 provides a summary of α_2 -adrenergic receptor agonists used in psychiatry.

Table 29.3-2
 α_2 -Adrenergic Receptor Agonists Used in Psychiatry^a

Drug	Preparations	Usual Child Starting Dosage	Usual Child Dosage Range	Usual Adult Starting Dosage	Usual Adult Dosage
Clonidine tablets (Catapres)	0.1, 0.2, 0.3 mg	0.05 mg/day	Up to 0.3 mg/day tablets in divided doses	0.1–0.2 mg, two to four times a day (0.2–0.8 mg/day)	0.3–1.2 mg/day, two to three times a day (1.2 mg/day maximal dosage)
Clonidine transdermal system (Catapres-TTS)	0.1, 0.2, 0.3 mg/day	0.05 mg/day	Up to 0.3 mg/day patch every 5 days (0.5 mg/day every 5 days maximal dosage)	0.1 mg/day every 7 days	0.1 mg/day patch per week 0.6 mg/day every 7 days
Guanfacine (Tenex)	1- and 2-mg tablets	1 mg/day at bedtime	1–2 mg/day at bedtime (3 mg/day maximal dosage)	1 mg/day at bedtime	1–2 mg at bedtime (3 mg/day maximal dosage)

^aDosages for medical indications, such as hypertension, vary.

29.4 β -Adrenergic Receptor Antagonists

Because of the innervations of many, if not most, peripheral organs and vasculature by the sympathetic division of the autonomic nervous system, their functions are ultimately controlled, in part, by one of the two major classes of adrenergic receptors: α -receptors (discussed in Section 29.3) and β -receptors. These receptors are further subdivided based on their action and location, and they are located both peripherally and in the central nervous system (CNS). Shortly after being introduced for cardiac indications, propranolol (Inderal) was reported to be useful for agitation, and its use in psychiatry spread rapidly. The five most commonly used β -receptor antagonists in psychiatry are propranolol, nadolol (Corgard), metoprolol (Lopressor, Toprol), pindolol (Visken), and atenolol (Tenormin) (Table 29.4-1).

Table 29.4-1
 β -Adrenergic Drugs Used in Psychiatry

Drug	Pregnancy Category	Trade Name	Protein Binding (%)	Lipophilic	ISA	Metabolism	Receptor Selectivity	Half-Life (hrs)	Usual Starting Dosage (mg)	Usual Maximal Dosage (mg)
Atenolol (Tenormin)	D	Tenormin	6–16	No		Renal	$\beta_1 > \beta_2$	6–9	50 OD	50–100 OD
Metoprolol (Lopressor)	C	Lopressor	5–10	Yes		Hepatic	$\beta_1 > \beta_2$	3–4	50 bid	75–150 bid
Nadolol (Corgard)	C	Corgard	30	No		Renal	$\beta_1 = \beta_2$	14–24	40 OD	80–240 OD
Propranolol (Inderal)	C	Inderal	>90	Yes		Hepatic	$\beta_1 = \beta_2$	3–6	10–20 bid/tid	80–140 tid
Pindolol (Visken)	B	Visken	40	Yes	Minimal	Hepatic	$\beta_1 > \beta_2$	3–4	5 tid/qid	60 bid/tid

ISA, intrinsic sympathomimetic activity; OD, once daily; bid, twice a day; tid, three times a day; qid, four times a day.

PHARMACOLOGIC ACTIONS

The β -receptor antagonists differ with regard to lipophilicities, metabolic routes, β -receptor selectivity, and half-lives. The absorption of the β -receptor antagonists from the gastrointestinal tract is variable. The agents that are most soluble in lipids (i.e., are lipophilic) are likely to cross the blood–brain barrier and enter the brain; those agents that are least lipophilic are less likely to enter the brain. When CNS effects are desired, a lipophilic drug may be preferred; when only peripheral effects are desired, a less lipophilic drug may be indicated.

Whereas propranolol, nadolol, pindolol, and labetalol (Normodyne, Trandate) have essentially equal potency at both the β_1 - and β_2 -receptors, metoprolol and atenolol have greater affinity for the β_1 -receptor than for the β_2 -receptor. Relative β_1 -selectivity confers few pulmonary and vascular effects of these drugs, although they must be used with caution in persons with asthma because the drugs retain

some activity at the β_2 -receptors.

Pindolol has sympathomimetic effects in addition to its β -antagonist effects, which has allowed its use for augmentation of antidepressant drugs. Pindolol, propranolol, and nadolol possess some antagonist activity at the serotonin 5-HT_{1A} receptors.

THERAPEUTIC INDICATIONS

Anxiety Disorders

Propranolol is useful for the treatment of social phobia, primarily of the performance type (e.g., disabling anxiety before a musical performance). Data are also available for its use in treatment of panic disorder, posttraumatic stress disorder, and generalized anxiety disorder. In social phobia, the common treatment approach is to take 10 to 40 mg of propranolol 20 to 30 minutes before the anxiety-provoking situation. The β -receptor antagonists are less effective for the treatment of panic disorder than are benzodiazepines or selective serotonin reuptake inhibitors (SSRIs).

Lithium-Induced Postural Tremor

The β -receptor antagonists are beneficial for lithium-induced postural tremor and other medication-induced postural tremors—for example, those induced by tricyclic antidepressants (TCAs) and valproate (Depakene). The initial approach to this movement disorder includes lowering the dose of lithium (Eskalith), eliminating aggravating factors, such as caffeine, and administering lithium at bedtime. If these interventions are inadequate, however, propranolol in the range of 20 to 160 mg a day given two or three times daily is generally effective for the treatment of lithium-induced postural tremor.

Neuroleptic-Induced Acute Akathisia

Many studies have shown that β -receptor antagonists can be effective in the treatment of neuroleptic-induced acute akathisia. They are generally more effective for this indication than are anticholinergics and benzodiazepines. The β -receptor antagonists are not effective in the treatment of such neuroleptic-induced movement disorders as acute dystonia and parkinsonism.

Aggression and Violent Behavior

The β -receptor antagonists may be effective in reducing the number of aggressive and violent outbursts in persons with impulse disorders, schizophrenia, and aggression associated with brain injuries such as trauma, tumors, anoxic injury, encephalitis, alcohol dependence, and degenerative disorders (e.g., Huntington's disease).

Alcohol Withdrawal

Propranolol is reported to be useful as an adjuvant to benzodiazepines but not as a sole agent in the treatment of alcohol withdrawal. The following dose schedule is suggested: no propranolol for a pulse rate below 50 beats per minute; 50 mg propranolol for a pulse rate between 50 and 79 beats per minute; and 100 mg propranolol for a pulse rate of 80 beats per minute or above.

Antidepressant Augmentation

Pindolol has been used to augment and hasten the antidepressant effects of SSRIs, tricyclic drugs, and electroconvulsive therapy. Small studies have shown that pindolol administered at the onset of antidepressant therapy may shorten the usual 2- to 4-week latency of antidepressant response by several days. Because the β -receptor antagonists may possibly induce depression in some persons, augmentation strategies with these drugs need to be further clarified in controlled trials.

Other Disorders

A number of case reports and controlled studies have reported data indicating that β -receptor antagonists may be of modest benefit for persons with schizophrenia and manic symptoms. They have also been used in some cases of stuttering (Table 29.4-2).

 **Table 29.4-2**
Psychiatric Uses for β -Adrenergic Receptor Antagonists

Definitely effective
Performance anxiety
Lithium-induced tremor
Neuroleptic-induced akathisia
Probably effective
Adjunctive therapy for alcohol withdrawal and other substance-related disorders
Adjunctive therapy for aggressive or violent behavior
Possibly effective
Antipsychotic augmentation
Antidepressant augmentation

PRECAUTIONS AND ADVERSE REACTIONS

The β -receptor antagonists are contraindicated for use in people with asthma, insulin-dependent diabetes, congestive heart failure, significant vascular disease, persistent angina, and hyperthyroidism. The contraindication in diabetic persons is because of the drugs' antagonizing the normal physiologic response to hypoglycemia. The β -receptor antagonists can worsen atrioventricular (AV) conduction defects and lead to complete AV heart block and death. If the clinician decides that the risk-to-benefit ratio warrants a trial of a β -receptor antagonist in a person with one of these coexisting medical conditions, a β_1 -selective agent should be the first choice, and the patient should be monitored. All currently available β -receptor antagonists are excreted in breast milk and should be administered with caution to nursing women.

The most common adverse effects of β -receptor antagonists are hypotension and bradycardia. In persons at risk for these adverse effects, a test dosage of 20 mg a day of propranolol can be given to assess the reaction to the drug. Depression has been associated with lipophilic β -receptor antagonists, such as propranolol, but it is probably rare. Nausea, vomiting, diarrhea, and constipation can also be caused by treatment with these agents. The β -receptor antagonists may blunt cognition in some people. Serious CNS adverse effects (e.g., agitation, confusion, and hallucinations) are rare. Table 29.4-3 lists the possible adverse effects of β -receptor antagonists.

 **Table 29.4-3**

Adverse Effects and Toxicity of β -Adrenergic Receptor Antagonists

Cardiovascular
Hypotension
Bradycardia
Congestive heart failure (in patients with compromised myocardial function)

Respiratory
Asthma (less risk with β_1 -selective drugs)

Metabolic
Worsened hypoglycemia in diabetic patients on insulin or oral agents

Gastrointestinal
Nausea
Diarrhea
Abdominal pain

Sexual function
Impotence

Neuropsychiatric
Lassitude
Fatigue
Dysphoria
Insomnia
Vivid nightmares
Depression (rare)
Psychosis (rare)

Other (rare)
Raynaud's phenomenon
Peyronie's disease

Withdrawal syndrome
Rebound worsening of preexisting angina pectoris when β -adrenergic receptor antagonists are discontinued

DRUG INTERACTIONS

Concomitant administration of propranolol results in increases in plasma concentrations of antipsychotics, anticonvulsants, theophylline (Theo-Dur, Slo-bid), and levothyroxine (Synthroid). Other β -receptor antagonists may have similar effects. The β -receptor antagonists that are eliminated by the kidneys may have similar effects on drugs that are also eliminated by the renal route. Barbiturates, phenytoin (Dilantin), and cigarette smoking increase the elimination of β -receptor antagonists that are metabolized by the liver. Several reports have associated hypertensive crises and bradycardia with the coadministration of β -receptor antagonists and monoamine oxidase inhibitors. Depressed myocardial contractility and AV nodal conduction can occur from concomitant administration of a β -receptor antagonist and calcium channel inhibitors.

LABORATORY INTERFERENCES

The β -receptor antagonists do not interfere with standard laboratory tests.

DOSAGE AND CLINICAL GUIDELINES

Propranolol is available in 10-, 20-, 40-, 60-, 80-, and 90-mg tablets; 4-, 8-, and 80-mg/mL solutions; and 60-, 80-, 120-, and 160-mg sustained-release capsules. Nadolol is available in 20-, 40-, 80-, 120-, and 160-mg tablets. Pindolol is available in 5- and 10-mg tablets. Metoprolol is available in 50- and 100-mg tablets and 50-, 100-, and 200-mg sustained-release tablets. Atenolol is available in 25-, 50-, and 100-mg tablets. Acebutolol is available in 200- and 400-mg capsules.

For the treatment of chronic disorders, propranolol administration is usually initiated at 10 mg by mouth three times a day or 20 mg by mouth twice daily. The dosage can be raised by 20 to 30 mg a day until a therapeutic effect emerges. The dosage should be leveled off at the appropriate range for the disorder under treatment. The treatment of aggressive behavior sometimes requires dosages up to 80 mg a day, and therapeutic effects may not be seen until the person has been receiving the maximal dosage for 4 to 8 weeks. For the treatment of social phobia, primarily the performance type, the patient should take 10 to 40 mg of propranolol 20 to 30 minutes before the performance.

Pulse and blood pressure (BP) readings should be taken regularly, and the drug should be withheld if the pulse rate is below 50 beats per minute or the systolic BP is below 90 mm Hg. The drug should be temporarily discontinued if it produces severe dizziness, ataxia, or wheezing. Treatment with β -receptor antagonists should never be discontinued abruptly. Propranolol should be tapered by 60 mg a day until a dosage of 60 mg a day is reached, after which the drug should be tapered by 10 to 20 mg a day every 3 or 4 days.

The clinical guidelines for the other drugs listed in this chapter are similar to propranolol, taking into consideration the different doses used. For example, if propranolol is prescribed initially at the lowest available dose (e.g., 10 mg) then metoprolol should be prescribed at its lowest available dose (e.g., 50 mg).

29.5 Anticholinergic Agents

Anticholinergic drugs block the actions of atropine. In the clinical practice of psychiatry, the anticholinergic drugs are primarily used to treat medication-induced movement disorders, particularly neuroleptic-induced Parkinsonism, neuroleptic-induced acute dystonia, and medication-induced postural tremor.

ANTICHOLINERGICS

Pharmacologic Actions

All anticholinergic drugs are well absorbed from the gastrointestinal (GI) tract after oral administration, and all are sufficiently lipophilic to enter the central nervous system (CNS). Trihexyphenidyl (Artane) and benzotropine (Cogentin) reach peak plasma concentrations in 2 to 3 hours after oral administration, and their duration of action is 1 to 12 hours. Benzotropine is absorbed equally rapidly by intramuscular (IM) and intravenous (IV) administration; IM administration is preferred because of its low risk for adverse effects.

All six anticholinergic drugs listed in this section (Table 29.5-1) block muscarinic acetylcholine receptors, and benzotropine has some antihistaminergic effects. None of the available anticholinergic drugs has any effect on the nicotinic acetylcholine receptors. Of these drugs, trihexyphenidyl is the most stimulating agent, perhaps acting through dopaminergic neurons, and benzotropine is the least stimulating and thus is least associated with abuse potential.

Table 29.5-1
Anticholinergic Drugs

Generic Name	Brand Name	Tablet Size	Injectable	Usual Daily Oral Dosage	Short-term Intramuscular or Intravenous Dosage
Benzotropine	Cogentin	0.5, 1, 2 mg	1 mg/mL	1–4 mg one to three times	1–2 mg
Biperiden	Akineton	2 mg	5 mg/mL	2 mg one to three times	2 mg
Ethopropazine	Parsidol	10, 50 mg	—	50–100 mg one to three times	—
Orphenadrine	Norflex, Disipal	100 mg	30 mg/mL	50–100 mg three times	60 mg IV given over 5 min
Procyclidine	Kemadrin	5 mg	—	2.5–5 mg three times	—
Trihexyphenidyl	Artane, Trihexane, Trihexy-5	2, 5 mg elixir 2 mg/5 mL	—	2–5 mg two to four times	—

IV, intravenous.

Therapeutic Indications

The primary indication for the use of anticholinergics in psychiatric practice is for the treatment of *neuroleptic-induced Parkinsonism*, characterized by tremor, rigidity, cogwheeling, bradykinesia, sialorrhea, stooped posture, and festination. All of the available anticholinergics are equally effective in the treatment of Parkinsonian symptoms. Neuroleptic-induced Parkinsonism is most common in elderly persons and is most frequently seen with high-potency dopamine receptor antagonists (DRAs), for example, haloperidol (Haldol). The onset of symptoms usually occurs after 2 or 3 weeks of treatment. The incidence of neuroleptic-induced Parkinsonism is lower with the newer antipsychotic drugs of the serotonin–dopamine antagonist (SDA) class.

Another indication for the use of anticholinergics is for the treatment of *neuroleptic-induced acute dystonia*, which is most common in young men. The syndrome often occurs early in the course of treatment; is commonly associated with high-potency DRAs (e.g., haloperidol); and most commonly affects the muscles of the neck, tongue, face, and back. Anticholinergic drugs are effective both in the short-term treatment of dystonias and in prophylaxis against neuroleptic-induced acute dystonias.

Akathisia is characterized by a subjective and objective sense of restlessness, anxiety, and agitation. Although a trial of anticholinergics for the treatment of neuroleptic-induced acute akathisia is reasonable, these drugs are not generally considered as effective as the β -adrenergic receptor antagonists, the benzodiazepines, and clonidine (Catapres).

Precautions and Adverse Reactions

The adverse effects of the anticholinergic drugs result from blockade of muscarinic acetylcholine receptors. Anticholinergic drugs should be used cautiously, if at all, by persons with prostatic hypertrophy, urinary retention, and narrow-angle glaucoma. The anticholinergics are occasionally used as drugs of abuse because of their mild mood-elevating properties, most notably, trihexyphenidyl.

The most serious adverse effect associated with anticholinergic toxicity is anticholinergic intoxication, which can be characterized by delirium, coma, seizures, agitation, hallucinations, severe hypotension, supraventricular tachycardia, and peripheral manifestations (flushing, mydriasis, dry skin, hyperthermia, and decreased bowel sounds). Treatment should begin with the immediate discontinuation of all anticholinergic drugs. The syndrome of anticholinergic intoxication can be diagnosed and treated with physostigmine (Antilirium, Eserine), an inhibitor of anticholinesterase, 1 to 2 mg IV (1 mg every 2 minutes) or IM every 30 or 60 minutes. Because physostigmine can lead to severe hypotension and bronchial constriction, it should be used only in severe cases and only when emergency cardiac monitoring and life-support services are available.

Drug Interactions

The most common drug–drug interactions with the anticholinergics occur when they are coadministered with psychotropics that also have high anticholinergic activity, such as DRAs, tricyclic and tetracyclic drugs, and monoamine oxidase inhibitors (MAOIs). Many other prescription drugs and over-the-counter cold preparations also induce significant anticholinergic activity. The coadministration of those drugs can result in a life-threatening anticholinergic intoxication syndrome. In addition, anticholinergic drugs can delay gastric emptying, thereby decreasing the absorption of drugs that are broken down in the stomach and usually absorbed in the duodenum (e.g., levodopa [Larodopa] and DRAs).

Laboratory Interferences

No known laboratory interferences have been associated with anticholinergics.

Dosage and Clinical Guidelines

The six anticholinergic drugs discussed in this chapter are available in a range of preparations (see Table 29.5-1).

Neuroleptic-induced Parkinsonism. For the treatment of neuroleptic-induced parkinsonism, the equivalent of 1 to 3 mg of benzotropine should be given one to two times daily. The anticholinergic drug should be administered for 4 to 8 weeks, and then it should be discontinued to assess whether the person still requires the drug. Anticholinergic drugs should be tapered over a period of 1 to 2 weeks.

Treatment with anticholinergics as prophylaxis against the development of neuroleptic-induced parkinsonism is usually not indicated, because the onset of its symptoms is usually sufficiently mild and gradual to allow the clinician to initiate treatment only after it is clearly indicated. In young men, prophylaxis may be indicated, however, especially if a high-potency DRA is being used. The clinician should

attempt to discontinue the antiparkinsonian agent in 4 to 6 weeks to assess whether its continued use is necessary.

Neuroleptic-induced Acute Dystonia. For the short-term treatment and prophylaxis of neuroleptic-induced acute dystonia, 1 to 2 mg of benztropine or its equivalent in another drug should be given IM. The dose can be repeated in 20 to 30 minutes, as needed. If the person still does not improve in another 20 to 30 minutes, a benzodiazepine (e.g., 1 mg IM or IV lorazepam [Ativan]) should be given. Laryngeal dystonia is a medical emergency and should be treated with benztropine, up to 4 mg in a 10-minute period, followed by 1 to 2 mg of lorazepam, administered slowly by the IV route.

Prophylaxis against dystonias is indicated in persons who have had one episode or in persons at high risk (young men taking high-potency DRAs). Prophylactic treatment is given for 4 to 8 weeks and then gradually tapered over 1 to 2 weeks to allow assessment of its continued need. The prophylactic use of anticholinergics in persons requiring antipsychotic drugs has largely become a moot issue because of the availability of SDAs, which are relatively free of parkinsonian effects.

Akathisia. As mentioned, anticholinergics are not the drugs of choice for this syndrome. The β -adrenergic receptor antagonists and perhaps the benzodiazepines and clonidine are preferable drugs to try initially.

29.6 Anticonvulsants

The newer anticonvulsants described in this section were developed for the treatment of epilepsy, but were also found to have beneficial effects in psychiatric disorders. In addition, these agents are used as skeletal muscle relaxants and in neurogenic pain. These drugs have a variety of mechanisms including increasing γ -aminobutyric acid (GABA)ergic function or decreasing glutamatergic function. This chapter includes six of the newer anticonvulsants: gabapentin (Neurontin), levetiracetam (Keppra), pregabalin (Lyrica), tiagabine (Gabitril), topiramate (Topamax), and zonisamide (Zonegran), as well as one of the first used anticonvulsants, phenytoin (Dilantin). Carbamazepine (Tegretol), valproate (Depakene, Depakote), lamotrigine (Lamictal), and oxcarbazepine (Trileptal) are discussed in separate sections.

In 2008, the U.S. Food and Drug Administration (FDA) issued a warning that these drugs may increase the risk of suicidal ideation or act in some persons compared with placebo; however, the relative risk for suicidality was higher in patients with epilepsy compared with those with psychiatric disorders. However, some published data contradict the warning by the FDA regarding the use of anticonvulsants and the risk of suicidal thoughts. These studies suggest that anticonvulsants may have a protective effect on suicidal thoughts in bipolar disorder. Considering the inherent increased risk of suicide in persons with bipolar disorder, clinicians should be aware of these warnings.

GABAPENTIN

Gabapentin was first introduced as an antiepileptic drug and was found to have sedative effects that were useful in some psychiatric disorders, especially insomnia. It was also found to be beneficial in reducing neuropathic pain, including postherpetic neuralgia. It is used in anxiety disorders (social phobia and panic disorder), but not as a main intervention in mania or treatment-resistant mood disorders.

Pharmacologic Actions

Gabapentin circulates in the blood largely unbound and is not appreciably metabolized in humans. It is eliminated unchanged by renal excretion and can be removed by hemodialysis. Food only moderately affects the rate and extent of absorption. Clearance is decreased in elderly persons, requiring dosage adjustments. Gabapentin appears to increase cerebral GABA and may inhibit glutamate synthesis as well. It increases human whole blood serotonin concentrations and modulates calcium channels to reduce monoamine release. It has antiseizure as well as antispastic activity and antinociceptive effects in pain.

Therapeutic Indications

In neurology, gabapentin is used for the treatment of both general and partial seizures. It is effective in reducing the pain of postherpetic neuralgia and other pain syndromes associated with diabetic neuropathy, neuropathic cancer pain, fibromyalgia, meralgia paresthetica, amputation, and headache. It has been found to be effective in some cases of chronic pruritus.

In psychiatry, gabapentin is used as a hypnotic agent because of its sedating effects. It has anxiolytic properties and benefits patients with social anxiety and panic disorder. It may decrease the craving for alcohol in some patients and improve mood as well; hence, it may have some use in depressed patients. Some bipolar patients have benefited when gabapentin is used adjunctively with mood stabilizers.

Precautions and Adverse Reactions

Adverse effects are mild, with the most common being daytime somnolence, ataxia, and fatigue, which are usually dose related. Overdose (over 45 g) has been associated with diplopia, slurred speech, lethargy, and diarrhea, but all patients recovered. The drug is classified as pregnancy category C and is excreted in breast milk, so it is best to avoid it in pregnant women and nursing mothers.

Drug Interactions

Gabapentin bioavailability may decrease as much as 20% when administered with antacids. In general, there are no drug interactions. Chronic use does not interfere with lithium administration.

Laboratory Interferences

Gabapentin does not interfere with any laboratory tests, although spontaneous reports of false-positive or positive drug toxicology screenings for amphetamines, barbiturates, benzodiazepines, and marijuana have been reported.

Dosages and Clinical Guidelines

Gabapentin is well tolerated, and the dosage can be increased to the maintenance range within a few days. A general approach is to start with 300 mg on day 1, increase to 600 mg on day 2, 900 mg on day 3, and subsequently increase up to 1,800 mg per day in divided doses as needed to relieve symptoms. Final total daily doses tend to be between 1,200 and 2,400 mg per day but occasionally results may be achieved with dosages as low as 200 to 300 mg per day, especially in elderly persons. Sedation is usually the limiting factor in determining the dosage. Some patients have taken dosages as high as 4,800 mg per day.

Gabapentin is available as 100, 300, and 400 mg capsules and as 600 and 800 mg tablets. A 250 mg/5 mL oral solution is also available. Although abrupt discontinuation of gabapentin does not cause withdrawal effects, use of all anticonvulsant drugs should be gradually tapered.

TOPIRAMATE

Topiramate (Topamax) was developed as an anticonvulsant and was found useful in a variety of psychiatric and neurologic conditions, including migraine prevention, treatment of obesity, bulimia, binge eating, and alcohol dependence.

Pharmacologic Actions

Topiramate has GABAergic effects and increases cerebral GABA in humans. It has 80% oral bioavailability and is not significantly altered by food. It is 15% protein bound, and about 70% of the drug is eliminated by renal excretion. With renal insufficiency topiramate clearance decreases about 50%, so the dosage needs to be decreased. It has a half-life of around 24 hours.

Therapeutic Indications

Topiramate is used mainly as an antiepileptic medication and has been found superior to placebo as monotherapy in patients with seizure disorders. It is also used in the prevention of migraine, smoking cessation, pain syndromes (e.g., low back pain), posttraumatic stress disorder (PTSD), and essential tremor. The drug has been associated with weight loss, and that fact has been used to counteract the weight gain caused by many psychotropic drugs. It has also been used in general obesity and in the treatment of bulimia and binge-eating disorder. Self-mutilating behavior may be decreased in borderline personality disorder. It is of little or no benefit in the treatment of psychotic disorders. In one study, the combination of topiramate with bupropion (Wellbutrin) showed some efficacy in bipolar depression, but double-blind, placebo-controlled trials failed to demonstrate topiramate monotherapy efficacy in acute mania in adults.

Precautions and Adverse Reactions

The most common adverse effects of topiramate include paresthesias, weight loss, somnolence, anorexia, dizziness, and memory problems. Sometimes disturbances in the sense of taste occur. In many cases, the adverse effects are mild to moderate and can be attenuated by decreasing the dose. No deaths have been reported during overdose. The drug affects acid-base balance (low serum bicarbonate), which can be associated with cardiac arrhythmias, and the formation of renal calculi in about 1.5% of cases. Patients taking the drug should be encouraged to drink plenty of fluids. It is not known if the drug passes through the placenta or is present in breast milk, and it should be avoided by pregnant women or nursing mothers.

Drug Interactions

Topiramate has few drug interactions with other anticonvulsant drugs. Topiramate may increase phenytoin concentrations up to 25% and valproic acid 11%; it does not affect the concentration of carbamazepine, phenobarbital (Luminal), or primidone. Topiramate concentrations are decreased by 40% to 48%, with concomitant administration of carbamazepine or phenytoin. Topiramate should not be combined with other carbonic anhydrase inhibitors, such as acetazolamide (Diamox) or dichlorphenamide (Daranide), because this could increase the risk of nephrolithiasis or heat-related problems (oligohidrosis and hyperthermia).

Laboratory Interferences

Topiramate does not interfere with any laboratory tests.

Dosages and Clinical Guidelines

Topiramate is available as unscored 25, 100, and 200 mg tablets. To reduce the risk of adverse cognitive and sedative effects, topiramate dosage is titrated gradually over 8 weeks to a maximum of 200 mg twice a day. Off-label topiramate is typically used adjunctively, starting with 25 mg at bedtime and increasing weekly by 25 mg as necessary and tolerated. Final doses in efforts to promote weight loss are often between 75 and 150 mg per day at bedtime. Doses higher than 400 mg are not associated with increased efficacy. All of the dose can be given at bedtime to take advantage of the sedative effects. Persons with renal insufficiency should reduce doses by half.

TIAGABINE

Tiagabine was introduced as a treatment for epilepsy in 1997 and was found to have efficacy in some psychiatric conditions, including acute mania. However, safety concerns (see later) along with a lack of controlled data have limited the use of tiagabine in disorders other than epilepsy.

Pharmacologic Actions

Tiagabine is well absorbed with a bioavailability of about 90% and is extensively (96%) bound to plasma proteins. Tiagabine is a cytochrome P450 (CYP)3A substrate and is extensively transformed into inactive 5-oxo-tiagabine and glucuronide metabolites, with only 2% being excreted unchanged in the urine. The remainder is excreted as metabolites in the feces (65%) and the urine (25%). Tiagabine blocks uptake of the inhibitory amino acid neurotransmitter GABA into neurons and glia, enhancing the inhibitory action of GABA at both GABA_A and GABA_B receptors, putatively yielding anticonvulsant and antinociceptive effects, respectively. It has mild blocking effects on histamine 1 (H₁), serotonin type 1B (5-HT_{1B}), benzodiazepine, and chloride channel receptors.

Therapeutic Indications

Tiagabine is rarely used for psychiatric disorders, and then it is used only for generalized anxiety disorder and insomnia. Its main indication is in generalized epilepsy.

Precautions and Adverse Reactions

Tiagabine may cause withdrawal seizures, cognitive or neuropsychiatric problems (impaired concentration, speech or language problems,

somnolence, and fatigue), status epilepticus, and sudden unexpected death in epilepsy (SUDEP). Acute oral overdoses of tiagabine have been associated with seizures, status epilepticus, coma, ataxia, confusion, somnolence, drowsiness, impaired speech, agitation, lethargy, myoclonus, stupor, tremors, disorientation, vomiting, hostility, temporary paralysis, and respiratory depression. Deaths have been reported in polydrug overdoses involving tiagabine. Cases of serious rash may occur, including Stevens-Johnson syndrome.

Tiagabine is classified as pregnancy category C because fetal loss and teratogenicity have been demonstrated in animals. It is not known if the drug is excreted in breast milk. Pregnant women and nursing mothers should not be given the drug.

Laboratory Tests

Tiagabine does not interfere with any laboratory tests.

Dosage and Administration

Tiagabine should not be rapidly loaded or rapidly initiated because of the risk of serious adverse effects. In adults and adolescents 12 years of age or older with epilepsy who are also taking enzyme inducers, tiagabine should be initiated at 4 mg per day and increased weekly by 4 mg per day during the first month. The dose should then be increased weekly by 4 to 8 mg per day for weeks 5 and 6, yielding 24 to 32 mg per day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 4 to 8 mg per day to as high as 56 mg per day. Plasma concentrations in patients with epilepsy commonly range between 20 and 100 ng/mL, but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored.

LEVETIRACETAM

Initially developed as a nootropic (memory enhancing) drug, levetiracetam proved to be a potent anticonvulsant and marketed as a treatment for partial seizures. It has been used to treat acute mania and anxiety and to augment antidepressant drug therapy.

Pharmacologic Actions

The central nervous system (CNS) effects are not well understood, but it appears to indirectly enhance GABA inhibition. It is rapidly and completely absorbed, and peak concentrations are reached in 1 hour. Food delays the rate of absorption and decreases the amount of absorption. Levetiracetam is not significantly plasma protein bound and is not metabolized through the hepatic CYP system. Its metabolism involves hydrolysis of the acetamide group. Serum concentrations are not correlated with therapeutic effects.

Therapeutic Indications

The major indication is for the treatment of convulsive disorders, including partial onset seizures, myoclonic seizures, and idiopathic generalized epilepsy. In psychiatry, levetiracetam has been used off label to treat acute mania, as an add-on treatment for major depression, and as an anxiolytic agent.

Precautions and Adverse Reactions

The most common side effects of levetiracetam include drowsiness, dizziness, ataxia, diplopia, memory impairment, apathy, and paresthesias. Some patients develop behavioral disturbances during treatment, and hallucinations may occur. Suicidal patients may become agitated. It should not be used in pregnant or lactating women.

Drug Interactions

There are few if any interactions with other drugs, including other anticonvulsants. There is no interaction with lithium.

Laboratory Interferences

No laboratory interferences have been reported.

Dosages and Clinical Guidelines

The drug is available as 250, 500, 750, and 1,000 mg tablets; 500 mg extended-release tablets; a 100 mg/mL oral solution; and a 100 mg/mL intravenous solution. In epilepsy, the typical adult daily dose is 1,000 mg.

In view of its renal clearance, dosages should be reduced in patients with impaired renal function.

ZONISAMIDE

Used originally as an anticonvulsant for the treatment of seizure disorders, zonisamide was also found to be useful in bipolar disorder, obesity, and binge-eating disorder.

Pharmacologic Actions

Zonisamide blocks sodium channels and may weakly potentiate dopamine and serotonin activity. It also inhibits carbonic anhydrase. Some evidence suggests that it may block calcium channels. Zonisamide is metabolized by the hepatic CYP3A system, so enzyme-inducing agents such as carbamazepine, alcohol, and phenobarbital increase the clearance and reduce the availability of the drug. Zonisamide does not affect the metabolism of other drugs. It has a long half-life of 60 hours, so it is easily dosed once daily, preferably at nighttime.

Therapeutic Indications

Its main use is in the treatment of generalized seizure disorders and in refractory partial seizures. In psychiatry, controlled studies found it to be of use in obesity and binge-eating disorder. Uncontrolled trials have found it useful in bipolar disorder, particularly mania; however, further studies are warranted for this indication.

Precautions and Adverse Reactions

Zonisamide is a sulfonamide and thus may cause fatal rash and blood dyscrasias, although these events are rare. About 4% of patients develop kidney stones. The most common side effects are drowsiness, cognitive impairment, insomnia, ataxia, nystagmus, paresthesia, speech abnormalities, constipation, diarrhea, nausea, and dry mouth. Weight loss is also a common side effect, which has been exploited as a therapy for patients who have gained weight during treatment with psychotropics or, as mentioned above, have ongoing difficulty controlling their eating. Zonisamide should not be used in pregnant women or breast-feeding mothers.

Drug Interactions

Zonisamide does not inhibit CYP isoenzymes and does not instigate drug interactions. It is important not to combine carbonic anhydrase inhibitors with zonisamide because of an increased risk of nephrolithiasis related to increased blood levels of urea.

Laboratory Interferences

Zonisamide can elevate hepatic alkaline phosphatase and increase blood urea nitrogen and creatinine.

Dosages and Clinical Guidelines

Zonisamide is available in 100 and 200 mg capsules. In epilepsy, the dosage range is 100 to 400 mg per day, with side effects becoming more pronounced at doses above 300 mg. Because of its long half-life, zonisamide can be given once a day.

PREGABALIN

Pregabalin is pharmacologically similar to gabapentin. It is believed to work by inhibiting the release of excess excitatory neurotransmitters. It increases neuronal GABA levels, its binding affinity is six times greater than that of gabapentin, and it has a longer half-life.

Pharmacologic Actions

Pregabalin exhibits linear pharmacokinetics. It is rapidly absorbed in proportion to its dose. The time to maximal plasma concentration is about 1 hour and that to steady state is within 24 to 48 hours. Pregabalin demonstrates high bioavailability, and it has a mean elimination half-life of about 6.5 hours. Food does not affect absorption. Pregabalin does not bind to plasma proteins and is excreted virtually unchanged (<2% metabolism) by the kidneys. It is not subject to hepatic metabolism and does not induce or inhibit liver enzymes such as the CYP system. Dose reduction may be necessary in patients with creatinine clearance (CLcr) less than 60 mL per minute. Daily doses should be further reduced by approximately 50 percent for each additional 50 percent decrease in CLcr. Pregabalin is highly cleared by hemodialysis, so additional doses may be needed for patients on chronic hemodialysis treatment after each hemodialysis treatment.

Therapeutic Indications

Pregabalin is approved for the management of diabetic peripheral neuropathy and postherpetic neuralgia, and for adjunctive treatment of partial onset seizures. It has been found to be of benefit to some patients with generalized anxiety disorder. In studies, no consistent dose-response relationship was found, although 300 mg of pregabalin per day was more effective than 150 mg or 450 mg. Some patients with panic disorder or social anxiety disorder may benefit from pregabalin, but little evidence supports its routine use in treating persons with these disorders. It was most recently approved for the treatment of fibromyalgia.

Precautions and Adverse Reactions

The most common adverse events associated with pregabalin use are dizziness, somnolence, blurred vision, peripheral edema, amnesia or loss of memory, and tremors. Pregabalin potentiates sedating effects of alcohol, antihistamines, benzodiazepines, and other CNS depressants. It remains to be seen if pregabalin is associated with benzodiazepine-type withdrawal symptoms. There are scant data about its use in pregnant women or nursing mothers, and it is best avoided in these patients.

Drug Interactions

In view of the absence of hepatic metabolism, pregabalin lacks metabolic drug interactions.

Laboratory Interferences

There are no effects on laboratory tests.

Dosage and Clinical Guidelines

The recommended dose for postherpetic neuralgia is 50 or 100 mg orally three times a day. The recommended dose for diabetic peripheral neuropathy is 100 to 200 mg orally three times a day. Patients with fibromyalgia may require up to 450 to 600 mg per day given in divided doses. Pregabalin is available as 25, 50, 75, 100, 150, 200, 225, and 300 mg capsules.

PHENYTOIN

Phenytoin sodium (Dilantin) is an antiepileptic drug and is related to the barbiturates in chemical structure. It is indicated for the control of generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or after neurosurgery. Studies have shown comparable efficacy of phenytoin to other anticonvulsants in bipolar disorder, but clinicians should take into account the danger of gingival hyperplasia, leukopenia, or anemia and the danger of toxicity caused by nonlinear pharmacokinetics.

Pharmacologic Action

Similar to other anticonvulsants, phenytoin causes blockade of voltage-activated sodium channels and hence is efficacious as an antimanic agent. The plasma half-life after oral administration averages 22 hours, with a range of 7 to 42 hours. Steady-state therapeutic levels are achieved at least 7 to 10 days (5 to 7 half-lives) after initiation of therapy, with recommended doses of 300 mg per day. Serum level should be obtained at least 5 to 7 half-lives after treatment initiation. Phenytoin is excreted in the bile, which is then reabsorbed from the intestinal tract and excreted in the urine. Urinary excretion of phenytoin occurs partly with glomerular filtration and by tubular secretion. Small incremental doses of phenytoin may increase the half-life and produce very substantial increases in serum levels. Patients should adhere strictly to the prescribed dosage, and serial monitoring of phenytoin levels is recommended.

Therapeutic Indications

Apart from its indication in generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures, phenytoin is also used for the treatment of acute mania in bipolar disorder.

Precautions and Adverse Reactions

The most common adverse reactions reported with phenytoin therapy are usually dose related and include nystagmus, ataxia, slurred speech, decreased coordination, and mental confusion. Other side effects include dizziness, insomnia, transient nervousness, motor twitching,

and headaches. There have been rare reports of phenytoin-induced dyskinesias, similar to those induced by phenothiazine and other neuroleptic drugs. More serious side effects include thrombocytopenia, leukopenia, agranulocytosis, and pancytopenia, with or without bone marrow suppression.

A number of reports have suggested the development of lymphadenopathy (local or generalized), including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's disease. Prenatal exposure to phenytoin may increase the risks for congenital malformations, and a potentially life-threatening bleeding disorder related to decreased levels of vitamin K-dependent clotting factors may occur in newborns exposed to phenytoin in utero. Hyperglycemia has been reported with phenytoin use; in addition, the agent may increase the serum glucose level in patients with diabetes.

Drug Interactions

Acute alcohol intake, amiodarone, chlorthalidone, cimetidine, diazepam, disulfiram, estrogens, fluoxetine, H₂-antagonists, isoniazid, methylphenidate, phenothiazines, salicylates, and trazodone may increase phenytoin serum levels. Drugs that may lower phenytoin levels include carbamazepine, chronic alcohol abuse, and reserpine.

Laboratory Interferences

Phenytoin may decrease serum concentrations of thyroxine. It may cause increased serum levels of glucose, alkaline phosphatase, and γ -glutamyl transpeptidase.

Dosage and Clinical Guidelines

Patients may be started on one 100 mg extended oral capsule three times daily, and the dosage then adjusted to suit individual requirements. Patients may then be switched to once-a-day dosing, which is more convenient. In this case, extended-release capsules may be used. Serial monitoring of phenytoin levels is recommended, and the normal range is usually 10 to 20 $\mu\text{g/mL}$.

29.7 Antihistamines

Antihistamines are frequently used in the treatment of a variety of psychiatric disorders because of their sedative and anticholinergic activities. Certain antihistamines (antagonists of histamine H₁ receptors) are used to treat neuroleptic-induced parkinsonism and neuroleptic-induced acute dystonia and as hypnotics and anxiolytics. Diphenhydramine (Benadryl) is used to treat neuroleptic-induced parkinsonism and neuroleptic-induced acute dystonia and sometimes as a hypnotic. Hydroxyzine hydrochloride (Atarax) and hydroxyzine pamoate (Vistaril) are used as anxiolytics. Promethazine (Phenergan) is used for its sedative and anxiolytic effects. Cyproheptadine (Periactin) has been used for the treatment of anorexia nervosa and inhibited male and female orgasms caused by serotonergic agents. The antihistamines most commonly used in psychiatry are listed in [Table 29.7-1](#). Second-generation, "nonsedating" H₁ blockers, such as fexofenadine (Allegra), loratadine (Claritin), and cetirizine (Zyrtec) are less commonly used in psychiatric practice. The newer H₂-receptor antagonists, such as cimetidine, work primarily on gastric mucosa, inhibiting gastric secretion.

Table 29.7-1
Histamine Antagonists Commonly Used in Psychiatry

Generic Name	Trade Name	Duration of Action (hr)
Diphenhydramine	Benadryl	4-6
Hydroxyzine	Atarax, Vistaril	6-24
Promethazine	Phenergan	4-6
Cyproheptadine	Periactin	4-6

[Table 29.7-2](#) lists antihistaminic drugs not used in psychiatry but that may have psychiatric adverse effects or drug-drug interactions.

Table 29.7-2
Other Histamine Antagonists Often Prescribed

Class	Generic Name	Trade Name
Second-generation histamine 1 receptor antagonists	Cetirizine	Zyrtec
	Loratadine	Claritin
	Fexofenadine	Allegra
Histamine 2 receptor antagonists	Nizatidine	Axid
	Famotidine	Pepcid
	Ranitidine	Zantac
	Cimetidine	Tagamet

PHARMACOLOGICAL ACTIONS

The H₁ antagonists used in psychiatry are well absorbed from the gastrointestinal (GI) tract. The antiparkinsonian effects of intramuscular (IM) diphenhydramine have their onset in 15 to 30 minutes, and the sedative effects of diphenhydramine peak in 1 to 3 hours. The sedative effects of hydroxyzine and promethazine begin after 20 to 60 minutes and last for 4 to 6 hours. Because all three drugs are metabolized in the liver, persons with hepatic disease, such as cirrhosis, may attain high plasma concentrations with long-term administration. Cyproheptadine is well absorbed after oral administration, and its metabolites are excreted in the urine.

Activation of H₁ receptors stimulates wakefulness; therefore, receptor antagonism causes sedation. All four agents also possess some antimuscarinic cholinergic activity. Cyproheptadine is unique among the drugs because it has both potent antihistamine and serotonin 5-HT₂-receptor antagonist properties.

THERAPEUTIC INDICATIONS

Antihistamines are useful as a treatment for neuroleptic-induced parkinsonism, neuroleptic-induced acute dystonia, and neuroleptic-induced akathisia. They are an alternative to anticholinergics and amantadine for these purposes. The antihistamines are relatively safe hypnotics, but they are not superior to the benzodiazepines, which have been much better studied in terms of efficacy and safety. The antihistamines have not been proven effective for long-term anxiolytic therapy; therefore, the benzodiazepines, buspirone (BuSpar), or selective serotonin reuptake inhibitors (SSRIs) are preferable for such treatment. Cyproheptadine is sometimes used to treat impaired orgasms, especially delayed orgasm resulting from treatment with serotonergic drugs.

Because it promotes weight gain, cyproheptadine may be of some use in the treatment of eating disorders, such as anorexia nervosa. Cyproheptadine can reduce recurrent nightmares with posttraumatic themes. The antiserotonergic activity of cyproheptadine may counteract the serotonin syndrome caused by concomitant use of multiple serotonin-activating drugs, such as SSRIs and monoamine oxidase inhibitors.

PRECAUTIONS AND ADVERSE REACTIONS

Antihistamines are commonly associated with sedation, dizziness, and hypotension, all of which can be severe in elderly persons, who are also likely to experience the anticholinergic effects of those drugs. Paradoxical excitement and agitation is an adverse effect seen in a small number of persons. Poor motor coordination can result in accidents; therefore, persons should be warned about driving and operating dangerous machinery. Other common adverse effects include epigastric distress, nausea, vomiting, diarrhea, and constipation. Because of mild anticholinergic activity, some people experience dry mouth, urinary retention, blurred vision, and constipation. For this reason also, antihistamines should be used only at very low doses, if at all, by persons with narrow-angle glaucoma or obstructive GI, prostate, or bladder conditions. A central anticholinergic syndrome with psychosis may be induced by either cyproheptadine or diphenhydramine. The use of cyproheptadine in some persons has been associated with weight gain, which may contribute to its reported efficacy in some persons with anorexia nervosa.

In addition to the above adverse effects, antihistamines have some potential for abuse. The coadministration of antihistamines and opioids can increase the euphoria experienced by persons with substance dependence. Overdoses of antihistamines can be fatal. Antihistamines are excreted in breast milk, so their use should be avoided by nursing mothers. Because of some potential for teratogenicity, pregnant women should avoid the use of antihistamines.

DRUG INTERACTIONS

The sedative property of antihistamines can be additive with other central nervous system (CNS) depressants, such as alcohol, other sedative-hypnotic drugs, and many psychotropic drugs, including tricyclic drugs and dopamine receptor antagonists (DRAs). Anticholinergic activity can also be additive with that of other anticholinergic drugs and may sometimes result in severe anticholinergic symptoms or intoxication.

LABORATORY INTERFERENCES

H₁ antagonists may eliminate the wheal and induration that form the basis of allergy skin tests. Promethazine may interfere with pregnancy tests and may increase blood glucose concentrations. Diphenhydramine may yield a false-positive urine test result for phencyclidine (PCP). Hydroxyzine use can falsely elevate the results of certain tests for urinary 17-hydroxycorticosteroids.

DOSAGE AND CLINICAL GUIDELINES

The antihistamines are available in a variety of preparations (Table 29.7-3). IM injections should be deep, because superficial administration can cause local irritation.

Table 29.7-3
Dosage and Administration of Common Histamine Antagonists

Medication	Route	Preparation	Common Dosage
Diphenhydramine (Benadryl)	PO	Capsules and tablets: 25 mg, 50 mg Liquid: 12.5 mg/5.0 mL	Adults: 25–50 mg three to four times per day Children: 5 mg/kg three to four times per day, not to exceed 300 mg/day
Hydroxyzine Hydrochloride (Atarax)	Deep IM or IV	Solution: 10 or 50 mg/mL	Same as oral
	PO	Tablets: 10, 25, 50, and 100 mg Syrup: 10 mg/5 mL	Adults: 50–100 mg three to four times daily Children younger than 6 yrs of age: 2 mg/kg/day in divided doses Children older than 6 yrs of age: 12.5–25.0 mg three to four times daily
Pamoate (Vistaril)	IM	Solution: 25 or 50 mg/mL	Same as oral
	PO	Suspension: 25 mg/mL Capsules: 25, 50, and 100 mg	Same as dosages for hydrochloride
Promethazine (Phenergan)	PO	Tablets: 15.2, 25.0, and 50.0 mg Syrup: 3.25 mg/5 mL	Adults: 50–100 mg three to four times daily for sedation Children: 12.5–25.0 mg at night for sedation
	Rectal	Suppositories: 12.5, 25.0, and 50.0 mg	
Cyproheptadine (Periactin)	IM	Solution: 25 and 50 mg/mL	
	PO	Tablets: 4 mg Syrup: 2 mg/5 mL	Adults: 4–20 mg/day Children 2–7 yr of age: 2 mg two to three times daily (maximum, 12 mg/day) Children 7–14 yrs of age: 4 mg two to three times daily (maximum of 16 mg/day)

IM, intramuscular; IV, intravenous; PO, oral.

Intravenous (IV) administration of 25 to 50 mg of diphenhydramine is an effective treatment for neuroleptic-induced acute dystonia, which may immediately disappear. Treatment with 25 mg three times a day—up to 50 mg four times a day, if necessary—can be used to treat neuroleptic-induced parkinsonism, akinesia, and buccal movements. Diphenhydramine can be used as a hypnotic at a 50 mg dose for mild transient insomnia. Doses of 100 mg have not been shown to be superior to doses of 50 mg, but they produce more anticholinergic effects than doses of 50 mg.

Hydroxyzine is most commonly used as a short-term anxiolytic. Hydroxyzine should not be given IV because it is irritating to the blood vessels. Dosages of 50 to 100 mg given orally four times a day for long-term treatment or 50 to 100 mg IM every 4 to 6 hours for short-term treatment are usually effective.

SSRI-induced anorgasmia may sometimes be reversed with 4 to 16 mg a day of cyproheptadine taken by mouth 1 or 2 hours before anticipated sexual activity. A number of case reports and small studies have also reported that cyproheptadine may be of some use in the treatment of eating disorders, such as anorexia nervosa. Cyproheptadine is available in 4 mg tablets and a 2 mg/5 mL solution. Children and elderly patients are more sensitive to the effects of antihistamines than are young adults.

29.8 Barbiturates and Similarly Acting Drugs

The first barbiturate to be used in medicine was barbital (Veronal), which was introduced in 1903. It was followed by phenobarbital (Luminal), amobarbital (Amytal), pentobarbital (Nembutal), secobarbital (Seconal), and thiopental (Pentothal). Many others have been synthesized, but only a handful has been used clinically (Table 29.8-1). Many problems are associated with these drugs, including high abuse and addiction potential, a narrow therapeutic range with low therapeutic index, and unfavorable side effects. The use of barbiturates and similar compounds such as meprobamate (Miltown) has practically been eliminated by the benzodiazepines and hypnotics, such as zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata), which have a lower abuse potential and a higher therapeutic index than the barbiturates. Nevertheless, the barbiturates still have an important role in the treatment of certain mental and convulsive disorders.

Table 29.8-1
Barbiturate Dosages (Adult)

Drug	Trade Name	Available Preparations	Hypnotic Dose Range	Anticonvulsant Dose Range
Amobarbital	Amytal	200 mg	50–300 mg	65–500 mg IV
Aprobarbital	Alurate	40 mg/5 mL elixir	40–120 mg	Not established
Butobarbital	Butisol	15, 30, and 50 mg tablets 30 mg/5 mL elixir	45–120 mg	Not established
Mephobarbital	Mebaral	32, 50, and 100 mg tablets	100–200 mg	200–600 mg
Methohexital	Brevital	500 mg/50 mL	1 mg/kg for electroconvulsive therapy	Not established
Pentobarbital	Nembutal	50 and 100 mg capsules 50 mg/mL injection or elixir 30, 60, 120, and 200 mg suppository	100–200 mg	100 mg IV, each minute up to 500 mg
Phenobarbital	Luminal	Tablets range from 15–100 mg 20 mg/5 mL elixir 30 to 130 mg/mL injection	30–150 mg	100–300 mg IV, up to 600 mg/day
Secobarbital	Seconal	100 mg capsule, 50 mg/mL injection	100 mg	5.5 mg/kg IV

IV, intravenous.

PHARMACOLOGICAL ACTIONS

The barbiturates are well absorbed after oral administration. The binding of barbiturates to plasma proteins is high, but lipid solubility varies. The individual barbiturates are metabolized by the liver and excreted by the kidneys. The half-lives of specific barbiturates range from 1 to 120 hours. The barbiturates may also induce hepatic enzymes (cytochrome P450, CYP), thereby reducing the levels of both the barbiturate and any other concurrently administered drugs metabolized by the liver. The mechanism of action of barbiturates involves the γ -aminobutyric acid (GABA) receptor–benzodiazepine receptor–chloride ion channel complex.

THERAPEUTIC INDICATIONS

Electroconvulsive Therapy

Methohexital (Brevital) is commonly used as an anesthetic agent for electroconvulsive therapy (ECT). It has lower cardiac risks than other barbiturate anesthetics. Used intravenously (IV), methohexital produces rapid unconsciousness, and because of its rapid redistribution, it has a brief duration of action (5 to 7 minutes). Typical dosing for ECT is 0.7 to 1.2 mg/kg. Methohexital can also be used to abort prolonged seizures in ECT or to limit postictal agitation.

Seizures

Phenobarbital (Solfonton, Luminal), the most commonly used barbiturate for treatment of seizures, has indications for the treatment of generalized tonic–clonic and simple partial seizures. Parenteral barbiturates are used in the emergency management of seizures independent of cause. Intravenous phenobarbital should be administered slowly at 10 to 20 mg/kg for status epilepticus.

Narcoanalysis

Amobarbital (Amytal) has been used historically as a diagnostic aid in a number of clinical conditions, including conversion reactions, catatonia, hysterical stupor, and unexplained muteness, and to differentiate stupor of depression, schizophrenia, and structural brain lesions.

The *Amytal interview* is performed by placing the patient in a reclining position and administering amobarbital IV at 50 mg a minute. Infusion is continued until lateral nystagmus is sustained or drowsiness is noted, usually at 75 to 150 mg. After this, 25 to 50 mg can be administered every 5 minutes to maintain narcosis. The patient should be allowed to rest for 15 to 30 minutes after the interview before attempting to walk.

Because of the risk of laryngospasm with IV amobarbital, diazepam has become the drug of choice for narcoanalysis.

Sleep

The barbiturates reduce sleep latency and the number of awakenings during sleep, although tolerance to these effects generally develops within 2 weeks. Discontinuation of barbiturates often leads to rebound increases on electroencephalographic measures of sleep and a worsening of the insomnia.

WITHDRAWAL FROM SEDATIVE-HYPNOTICS

Barbiturates are sometimes used to determine the extent of tolerance to barbiturates or other hypnotics to guide detoxification. After intoxication has resolved, a test dose of pentobarbital (200 mg) is given orally. One hour later, the patient is examined. Tolerance and dose requirements are determined by the degree to which the patient is affected. If the patient is not sedated, another 100 mg of pentobarbital can be administered every 2 hours, up to three times (maximum, 500 mg over 6 hours). The amount needed for mild intoxication corresponds to the approximate daily dose of barbiturate used. Phenobarbital (30 mg) may then be substituted for each 100 mg of pentobarbital. This daily dose requirement can be administered in divided doses and gradually tapered by 10 percent a day, with adjustments made according to withdrawal signs.

PRECAUTIONS AND ADVERSE REACTIONS

Some adverse effects of barbiturates are similar to those of benzodiazepines, including paradoxical dysphoria, hyperactivity, and cognitive disorganization. Rare adverse effects associated with barbiturate use include the development of Stevens–Johnson syndrome, megaloblastic anemia, and neutropenia.

Prior to the advent of benzodiazepines, the widespread use of barbiturates as hypnotics and anxiolytics made them the most common cause of acute porphyria reactions. Severe attacks of porphyria have decreased largely because barbiturates are now seldom used and are contraindicated in patients with the disease.

A major difference between the barbiturates and the benzodiazepines is the low therapeutic index of the barbiturates. An overdose of barbiturates can easily prove fatal. In addition to narrow therapeutic indexes, the barbiturates are associated with a significant risk of abuse potential and the development of tolerance and dependence. Barbiturate intoxication is manifested by confusion, drowsiness, irritability, hyporeflexia or areflexia, ataxia, and nystagmus. The symptoms of barbiturate withdrawal are similar to, but more marked than, those of benzodiazepine withdrawal.

Ten times the daily dose or 1 g of most barbiturates causes severe toxicity; 2–10 g generally proves fatal. Manifestations of barbiturate intoxication may include delirium, confusion, excitement, headache, and central nervous system (CNS) and respiratory depression, ranging from somnolence to coma. Other adverse reactions include Cheyne–Stokes respiration, shock, miosis, oliguria, tachycardia, hypotension,

hypothermia, irritability, hyporeflexia or areflexia, ataxia, and nystagmus. Treatment of overdose includes induction of emesis or lavage, activated charcoal, and saline cathartics; supportive treatment, including maintaining airway and respiration and treating shock as needed; maintaining vital signs and fluid balance; alkalinizing the urine, which increases excretion; forced diuresis if renal function is normal, or hemodialysis in severe cases.

Because of some evidence of teratogenicity, barbiturates should not be used by pregnant women or women who are breastfeeding. Barbiturates should be used with caution by patients with a history of substance abuse, depression, diabetes, hepatic impairment, renal disease, severe anemia, pain, hyperthyroidism, or hypoadrenalism. Barbiturates are also contraindicated in patients with acute intermittent porphyria, impaired respiratory drive, or limited respiratory reserve.

DRUG INTERACTIONS

The primary area for concern about drug interactions is the potentially dangerous effects of respiratory depression. Barbiturates should be used with great caution with other prescribed CNS drugs (including antipsychotic and antidepressant drugs) and nonprescribed CNS agents (e.g., alcohol). In addition, caution must be exercised when prescribing barbiturates to patients who are taking other drugs that are metabolized in the liver, especially cardiac drugs and anticonvulsants. Because individual patients have a wide range of sensitivities to barbiturate-induced enzyme induction, it is not possible to predict the degree to which the metabolism of concurrently administered medications may be affected. Drugs that have their metabolism enhanced by barbiturate administration include opioids, antiarrhythmic agents, antibiotics, anticoagulants, anticonvulsants, antidepressants, β -adrenergic receptor antagonists, dopamine receptor antagonists, contraceptives, and immunosuppressants.

LABORATORY INTERFERENCES

No known laboratory interferences are associated with the administration of barbiturates.

DOSE AND CLINICAL GUIDELINES

Barbiturates and other drugs described later begin to act within 1 to 2 hours of administration. The doses of barbiturates vary, and treatment should begin with low doses that are increased to achieve a clinical effect. Children and older people are more sensitive to the effects of the barbiturates than are young adults. The most commonly used barbiturates are available in a variety of dose forms. Barbiturates with half-lives in the 15- to 40-hour range are preferable, because long-acting drugs tend to accumulate in the body. Clinicians should instruct patients clearly about the adverse effects and the potential for dependence associated with barbiturates.

Although determining plasma concentrations of barbiturates is rarely necessary in psychiatry, monitoring of phenobarbital concentrations is standard practice when the drug is used as an anticonvulsant. The therapeutic blood concentrations for phenobarbital in this indication range from 15 to 40 mg/L, although some patients may experience significant adverse effects in that range.

Barbiturates are contained in combination products with which the clinician should be familiar.

OTHER SIMILARLY ACTING DRUGS

A number of agents that act similarly to the barbiturates have been used in the treatment of anxiety and insomnia. Three such available drugs are paraldehyde (Paral), meprobamate, and chloral hydrate (Noctec). These drugs are rarely used because of their abuse potential and potential toxic effects.

Paraldehyde

Paraldehyde is a cyclic ether and was first used in 1882 as a hypnotic. It has also been used to treat epilepsy, alcohol withdrawal symptoms, and delirium tremens. Because of its low therapeutic index, it has been supplanted by the benzodiazepines and other anticonvulsants.

Pharmacologic Actions. Paraldehyde is rapidly absorbed from the gastrointestinal (GI) tract and from intramuscular (IM) injections. It is primarily metabolized to acetaldehyde by the liver, and unmetabolized drug is expired by the lungs. Reported half-lives range from 3.4 to 9.8 hours. The onset of action is 15 to 30 minutes.

Therapeutic Indications. Paraldehyde is not indicated as an anxiolytic or a hypnotic and has little place in current psychopharmacology.

Precautions and Adverse Reactions. Paraldehyde frequently causes foul breath because of expired unmetabolized drug. It can inflame pulmonary capillaries and cause coughing. It can also cause local thrombophlebitis with IV use. Patients may experience nausea and vomiting with oral use. Overdose leads to metabolic acidosis and decreased renal output. There is risk of abuse among drug addicts.

Drug Interactions. Disulfiram (Antabuse) inhibits acetaldehyde dehydrogenase and reduces metabolism of paraldehyde, leading to possible toxic concentration of paraldehyde. Paraldehyde has addictive sedating effects in combination with other CNS depressants such as alcohol or benzodiazepines.

Laboratory Interferences. Paraldehyde can interfere with the metyrapone, phentolamine, and urinary 17-hydroxycorticosteroid tests.

Dosing and Clinical Guidelines. Paraldehyde is available in 30-mL vials for oral, IV, or rectal use. For seizures in adults, up to 12 mL (diluted to a 10% solution) can be administered by gastric tube every 4 hours. For children, the oral dose is 0.3 mg/kg.

Meprobamate

Meprobamate, a carbamate, was introduced shortly before the benzodiazepines, specifically to treat anxiety. It is also used for muscle relaxant effects.

Pharmacologic Actions. Meprobamate is rapidly absorbed from the GI tract and from IM injections. It is metabolized primarily by the liver, and a small portion is excreted unchanged in urine. The plasma half-life is approximately 10 hours.

Therapeutic Indications. Meprobamate is indicated for short-term treatment of anxiety disorders. It has also been used as a hypnotic and is prescribed as a muscle relaxant.

Precautions and Adverse Reactions. Meprobamate can cause CNS depression and death in overdose and carries the risk of abuse by patients with drug or alcohol dependence. Abrupt cessation after long-term use can lead to withdrawal syndrome, including seizures and hallucinations. Meprobamate can exacerbate acute intermittent porphyria. Other rare side effects include hypersensitivity reactions, wheezing, hives, paradoxical excitement, and leukopenia. It should not be used in patients with hepatic compromise.

Drug Interactions. Meprobamate has additive sedating effects in combination with other CNS depressants, such as alcohol, barbiturates, or benzodiazepines.

Laboratory Interferences. Meprobamate can interfere with the metyrapone, phentolamine, and urinary 17-hydroxycorticosteroid tests.

Dosing and Clinical Guidelines. Meprobamate is available in 200, 400, and 600 mg tablets; 200 and 400 mg extended-release capsules; and various combinations, for example, aspirin, 325 mg and 200 mg of meprobamate (Equagesic) for oral use. For adults, the usual dose is 400 to 800 mg twice daily. Elderly patients and children aged 6 to 12 years require half the adult dose.

Chloral Hydrate

Chloral hydrate is a hypnotic agent rarely used in psychiatry because numerous safer options, such as benzodiazepines, are available.

Pharmacological Actions. Chloral hydrate is well absorbed from the GI tract. The parent compound is metabolized within minutes by the liver to the active metabolite trichloroethanol, which has a half-life of 8 to 11 hours. A dose of chloral hydrate induces sleep in about 30 to 60 minutes and maintains sleep for 4 to 8 hours. It probably potentiates GABAergic neurotransmission, which suppresses neuronal excitability.

Therapeutic Indications. The major indication for chloral hydrate is to induce sleep. It should be used for no more than 2 or 3 days because longer-term treatment is associated with an increased incidence and severity of adverse effects. Tolerance develops to the hypnotic effects of chloral hydrate after 2 weeks of treatment. The benzodiazepines are superior to chloral hydrate for all psychiatric uses.

Precautions and Adverse Reactions. Chloral hydrate has adverse effects on the CNS, GI system, and skin. High doses (> 4 g) may be associated with stupor, confusion, ataxia, falls, or coma. The GI effects include nonspecific irritation, nausea, vomiting, flatulence, and an unpleasant taste. With long-term use and overdose, gastritis and gastric ulceration can develop. In addition to the development of tolerance, dependence on chloral hydrate can occur, with symptoms similar to those of alcohol dependence. With a lethal dose between 5,000 and 10,000 mg, chloral hydrate is a particularly poor choice for potentially suicidal persons.

Drug Interactions. Because of metabolic interference, chloral hydrate should be strictly avoided with alcohol, a notorious concoction known as a *Mickey Finn*. Chloral hydrate may displace warfarin (Coumadin) from plasma proteins and enhance anticoagulant activity; this combination should be avoided.

Laboratory Interferences. Chloral hydrate administration can lead to false-positive results for urine glucose determinations that use cupric sulfate (e.g., Clinitest) but not in tests that use glucose oxidase (e.g., Clinistix and Tes-Tape). Chloral hydrate can also interfere with the determination of urinary catecholamines in 17-hydroxycorticosteroids.

Dosing and Clinical Guidelines. Chloral hydrate is available in 500 mg capsules; 500 mg/5 mL solution; and 324, 500, and 648 mg rectal suppositories. The standard dose of chloral hydrate is 500 to 2,000 mg at bedtime. Because the drug is a GI irritant, it should be administered with excess water, milk, other liquids, or antacids to decrease gastric irritation.

Propofol

Propofol (Diprivan) is a GABA_A agonist that is used as an anesthetic. It induces presynaptic release of GABA and dopamine (the latter possibility through an action on GABA_B receptors) and is a partial agonist at dopamine D₂ and N-methyl-D-aspartate (NMDA) receptors. Because it is very lipid soluble, it crosses the blood-brain barrier readily and induces anesthesia in less than 1 minute. Rapid redistribution from the CNS results in offset of action within 3 to 8 minutes after the infusion is discontinued. It is well tolerated when used for conscious sedation, but it has a potential for acute adverse effects, including respiratory depression, apnea, and bradyarrhythmias, and prolonged infusion can cause acidosis and mitochondrial myopathies. The carrier used for the infusion is a soybean emulsion that can be a culture medium for various organisms. In addition, the carrier can impair macrophage function and cause hematologic and lipid abnormalities and anaphylactic reactions.

Etomidate

Etomidate is a carboxylated imidazole that acts at the β_2 and β_3 subunits of the GABA_A receptor. It has a rapid onset (1 minute) and short duration (less than 5 minutes) of action. The propylene glycol vehicle has been linked to hyperosmolar metabolic acidosis. It has both proconvulsant and anticonvulsant properties, and it inhibits cortisol release, with possible adverse consequences after long-term use.

29.9 Benzodiazepines and Drugs Acting on GABA Receptors

The first benzodiazepine to be introduced was chlordiazepoxide (Librium), in 1959. In 1963, diazepam (Valium) became available. Over

the next three decades, superior safety and tolerability helped the benzodiazepines replace the older antianxiety and hypnotic medications, such as the barbiturates and meprobamate (Miltown). Dozens of benzodiazepines and drugs acting on benzodiazepine receptors have been synthesized and marketed worldwide. Many of these agents are not in the United States, and some benzodiazepines have been discontinued because of lack of use. [Table 29.9-1](#) lists agents currently available in the United States.

Table 29.9-1
Preparations and Doses of Medications Acting on the Benzodiazepine Receptor Available in the United States

Medication	Brand Name	Dose Equivalent	Usual Adult Dose (mg)	How Supplied
Diazepam	Valium	5	2.5–40.0	2-, 5-, and 10-mg tablets 15-mg slow-release tablets
Clonazepam	Klonopin	0.25	0.5–4.0	0.5-, 1.0-, and 2.0-mg tablets
Alprazolam	Xanax	0.5	0.5–6.0	0.25-, 0.5-, 1.0-, and 2.0-mg tablets 1.5-mg sustained-release tablet
Lorazepam	Ativan	1	0.5–6.0	0.5-, 1.0-, and 2.0-mg tablets 4 mg/mL parenteral
Oxazepam	Serax	15	15–120	7.5-, 10.0-, 15.0-, and 30.0-mg capsules 15-mg tablets
Chlordiazepoxide	Librium	25	10–100	5-, 10-, and 25-mg capsules and tablets
Clorazepate	Tranxene	7.5	15–60	3.75-, 7.50-, and 15.00-mg tablets 11.25- and 22.50-mg slow-release tablets
Midazolam	Versed	0.25	1–50	5 mg/mL parenteral 1-, 2-, 5-, and 10-mL vials
Flurazepam	Dalmane	15	15–30	15- and 30-mg capsules
Temazepam	Restoril	15	7.5–30.0	7.5-, 15.0-, and 30.0-mg capsules
Triazolam	Halcion	0.125	0.125–0.250	0.125- and 0.250-mg tablets
Estazolam	ProSom	1	1–2	1- and 2-mg tablets
Quazepam	Doral	5	7.5–15.0	7.5- and 15.0-mg tablets
Zolpidem	Ambien	10	5–10	5- and 10-mg tablets
	Ambien CR	5	6.25–12.5	6.25- and 12.5-mg tablets
Zaleplon	Sonata	10	5–20	5- and 10-mg capsules
Eszopiclone	Lunesta	1	1–3	1-, 2- and 3-mg tablets
Flumazenil	Romazicon	0.05	0.2–0.5 per min	0.1 mg/mL 5- and 10-mL vials

The benzodiazepines derive their name from their molecular structure. They share a common effect on receptors that have been termed benzodiazepine receptors, which in turn modulate γ -aminobutyric acid (GABA) activity. Nonbenzodiazepine agonists, such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta)—the so-called “Z drugs”—are discussed in this chapter because their clinical effects result from binding domains located close to benzodiazepine receptors. Flumazenil (Romazicon), a benzodiazepine receptor antagonist used to reverse benzodiazepine-induced sedation and in emergency care of benzodiazepine overdose, is also covered here.

Because benzodiazepines have a rapid anxiolytic sedative effect, they are most commonly used for acute treatment of insomnia, anxiety, agitation, or anxiety associated with any psychiatric disorder. In addition, the benzodiazepines are used as anesthetics, anticonvulsants, and muscle relaxants and as the preferred treatment for catatonia. Because of the risk of psychological and physical dependence associated with long-term use of benzodiazepines, ongoing assessment should be made as to the continued clinical need for these drugs in treating patients. In most patients, given the nature of their disorders, it is often best if benzodiazepine agents are used in conjunction with psychotherapy and when alternative agents have been tried and proven ineffective or poorly tolerated. In many forms of chronic anxiety disorders, antidepressant drugs such as the selective serotonin reuptake inhibitor (SSRI) and serotonin–norepinephrine reuptake inhibitors (SNRIs) are now used as primary treatments, with benzodiazepines used as adjuncts. Benzodiazepine abuse is rare, usually found in patients who abuse multiple prescription and recreational drugs.

PHARMACOLOGIC ACTIONS

All benzodiazepines except clorazepate (Tranxene) are completely absorbed after oral administration and reach peak serum levels within 30 minutes to 2 hours. Metabolism of clorazepate in the stomach converts it to desmethyldiazepam, which is then completely absorbed.

The absorption, the attainment of peak concentrations, and the onset of action are quickest for diazepam (Valium), lorazepam (Ativan), alprazolam (Xanax), triazolam (Halcion), and estazolam (ProSom). The rapid onset of effects is important to persons who take a single dose of a benzodiazepine to calm an episodic burst of anxiety or to fall asleep rapidly. Several benzodiazepines are effective after intravenous (IV) injection, but only lorazepam and midazolam (Versed) have rapid and reliable absorption after intramuscular (IM) administration.

Diazepam, chlordiazepoxide, clonazepam (Klonopin), clorazepate, flurazepam (Dalmane), and quazepam (Doral) have plasma half-lives of 30 hours to more than 100 hours and are technically described as long-acting benzodiazepines. The plasma half-lives of these compounds can be as high as 200 hours in persons whose metabolism is genetically slow. Because the attainment of steady-state plasma concentrations of the drugs can take up to 2 weeks, persons may experience symptoms and signs of toxicity after only 7 to 10 days of treatment with a dosage that seemed initially to be in the therapeutic range.

Clinically, half-life alone does not necessarily determine the duration of therapeutic action for most benzodiazepines. The fact that all benzodiazepines are lipid soluble to varying degrees means that benzodiazepines and their active metabolites bind to plasma proteins. The extent of this binding is proportional to their lipid solubility. The amount of protein binding varies from 70 to 99 percent. Distribution, onset, and termination of action after a single dose are thus largely determined by benzodiazepine lipid solubility, not elimination half-life. Preparations with high lipid solubility, such as diazepam and alprazolam, are absorbed rapidly from the GI tract and distribute rapidly to the brain by passive diffusion along a concentration gradient, resulting in a rapid onset of action. However, as the concentration of the medication increases in the brain and decreases in the bloodstream, the concentration gradient reverses itself, and these medications leave the brain rapidly, resulting in fast cessation of drug effect. Drugs with longer elimination half-lives, such as diazepam, may remain in the bloodstream for a substantially longer period of time than their actual pharmacologic action at benzodiazepine receptors because the concentration in the brain decreases rapidly below the level necessary for a noticeable effect. In contrast, lorazepam, which has a shorter elimination half-life than diazepam but is less lipid soluble, has a slower onset of action after a single dose because the drug is absorbed and enters the brain more slowly. However, the duration of action after a single dose is longer because it takes longer for lorazepam to leave the brain and for brain levels to decrease below the concentration that produces an effect. In chronic dosing, some of these differences are not as apparent because brain levels are in equilibrium with higher and more consistent steady-state blood levels, but additional doses still produce a more rapid but briefer action with diazepam than with lorazepam. Benzodiazepines are distributed widely in adipose tissue. As a result, medications may persist in the body after discontinuation longer than would be predicted from their elimination half-lives. In addition, the dynamic half-life (i.e., duration of action on the receptor) may be longer than the elimination half-life.

The advantages of long-half-life drugs over short-half-life drugs include less frequent dosing, less variation in plasma concentration, and less severe withdrawal phenomena. The disadvantages include drug accumulation, increased risk of daytime psychomotor impairment, and

increased daytime sedation.

The half-lives of lorazepam, oxazepam (Serax), temazepam (Restoril), and estazolam are between 8 and 30 hours. Alprazolam has a half-life of 10 to 15 hours, and triazolam has the shortest half-life (2 to 3 hours) of all the orally administered benzodiazepines. Rebound insomnia and anterograde amnesia are thought to be more of a problem with the short-half-life drugs than with the long-half-life drugs.

Because administration of medications more frequently than the elimination half-life leads to drug accumulation, medications such as diazepam and flurazepam accumulate with daily dosing, eventually resulting in increased daytime sedation.

Some benzodiazepines (e.g., oxazepam) are conjugated directly by glucuronidation and are excreted. Most benzodiazepines are oxidized first by CYP3A4 and CYP2C19, often to active metabolites. These metabolites may then be hydroxylated to another active metabolite. For example, diazepam is oxidized to desmethyldiazepam, which, in turn, is hydroxylated to produce oxazepam. These products undergo glucuronidation to inactive metabolites. A number of benzodiazepines (e.g., diazepam, chlordiazepoxide) have the same active metabolite (desmethyldiazepam), which has an elimination half-life of more than 120 hours. Flurazepam (Dalmane), a lipid-soluble benzodiazepine used as a hypnotic that has a short elimination half-life, has an active metabolite (desalkylflurazepam) with a half-life greater than 100 hours. This is another reason that the duration of action of a benzodiazepine may not correspond to the half-life of the parent drug.

Zaleplon, zolpidem, and eszopiclone are structurally distinct and vary in their binding to the GABA receptor subunits. Benzodiazepines activate all three specific GABA–benzodiazepine (GABA–BZ) binding sites of the GABA_A-receptor, which opens chloride channels and reduces the rate of neuronal and muscle firing. Zolpidem, zaleplon, and eszopiclone have selectivity for certain subunits of the GABA receptor. This may account for their selective sedative effects and relative lack of muscle relaxant and anticonvulsant effects.

Zolpidem, zaleplon, and eszopiclone are rapidly and well absorbed after oral administration, although absorption can be delayed by as long as 1 hour if they are taken with food. Zolpidem reaches peak plasma concentrations in 1.6 hours and has a half-life of 2.6 hours. Zaleplon reaches peak plasma concentrations in 1 hour and has a half-life of 1 hour. If taken immediately after a high-fat or heavy meal, the peak is delayed by approximately 1 hour, reducing the effects of eszopiclone on sleep onset. The terminal-phase elimination half-life is approximately 6 hours in healthy adults. Eszopiclone is weakly bound to plasma protein (52 to 59 percent).

The rapid metabolism and lack of active metabolites of zolpidem, zaleplon, and eszopiclone avoid the accumulation of plasma concentrations compared with the long-term use of benzodiazepines.

THERAPEUTIC INDICATIONS

Insomnia

Because insomnia may be a symptom of a physical or psychiatric disorder, hypnotics should not be used for more than 7 to 10 consecutive days without a thorough investigation of the cause of the insomnia. However, many patients have long-standing sleep difficulties and benefit greatly from long-term use of hypnotic agents. Temazepam, flurazepam, and triazolam are benzodiazepines with a sole indication for insomnia. Zolpidem, zaleplon, and eszopiclone are also indicated only for insomnia. Although these “Z drugs” are not usually associated with rebound insomnia after the discontinuation of their use for short periods, some patients experience increased sleep difficulties the first few nights after discontinuing their use. Use of zolpidem, zaleplon, and eszopiclone for periods longer than 1 month is not associated with the delayed emergence of adverse effects. No development of tolerance to any parameter of sleep measurement was observed over 6 months in clinical trials of eszopiclone.

Flurazepam, temazepam, quazepam, estazolam, and triazolam are the benzodiazepines approved for use as hypnotics. The benzodiazepine hypnotics differ principally in their half-lives; flurazepam has the longest half-life, and triazolam has the shortest. Flurazepam may be associated with minor cognitive impairment on the day after its administration, and triazolam may be associated with mild rebound anxiety and anterograde amnesia. Quazepam may be associated with daytime impairment when used for a long time. Temazepam or estazolam may be a reasonable compromise for most adults. Estazolam produces rapid onset of sleep and a hypnotic effect for 6 to 8 hours.

γ-Hydroxybutyrate (GHB, Xyrem), which is approved for the treatment of narcolepsy and improves slow-wave sleep, is also an agonist at the GABA_A receptor, where it binds to specific GHB receptors. GHB has the capacity both to reduce drug craving and to induce dependence, abuse, and absence seizures as a result of complex actions on tegmental dopaminergic systems.

Anxiety Disorders

Generalized Anxiety Disorder. Benzodiazepines are highly effective for the relief of anxiety associated with generalized anxiety disorder (GAD). Most persons should be treated for a predetermined, specific, and relatively brief period. However, because GAD is a chronic disorder with a high rate of recurrence, some persons with GAD may warrant long-term maintenance treatment with benzodiazepines.

Panic Disorder. Alprazolam and clonazepam, both high-potency benzodiazepines, are commonly used medications for panic disorder with or without agoraphobia. Although the SSRIs are also indicated for treatment of panic disorder, the benzodiazepines have the advantage of working quickly and not causing significant sexual dysfunction and weight gain. However, the SSRIs are still often preferred because they target common comorbid conditions, such as depression or obsessive-compulsive disorder (OCD). Benzodiazepines and SSRIs can be initiated together to treat acute panic symptoms; use of the benzodiazepine can be tapered after 3 to 4 weeks after the therapeutic benefits of the SSRI have emerged.

Social Phobia. Clonazepam has been shown to be an effective treatment for social phobia. In addition, several other benzodiazepines (e.g., diazepam) have been used as adjunctive medications for treatment of social phobia.

Other Anxiety Disorders. Benzodiazepines are used adjunctively for treatment of adjustment disorder with anxiety, pathological anxiety associated with life events (e.g., after an accident), OCD, and posttraumatic stress disorder.

Anxiety Associated with Depression. Depressed patients often experience significant anxiety, and antidepressant drugs may cause initial exacerbation of these symptoms. Accordingly, benzodiazepines are indicated for the treatment of anxiety associated with depression.

Bipolar I and II Disorders

Clonazepam, lorazepam, and alprazolam are effective in the management of acute manic episodes and as an adjuvant to maintenance therapy in lieu of antipsychotics. As an adjuvant to lithium (Eskalith) or lamotrigine (Lamictal), clonazepam may result in an increased time between cycles and fewer depressive episodes. Benzodiazepines may help patients with bipolar disorder sleep better.

Catatonia

Lorazepam, sometimes in low doses (less than 5 mg per day) and sometimes in very high doses (12 mg per day or more), is regularly used to treat acute catatonia, which is more frequently associated with bipolar disorder than with schizophrenia. Other benzodiazepines have also

been said to be helpful. However, there are no valid controlled trials of benzodiazepines in catatonia. Chronic catatonia does not respond as well to benzodiazepines. The definitive treatment for catatonia is electroconvulsive therapy.

Akathisia

The first-line drug for akathisia is most commonly a β -adrenergic receptor antagonist. However, benzodiazepines are also effective in treating some patients with akathisia.

Parkinson's Disease

A small number of persons with idiopathic Parkinson's disease respond to long-term use of zolpidem with reduced bradykinesia and rigidity. Zolpidem dosages of 10 mg four times daily may be tolerated without sedation for several years.

Other Psychiatric Indications

Chlordiazepoxide (Librium) and clorazepate (Tranxene) are used to manage the symptoms of alcohol withdrawal. The benzodiazepines (especially IM lorazepam) are used to manage substance induced and psychotic agitation in the emergency department. Benzodiazepines have been used instead of amobarbital (Amytal) for drug-assisted interviewing.

Flumazenil for Benzodiazepine Overdosage

Flumazenil is used to reverse the adverse psychomotor, amnesic, and sedative effects of benzodiazepine receptor agonists, including benzodiazepines, zolpidem, and zaleplon. Flumazenil is administered IV and has a half-life of 7 to 15 minutes. The most common adverse effects of flumazenil are nausea, vomiting, dizziness, agitation, emotional lability, cutaneous vasodilation, injection-site pain, fatigue, impaired vision, and headache. The most common serious adverse effect associated with the use of flumazenil is the precipitation of seizures, which is especially likely to occur in persons with seizure disorders, those who are physically dependent on benzodiazepines, and those who have ingested large quantities of benzodiazepines. Flumazenil alone may impair memory retrieval.

In mixed-drug overdosage, the toxic effects (e.g., seizures and cardiac arrhythmias) of other drugs (e.g., tricyclic antidepressants) may emerge with the reversal of the benzodiazepine effects of flumazenil. For example, seizures caused by an overdosage of tricyclic antidepressants may have been partially treated in a person who had also taken an overdosage of benzodiazepines. With flumazenil treatment, the tricyclic-induced seizures or cardiac arrhythmias may appear and result in a fatal outcome. Flumazenil does not reverse the effects of ethanol, barbiturates, or opioids.

For the initial management of a known or suspected benzodiazepine overdosage, the recommended initial dosage of flumazenil is 0.2 mg (2 mL) administered IV over 30 seconds. If the desired consciousness is not obtained after 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over 30 seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3.0 mg. The clinician should not rush the administration of flumazenil. A secure airway and IV access should be established before the administration of the drug. Persons should be awakened gradually.

Most persons with a benzodiazepine overdosage respond to a cumulative dose of 1 to 3 mg of flumazenil; doses above 3 mg of flumazenil do not reliably produce additional effects. If a person has not responded 5 minutes after receiving a cumulative dose of 5 mg of flumazenil, the major cause of sedation is probably not benzodiazepine receptor agonists, and additional flumazenil is unlikely to have an effect.

Sedation can return in 1 to 3 percent of persons treated with flumazenil. It can be prevented or treated by giving repeated dosages of flumazenil at 20-minute intervals. For repeat treatment, no more than 1 mg (given as 0.5 mg a minute) should be given at any one time, and no more than 3 mg should be given in any 1 hour.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effect of the benzodiazepines is drowsiness, which occurs in about 10 percent of all persons. Because of this adverse effect, persons should be advised to be careful while driving or using dangerous machinery when taking the drugs. Drowsiness can be present during the day after the use of a benzodiazepine for insomnia the previous night, the so-called residual daytime sedation. Some persons also experience ataxia (fewer than 2 percent) and dizziness (less than 1 percent). These symptoms can result in falls and hip fractures, especially in elderly persons. The most serious adverse effects of the benzodiazepines occur when other sedative substances, such as alcohol, are taken concurrently. These combinations can result in marked drowsiness, disinhibition, or even respiratory depression. Infrequently, benzodiazepine receptor agonists cause mild cognitive deficits that may impair job performance. Persons taking benzodiazepine receptor agonists should be advised to exercise additional caution when driving or operating dangerous machinery.

High-potency benzodiazepines, especially triazolam, can cause anterograde amnesia. A paradoxical increase in aggression has been reported in persons with preexisting brain damage. Allergic reactions to the drugs are rare, but a few studies report maculopapular rashes and generalized itching. The symptoms of benzodiazepine intoxication include confusion, slurred speech, ataxia, drowsiness, dyspnea, and hyporeflexia.

Triazolam has received significant attention in the media because of an alleged association with serious aggressive behavioral manifestations. Therefore, the manufacturer recommends that the drug be used for no more than 10 days for treatment of insomnia and that physicians carefully evaluate the emergence of any abnormal thinking or behavioral changes in persons treated with triazolam, giving appropriate consideration to all potential causes. Triazolam was banned in Great Britain in 1991.

Zolpidem (Ambien) has also been associated with automatic behavior and amnesia.

Persons with hepatic disease and elderly persons are particularly likely to have adverse effects and toxicity from the benzodiazepines, including hepatic coma, especially when the drugs are administered repeatedly or in high dosages. Benzodiazepines can produce clinically significant impairment of respiration in persons with chronic obstructive pulmonary disease and sleep apnea. Alprazolam may exert a direct appetite stimulant effect and may cause weight gain. The benzodiazepines should be used with caution by persons with a history of substance abuse, cognitive disorders, renal disease, hepatic disease, porphyria, central nervous system (CNS) depression, or myasthenia gravis.

Some data indicate that benzodiazepines are teratogenic; therefore, their use during pregnancy is not advised. Moreover, the use of benzodiazepines in the third trimester can precipitate a withdrawal syndrome in newborns. The drugs are secreted in the breast milk in sufficient concentrations to affect newborns. Benzodiazepines may cause dyspnea, bradycardia, and drowsiness in nursing babies.

Zolpidem and zaleplon are generally well tolerated. At zolpidem dosages of 10 mg per day and zaleplon dosages above 10 mg per day, a small number of persons will experience dizziness, drowsiness, dyspepsia, or diarrhea. Zolpidem and zaleplon are secreted in breast milk and are therefore contraindicated for use by nursing mothers. The dosage of zolpidem and zaleplon should be reduced in elderly persons and persons with hepatic impairment.

In rare cases, zolpidem may cause hallucinations and behavioral changes. The coadministration of zolpidem and SSRIs may extend the duration of hallucinations in susceptible patients.

Eszopiclone exhibits a dose-response relationship in elderly adults for the side effects of pain, dry mouth, and unpleasant taste.

Tolerance, Dependence, and Withdrawal

When benzodiazepines are used for short periods (1 to 2 weeks) in moderate dosages, they usually cause no significant tolerance, dependence, or withdrawal effects. The short-acting benzodiazepines (e.g., triazolam) may be an exception to this rule because some persons have reported increased anxiety the day after taking a single dose of the drug and then stopping its use. Some persons also report a tolerance for the anxiolytic effects of benzodiazepines and require increased doses to maintain the clinical remission of symptoms.

The appearance of a withdrawal syndrome, also called a discontinuation syndrome, depends on the length of time the person has been taking a benzodiazepine, the dosage the person has been taking, the rate at which the drug is tapered, and the half-life of the compound. Benzodiazepine withdrawal syndrome consists of anxiety, nervousness, diaphoresis, restlessness, irritability, fatigue, lightheadedness, tremor, insomnia, and weakness (Table 29.9-2). Abrupt discontinuation of benzodiazepines, particularly those with short half-lives, is associated with severe withdrawal symptoms, which may include depression, paranoia, delirium, and seizures. These severe symptoms are more likely to occur if flumazenil is used for rapid reversal of the benzodiazepine receptor agonist effects. Some features of the syndrome may occur in as many as 90 percent of persons treated with the drugs. The development of a severe withdrawal syndrome is seen only in persons who have taken high dosages for long periods. The appearance of the syndrome may be delayed for 1 or 2 weeks in persons who had been taking benzodiazepines with long half-lives. Alprazolam seems to be particularly associated with an immediate and severe withdrawal syndrome and should be tapered gradually.

Table 29.9-2
Signs and Symptoms of Benzodiazepine Withdrawal

Anxiety	Tremor
Irritability	Depersonalization
Insomnia	Hyperesthesia
Hyperacusis	Myoclonus
Nausea	Delirium
Difficulty concentrating	Seizures

When the medication is to be discontinued, the drug must be tapered slowly (25 percent a week); otherwise, recurrence or rebound of symptoms is likely. Monitoring of any withdrawal symptoms (possibly with a standardized rating scale) and psychological support of the person are helpful in the successful accomplishment of benzodiazepine discontinuation. Concurrent use of carbamazepine (Tegretol) during benzodiazepine discontinuation has been reported to permit a more rapid and better tolerated withdrawal than does a gradual taper alone. The dosage range of carbamazepine used to facilitate withdrawal is 400 to 500 mg a day. Some clinicians report particular difficulty in tapering and discontinuing alprazolam, especially in persons who have been receiving high dosages for long periods. There have been reports of successful discontinuation of alprazolam by switching to clonazepam, which is then gradually withdrawn.

Zolpidem and zaleplon can produce a mild withdrawal syndrome lasting 1 day after prolonged use at higher therapeutic dosages. Rarely, a person taking zolpidem has self-titrated up the daily dosage to 30 to 40 mg a day. Abrupt discontinuation of such a high dosage of zolpidem may cause withdrawal symptoms for 4 or more days. Tolerance does not develop to the sedative effects of zolpidem and zaleplon.

DRUG INTERACTIONS

The most common and potentially serious benzodiazepine receptor agonist interaction is excessive sedation and respiratory depression occurring when benzodiazepines, zolpidem, or zaleplon are administered concomitantly with other CNS depressants, such as alcohol, barbiturates, tricyclic and tetracyclic drugs, dopamine receptor antagonists, opioids, and antihistamines. Ataxia and dysarthria may be likely to occur when lithium, antipsychotics, and clonazepam are combined. The combination of benzodiazepines and clozapine (Clozaril) has been reported to cause delirium and should be avoided. Cimetidine (Tagamet), disulfiram (Antabuse), isoniazid, estrogen, and oral contraceptives increase the plasma concentration of diazepam, chlordiazepoxide, clorazepate, and flurazepam. Cimetidine increases the plasma concentrations of zaleplon. However, antacids may reduce the GI absorption of benzodiazepines. The plasma concentrations of triazolam and alprazolam are increased to potentially toxic concentrations by nefazodone (Serzone) and fluvoxamine (Luvox). The manufacturer of nefazodone recommends that the dosage of triazolam be lowered by 75 percent and the dosage of alprazolam be lowered by 50 percent when given concomitantly with nefazodone. Over-the-counter preparations of kava plant, advertised as a “natural tranquilizer,” can potentiate the action of benzodiazepine receptor agonists through synergistic overactivation of GABA receptors. Carbamazepine can lower the plasma concentration of alprazolam. Antacids and food may decrease the plasma concentrations of benzodiazepines, and smoking may increase the metabolism of benzodiazepines. Rifampin (Rifadin), phenytoin (Dilantin), carbamazepine, and phenobarbital (Solfoton, Luminal) significantly increase the metabolism of zaleplon. The benzodiazepines may increase the plasma concentrations of phenytoin and digoxin (Lanoxin). The SSRIs may prolong and exacerbate the severity of zolpidem-induced hallucinations. Deaths have been reported when parental lorazepam is given with parental olanzapine.

The CYP3A4 and CYP2E1 enzymes are involved in the metabolism of eszopiclone. Eszopiclone did not show any inhibitory potential on CYP450 1A2, 2A6, 2C9, 2C19, 2D6, 2E1, and 3A4 in cryopreserved human hepatocytes. Coadministration of 3 mg of eszopiclone to subjects receiving 400 mg of ketoconazole, a potent inhibitor of CYP3A4, resulted in a 2.2-fold increase in exposure to eszopiclone.

LABORATORY INTERFERENCES

No known laboratory interferences are associated with the use of the benzodiazepines, zolpidem, and zaleplon.

DOSAGE AND CLINICAL GUIDELINES

The clinical decision to treat an anxious person with a benzodiazepine should be carefully considered. Medical causes of anxiety (e.g., thyroid dysfunction, caffeineism, and prescription medications) should be ruled out. Benzodiazepine use should be started at a low dosage, and the person should be instructed regarding the drug’s sedative properties and abuse potential. An estimated length of therapy should be decided at the beginning of therapy, and the need for continued therapy should be reevaluated at least monthly because of the problems associated with long-term use. However, certain persons with anxiety disorders are unresponsive to treatments other than benzodiazepines in long-term use.

Benzodiazepines are available in a wide range of formulations. Clonazepam is available in a wafer formulation that facilitates its use in patients who have trouble swallowing pills. Alprazolam is available in an extended-release form, which reduces the frequency of dosing. Some benzodiazepines are more potent than others in that one compound requires a relatively smaller dosage than another compound to achieve the same effect. For example, clonazepam requires 0.25 mg to achieve the same effect as 5 mg of diazepam; thus, clonazepam is considered a high-potency benzodiazepine. Conversely, oxazepam has an approximate dosage equivalence of 15 mg and is a low-potency drug.

Zaleplon is available in 5- and 10-mg capsules. A single 10-mg dose is the usual adult dose. The dose can be increased to a maximum of 20 mg as tolerated. A single dose of zaleplon can be expected to provide 4 hours of sleep with minimal residual impairment. For persons older than age 65 years or persons with hepatic impairment, an initial dose of 5 mg is advised.

Eszopiclone is available in 1-, 2-, and 3-mg tablets. The starting dose should not exceed 1 mg in patients with severe hepatic impairment or those taking potent CYP3A4 inhibitors. The recommended dosing to improve sleep onset or maintenance is 2 or 3 mg for adult patients

(ages 18 to 64 years) and 2 mg for older adult patients (ages 65 years and older). The 1-mg dose is for sleep onset in older adult patients whose primary complaint is difficulty falling asleep.

Table 29.9-1 lists preparations and doses of medications discussed in this chapter.

▲ 29.10 Bupropion

Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL, Zyban) is an antidepressant drug that inhibits the reuptake of norepinephrine and, possibly, dopamine. Most significantly, it does not act on the serotonin system like SSRI antidepressants. This results in a side effect profile characterized by a low risk of sexual dysfunction and sedation and with modest weight loss during acute and long-term treatment. No withdrawal syndrome has been linked to discontinuation of bupropion. Although increasingly used as first-line monotherapy, a significant percentage of bupropion use occurs as add-on therapy to other antidepressants, usually SSRIs. Bupropion has been marketed under the name Zyban for use in smoking cessation regimens.

PHARMACOLOGIC ACTIONS

Three formulations of bupropion are available: immediate release (taken three times daily), sustained release (taken twice daily), and extended release (taken once daily). The different versions of the drug contain the same active ingredient but differ in their pharmacokinetics and dosing. There have been reports of inconsistencies in bioequivalence between various branded and generic versions of bupropion. Any changes with this drug in tolerability or clinical efficacy in a patient who had been doing well should prompt an inquiry about whether these changes correspond to a switch to a new formulation.

Immediate-release bupropion is well absorbed from the GI tract. Peak plasma concentrations of bupropion are usually reached within 2 hours of oral administration, and peak levels of the sustained-release version are seen after 3 hours. The mean half-life of the compound is 12 hours, ranging from 8 to 40 hours. Peak levels of extended-release bupropion occur 5 hours after ingestion. This provides a longer time to maximum plasma concentration (t_{max}) but comparable peak and trough plasma concentrations. The 24-hour exposure occurring after administration of the extended-release version of 300 mg once daily is equivalent to that provided by sustained release of 150 mg twice daily. Clinically, this permits the drug to be taken once a day in the morning. Plasma levels are also reduced in the evening, making it less likely for some patients to experience treatment-related insomnia.

The mechanism of action for the antidepressant effects of bupropion is presumed to involve the inhibition of dopamine and norepinephrine reuptake. Bupropion binds to the dopamine transporter in the brain. The effects of bupropion on smoking cessation may be related to its effects on dopamine reward pathways or to inhibition of nicotinic acetylcholine receptors.

THERAPEUTIC INDICATIONS

Depression

Although overshadowed by the SSRIs as first-line treatment for major depression, the therapeutic efficacy of bupropion in depression is well established in both outpatient and inpatient settings. Observed rates of response and remission are comparable to those seen with the SSRIs. Bupropion has been found to prevent seasonal major depressive episodes in patients with a history of seasonal pattern or affective disorder.

Smoking Cessation

As the brand name Zyban, bupropion is indicated for use in combination with behavioral modification programs for smoking cessation. It is intended to be used in patients who are highly motivated and who receive some form of structured behavioral support. Bupropion is most effective when combined with nicotine substitutes (Nico-Derm, Nicotrol).

Bipolar Disorders

Bupropion is less likely than tricyclic antidepressants to precipitate mania in persons with bipolar I disorder and less likely than other antidepressants to exacerbate or induce rapid-cycling bipolar II disorder; however, the evidence about use of bupropion in the treatment of patients with bipolar disorder is limited.

Attention-Deficit/Hyperactivity Disorder

Bupropion is used as a second-line agent, after the sympathomimetics, for treatment of attention-deficit/hyperactivity disorder (ADHD). It has not been compared with proven ADHD medications such as methylphenidate (Ritalin) or atomoxetine (Strattera) for childhood and adult ADHD. Bupropion is an appropriate choice for persons with comorbid ADHD and depression or persons with comorbid ADHD, conduct disorder, or substance abuse. It may also be considered for use in patients who develop tics when treated with psychostimulants.

Cocaine Detoxification

Bupropion may be associated with a euphoric feeling; thus, it may be contraindicated in persons with histories of substance abuse. However, because of its dopaminergic effects, bupropion has been explored as a treatment to reduce the cravings for cocaine in persons who have withdrawn from the substance. Results have been inconclusive, with some patients showing a reduction in drug craving and others finding their cravings increased.

Hypoactive Sexual Desire Disorder

Bupropion is often added to drugs such as SSRIs to counteract sexual side effects and may be helpful as a treatment for nondepressed individuals with hypoactive sexual desire disorder. Bupropion may improve sexual arousal, orgasm completion, and sexual satisfaction.

PRECAUTIONS AND ADVERSE REACTIONS

Headache, insomnia, dry mouth, tremor, and nausea are the most common side effects. Restlessness, agitation, and irritability may also occur. Patients with severe anxiety or panic disorder should not be prescribed bupropion. Most likely because of its potentiating effects on dopaminergic neurotransmission, bupropion can cause psychotic symptoms, including hallucinations, delusions, and catatonia, as well as delirium. Most notable about bupropion is the absence of significant drug-induced orthostatic hypotension, weight gain, daytime drowsiness, and anticholinergic effects. Some persons, however, may experience dry mouth or constipation and weight loss. Hypertension may occur in some patients, but bupropion causes no other significant cardiovascular or clinical laboratory changes. Bupropion exerts indirect sympathomimetic activity, producing positive inotropic effects in human myocardium, an effect that may reflect catecholamine release. Some patients experience cognitive impairment, most notably word-finding difficulties.

Concern about seizure has deterred some physicians from prescribing bupropion. The risk of seizure is dose dependent. Studies show that at dosages of 300 mg a day or less of sustained-release bupropion, the incidence of seizures is 0.05 percent, which is no worse than the incidence of seizures with other antidepressants. The risk of seizures increases to about 0.1 percent with dosages of 400 mg a day.

Changes in electroencephalographic (EEG) waveforms have been reported to be associated with bupropion use. About 20 percent of individuals treated with bupropion exhibit spike waves, sharp waves, and focal slowing. The likelihood of women having sharp waves is higher than for men. The presence of these waveforms in individuals taking a medication known to lower the seizure threshold may be a risk factor for developing seizures. Other risk factors for seizures include a history of seizures, use of alcohol, recent benzodiazepine withdrawal, organic brain disease, head trauma, or pretreatment epileptiform discharges on EEG.

The use of bupropion by pregnant women is not associated with specific risk of increased rate of birth defects. Bupropion is secreted in breast milk, so the use of bupropion in nursing women should be based on the clinical circumstances of the patient and the judgment of the clinician.

Few deaths have been reported after overdoses of bupropion. Poor outcomes are associated with cases of huge doses and mixed-drug overdoses. Seizures occur in about one-third of all overdoses and are dose dependent, with those having seizures ingesting a significantly higher median dose. Fatalities can involve uncontrollable seizures, sinus bradycardia, and cardiac arrest. Symptoms of poisoning most often involve seizures, sinus tachycardia, hypertension, GI symptoms, hallucinations, and agitation. All seizures are typically brief and self-limited. In general, however, bupropion is safer in overdose cases than are other antidepressants except perhaps SSRIs.

DRUG INTERACTIONS

Given the fact that bupropion is frequently combined with SSRIs or venlafaxine, potential interactions are significant. Bupropion has been found to have an effect on the pharmacokinetics of venlafaxine. One study noted a significant increase in venlafaxine levels and a consequent decrease in its main metabolite O-desmethylvenlafaxine during combined treatment with sustained-release bupropion. Bupropion hydroxylation is weakly inhibited by venlafaxine. No significant changes in plasma levels of the SSRIs paroxetine and fluoxetine have been reported. However, few case reports indicate that the combination of bupropion and fluoxetine (Prozac) may be associated with panic, delirium, or seizures. Bupropion in combination with lithium (Eskalith) may rarely cause CNS toxicity, including seizures.

Because of possibility of inducing a hypertensive crisis, bupropion should not be used concurrently with monoamine oxidase inhibitors (MAOIs). At least 14 days should pass after the discontinuation of an MAOI before initiating treatment with bupropion. In some cases, the addition of bupropion may permit persons taking antiparkinsonian medications to lower the doses of their dopaminergic drugs. However, delirium, psychotic symptoms, and dyskinetic movements may be associated with the coadministration of bupropion and dopaminergic agents such as levodopa (Larodopa), pergolide (Permax), ropinirole (Requip), pramipexole (Mirapex), amantadine (Symmetrel), and bromocriptine (Parlodel). Sinus bradycardia may occur when bupropion is combined with metoprolol.

Carbamazepine (Tegretol) may decrease plasma concentrations of bupropion, and bupropion may increase plasma concentrations of valproic acid (Depakene).

In vitro biotransformation studies of bupropion have found that formation of a major active metabolite, hydroxybupropion, is mediated by CYP2B6. Bupropion has a significant inhibitory effect on CYP2D6.

LABORATORY INTERFERENCES

A report has appeared indicating that bupropion may give a false-positive result on urinary amphetamine screens. No other reports have appeared of laboratory interferences clearly associated with bupropion treatment. Clinically nonsignificant changes in the electrocardiogram (premature beats and nonspecific ST-T changes) and decreases in the white blood cell count (by about 10 percent) have been reported in a small number of persons.

DOSAGE AND CLINICAL GUIDELINES

Immediate-release bupropion is available in 75-, 100-, and 150-mg tablets. Sustained-release bupropion is available in 100-, 150-, 200-, and 300-mg tablets. Extended-release bupropion comes in 150- and 300-mg strengths.

There have been problems associated with one of the extended-release generic versions called Budeprion XL 300-mg tablets, which was found not to be therapeutically equivalent to Wellbutrin XL 300 mg and was removed from the market.

Initiation of immediate-release bupropion in the average adult person should be 75 mg orally twice a day. On the fourth day of treatment, the dosage can be increased to 100 mg three times a day. Because 300 mg is the recommended dose, the person should be maintained on this dose for several weeks before increasing it further. The maximum dosage, 450 mg a day, should be given as 150 mg three times a day. Because of the risk of seizures, increases in dose should never exceed 100 mg in a 3-day period; a single dose of immediate-release bupropion should never exceed 150 mg, and the total daily dosage should not exceed 450 mg. The maximum of 400 mg of the sustained-release version should be used as a twice-a-day regimen of either 200 mg twice daily or 300 mg in the morning and 100 mg in the afternoon. A starting dosage of the sustained-release version, 100 mg once a day, can be increased to 100 mg twice a day after 4 days. Then 150 mg twice a day may be used. A single dose of sustained-release bupropion should never exceed 300 mg. The maximum dosage is 200 mg twice a day of the immediate-release or extended-release formulations. An advantage of the extended-release preparation is that after appropriate titration, a total of 450 mg can be given all at once in the morning.

For smoking cessation, the patient should start taking 150 mg a day of sustained-release bupropion 10 to 14 days before quitting smoking. On the fourth day, the dosage should be increased to 150 mg twice daily. Treatment generally lasts 7 to 12 weeks.

▲ 29.11 Bupirone

Bupirone hydrochloride (BuSpar) is classified as an azapirone and is chemically distinct from other psychotropic agents. It acts on two types of receptors, serotonin (5-HT) and dopamine (D). It has high affinity for the 5-HT_{1A} serotonin receptor, acting as an agonist or partial agonist, and moderate affinity for the D₂ dopamine receptor, acting as both an agonist and an antagonist. The approved indication for this psychotropic drug is for the treatment of GAD. It was initially believed to be a better alternative to the benzodiazepine drug group because bupirone does not possess anticonvulsant and muscle relaxant effects. Reports continue to appear that some patients benefit from the addition of bupirone to their antidepressant regimen. Its use in this role is more common than its use as an anxiolytic. Interestingly, the antidepressant drug vilazodone (Viibryd) inhibits 5-HT reuptake and acts as a 5-HT_{1A} receptor partial agonist.

PHARMACOLOGIC ACTIONS

Bupirone is well absorbed from the GI tract, but absorption is delayed by food ingestion. Peak plasma levels are achieved 40 to 90 minutes after oral administration. At doses of 10 to 40 mg, single-dose linear pharmacokinetics are observed. Nonlinear pharmacokinetics are observed after multiple doses. Because of its short half-life (2 to 11 hours), bupirone is dosed three times daily. An active metabolite of bupirone, 1-pyrimidinylpiperazine (1-PP), is about 20 percent less potent than bupirone but is up to 30 percent more concentrated in the brain than the parent compound. The elimination half-life of 1-PP is 6 hours.

Bupirone has no effect on the GABA-associated chloride ion channel or the serotonin reuptake transporter, targets of other drugs that are effective in GAD. Bupirone also has activity at 5-HT₂ and dopamine type 2 (D₂) receptors, although the significance of the effects at these receptors is unknown. At D₂ receptors, it has properties of both an agonist and an antagonist.

THERAPEUTIC INDICATIONS

Generalized Anxiety Disorder

Bupirone is a narrow-spectrum antianxiety agent with demonstrated efficacy only in the treatment of GAD. In contrast to the SSRIs or venlafaxine, bupirone is not effective in the treatment of panic disorder, OCD, or social phobia. Bupirone, however, has an advantage over these agents in that it does not typically cause sexual dysfunction or weight gain.

Some evidence suggests that compared with benzodiazepines, bupirone is generally more effective for symptoms of anger and hostility, equally effective for psychic symptoms of anxiety, and less effective for somatic symptoms of anxiety. The full benefit of bupirone is evident only at dosages above 30 mg a day. Compared with the benzodiazepines, bupirone has a delayed onset of action and lacks any euphoric effect. Unlike benzodiazepines, bupirone has no immediate effects, and patients should be told that a full clinical response may take 2 to 4 weeks. If an immediate response is needed, patients can be started on a benzodiazepine and then withdrawn from the drug after bupirone's effects begin. Sometimes the sedative effects of benzodiazepines, which are not found with bupirone, are desirable; however, these sedative effects may cause impaired motor performance and cognitive deficits.

Other Disorders

Many other clinical uses of bupirone have been reported, but most have not been confirmed in controlled trials. Evidence of the efficacy of high-dosage bupirone (30 to 90 mg a day) for depressive disorders is mixed. Bupirone appears to have weak antidepressant activity, which has led to its use as an augmenting agent in patients who have failed standard antidepressant therapy. In a large study, bupirone augmentation of SSRIs worked as well as other commonly used strategies. Bupirone is sometimes used to augment SSRIs in the treatment of OCD. There are reports that bupirone may be beneficial against the increased arousal and flashbacks associated with posttraumatic stress disorder.

Because bupirone does not act on the GABA–chloride ion channel complex, the drug is not recommended for the treatment of withdrawal from benzodiazepines, alcohol, or sedative–hypnotic drugs, except as treatment of comorbid anxiety symptoms.

Scattered trials suggest that bupirone reduces aggression and anxiety in persons with organic brain disease or traumatic brain injury. It is also used for SSRI-induced bruxism and sexual dysfunction, nicotine craving, and ADHD.

PRECAUTIONS AND ADVERSE REACTIONS

Bupirone does not cause weight gain, sexual dysfunction, discontinuation symptoms, or significant sleep disturbance. It does not produce sedation or cognitive and psychomotor impairment. The most common adverse effects of bupirone are headache, nausea, dizziness, and (rarely) insomnia. No sedation is associated with bupirone. Some persons may report a minor feeling of restlessness, although that symptom may reflect an incompletely treated anxiety disorder. No deaths have been reported from overdoses of bupirone, and the median lethal dose is estimated to be 160 to 550 times the recommended daily dose. Bupirone should be used with caution by persons with hepatic and renal impairment, pregnant women, and nursing mothers. Bupirone can be used safely by the elderly.

DRUG INTERACTIONS

The coadministration of bupirone and haloperidol (Haldol) results in increased blood concentrations of haloperidol. Bupirone should not be used with MAOIs to avoid hypertensive episodes, and a 2-week washout period should pass between the discontinuation of MAOI use and the initiation of treatment with bupirone. Drugs or foods that inhibit CYP3A4, for example, erythromycin (E-mycin), itraconazole (Sporanox), nefazodone (Serzone), and grapefruit juice, increase bupirone plasma concentrations.

LABORATORY INTERFERENCES

Single doses of buspirone can cause transient elevations in growth hormone, prolactin, and cortisol concentrations, although the effects are not clinically significant.

DOSAGE AND CLINICAL GUIDELINES

Buspirone is available in single-scored 5- and 10-mg tablets and triple-scored 15- and 30-mg tablets; treatment is usually initiated with either 5 mg orally three times daily or 7.5 mg orally twice daily. The dosage can be raised 5 mg every 2 to 4 days to the usual dosage range of 15 to 60 mg a day.

Buspirone should not be used in patients with past hypersensitivity to buspirone, in cases of diabetes-associated metabolic acidosis, or in patients with severely compromised liver or renal function.

Switching from a Benzodiazepine to Buspirone

Buspirone is not cross-tolerant with benzodiazepines, barbiturates, or alcohol. A common clinical problem, therefore, is how to initiate buspirone therapy in a person who is currently taking benzodiazepines. There are two alternatives. First, the clinician can start buspirone treatment gradually while the benzodiazepine is being withdrawn. Second, the clinician can start buspirone treatment and bring the person up to a therapeutic dosage for 2 to 3 weeks while the person is still receiving the regular dosage of the benzodiazepine and then slowly taper the benzodiazepine dosage. Patients who have received benzodiazepines in the past, especially in recent months, may find that buspirone is not as effective as the benzodiazepines in the treatment of their anxiety. This might be explained by the absence of the immediate mildly euphoric and sedative effects of the benzodiazepines. The coadministration of buspirone and benzodiazepines may be effective in the treatment of persons with anxiety disorders who have not responded to treatment with either drug alone.

29.12 Calcium Channel Blockers

The intracellular calcium ion regulates activity of multiple neurotransmitters such as serotonin and dopamine, and that action may account for its role as a treatment in mood disorders. Calcium channel inhibitors are used in psychiatry as antimanic agents for persons who are refractory to or cannot tolerate treatment with first-line mood-stabilizing agents such as lithium (Eskalith), carbamazepine (Tegretol), and divalproex (Depakote). Calcium channel inhibitors include nifedipine (Procardia, Adalat), nimodipine (Nimotop), isradipine (DynaCirc), amlodipine (Norvasc, Lotrel), nicardipine (Cardene), nisoldipine (Sular), nifedipine, and verapamil (Calan). They are used for control of mania and ultradian bipolar disorder (mood cycling in less than 24 hours).

The results of a large genetic study have rekindled interest in the potential clinical uses of calcium channel blockers (CCBs). Two genome-wide findings implicated genes encoding L-type voltage-gated calcium channel subunits as susceptibility genes for bipolar disorder, schizophrenia, major depressive disorder, ADHD, and autism.

PHARMACOLOGIC ACTIONS

The calcium channel inhibitors are nearly completely absorbed after oral use, with significant first-pass hepatic metabolism. Considerable intraindividual and interindividual variations are seen in the plasma concentrations of the drugs after a single dose. Peak plasma levels of most of these agents are achieved within 30 minutes. Amlodipine does not reach peak plasma levels for about 6 hours. The half-life of verapamil after the first dose is 2 to 8 hours; the half-life increases to 5 to 12 hours after the first few days of therapy. The half-lives of the other CCBs range from 1 to 2 hours for nimodipine and isradipine to 30 to 50 hours for amlodipine (Table 29.12-1).

Table 29.12-1
Half-lives, Dosages, and Effectiveness of Selected Calcium Channel Inhibitors in Psychiatric Disorders

	Verapamil (Calan, Isoptin)	Nimodipine (Nimotop)	Isradipine (DynaCirc)	Amlodipine (Norvasc)
Half-Life	Short (5–12 hr)	Short (1–2 hr)	Short (1–2 hr)	Long (30–50 hr)
Starting Dosage	30 mg TID	30 mg TID	2.5 mg BID	5 mg HS
Peak Daily Dosage	480 mg	240–450 mg	20 mg	10–15 mg
Antimanic	++	++	++	*
Antidepressant	±	+	+	*
Antiultradian [†]	±	++	(++)	*

BID, twice a day; HS, half strength; TID, three times a day.

*No systematic studies, only case reports.

[†]Rapid-cycling bipolar disorder.

Table adapted from Robert M. Post, MD.

The primary mechanism of action of CCBs in bipolar illness is not known. The calcium channel inhibitors discussed in this section inhibit the influx of calcium into neurons through L-type (long-acting) voltage-dependent calcium channels.

THERAPEUTIC INDICATIONS

Bipolar Disorder

Nimodipine and verapamil have been demonstrated to be effective as maintenance therapy in persons with bipolar illness. Patients who respond to lithium appear to also respond to treatment with verapamil. Nimodipine may be useful for ultradian cycling and recurrent brief depression. The clinician should begin treatment with a short-acting drug such as nimodipine or isradipine, beginning with a low dosage and increasing the dosage every 4 to 5 days until a clinical response is seen or adverse effects appear. When symptoms are controlled, a longer acting drug, such as amlodipine, can be substituted as maintenance therapy. Failure to respond to verapamil does not exclude a favorable response to one of the other drugs. Verapamil has been shown to prevent antidepressant-induced mania. The CCBs can be combined with other agents, such as carbamazepine, in patients who are partial responders to monotherapy.

Depression

None of the CCBs is effective as treatment for depression and may in fact prevent response to antidepressants.

Other Psychiatric Indications

Nifedipine is used to treat hypertensive crises associated with the use of MAOIs. Isradipine may reduce the subjective response to methamphetamine. Calcium channel inhibitors may be beneficial in Tourette's disorder, Huntington's disease, panic disorder, intermittent explosive disorder, and tardive dyskinesia.

Other Medical Uses

These drugs have been used to treat medical conditions such as angina, hypertension, migraine headaches, Raynaud's phenomenon, esophageal spasm, premature labor, and headache. Verapamil has antiarrhythmic activity and has been used to treat supraventricular arrhythmias.

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects associated with calcium channel inhibitors are those attributable to vasodilation: dizziness, headache, tachycardia, nausea, dysesthesias, and peripheral edema. Verapamil and diltiazem (Cardizem) in particular can cause hypotension, bradycardia, and atrioventricular heart block, which necessitate close monitoring and sometimes discontinuation of the drugs. In all patients with cardiovascular disease, the drugs should be used with caution. Other common adverse effects include constipation, fatigue, rash, coughing, and wheezing. Adverse effects noted with diltiazem include hyperactivity, akathisia, and parkinsonism; with verapamil, delirium, hyperprolactinemia, and galactorrhea; with nimodipine, subjective sense of chest tightness and skin flushing; and with nifedipine, depression. The drugs have not been evaluated for safety in pregnant women and are best avoided. Because the drugs are secreted in breast milk, nursing mothers should also avoid the drugs.

DRUG INTERACTIONS

All CCBs have a potential for drug-drug interactions. The types and risks of these interactions vary by compound. Verapamil raises serum levels of carbamazepine, digoxin, and other CYP3A4 substrates. Verapamil and diltiazem but not nifedipine have been reported to precipitate carbamazepine-induced neurotoxicity. Calcium channel inhibitors should not be used by persons taking β -adrenergic receptor antagonists, hypotensives (e.g., diuretics, vasodilators, and angiotensin-converting enzyme inhibitors), or antiarrhythmic drugs (e.g., quinidine and digoxin) without consultation with an internist or cardiologist. Cimetidine (Tagamet) has been reported to increase plasma concentrations of nifedipine and diltiazem. Some patients who are treated with lithium and calcium channel inhibitors concurrently may be at increased risk for the signs and symptoms of neurotoxicity, and deaths have occurred.

LABORATORY INTERFERENCES

No known laboratory interferences are associated with the use of calcium channel inhibitors.

DOSAGE AND CLINICAL GUIDELINES

Verapamil is available in 40-, 80-, and 120-mg tablets; 120-, 180-, and 240-mg sustained-release tablets; and 100-, 120-, 180-, 200-, 240-, 300-, and 360-mg sustained-release capsules. The starting dosage is 40 mg orally three times a day and can be increased in increments every 4 to 5 days up to 80 to 120 mg three times a day. The patient's blood pressure, pulse, and electrocardiogram (in patients older than 40 years old or with a history of cardiac illness) should be routinely monitored.

Nifedipine is available in 10- and 20-mg capsules and 30-, 60-, and 90-mg extended-release tablets. Administration should be started at 10 mg orally three or four times a day and can be increased up to a maximum dosage of 120 mg a day.

Nimodipine is available in 30-mg capsules. It has been used at 60 mg every 4 hours for ultra-rapid-cycling bipolar disorder and sometimes briefly at up to 630 mg per day.

Isradipine is available in 2.5- and 5-mg capsules, with a maximum of 20 mg/day. An extended-release formulation of isradipine has been discontinued.

Amlodipine is available in 2.5-, 5-, and 10-mg tablets. Administration should start at 5 mg once at night and can be increased to a maximum dosage of 10 to 15 mg a day.

Diltiazem is available in 30-, 60-, 90-, and 120-mg tablets; 60-, 90-, 120-, 180-, 240-, 300-, and 360-mg extended-release capsules; and 60-, 90-, 120-, 180-, 240-, 300-, and 360-mg extended-release tablets. Administration should start with 30 mg orally four times a day and can be increased up to a maximum of 360 mg a day.

Elderly persons are more sensitive to the calcium channel inhibitors than are younger adults. No specific information is available regarding the use of the agents for children.

29.13 Carbamazepine and Oxcarbazepine

Carbamazepine (Tegretol) possesses some structural similarity to the tricyclic antidepressant imipramine (Tofranil). It was approved for use in the United States for the treatment of trigeminal neuralgia in 1968 and for temporal lobe epilepsy (complex partial seizures) in 1974. Interestingly, carbamazepine was first synthesized as a potential antidepressant, but because of its atypical profile in a number of animal models, it was initially developed for use in pain and seizure disorders. It is now recognized in most guidelines as a second-line mood stabilizer useful in the treatment and prevention of both phases of bipolar affective disorder. A long-acting sustained release formulation (Equetro) was approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute mania in 2002.

An analog of carbamazepine, oxcarbazepine (Trileptal), was marketed as an antiseizure medication in the United States in 2000, after being used as a treatment for pediatric epilepsy in Europe since 1990. Because of its similarity to carbamazepine, many clinicians began to use it as a treatment for patients with bipolar disorder. Despite some reports that oxcarbazepine has mood-stabilizing properties, this has not been confirmed in large, placebo-controlled trials.

CARBAMAZEPINE

Pharmacologic Actions

Absorption of carbamazepine is slow and unpredictable. Food enhances absorption. Peak plasma concentrations are reached 2 to 8 hours after a single dose, and steady-state levels are reached after 2 to 4 days on a steady dosage. It is 70 to 80 percent protein bound. The half-life of carbamazepine ranges from 18 to 54 hours, with an average of 26 hours. However, with chronic administration, the half-life of carbamazepine decreases to an average of 12 hours. This results from induction of hepatic CYP450 enzymes by carbamazepine, specifically autoinduction of carbamazepine metabolism. The induction of hepatic enzymes reaches its maximum level after about 3 to 5 weeks of therapy.

The pharmacokinetics of carbamazepine are different for two long-acting preparations of carbamazepine, each of which uses slightly different technology. One formulation, Tegretol XR, requires food to ensure normal gastrointestinal (GI) transit time. The other preparation, Carbatrol, relies on a combination of intermediate, extended-release, and very slow release beads, making it suitable for bedtime administration.

Carbamazepine is metabolized in the liver, and the 10,11-epoxide metabolite is active as an anticonvulsant. Its activity in the treatment of bipolar disorders is unknown. Long-term use of carbamazepine is associated with an increased ratio of the epoxide to the parent molecule.

The anticonvulsant effects of carbamazepine are thought to be mediated mainly by binding to voltage-dependent sodium channels in the inactive state and prolonging their inactivation. This secondarily reduces voltage-dependent calcium channel activation and, thus, synaptic transmission. Additional effects include reduction of currents through *N*-methyl-*D*-aspartate (NMDA) glutamate-receptor channels, competitive antagonism of adenosine α_1 -receptors, and potentiation of central nervous system (CNS) catecholamine neurotransmission.

Whether any or all of these mechanisms also result in mood stabilization is not known.

Therapeutic Indications

Bipolar Disorder

ACUTE MANIA. The acute antimanic effects of carbamazepine are typically evident within the first several days of treatment. About 50 to 70 percent of all persons respond within 2 to 3 weeks of initiation. Studies suggest that carbamazepine may be especially effective in persons who are not responsive to lithium (Eskalith), such as persons with dysphoric mania, rapid cycling, or a negative family history of mood disorders. The antimanic effects of carbamazepine can be, and often are, augmented by concomitant administration of lithium, valproic acid (Depakene), thyroid hormones, dopamine receptor antagonists (DRAs), or serotonin-dopamine antagonists (SDAs). Some persons may respond to carbamazepine but not lithium or valproic acid and vice versa.

PROPHYLAXIS. Carbamazepine is effective in preventing relapses, particularly among patients with bipolar II disorder and schizoaffective disorder, and dysphoric mania.

ACUTE DEPRESSION. A subgroup of treatment-refractory patients with acute depression responds well to carbamazepine. Patients with more severe episodic and less chronic depression seem to be better responders to carbamazepine. Nevertheless, carbamazepine remains an alternative drug for depressed persons who have not responded to conventional treatments, including electroconvulsive therapy (ECT).

Other Disorders. Carbamazepine helps to control symptoms associated with acute alcohol withdrawal, although benzodiazepines are more effective in this population. Carbamazepine has been suggested as a treatment for the paroxysmal recurrent component of posttraumatic stress disorder (PTSD). Uncontrolled studies suggest that carbamazepine is effective in controlling impulsive, aggressive behavior in nonpsychotic persons of all ages, including children and elderly persons. Carbamazepine is also effective in controlling nonacute agitation and aggressive behavior in patients with schizophrenia and schizoaffective disorder. Persons with prominent positive symptoms (e.g., hallucinations) may be likely to respond, as are persons who display impulsive aggressive outbursts.

Precautions and Adverse Reactions

Carbamazepine is relatively well tolerated. Mild GI (nausea, vomiting, gastric distress, constipation, diarrhea, and anorexia) and CNS (ataxia, drowsiness) side effects are the most common. The severity of these adverse effects is reduced if the dosage of carbamazepine is increased slowly and kept at the minimal effective plasma concentration. In contrast to lithium and valproate (other drugs used to manage bipolar disorder), carbamazepine does not appear to cause weight gain. Because of the phenomena of autoinduction, with consequent reductions in carbamazepine concentrations, side effect tolerability may improve over time. Most of the adverse effects of carbamazepine are correlated with plasma concentrations above 9 $\mu\text{g/mL}$. The rarest but most serious adverse effects of carbamazepine are blood dyscrasias, hepatitis, and serious skin reactions (Table 29.13-1).

Table 29.13-1
Adverse Events Associated with Carbamazepine

Dosage-Related Adverse Effects	Idiosyncratic Adverse Effects
Double or blurred vision	Agranulocytosis
Vertigo	Stevens-Johnson syndrome
Gastrointestinal disturbances	Aplastic anemia
Task performance impairment	Hepatic failure
Hematologic effects	Rash
	Pancreatitis

Blood Dyscrasias. The drug's hematologic effects are not dose related. Severe blood dyscrasias (aplastic anemia, agranulocytosis) occur in about 1 in 125,000 persons treated with carbamazepine. There does not appear to be a correlation between the degree of benign white blood cell (WBC) suppression (leukopenia), which is seen in 1 to 2 percent of persons, and the emergence of life-threatening blood dyscrasias. Persons should be warned that the emergence of such symptoms as fever, sore throat, rash, petechiae, bruising, and easy bleeding can potentially herald a serious dyscrasia, and they should seek medical evaluation immediately. Routine hematologic monitoring in carbamazepine-treated persons is recommended at 3, 6, 9, and 12 months. If there is no significant evidence of bone marrow suppression by that time, many experts would reduce the interval of monitoring. However, even assiduous monitoring may fail to detect severe blood dyscrasias before they cause symptoms.

Hepatitis. Within the first few weeks of therapy, carbamazepine can cause both hepatitis associated with increases in liver enzymes, particularly transaminases, and cholestasis associated with elevated bilirubin and alkaline phosphatase. Mild transaminase elevations warrant observation only, but persistent elevations more than three times the upper limit of normal indicate the need to discontinue the drug. Hepatitis can recur if the drug is reintroduced to the person and can result in death.

Dermatologic Effects. About 10 to 15 percent of those treated with carbamazepine develop a benign maculopapular rash within the first 3 weeks of treatment. Stopping the medication usually leads to resolution of the rash. Some patients may experience life-threatening dermatologic syndromes, including exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. The possible emergence of these serious dermatologic problems causes most clinicians to discontinue carbamazepine use in people who develop any type of rash. The risk of drug rash is about equal between valproic acid and carbamazepine in the first 2 months of use but is subsequently much higher for carbamazepine. If carbamazepine seems to be the only effective drug for a person who has a benign rash with carbamazepine treatment, a retreatment of the drug can be undertaken. Many patients can be rechallenged without reemergence of the rash. Pretreatment with prednisone (Deltasone; 40 mg a day) may suppress the rash, although other symptoms of an allergic reaction (e.g., fever and pneumonitis) may develop even with steroid pretreatment.

Renal Effects. Carbamazepine is occasionally used to treat diabetes insipidus not associated with lithium use. This activity results from direct or indirect effects at the vasopressin receptor. It may also lead to the development of hyponatremia and water intoxication in some patients, particularly elderly persons, or when used in high doses.

Other Adverse Effects. Carbamazepine decreases cardiac conduction (although less than the tricyclic drugs do) and can thus exacerbate preexisting cardiac disease. Carbamazepine should be used with caution in persons with glaucoma, prostatic hypertrophy, diabetes, or a history of alcohol abuse. Carbamazepine occasionally activates vasopressin receptor function, which results in a condition resembling the syndrome of secretion of inappropriate antidiuretic hormone, characterized by hyponatremia and, rarely, water intoxication. This is the opposite of the renal effects of lithium (i.e., nephrogenic diabetes insipidus). Augmentation of lithium with carbamazepine does not reverse the lithium effect, however. Emergence of confusion, severe weakness, or headache in a person taking carbamazepine should prompt measurement of serum electrolytes.

Carbamazepine use rarely elicits an immune hypersensitivity response consisting of fever, rash, eosinophilia, and possibly fatal myocarditis.

Cleft palate, fingernail hypoplasia, microcephaly, and spina bifida in infants may be associated with the maternal use of carbamazepine during pregnancy. Pregnant women should not use carbamazepine unless absolutely necessary. All women with childbearing potential should take 1 to 4 mg of folic acid daily even if they are not trying to conceive. Carbamazepine is secreted in breast milk.

Drug Interactions

Carbamazepine decreases serum concentrations of numerous drugs as a result of prominent induction of hepatic CYP3A4 (Table 29.13-2). Monitoring for a decrease in clinical effects is frequently indicated. Carbamazepine can decrease the blood concentrations of oral contraceptives, resulting in breakthrough bleeding and uncertain prophylaxis against pregnancy. Carbamazepine should not be administered with monoamine oxidase inhibitors (MAOIs), which should be discontinued at least 2 weeks before initiating treatment with carbamazepine. Grapefruit juice inhibits the hepatic metabolism of carbamazepine. When carbamazepine and valproate are used in combination, the dosage of carbamazepine should be decreased because valproate displaces carbamazepine binding on proteins, and the dosage of valproate may need to be increased.

 **Table 29.13-2**
Carbamazepine: Drug Interactions

Effect of Carbamazepine on Plasma Concentrations of Concomitant Agents	Agents that May Affect Carbamazepine Plasma Concentrations
<i>Carbamazepine may decrease drug plasma concentration of:</i>	<i>Agents that may increase carbamazepine plasma concentration:</i>
Acetaminophen	Allopurinol
Alprazolam	Cimetidine
Amitriptyline	Clarithromycin
Bupropion	Danazol
Clomipramine	Diltiazem
Clonazepam	Erythromycin
Clozapine	Fluoxetine
Cyclosporine	Fluvoxamine
Desipramine	Gemfibrozil
Dicumarol	Itraconazole
Doxepin	Ketoconazole
Doxycycline	Isoniazid ^a
Ethosuximide	Itraconazole
Felbamate	Lamotrigine
Fentanyl	Loratadine
Fluphenazine	Macrolides
Haloperidol	Nefazodone
Hormonal contraceptives	Nicotinamide
Imipramine	Propoxyphene
Lamotrigine	Terfenadine
Methadone	Troleandomycin
Methsuximide	Valproate ^c
Methylprednisolone	Verapamil
Nimodipino	Viloxazine
Pancuronium	<i>Drugs that may decrease carbamazepine plasma concentrations</i>
Phensuximide	Carbamazepine (autoinduction)
Phenytoin	Cisplatin
Primidone	Doxorubicin HCl
Theophylline	Felbamate
Valproate	Phenobarbital
Warfarin	Phenytoin
<i>Carbamazepine may increase drug plasma concentrations of</i>	Primidone
Clomipramine	Rifampin ^b
Phenytoin	Theophylline
Primidone	Valproate

^aIncreased concentrations of the active 10,11-epoxide.

^bDecreased concentrations of carbamazepine and increased concentrations of the 10,11-epoxide.

(Table by Carlos A. Zarate, Jr., M.D., and Mauricio Tohen, M.D.)

Laboratory Interferences

Circulating levels of thyroxine and triiodothyronine are associated with a decrease in thyroid-stimulating hormone and may be associated with treatment. Carbamazepine is also associated with an increase in total serum cholesterol, primarily by increasing high-density lipoproteins. The thyroid and cholesterol effects are not clinically significant. Carbamazepine may interfere with the dexamethasone (Decadron) suppression test and may also cause false-positive pregnancy test results.

Dosing and Administration

The target dose for antimanic activity is 1,200 mg a day, although this varies considerably. Immediate-release carbamazepine needs to be taken three or four times a day, which leads to lapses in compliance. Extended-release formulations are thus preferred because they can be taken once or twice a day. One form of extended-release carbamazepine, Carbatrol, comes as 100-, 200-, and 300-mg capsules. Another form, Equetro, is identical to Carbatrol and is marketed as a treatment for bipolar disorder. These capsules contain tiny beads with three different types of coatings so they dissolve at different times. Capsules should not be crushed or chewed. The contents can be sprinkled over food, however, without affecting the extended-release qualities. This formulation can be taken either with or without meals. The entire daily dose can be given at bedtime. The rate of absorption is faster when it is given with a high-fat meal. Another extended-release form of carbamazepine, Tegretol XR, uses a different drug-delivery system than Carbatrol. It is available in 100-, 200-, and 300-mg tablets.

Preexisting hematologic, hepatic, and cardiac diseases can be relative contraindications for carbamazepine treatment. Persons with hepatic disease require only one third to one half the usual dosage; the clinician should be cautious about raising the dosage in such persons and should do so only slowly and gradually. The laboratory examination should include a complete blood count with platelet count, liver function tests, serum electrolytes, and an electrocardiogram in persons older than 40 years of age or with a preexisting cardiac disease. An electroencephalogram is not necessary before the initiation of treatment, but it may be helpful in some cases for the documentation of objective changes correlated with clinical improvement. [Table 29.13-3](#) presents a brief user's guide to carbamazepine in bipolar disorder.

 **Table 29.13-3**
Carbamazepine in Bipolar Illness: A Brief User's Guide

1. Start with low (200 mg) bedtime dose in depression or euthymia; higher doses (600–800 mg/day in divided doses) in manic inpatients.
2. All bedtime dosing is reasonable with carbamazepine extended-release preparation.
3. Titrate slowly to the individual's response or side effects threshold.
4. Hepatic enzyme CYP450 (3A4) induction and autoinduction occur in 2 to 3 weeks; slightly higher doses may be needed or tolerated at that time.
5. Warn regarding benign rash, which occurs in 5%–10% of those taking the drug; progression to rare, severe rash is unpredictable, so the drug should be discontinued if any rash develops.
6. Benign white blood cell count decreases occur regularly (usually inconsequential).
7. Rarely, agranulocytosis and aplastic anemia may develop (several per million new exposures); warn regarding appearance of fever, sore throat, petechiae, and bleeding gums and to check with physician to obtain an immediate complete blood cell count.
8. Use adequate birth control methods, including higher dosage forms of estrogen (as carbamazepine lowers estrogen levels).
9. Avoid carbamazepine in pregnancy (spina bifida occurs in 0.5%; other severe adverse outcomes occur in about 8%).
10. Some people will respond well to carbamazepine and not other mood stabilizers (lithium) or anticonvulsants (valproic acid).
11. Combination treatment often required to maintain remission and prevent loss of effect via tolerance.
12. Major drug interactions associated with increases in carbamazepine and potential toxicity from 3A4 enzyme inhibition include calcium channel blockers (isradipine and verapamil); erythromycin and related macrolide antibiotics; and valproate.

Routine Laboratory Monitoring

Serum levels for antimanic efficacy have not been established. The anticonvulsant blood concentration range for carbamazepine is 4 to 12 µg/mL, and this range should be reached before determining that carbamazepine is not effective in the treatment of a mood disorder. A clinically insignificant suppression of the WBC count commonly occurs during carbamazepine treatment. This benign decrease can be reversed by adding lithium, which enhances colony-stimulating factor. Potential serious hematologic effects of carbamazepine, such as pancytopenia, agranulocytosis, and aplastic anemia, occur in about 1 in 125,000 patients. Complete laboratory blood assessments may be performed every 2 weeks for the first 2 months of treatment and quarterly thereafter, but the FDA has revised the package insert for carbamazepine to suggest that blood monitoring be performed at the discretion of the physician. Patients should be informed that fever, sore throat, rash, petechiae, bruising, or unusual bleeding may indicate a hematologic problem and should prompt immediate notification of a physician. This approach is probably more effective than is frequent blood monitoring during long-term treatment. It has also been suggested that liver and renal function tests be conducted quarterly, although the benefit of conducting tests this frequently has been questioned. It seems reasonable, however, to assess hematologic status, along with liver and renal functions whenever a routine examination of the person is being conducted. A monitoring protocol is listed in [Table 29.13-4](#).

Table 29.13-4
Laboratory Monitoring of Carbamazepine for Adult Psychiatric Disorders

	Baseline	Weekly to Stability	Monthly for 6 Months	6–12 Months
CBC	+	+	+	+
Bilirubin	+		+	+
Alanine aminotransferase	+		+	+
Aspartate aminotransferase	+		+	+
Alkaline phosphatase	+		+	+
Carbamazepine level	+	+		+

CBC, complete blood count.

Carbamazepine treatment should be discontinued and a consult with a hematologist should be obtained if the following laboratory values are found: total WBC count below 3,000/mm³, erythrocytes below 4.0 × 10⁶/mm³, neutrophils below 1,500/mm³, hematocrit less than 32 percent, hemoglobin less than 11 g/100 mL, platelet count below 100,000/mm³, reticulocyte count below 0.3 percent, and a serum iron concentration below 150 mg/100 mL.

OXCARBAZEPINE

Although structurally related to carbamazepine, the usefulness of oxcarbazepine as a treatment for mania has not been established in controlled trials.

Pharmacokinetics

Absorption is rapid and unaffected by food. Peak concentrations occur after about 45 minutes. The elimination half-life of the parent compound is 2 hours, which remains stable over long-term treatment. The monohydroxide has a half-life of 9 hours. Most of the drug's anticonvulsant activity is presumed to result from this monohydroxy derivative.

Side Effects

The most common side effects are sedation and nausea. Less frequent side effects are cognitive impairment, ataxia, diplopia, nystagmus, dizziness, and tremor. In contrast to carbamazepine, oxcarbazepine does not have an increased risk of serious blood dyscrasias, so hematologic monitoring is not necessary. The frequency of benign rash is lower than observed with carbamazepine, and serious rashes are

extremely rare. However, about 25 to 30 percent of patients who develop an allergic rash while taking carbamazepine also develop a rash with oxcarbazepine. Oxcarbazepine is more likely to cause hyponatremia than carbamazepine. Approximately 3 to 5 percent of patients taking oxcarbazepine develop this side effect. It is advisable to obtain serum sodium concentrations early in the course of treatment because hyponatremia may be clinically silent. In severe cases, confusion and seizure may occur.

Dosing and Administration

Oxcarbazepine dosing for bipolar disorder has not been established. It is available in 150-, 300-, and 600-mg tablets. The dose range may vary from 150 to 2,400 mg per day given in divided doses twice a day. In clinical trials for mania, the doses typically used were from 900 to 1,200 mg per day with a starting dose of 150 or 300 mg at night.

Drug Interactions

Drugs such as phenobarbital and alcohol, which induce CYP3A4, increase the clearance and reduce oxcarbazepine concentrations. Oxcarbazepine induces CYP3A4/5 and inhibits CYP2C19, which may affect the metabolism of drugs that use that pathway. Women taking oral contraceptives should be told to consult with their gynecologists because oxcarbazepine may reduce concentrations of their contraceptive and thus decrease its efficacy.

29.14 Cholinesterase Inhibitors and Memantine

Donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) are cholinesterase inhibitors used to treat mild to moderate cognitive impairment in dementia of the Alzheimer's type. They reduce the inactivation of the neurotransmitter acetylcholine and, thus, potentiate cholinergic neurotransmission, which in turn produces a modest improvement in memory and goal-directed thought. Memantine (Namenda) is not a cholinesterase inhibitor, producing its effects through blockade of N-methyl-D-aspartate (NMDA) receptors. Unlike the cholinesterase inhibitors, which are indicated for the mild to moderate stages of Alzheimer's disease, memantine is indicated for the moderate to severe stages of the disease. Tacrine (Cognex), the first cholinesterase inhibitor to be introduced, is no longer used because of its multiple daily dosing regimens, its potential for hepatotoxicity, and the consequent need for frequent laboratory monitoring. Routine clinical practice often combines a cholinesterase inhibitor with memantine, and recent studies have shown that this combination may provide beneficial response compared with only cholinesterase inhibitor pharmacotherapy.

PHARMACOLOGICAL ACTIONS

Donepezil is absorbed completely from the gastrointestinal (GI) tract. Peak plasma concentrations are reached about 3 to 4 hours after oral dosing. The half-life of donepezil is 70 hours in elderly persons, and it is taken only once daily. Steady-state levels are achieved within about 2 weeks. The presence of stable alcoholic cirrhosis reduces clearance of donepezil by 20 percent. Rivastigmine (Exelon) is rapidly and completely absorbed from the GI tract and reaches peak plasma concentrations in 1 hour, but this is delayed by up to 90 minutes if rivastigmine is taken with food. The half-life of rivastigmine is 1 hour, but because it remains bound to cholinesterases, a single dose is therapeutically active for 10 hours, and it is taken twice daily. Galantamine (Reminyl) is an alkaloid similar to codeine and is extracted from daffodils of the plant *Galanthus nivalis*. It is readily absorbed, with maximum concentrations reached after 30 minutes to 2 hours. Food decreases the maximum concentration by 25 percent. The elimination half-life of galantamine is approximately 6 hours.

Tacrine (Cognex) is absorbed rapidly from the GI tract. Peak plasma concentrations are reached about 90 minutes after oral dosing. The half-life of tacrine is about 2 to 4 hours, thereby necessitating four-times-daily dosing.

The primary mechanism of action of cholinesterase inhibitors is reversible, nonacylating inhibition of acetylcholinesterase and butyrylcholinesterase, the enzymes that catabolize acetylcholine in the central nervous system (CNS). The enzyme inhibition increases synaptic concentrations of acetylcholine, especially in the hippocampus and cerebral cortex. Unlike tacrine, which is nonselective for all forms of acetylcholinesterase, donepezil appears to be selectively active within the CNS and has little activity in the periphery. Donepezil's favorable side effect profile appears to correlate with its lack of inhibition of cholinesterases in the GI tract. Rivastigmine appears to have somewhat more peripheral activity than donepezil and is thus more likely to cause GI adverse effects than is donepezil.

THERAPEUTIC INDICATIONS

Cholinesterase inhibitors are effective for the treatment of mild to moderate cognitive impairment in dementia of the Alzheimer's type. In long-term use, they slow the progression of memory loss and diminish apathy, depression, hallucinations, anxiety, euphoria, and purposeless motor behaviors. Functional autonomy is less well preserved. Some persons note immediate improvement in memory, mood, psychotic symptoms, and interpersonal skills. Others note little initial benefit but are able to retain their cognitive and adaptive faculties at a relatively stable level for many months. A practical benefit of cholinesterase inhibitor use is a delay or reduction of the need for nursing home placement.

Donepezil and rivastigmine may be beneficial for patients with Parkinson's disease and Lewy body disease and for treatment of cognitive deficits caused by traumatic brain injury. Donepezil is under study for treatment of mild cognitive impairment that is less severe than that caused by Alzheimer's disease. People with vascular dementia may respond to acetylcholinesterase inhibitors. Occasionally, cholinesterase inhibitors elicit an idiosyncratic catastrophic reaction, with signs of grief and agitation, which is self-limited after the drug is discontinued. Use of cholinesterase inhibitors to improve cognition by nondemented individuals should be discouraged.

PRECAUTIONS AND ADVERSE REACTIONS

Donepezil

Donepezil is generally well tolerated at recommended dosages. Fewer than 3 percent of those taking donepezil experience nausea, diarrhea, and vomiting. These mild symptoms are more common with a 10-mg dose than with a 5-mg dose, and when present, they tend to resolve after 3 weeks of continued use. Donepezil may cause weight loss. Donepezil treatment has been infrequently associated with bradyarrhythmias, especially in those with underlying cardiac disease. A small number of persons experience syncope.

Rivastigmine

Rivastigmine is generally well tolerated, but recommended dosages may need to be scaled back in the initial period of treatment to limit GI and CNS adverse effects. These mild symptoms are more common at dosages above 6 mg a day, and when present, they tend to resolve after the dosage is lowered. The most common adverse effects associated with rivastigmine are nausea, vomiting, dizziness, headache, diarrhea, abdominal pain, anorexia, fatigue, and somnolence. Rivastigmine may cause weight loss, but it does not appear to cause hepatic, renal, hematologic, or electrolyte abnormalities.

Galantamine

The most common side effects of galantamine are dizziness, headache, nausea, vomiting, diarrhea, and anorexia. These side effects tend to be mild and transient.

Tacrine

Tacrine is the least used of the cholinesterase inhibitors but requires more discussion than the others because it is cumbersome to titrate and use, and it poses the risk of potentially significant elevations in hepatic transaminase levels. These increases occur in 25 to 30 percent of persons. Aside from elevated transaminase levels, the most common specific adverse effects associated with tacrine treatment are nausea, vomiting, myalgia, anorexia, and rash, but only nausea, vomiting, and anorexia have been found to have a clear relation to the dosage. Transaminase elevations characteristically develop during the first 6 to 12 weeks of treatment, and cholinergically mediated events are dosage related.

Hepatotoxicity. Tacrine is associated with increases in the plasma activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The ALT measurement is the more sensitive indicator of the hepatic effects of tacrine. About 95 percent of patients who develop elevated ALT serum levels do so in the first 18 weeks of treatment. The average length of time for elevated ALT concentrations to return to normal after stopping tacrine treatment is 4 weeks.

For routine monitoring of hepatic enzymes, AST and ALT activities should be measured weekly for the first 18 weeks, every month for the second 4 months, and every 3 months thereafter. Weekly assessments of AST and ALT should be performed for at least 6 weeks after any increase in dosage. Patients with mildly elevated ALT activity should be monitored weekly and not be rechallenged with tacrine until the ALT activity returns to the normal range. For any patient with elevated ALT activity and jaundice, tacrine treatment should be stopped, and the patient should not be given the drug again.

Table 29.14-1 summarizes the incidence of major adverse side effects associated with each of the cholinesterase inhibitors.

Table 29.14-1
Incidence of Major Adverse Side Effects with Cholinesterase Inhibitors (%)

Drug	Dose (mg/day)	Nausea	Vomiting	Diarrhea	Dizziness	Muscle Cramps	Insomnia
Donepezil	5	4	3	9	15	9	7
Donepezil	10	17	10	17	13	12	8
Rivastigmine	1-4	14	7	10	15	NR	NR
Rivastigmine	6-12	48	27	17	24	NR	NR
Galantamine	8	5.7	3.6	5	NR	NR	NR
Galantamine	16	13.3	6.1	12.2	NR	NR	NR
Galantamine	24	16.5	9.9	5.5	NR	NR	NR

NR, not reported from clinical trial data; incidence less than 5%.

Drug Interactions

All cholinesterase inhibitors should be used cautiously with drugs that also possess cholinomimetic activity, such as succinylcholine (Anectine) and bethanechol (Urecholine). The coadministration of cholinesterase inhibitors and drugs that have cholinergic antagonist activity (e.g., tricyclic drugs) is probably counterproductive. Paroxetine (Paxil) has the most marked anticholinergic effects of any of the newer antidepressant and anxiolytic drugs and should be avoided for that reason, as well as its inhibiting effect on the metabolism of some of the cholinesterase inhibitors.

Donepezil undergoes extensive metabolism via both CYP2D6 and 3A4 isozymes. The metabolism of donepezil may be increased by phenytoin (Dilantin), carbamazepine (Tegretol), dexamethasone (Decadron), rifampin (Rifadin), and phenobarbital (Solfoton). Commonly used agents such as paroxetine, ketoconazole (Nizoral), and erythromycin can significantly increase donepezil concentrations. Donepezil is highly protein bound, but it does not displace other protein-bound drugs, such as furosemide (Lasix), digoxin (Lanoxin), or warfarin (Coumadin). Rivastigmine circulates mostly unbound to serum proteins and has no significant drug interactions.

Similar to donepezil, galantamine is metabolized by both CYP2D6 and 3A4 isozymes and thus may interact with drugs that inhibit these pathways. Paroxetine and ketoconazole should be used with great caution.

Laboratory Interferences

No laboratory interferences have been associated with the use of cholinesterase inhibitors.

Dosage and Clinical Guidelines

Before initiation of cholinesterase inhibitor therapy, potentially treatable causes of dementia should be ruled out and the diagnosis of dementia of the Alzheimer's type established.

Donepezil is available in 5- and 10-mg tablets. Treatment should be initiated at 5 mg each night. If well tolerated and of some discernible benefit after 4 weeks, the dosage should be increased to a maintenance dosage of 10-mg each night. Donepezil absorption is unaffected by meals.

Rivastigmine is available in 1.5-, 3-, 4.5-, and 6-mg capsules. The recommended initial dosage is 1.5 mg twice daily for a minimum of 2 weeks, after which increases of 1.5 mg a day can be made at intervals of at least 2 weeks to a target dosage of 6 mg a day, taken in two

equal dosages. If tolerated, the dosage may be further titrated upward to a maximum of 6 mg twice daily. The risk of adverse GI events can be reduced by administration of rivastigmine with food.

Galantamine is available in 4-, 8-, and 16-mg tablets. The suggested dose range is 16 to 32 mg per day given twice a day. The higher dose is actually better tolerated than the lower dose. The initial dosage is 8 mg per day, and after a minimum of 4 weeks, the dose can be raised. All subsequent dosage increases should occur at 4-week intervals and should be based on tolerability.

Tacrine is available in 10-, 20-, 30-, and 40-mg capsules. Before the initiation of tacrine treatment, a complete physical and laboratory examination should be conducted, with special attention to liver function tests and baseline hematologic indexes. Treatment should be initiated at 10 mg four times a day and then raised by increments of 10 mg a dose every 6 weeks up to 160 mg a day; the person's tolerance of each dosage is indicated by the absence of unacceptable side effects and lack of elevation of ALT activity. Tacrine should be given four times daily—ideally 1 hour before meals because the absorption of tacrine is reduced by about 25 percent when it is taken during the first 2 hours after meals. If tacrine is used, the specific guidelines for tacrine-induced ALT listed above should be followed.

MEMANTINE

Pharmacological Actions

Memantine is well absorbed after oral administration, with peak concentrations reached in about 3 to 7 hours. Food has no effect on the absorption of memantine. Memantine has linear pharmacokinetics over the therapeutic dosage range and has a terminal elimination half-life of about 60 to 80 hours. Plasma protein binding is 45 percent.

Memantine undergoes little metabolism, with the majority (57 to 82 percent) of an administered dose excreted unchanged in urine; the remainder is converted primarily to three polar metabolites: the *N*-gludantan conjugate, 6-hydroxy memantine, and 1-nitroso-deaminated memantine. These metabolites possess minimal NMDA receptor antagonist activity. Memantine is a low- to moderate-affinity NMDA receptor antagonist. It is thought that overexcitation of NMDA receptors by the neurotransmitter glutamate may play a role in Alzheimer's disease because glutamate plays an integral role in the neural pathways associated with learning and memory. Excess glutamate overstimulates NMDA receptors to allow too much calcium into nerve cells, leading to the eventual cell death observed in Alzheimer's disease. Memantine may protect cells against excess glutamate by partially blocking NMDA receptors associated with abnormal transmission of glutamate while allowing for physiologic transmission associated with normal cell functioning.

Therapeutic Indications

Memantine is the only approved therapy in the United States for moderate to severe Alzheimer's disease.

Precautions and Adverse Reactions

Memantine is safe and well tolerated. The most common adverse effects are dizziness, headache, constipation, and confusion. The use of memantine in patients with severe renal impairment is not recommended. In a documented case of an overdose with up to 400 mg of memantine, the patient experienced restlessness, psychosis, visual hallucinations, somnolence, stupor, and loss of consciousness. The patient recovered without permanent sequelae.

Drug Interactions

In vitro studies conducted with marker substrates of CYP450 enzymes (CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4) showed minimal inhibition of these enzymes by memantine. No pharmacokinetic interactions with drugs metabolized by these enzymes are expected.

Because memantine is eliminated in part by tubular secretion, coadministration of drugs that use the same renal cationic system, including hydrochlorothiazide triamterene (Dyrenium), cimetidine (Tagamet), ranitidine (Zantac), quinidine, and nicotine, could potentially result in altered plasma levels of both agents. Coadministration of memantine and a combination of hydrochlorothiazide and triamterene did not affect the bioavailability of either memantine or triamterene, and the bioavailability of hydrochlorothiazide decreased by 20 percent.

Urine pH is altered by diet, drugs (e.g., carbonic anhydrase inhibitors, topiramate [Topamax], sodium bicarbonate), and the clinical state of the patient (e.g., renal tubular acidosis or severe infections of the urinary tract). The clearance of memantine is reduced by about 80 percent under alkaline urine conditions at pH 8. Therefore, alterations of urine pH toward the alkaline condition may lead to an accumulation of the drug with a possible increase in adverse effects. Hence, memantine should be used with caution under these conditions.

Laboratory Interferences

No laboratory interferences have been associated with the use of memantine.

Dosage and Clinical Guidelines

Memantine is available in 5- and 10-mg tablets, with a recommended starting dose of 5 mg daily. The recommended target dose is 20 mg per day. The drug is administered twice daily in separate doses with 5-mg increment increases weekly depending on tolerability.

Patients with mild to moderate disease receiving memantine in combination with a cholinesterase inhibitor have not been found to experience significantly greater benefit in cognition or overall function than those who receive a cholinesterase inhibitor alone.

▲ 29.15 Disulfiram and Acamprostate

Disulfiram (Antabuse) and acamprostate (Campral) are drugs used to treat alcohol dependence. Disulfiram has suffered from a reputation as a dangerous medication only suitable for highly motivated and strictly supervised drinkers because of the severe physical reactions the drug causes after drinking. Experience has shown, however, that at recommended doses it is an acceptable and safe medication for dependent drinkers seeking to sustain abstinence. The properties that constitute disulfiram's main therapeutic effect (i.e., the ability to produce unpleasant symptoms after alcohol intake, also known as disulfiram–alcohol reaction) have created that perception of dangerousness.

In the most severe cases, when disulfiram is combined with alcohol serious clinical conditions can occur. These include respiratory depression, cardiovascular collapse, acute heart failure, convulsions, loss of consciousness, and death in rare cases. These potential complications as well as the development of alternative antialcohol medications have been the limiting factors for the wider use of disulfiram. Unlike disulfiram, acamprostate, the other drug discussed in this section, does not produce aversive side effects. Acamprostate is now prescribed more commonly than disulfiram in outpatient settings, but disulfiram is prescribed more often in inpatient settings because it helps facilitate initial abstinence.

Other drugs that are useful in reducing alcohol consumption include naltrexone (ReVia, Trexan), nalmefene (Revex), topiramate (Topamax), and gabapentin (Neurontin). These agents are discussed in their respective sections.

DISULFIRAM

Pharmacologic Actions

Disulfiram is almost completely absorbed from the gastrointestinal (GI) tract after oral administration. Its half-life is estimated to be 60 to 120 hours. Therefore, 1 or 2 weeks may be needed before disulfiram is totally eliminated from the body after the last dose has been taken.

The metabolism of ethanol proceeds through oxidation via alcohol dehydrogenase to the formation of acetaldehyde, which is further metabolized to acetyl-coenzyme A (acetyl-CoA) by aldehyde dehydrogenase. Disulfiram is an aldehyde dehydrogenase inhibitor that interferes with the metabolism of alcohol by producing a marked increase in blood acetaldehyde concentration. The accumulation of acetaldehyde (to a level up to 10 times higher than occurs in the normal metabolism of alcohol) produces a wide array of unpleasant reactions, called the *disulfiram–alcohol reaction*, characterized by nausea, throbbing headache, vomiting, hypertension, flushing, sweating, thirst, dyspnea, tachycardia, chest pain, vertigo, and blurred vision. The reaction occurs almost immediately after the ingestion of one alcoholic drink and may last from 30 minutes to 2 hours.

Blood Concentrations in Relation to Action. Plasma concentrations of disulfiram varies among individuals because of a number of factors, most notably age and hepatic function. In general, the severity of disulfiram–alcohol reaction has been shown to be proportional to the amount of the ingested disulfiram and alcohol. Nevertheless, disulfiram plasma levels are rarely obtained in clinical practice. The positive correlation between plasma concentrations of alcohol and the intensity of the reaction is described as follows: in sensitive individuals, as little as 5 to 10 mg per 100 mL increase of the plasma alcohol level may produce mild symptoms; fully developed symptoms occur at alcohol levels of 50 mg per 100 mL; and levels as high as 125 to 150 mg per 100 mL result in loss of consciousness and coma.

Therapeutic Indications

The primary indication for disulfiram use is as an aversive conditioning treatment for alcohol dependence. Either the fear of having a disulfiram–alcohol reaction or the memory of having had one is meant to condition the person not to use alcohol. Usually, describing the severity and the unpleasantness of the disulfiram–alcohol reaction graphically enough discourages the person from imbibing alcohol. Disulfiram treatment should be combined with such treatments as psychotherapy, group therapy, and support groups such as Alcoholics Anonymous (AA). Treatment with disulfiram requires careful monitoring because a person can simply decide not to take the medication.

Precautions and Adverse Reactions

With Alcohol Consumption. The intensity of the disulfiram–alcohol reaction varies with each person. In extreme cases, it is marked by respiratory depression, cardiovascular collapse, myocardial infarction, convulsions, and death. Therefore, disulfiram is contraindicated for persons with significant pulmonary or cardiovascular disease. In addition, disulfiram should be used with caution, if at all, by persons with nephritis, brain damage, hypothyroidism, diabetes, hepatic disease, seizures, polydrug dependence, or an abnormal electroencephalogram. Most fatal reactions occur in persons who take more than 500 mg a day of disulfiram and who consume more than 3 oz of alcohol. The treatment of a severe disulfiram–alcohol reaction is primarily supportive to prevent shock. The use of oxygen, intravenous vitamin C, ephedrine, and antihistamines has been reported to aid in recovery.

Without Alcohol Consumption. The adverse effects of disulfiram in the absence of alcohol consumption include fatigue, dermatitis, impotence, optic neuritis, a variety of mental changes, and hepatic damage. A metabolite of disulfiram inhibits dopamine- β -hydroxylase, the enzyme that metabolizes dopamine into norepinephrine and epinephrine, and thus may exacerbate psychosis in persons with psychotic disorders. Catatonic reactions may also occur.

Drug Interactions

Disulfiram increases the blood concentration of diazepam (Valium), paraldehyde, phenytoin (Dilantin), caffeine, tetrahydrocannabinol (the active ingredient in marijuana), barbiturates, anticoagulants, isoniazid (Nydrazid), and tricyclic drugs. Disulfiram should not be administered concomitantly with paraldehyde because paraldehyde is metabolized to acetaldehyde in the liver.

Laboratory Interferences

In rare instances, disulfiram has been reported to interfere with the incorporation of iodine-131 into protein-bound iodine. Disulfiram may reduce urinary concentrations of homovanillic acid, the major metabolite of dopamine, because of its inhibition of dopamine hydroxylase.

Dosage and Clinical Guidelines

Disulfiram is supplied in 250- and 500-mg tablets. The usual initial dosage is 500 mg a day taken by mouth for the first 1 or 2 weeks followed by a maintenance dosage of 250 mg a day. The dosage should not exceed 500 mg a day. The maintenance dosage range is 125 to 500 mg a day.

Persons taking disulfiram must be instructed that the ingestion of even the smallest amount of alcohol will bring on a disulfiram–alcohol reaction, with all of its unpleasant effects. In addition, persons should be warned against ingesting any alcohol-containing preparations, such as cough drops, tonics of any kind, and alcohol-containing foods and sauces. Some reactions have occurred in patients who used alcohol-based lotions, toilet water, colognes, or perfumes and inhaled the fumes; therefore, precautions must be explicit and should include any topically applied preparations containing alcohol, such as perfume.

Disulfiram should not be administered until the person has abstained from alcohol for at least 12 hours. Persons should be warned that the disulfiram–alcohol reaction may occur as long as 1 or 2 weeks after the last dose of disulfiram. Persons taking disulfiram should carry identification cards describing the disulfiram–alcohol reaction and listing the name and telephone number of the physician to be called.

ACAMPROSATE

Pharmacologic Actions

Acamprosate's mechanism of action is not fully understood, but it is thought to antagonize neuronal overactivity related to the actions of the excitatory neurotransmitter glutamate. In part, this may result from antagonism of *N*-methyl-*D*-aspartate (NMDA) receptors.

Indications

Acamprosate is used for treating alcohol-dependent individuals seeking to continue to remain alcohol free after they have stopped drinking. Its efficacy in promoting abstinence has not been demonstrated in persons who have not undergone detoxification and who have not achieved alcohol abstinence before beginning treatment.

Precautions and Adverse Effects

Side effects are mostly seen early in treatment and are usually mild and transient in nature. The most common side effects are headache, diarrhea, flatulence, abdominal pain, paresthesias, and various skin reactions. No adverse events occur after abrupt withdrawal of acamprosate, even after long-term use. There is no evidence of addiction to the drug. Patients with severe renal impairment (creatinine clearance of less than 30 mL per minute) should not be given acamprosate.

Drug Interactions

The concomitant intake of alcohol and acamprosate does not affect the pharmacokinetics of either alcohol or acamprosate. Administration of disulfiram or diazepam does not affect the pharmacokinetics of acamprosate. Coadministration of naltrexone with acamprosate produces an increase in concentrations of acamprosate. No adjustment of dosage is recommended in such patients. The pharmacokinetics of naltrexone and its major metabolite 6- β -naltrexol were unaffected after coadministration with acamprosate. During clinical trials, patients taking acamprosate concomitantly with antidepressants more commonly reported both weight gain and weight loss compared with patients taking either medication alone.

Laboratory Interferences

Acamprosate has not been shown to interfere with commonly done laboratory tests.

Dosage and Clinical Guidelines

It is important to remember that acamprosate should not be used to treat alcohol withdrawal symptoms. It should only be started after the individual has been successfully weaned off alcohol. Patients should show a commitment to remaining abstinent, and treatment should be part of a comprehensive management program that includes counseling or support group attendance.

Each tablet contains acamprosate calcium 333 mg, which is equivalent to 300 mg of acamprosate. The dose of acamprosate is different for different patients. The recommended dosage is two 333-mg tablets (each dose should total 666 mg) taken three times daily. Although dosing may be done without regard to meals, dosing with meals was used during clinical trials and is suggested as an aid to compliance in patients who regularly eat three meals daily. A lower dose may be effective in some patients. A missed dose should be taken as soon as possible. However, if it is almost time for the next dose, the missed dose should be skipped, and then the regular dosing schedule should be resumed. Doses should not be doubled up. For patients with moderate renal impairment (creatinine clearance of 30 to 50 mL minute), a starting dosage of one 333-mg tablet taken three times daily is recommended. People with severe renal insufficiency should not take acamprosate.

29.16 Dopamine Receptor Agonists and Precursors

Dopamine agonists activate dopamine receptors in the absence of endogenous dopamine and have been widely used to treat idiopathic Parkinson's disease, hyperprolactinemia, and certain pituitary tumors (prolactinoma). Because dopamine stimulates the heart and increases blood flow to the liver, kidneys, and other organs, low levels of dopamine are associated with low blood pressure and low cardiac input. Dopamine agonist drugs are also administered to treat shock and congestive heart failure.

Their use in psychiatry has been limited to treat such adverse effects of antipsychotic drugs as parkinsonism, extrapyramidal symptoms, akinesia, focal perioral tremors, hyperprolactinemia, galactorrhea, and neuroleptic malignant syndrome. The drugs in this class most commonly prescribed are bromocriptine (Parlodel), levodopa (also called *L*-Dopa; Larodopa), carbidopa-levodopa (Sinemet), and amantadine (Symmetrel). Amantadine is used primarily for the treatment of medication-induced movement disorders, such as neuroleptic-induced parkinsonism. It is also used as an antiviral agent for the prophylaxis and treatment of influenza A infection and Cotard's syndrome, a rare neuropsychiatric disorder in which a person holds a delusional belief that he or she is dead. There are also a few reports of amantadine's role in augmenting antidepressant medications in patients with treatment-resistant depression.

New dopamine receptor agonists include ropinirole (Requip), pramipexole (Mirapex), apomorphine (Apokyn), and pergolide (Permax). Of these drugs, pramipexole is the most widely prescribed in psychiatry as an augmentor of antidepressants. In 2007, pergolide was removed from the market because of the risk of serious damage to patients' heart valves. In 2012, the U.S. Food and Drug Administration (FDA) notified health care professionals about a possible increased risk of heart failure with pramipexole. This warning was based on studies that suggested a potential risk of heart failure; however, further review is required because of study limitations.

PHARMACOLOGICAL ACTIONS

l-Dopa is rapidly absorbed after oral administration, and peak plasma levels are reached after 30 to 120 minutes. The half-life of l-Dopa is 90 minutes. Absorption of l-Dopa can be significantly reduced by changes in gastric pH and by ingestion with meals. Bromocriptine and ropinirole are rapidly absorbed but undergo first-pass metabolism such that only about 30 to 55 percent of the dose is bioavailable. Peak concentrations are achieved 1.5 to 3 hours after oral administration. The half-life of ropinirole is 6 hours. Pramipexole is rapidly absorbed with little first-pass metabolism and reaches peak concentrations in 2 hours. Its half-life is 8 hours. Oral forms of apomorphine have been studied, but this form is not available in the United States. Subcutaneous apomorphine injection results in rapid and controlled systemic delivery, with linear pharmacokinetics over a dose ranging from 2 to 8 mg.

After l-Dopa enters the dopaminergic neurons of the central nervous system (CNS), it is converted into the neurotransmitter dopamine. Apomorphine, bromocriptine, ropinirole, and pramipexole act directly on dopamine receptors. l-Dopa, pramipexole, and ropinirole bind about 20 times more selectively to dopamine D₃ than D₂ receptors; the corresponding ratio for bromocriptine is less than 2 to 1. Apomorphine binds selectively to D₁ and D₂ receptors, with little affinity for D₃ and D₄ receptors. l-Dopa, pramipexole, and ropinirole have no significant activity at nondopaminergic receptors, but bromocriptine binds to serotonin 5-HT₁ and 5-HT₂ and α_1 -, α_2 -, and β -adrenergic receptors.

THERAPEUTIC INDICATIONS

Medication-induced Movement Disorders

In present-day clinical psychiatry, dopamine receptor agonists are used for the treatment of medication-induced parkinsonism, extrapyramidal symptoms, akinesia, and focal perioral tremors. Their use has diminished sharply, however, because the incidence of medication-induced movement disorders is much lower with the use of the newer, atypical antipsychotics (serotonin-dopamine antagonists). Dopamine receptor agonists are effective in treating idiopathic restless legs syndrome and may also be helpful when this is a medication side effect. Ropinirole has an indication for restless legs syndrome.

For the treatment of medication-induced movement disorders, most clinicians rely on anticholinergics, amantadine, and antihistamines because they are equally effective and have few adverse effects. Bromocriptine remains in use in the treatment of neuroleptic malignant syndrome; however, the incidence of this disorder is diminishing with the decreased use of dopamine receptor antagonists (DRAs).

Dopamine receptor agonists are also used to counteract the hyperprolactinemic effects of DRAs, which result in the side effects of amenorrhea and galactorrhea.

Mood Disorders

Bromocriptine has long been used to enhance response to antidepressant drugs in refractory patients. Ropinirole has been reported to be useful as augmentation to antidepressant therapy and as a treatment for medication-resistant bipolar II depression. Ropinirole may also be helpful in the treatment of antidepressant-induced sexual dysfunction. Pramipexole is often used in the augmentation of antidepressants in treatment-resistant depression. Some studies have found pramipexole to be superior to sertraline (Zoloft) in the treatment of depression in Parkinson's disease, as well as reducing anhedonia in Parkinson's patients.

Sexual Dysfunction

Dopamine receptor agonists improve erectile dysfunction in some patients. However, they are rarely used because they frequently cause adverse effects at therapeutic dosages. Phosphodiesterase-5 inhibitor agents are better tolerated and more effective (see [Section 29.26](#)).

PRECAUTIONS AND ADVERSE REACTIONS

Adverse effects are common with dopamine receptor agonists, thus limiting the usefulness of these drugs. Adverse effects are dosage dependent and include nausea, vomiting, orthostatic hypotension, headache, dizziness, and cardiac arrhythmias. To reduce the risk of orthostatic hypotension, the initial dosage of all dopamine receptor agonists should be quite low, with incremental increases at intervals of at least 1 week. These drugs should be used with caution in persons with hypertension, cardiovascular disease, and hepatic disease. After long-term use, persons, particularly elderly persons, may experience choreiform and dystonic movements and psychiatric disturbances—including hallucinations, delusions, confusion, depression, and mania—and other behavioral changes.

Long-term use of bromocriptine can produce retroperitoneal and pulmonary fibrosis, pleural effusions, and pleural thickening.

In general, ropinirole and pramipexole have a similar but milder adverse effect profile than l-Dopa and bromocriptine. Pramipexole and ropinirole may cause irresistible sleep attacks that occur suddenly without warning and have caused motor vehicle accidents.

The most common adverse effects of apomorphine are yawning, dizziness, nausea, vomiting, drowsiness, bradycardia, syncope, and perspiration. Hallucinations have also been reported. Apomorphine's sedative effects are exacerbated with concurrent use of alcohol or other CNS depressants.

Dopamine receptor agonists are contraindicated during pregnancy, especially for nursing mothers, because they inhibit lactation.

DRUG INTERACTIONS

DRAs are capable of reversing the effects of dopamine receptor agonists, but this is not usually clinically significant. The concurrent use of tricyclic drugs and dopamine receptor agonists has been reported to cause symptoms of neurotoxicity, such as rigidity, agitation, and tremor. They may also potentiate the hypotensive effects of diuretics and other antihypertensive medications. Dopamine receptor agonists should not be used in conjunction with monoamine oxidase inhibitors (MAOIs), including selegiline (Eldepryl), and MAOIs should be discontinued at least 2 weeks before the initiation of dopamine receptor agonist therapy.

Benzodiazepines, phenytoin (Dilantin), and pyridoxine may interfere with the therapeutic effects of dopamine receptor agonists. Ergot alkaloids and bromocriptine should not be used concurrently because they may cause hypertension and myocardial infarction. Progestins, estrogens, and oral contraceptives may interfere with the effects of bromocriptine and may raise plasma concentrations of ropinirole. Ciprofloxacin (Cipro) can raise plasma concentrations of ropinirole, and cimetidine (Tagamet) can raise plasma concentrations of pramipexole.

LABORATORY INTERFERENCES

l-Dopa administration has been associated with false reports of elevated serum and urinary uric acid concentrations, urinary glucose test results, urinary ketone test results, and urinary catecholamine concentrations. No laboratory interferences have been associated with the administration of the other dopamine receptor agonists.

DOSAGE AND CLINICAL GUIDELINES

Table 29.16-1 lists the various dopamine receptor agonists and their formulations. For the treatment of antipsychotic-induced parkinsonism, the clinician should start with a 100-mg dose of levodopa three times a day, which may be increased until the person is functionally improved. The maximum dosage of l-Dopa is 2,000 mg a day, but most persons respond to dosages below 1,000 mg per day. The dosage of the carbidopa component of the l-Dopa-carbidopa formulation should total at least 75 mg a day.

Table 29.16-1
A available Preparations of Dopamine Receptor Agonists and Carbidopa

Generic Name	Trade Name	Preparations
Amantadine	Symmetrel	100-mg capsule, 50-mg/5-mL syrup (teaspoon)
Bromocriptine	Parlodel	2.5-, 5-mg tablets
Carbidopa	Lodosyn	25 mg ^a
Levodopa (l-Dopa)	Larodopa	100-, 250-, 500-mg tablets
Levodopa-carbidopa (co-careldopa)	Sinemet, Atamet	100/10-mg, 100/25-mg, 250/25-mg tablets; 100/25-, 200/50-mg extended-release tablets
Pramipexole	Mirapex	0.125-, 0.375-, 0.75-, 1.5-, 3-, 4-mg extended-release tablets
Ropinirole	Requip	0.25-, 0.5-, 1-, 2-, 5-mg tablets

^aDrug only available directly through the manufacturer.

The dosage of bromocriptine for mental disorders is uncertain, although it seems prudent to begin with low dosages (1.25 mg twice daily) and to increase the dosage gradually. Bromocriptine is usually taken with meals to help reduce the likelihood of nausea.

The starting dosage of pramipexole is 0.125 mg three times daily, which is increased to 0.25 mg three times daily in the second week and is increased by 0.25 mg per dose each week until therapeutic benefit or adverse effects emerge. Persons with idiopathic Parkinson's disease usually experience benefit at total daily doses of 1.5 mg, and the maximum daily dose is 4.5 mg.

For ropinirole, the starting dosage is 0.25 mg three times daily and is increased by 0.25 mg per dose each week to a total daily dose of 3 mg, then by 0.5 mg per dose each week to a total daily dose of 9 mg, and then by 1 mg per dose each week to a maximum dosage of 24 mg a day until therapeutic benefit or adverse effects emerge. The average daily dose for persons with idiopathic Parkinson's disease is about 16 mg.

The recommended subcutaneous dose of apomorphine in Parkinson's disease is 0.2 to 0.6 mL subcutaneously during acute hypomobility episodes delivered via metered injector pen. Apomorphine can be administered three times daily, with a maximum dose of 0.6 mL five times daily.

AMANTADINE

Amantadine is an antiviral drug used for the prophylaxis and treatment of influenza. It was found to have antiparkinsonian properties and is now used to treat that disorder as well as akinesias and other extrapyramidal signs, including focal perioral tremors (rabbit syndrome).

Pharmacologic Actions

Amantadine is well absorbed from the GI tract after oral administration, reaches peak plasma concentrations in approximately 2 to 3 hours, has a half-life of about 12 to 18 hours, and attains steady-state concentrations after approximately 4 to 5 days of therapy. Amantadine is excreted unmetabolized in the urine. Amantadine plasma concentrations can be twice as high in elderly persons as in younger adults. Patients with renal failure accumulate amantadine in their bodies.

Amantadine augments dopaminergic neurotransmission in the CNS; however, the precise mechanism for the effect is unknown. The mechanism may involve dopamine release from presynaptic vesicles, blocking reuptake of dopamine into presynaptic nerve terminals, or an agonist effect on postsynaptic dopamine receptors.

Therapeutic Indications

The primary indication for amantadine use in psychiatry is to treat extrapyramidal signs and symptoms, such as parkinsonism, akinesia, and rabbit syndrome (focal perioral tremor of the choreoathetoid type) caused by the administration of DRA or SDA drugs. Amantadine is as effective as the anticholinergics (e.g., benzotropine [Cogentin]) for these indications and results in improvement in approximately half of all persons who take it. Amantadine, however, is not generally considered as effective as the anticholinergics for the treatment of acute dystonic reactions and is not effective in treating tardive dyskinesia and akathisia.

Amantadine is a reasonable compromise for persons with extrapyramidal symptoms who would be sensitive to additional anticholinergic effects, particularly those taking a low-potency DRA or the elderly. Elderly persons are susceptible to anticholinergic adverse effects, both in the CNS, such as anticholinergic delirium, and in the peripheral nervous system, such as urinary retention. Amantadine is associated with less memory impairment than are the anticholinergics.

Amantadine has been reported to be of benefit in treating some selective serotonin reuptake inhibitor-associated side effects, such as lethargy, fatigue, anorgasmia, and ejaculatory inhibition.

Amantadine is used in general medical practice for the treatment of parkinsonism of all causes, including idiopathic parkinsonism.

Precautions and Adverse Effects

The most common CNS effects of amantadine are mild dizziness, insomnia, and impaired concentration (dosage related), which occur in 5 to 10 percent of all persons. Irritability, depression, anxiety, dysarthria, and ataxia occur in 1 to 5 percent of all persons. More severe CNS adverse effects, including seizures and psychotic symptoms, have been reported. Nausea is the most common peripheral adverse effect of amantadine. Headache, loss of appetite, and blotchy spots on the skin have also been reported.

Livedo reticularis of the legs (a purple discoloration of the skin caused by dilation of blood vessels) has been reported in up to 5 percent of persons who take the drug for longer than 1 month. It usually diminishes with elevation of the legs and resolves in almost all cases when drug use is terminated.

Amantadine is relatively contraindicated in persons with renal disease or a seizure disorder. Amantadine should be used with caution in persons with edema or cardiovascular disease. Some evidence indicates that amantadine is teratogenic and therefore should not be taken by pregnant women. Because amantadine is excreted in breast milk, women who are breast-feeding should not take the drug.

Suicide attempts with amantadine overdoses are life-threatening. Symptoms can include toxic psychoses (confusion, hallucinations, aggressiveness) and cardiopulmonary arrest. Emergency treatment beginning with gastric lavage is indicated.

Drug Interactions

Coadministration of amantadine with phenelzine (Nardil) or other MAOIs can result in a significant increase in resting blood pressure. The coadministration of amantadine with CNS stimulants can result in insomnia, irritability, nervousness, and possibly seizures or irregular heartbeat. Amantadine should not be coadministered with anticholinergics because unwanted side effects—such as confusion, hallucinations, nightmares, dry mouth, and blurred vision—may be exacerbated.

Dosage and Clinical Guidelines

Amantadine is available in 100-mg capsules and as a 50-mg per 5-mL syrup. The usual starting dosage of amantadine is 100 mg given orally twice a day, although the dosage can be cautiously increased up to 200 mg given orally twice a day if indicated. Amantadine should be used in persons with renal impairment *only* in consultation with the physician treating the renal condition. If amantadine is successful in the treatment of the drug-induced extrapyramidal symptoms, it should be continued for 4 to 6 weeks and then discontinued to see whether the person has become tolerant to the neurological adverse effects of the antipsychotic medication. Amantadine should be tapered over 1 to 2 weeks after a decision has been made to discontinue the drug. Persons taking amantadine should not drink alcoholic beverages.

29.17 Dopamine Receptor Antagonists (First-Generation Antipsychotics)

The dopamine receptor antagonists (DRAs) represent the first group of effective agents for schizophrenia and other psychotic illnesses. The first of these drugs, the phenothiazine chlorpromazine (Thorazine), was introduced in the early 1950s. Other DRAs include all of the antipsychotics in the following groups: phenothiazines, butyrophenones, thioxanthenes, dibenzoxazepines, dihydroindoles, and diphenylbutylpiperidines. Because these agents are associated with extrapyramidal syndromes (EPSs) at clinically effective dosages, newer antipsychotic drugs—the serotonin–dopamine antagonists (SDAs)—have gradually replaced the older agents in the United States. The SDAs are differentiated from earlier drugs by their lower liability to cause extrapyramidal side effects. These newer drugs have other liabilities, most notably a propensity to cause weight gain, lipid elevations, and diabetes. Therefore, a reason to still consider use of the DRAs is their lower risk of causing significant metabolic abnormalities. Intermediate-potency DRAs, such as perphenazine (Trilafon), have been shown to be as effective and well tolerated as the SDAs. Manufacturing of molindone (Moban), the DRA with the lowest risk of weight gain and metabolic side effects, was discontinued in the United States.

PHARMACOLOGICAL ACTIONS

All of the DRAs are well absorbed after oral administration, with liquid preparations being absorbed more efficiently than tablets or capsules. Peak plasma concentrations are usually reached 1 to 4 hours after oral administration and 30 to 60 minutes after parenteral administration. Smoking, coffee, antacids, and food interfere with absorption of these drugs. Steady-state levels are reached in approximately 3 to 5 days. The half-lives of these drugs are approximately 24 hours. All can be given in one daily oral dose, if tolerated, after the patient is in a stable condition. Most DRAs are highly protein bound. Parenteral formulation of the DRAs results in a more rapid and more reliable onset of action. Bioavailability is also up to tenfold higher with parenteral administration. Most DRAs are metabolized by cytochrome P450 (CYP) CYP2D6 and 3A isozymes. However, there are differences among the specific agents.

Long-acting depot parenteral formulations of haloperidol (Haldol, Decanoate) and fluphenazine are available in the United States. These agents are usually administered once every 1 to 4 weeks, depending on the dose and the patient. It can take up to 6 months of treatment with depot formulations to reach steady-state plasma levels, indicating that oral therapy should be continued during the first month or so of depot antipsychotic treatment.

Antipsychotic activity derives from inhibition of dopaminergic neurotransmission. The DRAs are effective when approximately 72% of dopamine D₂ receptors in the brain are occupied. The DRAs also block noradrenergic, cholinergic, and histaminergic receptors, with different drugs having different effects on these receptor systems.

Some generalizations can be made about the DRAs based on their potency. Potency refers to the amount of drug that is required to achieve therapeutic effects. Low-potency drugs such as chlorpromazine and thioridazine (Mellaril), given in doses of several 100 mg per day, typically produce more weight gain and sedation than high-potency agents such as haloperidol and fluphenazine, usually given in doses of less than 10 mg per day. High-potency agents are also more likely to cause EPS. Some factors influencing the pharmacological actions of DRAs are listed in [Table 29.17-1](#).

 **Table 29.17-1**
Factors Influencing the Pharmacokinetics of Antipsychotics

Age	Elderly patients may demonstrate reduced clearance rates.
Medical condition	Decreased hepatic blood flow can reduce clearance. Hepatic disease can decrease clearance.
Enzyme inducers	Carbamazepine, phenytoin, ethambutol, barbiturates.
Clearance inhibitors	Include SSRIs, TCAs, cimetidine, β -blockers, isoniazid, methylphenidate, erythromycin, triazolobenzodiazepines, ciprofloxacin, and ketoconazole.
Changes in binding protein	Hypoalbuminemia can occur with malnutrition or hepatic failure.

SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.
(Adapted from Ereshesky L. Pharmacokinetics and drug interactions: Update for new antipsychotics. *J Clin Psychiatry*, 1996, 57(Suppl 1):12-25.)

THERAPEUTIC INDICATIONS

Many types of psychiatric and neurological disorders may benefit from treatment with DRAs. Some of these indications are shown in [Table 29.17-2](#).

 **Table 29.17-2**
Indications for Dopamine Receptor Antagonists

Acute psychotic episodes in schizophrenia and schizoaffective disorder
Maintenance treatment in schizophrenia and schizoaffective disorders
Mania
Depression with psychotic symptoms
Delusional disorder
Borderline personality disorder
Substance-induced psychotic disorder
Delirium and dementia
Mental disorders caused by a medical condition
Childhood schizophrenia
Pervasive developmental disorder
Tourette's disorder
Huntington's disease

Schizophrenia and Schizoaffective Disorder

The DRAs are effective in both the short-term and long-term management of schizophrenia and schizoaffective disorder. They both reduce acute symptoms and prevent future exacerbations. These agents produce their most dramatic effects against the positive symptoms of schizophrenia (e.g., hallucinations, delusions, and agitation). Negative symptoms (e.g., emotional withdrawal and ambivalence) are less likely to improve significantly, and they may appear to worsen, because these drugs produce constriction of facial expression and akinesia, side effects that mimic negative symptoms.

Schizophrenia and schizoaffective disorder are characterized by remission and relapse. DRAs decrease the risk of reemergence of psychosis in patients who have recovered while on medication. After a first episode of psychosis, patients should be maintained on medication for 1 to 2 years; after multiple episodes, for 2 to 5 years.

Mania

DRAs are effective for treating psychotic symptoms of acute mania. Because antimanic agents (e.g., lithium) generally have a slower onset of action than do antipsychotics in the treatment of acute symptoms, it is standard practice to initially combine either a DRA or an SDA with lithium (Eskalith), divalproex (Depakote), lamotrigine (Lamictal), or carbamazepine (Tegretol) and then to gradually withdraw the antipsychotic.

Depression with Psychotic Symptoms

Combination treatment with an antipsychotic and an antidepressant is one of the treatments of choice for major depressive disorder with psychotic features; the other is electroconvulsive therapy (ECT).

Delusional Disorder

Patients with delusional disorder often respond favorably to treatment with these drugs. Some persons with borderline personality disorder who may develop paranoid thinking in the course of their disorder may respond to antipsychotic drugs.

Severe Agitation and Violent Behavior

Severely agitated and violent patients, regardless of diagnosis, may be treated with DRAs. Symptoms such as extreme irritability, lack of impulse control, severe hostility, gross hyperactivity, and agitation respond to short-term treatment with these drugs. Children with mental disabilities, especially those with profound mental retardation and autistic disorder, often have associated episodes of violence, aggression, and agitation that respond to treatment with antipsychotic drugs; however, the repeated administration of antipsychotics to control disruptive behavior in children is controversial.

Tourette's Disorder

DRAs are used to treat Tourette's disorder, a neurobehavioral disorder marked by motor and vocal tics. Haloperidol and pimozide (Orap) are the drugs most frequently used, but other DRAs are also effective. Some clinicians prefer to use clonidine (Catapres) for this disorder because of its lower risk of neurological side effects.

Borderline Personality Disorder

Patients with borderline personality disorder who experience transient psychotic symptoms, such as perceptual disturbances, suspiciousness, ideas of reference, and aggression, may need to be treated with a DRA. This disorder is also associated with mood instability, so patients should be evaluated for possible treatment with mood-stabilizing agents.

Dementia and Delirium

About two thirds of agitated, elderly patients with various forms of dementia improve when given a DRA. Low doses of high-potency drugs (e.g., 0.5 to 1 mg a day of haloperidol) are recommended. DRAs are also used to treat psychotic symptoms and agitation associated with delirium. The cause of the delirium needs to be determined because toxic deliriums caused by anticholinergic agents can be exacerbated by low-potency DRAs, which often have significant antimuscarinic activity. Orthostasis, parkinsonism, and worsened cognition are the most problematic side effects in this elderly population.

Substance-induced Psychotic Disorder

Intoxication with cocaine, amphetamines, alcohol, phencyclidine, or other drugs can cause psychotic symptoms. Because these symptoms tend to be time limited, it is preferable to avoid use of a DRA unless the patient is severely agitated and aggressive. Usually, benzodiazepines can be used to calm the patient. Benzodiazepines should be used instead of DRAs in cases of phencyclidine intoxication. When a patient is experiencing hallucinations or delusions as a result of alcohol withdrawal, DRAs may increase the risk of seizure.

Childhood Schizophrenia

Children with schizophrenia benefit from treatment with antipsychotic medication, although considerably less research has been devoted to this population. Studies are currently under way to determine if intervention with medication at the very earliest signs of disturbance in children genetically at risk for schizophrenia can prevent the emergence of more florid symptoms. Careful consideration needs to be given to side effects, especially those involving cognition and alertness.

Other Psychiatric and Nonpsychiatric Indications

The DRAs reduce the chorea in the early stages of Huntington's disease. Patients with this disease may develop hallucinations, delusions, mania, or hypomania. These and other psychiatric symptoms respond to DRAs. High-potency DRAs should be used. However, clinicians should be aware that patients with the rigid form of this disorder may experience acute EPS. The use of DRAs to treat impulse control disorders should be reserved for patients in whom other interventions have failed. Patients with pervasive developmental disorder may exhibit hyperactivity, screaming, and agitation with combativeness. Some of these symptoms respond to high-potency DRAs, but there is little research evidence supporting benefits in these patients.

The rare neurological disorders ballismus and hemiballismus (which affect only one side of the body), characterized by propulsive movements of the limbs away from the body, also respond to treatment with antipsychotic agents. Other miscellaneous indications for the use of DRAs include the treatment of nausea, emesis, intractable hiccups, and pruritus. Endocrine disorders and temporal lobe epilepsy may be associated with psychosis that responds to antipsychotic treatment.

The most common side effects of DRAs are neurological. As a rule, low-potency drugs cause most nonneurological adverse effects, and the high-potency drugs cause most neurological adverse effects.

PRECAUTIONS AND ADVERSE REACTIONS

Table 29.17-3 summarizes the most common adverse events associated with the use of DRAs.

Table 29.17-3
Dopamine Receptor Antagonists: Potency and Adverse Effects

Drug Name	Chemical Classification	Therapeutically Equivalent Oral	Side Effects		
			Sedation	Autonomic ^c	Extrapyramidal Reactions ^b
Pimozide ^c	Diphenylbutyl-piperidine	1.5	+	+	+++
Fluphenazine	Phenothiazine: piperazine compound	2	+	+	+++
Haloperidol	Butyrophenone	2	+	+	+++
Thiothixene	Thioxanthene	4	+	+	+++
Trifluoperazine	Phenothiazine: piperazine compound	5	++	+	+++
Perphenazine	Phenothiazine: piperazine compound	8	++	+	+++
Molindone	Dihydroindolone	10	++	+	+
Loxapine	Dibenzoxazepine	10	++	+ / ++	+++
Prochlorperazine ^c	Phenothiazine: piperazine compound	15	++	+	+++
Aceto-phenazine	Phenothiazine: piperazine compound	20	++	+	+++
Triflupromazine	Phenothiazine: aliphatic compound	25	+++	+ / +++	++
Mesoridazine	Phenothiazine: piperidine compound	50	+++	++	+
Chlorpromazine	Phenothiazine: aliphatic compound	100	+++	+++	++
Chlorprothixene	Thioxanthene	100	+++	+++	+ / ++
Thioridazine	Phenothiazine: piperidine compound	100	+++	+++	+

^aAnti- α -adrenergic and anticholinergic effects.

^bExcluding tardive dyskinesia, which appears to be produced to the same degree and frequency by all agents with equieffective antipsychotic dosages.

^cPimozide is used principally in the treatment of Tourette's disorder; prochlorperazine is used rarely, if ever, as an antipsychotic agent.

(Adapted from American Medical Association. *AMA Drug Evaluations: Annual 1992*. Chicago: American Medical Association, 1992.)

Neuroleptic Malignant Syndrome

A potentially fatal side effect of DRA treatment, neuroleptic malignant syndrome, can occur at any time during the course of DRA treatment. Symptoms include extreme hyperthermia, severe muscular rigidity and dystonia, akinesia, mutism, confusion, agitation, and increased pulse rate and blood pressure. Laboratory findings include increased white blood cell (WBC) count, and levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure. The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect increased psychosis. Men are affected more frequently than are women, and young persons are affected more commonly than are elderly persons. The mortality rate can reach 20 to 30 percent, or even higher when depot medications are involved. Rates are also increased when high doses of high-potency agents are used.

If neuroleptic malignant syndrome is suspected, the DRA should be stopped immediately and the following done: medical support to cool the person; monitoring of vital signs, electrolytes, fluid balance, and renal output; and symptomatic treatment of fever. Antiparkinsonian medications may reduce some of the muscle rigidity. Dantrolene (Dantrium), a skeletal muscle relaxant (0.8 to 2.5 mg/kg every 6 hours, up to a total dosage of 10 mg a day) may be useful in the treatment of this disorder. When the person can take oral medications, dantrolene can be given in doses of 100 to 200 mg a day. Bromocriptine (20 to 30 mg a day in four divided doses) or amantadine can be added to the regimen. Treatment should usually be continued for 5 to 10 days. When drug treatment is restarted, the clinician should consider switching to a low-potency drug or an SDA, although these agents—including clozapine—may also cause neuroleptic malignant syndrome.

Seizure Threshold

DRAs may lower the seizure threshold. Chlorpromazine, thioridazine, and other low-potency drugs are thought to be more epileptogenic than are high-potency drugs. The risk of inducing a seizure by drug administration warrants consideration when the person already has a seizure disorder or brain lesion.

Sedation

Blockade of histamine H₁ receptors is the usual cause of sedation associated with DRAs. Chlorpromazine is the most sedating typical antipsychotic. The relative sedative properties of the drugs are summarized in [Table 29.17-3](#). Giving the entire daily dose at bedtime usually eliminates any problems from sedation, and tolerance for this adverse effect often develops.

Central Anticholinergic Effects

The symptoms of central anticholinergic activity include severe agitation; disorientation to time, person, and place; hallucinations; seizures; high fever; and dilated pupils. Stupor and coma may ensue. The treatment of anticholinergic toxicity consists of discontinuing the causal agent or agents, close medical supervision, and physostigmine (Antilirium, Eserine), 2 mg by slow intravenous (IV) infusion, repeated within 1 hour as necessary. Too much physostigmine is dangerous, and symptoms of physostigmine toxicity include hypersalivation and sweating. Atropine sulfate (0.5 mg) can reverse the effects of physostigmine toxicity.

Cardiac Effects

The DRAs decrease cardiac contractility, disrupt enzyme contractility in cardiac cells, increase circulating levels of catecholamines, and prolong atrial and ventricular conduction time and refractory periods. Low-potency DRAs, particularly the phenothiazines, are usually more cardiotoxic than are high-potency drugs. One exception is haloperidol, which has been linked to abnormal heart rhythm, ventricular arrhythmias, torsades de pointes, and sudden death when injected IV. Pimozide, sulpiride, and droperidol (a butyrophenone) also prolong the QTc interval and have clearly been associated with torsades de pointes and sudden death. In one study, thioridazine was responsible for 28 (61 percent) of the 46 sudden antipsychotic deaths. In 15 of these cases, it was the only drug ingested. Chlorpromazine also causes prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. These drugs are thus indicated only when other agents have been ineffective.

Sudden Death

Occasional reports of sudden cardiac death during treatment with DRAs may be the result of cardiac arrhythmias. Other causes may include seizure, asphyxiation, malignant hyperthermia, heat stroke, and neuroleptic malignant syndrome. However, there does not appear to be an overall increase in the incidence of sudden death linked to the use of antipsychotics.

Orthostatic (Postural) Hypotension

Orthostatic (postural) hypotension is most common with low-potency drugs, particularly chlorpromazine, thioridazine, and chlorprothixene. When using intramuscular (IM) low-potency DRAs, the clinician should measure the patient's blood pressure (lying and standing) before and after the first dose and during the first few days of treatment.

Orthostatic hypotension is mediated by adrenergic blockade and occurs most frequently during the first few days of treatment. Tolerance often develops for this side effect, which is why initial dosing of these drugs is lower than the usual therapeutic dose. Fainting or falls, although uncommon, may lead to injury. Patients should be warned of this side effect and instructed to rise slowly after sitting and reclining. Patients should avoid all caffeine and alcohol; should drink at least 2 L of fluid a day; and if not under treatment for hypertension, should add liberal amounts of salt to their diet. Support hose may help some persons.

Hypotension can usually be managed by having patients lie down with their feet higher than their heads and pump their legs as if bicycling. Volume expansion or vasopressor agents, such as norepinephrine (Levophed), may be indicated in severe cases. Because hypotension is produced by α -adrenergic blockade, the drugs also block the α -adrenergic stimulating properties of epinephrine, leaving the β -adrenergic stimulating effects untouched. Therefore, the administration of epinephrine results in a paradoxical worsening of hypotension and is contraindicated in cases of antipsychotic-induced hypotension. Pure α -adrenergic pressor agents, such as metaraminol (Aramine) and norepinephrine, are the drugs of choice in the treatment of the disorder.

Hematologic Effects

Temporary leukopenia with a WBC count of about 3,500 is a common but not serious problem. Agranulocytosis, a life-threatening hematologic problem, occurs in about 1 in 10,000 persons treated with DRAs. Thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemias, and pancytopenia may occur rarely in persons treated with DRAs. Although routine complete blood counts (CBCs) are not indicated, if a person reports a sore throat and fever, a CBC should be done immediately to check for the possibility of a serious blood dyscrasia. If blood index values are low, administration of DRAs should be stopped, and the patient should be transferred to a medical facility. The mortality rate for the complication may be as high as 30 percent.

Peripheral Anticholinergic Effects

Peripheral anticholinergic effects, consisting of dry mouth and nose, blurred vision, constipation, urinary retention, and mydriasis, are common, especially with low-potency DRAs, for example, chlorpromazine, thioridazine, mesoridazine (Serentil). Some persons may also have nausea and vomiting.

Constipation should be treated with the usual laxative preparations, but severe constipation can progress to paralytic ileus. A decrease in the DRA dosage is warranted in such cases. Pilocarpine (Salagen) may be used to treat paralytic ileus, although the relief is only transitory. Bethanechol (Urecholine) (20 to 40 mg a day) may be useful in some persons with urinary retention.

Weight gain is associated with increased mortality and morbidity and with medication noncompliance. Low-potency DRAs may cause significant weight gain but not as much as is seen with the SDAs olanzapine (Zyprexa) and clozapine (Clozaril). Molindone and perhaps loxapine (Loxitane) appear to be least likely to cause weight gain.

Endocrine Effects

Blockade of the dopamine receptors in the tuberoinfundibular tract results in the increased secretion of prolactin, which can result in breast enlargement, galactorrhea, amenorrhea, and inhibited orgasm in women and impotence in men. The SDAs, with the exception of risperidone (Risperdal), are not particularly associated with an increase in prolactin levels and may be the drugs of choice for persons experiencing disturbing side effects from increased prolactin release.

Sexual Adverse Effects

Both men and women taking DRAs can experience anorgasmia and decreased libido. Up to 50 percent of men who take antipsychotics report ejaculatory and erectile disturbances. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) are often used to treat psychotropic-induced orgasmic dysfunction, but they have not been studied in combination with the DRAs. Thioridazine is particularly associated with decreased libido and retrograde ejaculation in men. Priapism and reports of painful orgasms have also been described, both possibly resulting from α_1 -adrenergic antagonist activity.

Skin and Eye Effects

Allergic dermatitis and photosensitivity may occur, especially with low-potency agents. Urticarial, maculopapular, petechial, and edematous eruptions may occur early in treatment, generally in the first few weeks, and remit spontaneously. A photosensitivity reaction that resembles a severe sunburn also occurs in some persons taking chlorpromazine. Persons should be warned of this adverse effect, should spend no more than 30 to 60 minutes in the sun, and should use sunscreens. Long-term chlorpromazine use is associated with blue-gray discoloration of skin areas exposed to sunlight. The skin changes often begin with a tan or golden brown color and progress to such colors as slate gray, metallic blue, and purple. These discolorations resolve when the patient is switched to another medication.

Irreversible retinal pigmentation is associated with the use of thioridazine at dosages above 1,000 mg a day. An early symptom of the side effect can sometimes be nocturnal confusion related to difficulty with night vision. The pigmentation can progress even after thioridazine administration is stopped, finally resulting in blindness. It is for this reason that the maximum recommended dosage of thioridazine is 800 mg per day.

Patients taking chlorpromazine may develop a relatively benign pigmentation of the eyes, characterized by whitish brown granular deposits concentrated in the anterior lens and posterior cornea and visible only by slit-lens examination. The deposits can progress to opaque white and yellow-brown granules, often stellate. Occasionally, the conjunctiva is discolored by a brown pigment. No retinal damage is seen, and vision is almost never impaired. This condition gradually resolves when chlorpromazine is discontinued.

Jaundice

Elevations of liver enzymes during treatment with a DRA tend to be transient and not clinically significant. When chlorpromazine first came into use, cases of obstructive or cholestatic jaundice were reported, usually in the first month of treatment and heralded by symptoms of upper abdominal pain, nausea, and vomiting. This was followed by fever; rash; eosinophilia; bilirubin in the urine; and increases in levels of serum bilirubin, alkaline phosphatase, and hepatic transaminases. Reported cases are now extremely rare, but if jaundice occurs, the medication should be discontinued.

Overdoses

Overdoses typically consist of exaggerated DRA side effects. Symptoms and signs include central nervous system (CNS) depression, EPS, mydriasis, rigidity, restlessness, decreased deep tendon reflexes, tachycardia, and hypotension. The severe symptoms of overdose include delirium, coma, respiratory depression, and seizures. Haloperidol may be among the safest typical antipsychotics in overdose. After an overdose, electroencephalography (EEG) shows diffuse slowing and low voltage. Extreme overdose may lead to delirium and coma, with respiratory depression and hypotension. Life-threatening overdose usually involves ingestion of other CNS depressants, such as alcohol or benzodiazepines.

Activated charcoal, if possible, and gastric lavage should be administered if the overdose is recent. Emetics are not indicated because the antiemetic actions of the DRAs inhibit their efficacy. Seizures can be treated with IV diazepam (Valium) or phenytoin (Dilantin). Hypotension can be treated with either norepinephrine or dopamine but not epinephrine.

Pregnancy and Lactation

There is a low correlation between the use of antipsychotics during pregnancy and congenital malformations. Nevertheless, antipsychotics should be avoided during pregnancy, particularly in the first trimester unless the benefit outweighs the risk. High-potency drugs are preferable to low-potency drugs because the low-potency drugs are associated with hypotension.

DRAs are secreted in the breast milk, although concentrations are low. Women taking these agents should be advised against breastfeeding.

DRUG INTERACTIONS

Many pharmacokinetic and pharmacodynamic drug interactions are associated with these drugs (Table 29.17-4). CYP2D6 is the most common hepatic isozyme involved in DRA pharmacokinetic interactions. Other common drug interactions affect the absorption of the DRAs.

Table 29.17-4

Antipsychotic Drug Interactions

Interacting Medication	Mechanism	Clinical Effect
Drug interactions assessed to have major severity		
β -Adrenergic receptor antagonists	Synergistic pharmacologic effect; antipsychotic inhibits metabolism of propranolol; antipsychotic increases plasma concentrations	Severe hypotension
Anticholinergics	Pharmacodynamic effects Additive anticholinergic effect	Decreased antipsychotic effect Anticholinergic toxicity
Barbiturates	Phenobarbital induces antipsychotic metabolism	Decreased antipsychotic concentrations
Carbamazepine	Induces antipsychotic metabolism	Up to 50% reduction in antipsychotic concentrations
Charcoal	Reduces GI absorption of antipsychotic and adsorbs drug during enterohepatic circulation	May reduce antipsychotic effect or cause toxicity when used to treat overdose or for GI disturbances
Cigarette smoking	Induction of microsomal enzymes	Reduced plasma concentrations of antipsychotic agents
Epinephrine, norepinephrine	Antipsychotic antagonizes pressor effect	Hypotension
Ethanol	Additive CNS depression	Impaired psychomotor status
Fluvoxamine	Fluvoxamine inhibits metabolism of haloperidol and clozapine	Increased concentrations of haloperidol and clozapine
Guanethidine	Antipsychotic antagonizes guanethidine reuptake	Impaired antihypertensive effect
Lithium	Unknown	Rare reports of neurotoxicity
Meperidine	Additive CNS depression	Hypotension and sedation
Drug interactions assessed to have minor or moderate severity		
Amphetamines, anorexians	Decreased pharmacologic effect of amphetamine	Diminished weight loss effect; amphetamines may exacerbate psychosis
ACEIs	Additive hypotensive crisis	Hypotension, postural intolerance
Antacids containing aluminum	Insoluble complex formed in GI tract	Possible reduced antipsychotic effect
AD nonspecific	Decreased metabolism of AD through competitive inhibition	Increased AD concentration
Benzodiazepines	Increased pharmacologic effect of the benzodiazepine	Respiratory depression, stupor, hypotension
Bromocriptine	Antipsychotic antagonizes dopamine receptor stimulation	Increased prolactin
Caffeinated beverages	Form precipitate with antipsychotic solutions	Possible diminished antipsychotic effect
Cimetidine	Reduced antipsychotic absorption and clearance	Decreased antipsychotic effect
Clonidine	Antipsychotic potentiates α -adrenergic hypotensive effect	Hypotension or hypertension
Disulfiram	Impairs antipsychotic metabolism	Increased antipsychotic concentrations
Methyl dopa	Unknown	BP elevations
Phenytoin	Induction of antipsychotic metabolism; decreased phenytoin metabolism	Decreased antipsychotic concentrations; increased phenytoin levels
SSRIs	Impair antipsychotic metabolism; pharmacodynamic interaction	Sudden onset of extrapyramidal symptoms
Valproic acid	Antipsychotic inhibits valproic acid metabolism	Increased valproic acid half-life and levels

ACEI, angiotensin-converting enzyme inhibitor; AD, antidepressant; BP, blood pressure; CNS, central nervous system; GI, gastrointestinal; SSRI, selective serotonin reuptake inhibitor.

(From FRESHOSKY L, OVERMAN GP, KARP JK. Current psychotropic dosing and monitoring guidelines. *Prim Psychiatry*, 1996, 3:21, with permission.)

Antacids, activated charcoal, cholestyramine (Questran), kaolin, pectin, and cimetidine (Tagamet) taken within 2 hours of antipsychotic administration can reduce the absorption of these drugs. Anticholinergics may decrease the absorption of the DRAs. The additive anticholinergic activity of the DRAs, anticholinergics, and tricyclic drugs may result in anticholinergic toxicity. Digoxin (Lanoxin) and steroids, both of which decrease gastric motility, can increase DRA absorption.

Phenothiazines, especially thioridazine, may decrease the metabolism of and cause toxic concentrations of phenytoin. Barbiturates may increase the metabolism of DRAs.

Tricyclic drugs and selective serotonin reuptake inhibitors (SSRIs) that inhibit CYP2D6—paroxetine (Paxil), fluoxetine (Prozac), and fluvoxamine (Luvox)—interact with DRAs, resulting in increased plasma concentrations of both drugs. The anticholinergic, sedative, and hypotensive effects of the drugs may also be additive.

Typical antipsychotics may inhibit the hypotensive effects of α -methyl dopa (Aldomet). Conversely, typical antipsychotics may have an additive effect on some hypotensive drugs. Antipsychotic drugs have a variable effect on the hypotensive effects of clonidine. Propranolol (Inderal) coadministration increases the blood concentrations of both drugs.

The DRAs potentiate the CNS-depressant effects of the sedatives, antihistamines, opiates, opioids, and alcohol, particularly in persons with impaired respiratory status. When these agents are taken with alcohol, the risk for heat stroke may be increased.

Cigarette smoking may decrease the plasma levels of the typical antipsychotic drugs. Epinephrine has a paradoxical hypotensive effect in persons taking typical antipsychotics. These drugs may decrease the blood concentration of warfarin (Coumadin), resulting in decreased bleeding time. The phenothiazines, thioridazine, and pimozide should not be coadministered with other agents that prolong the QT interval. Thioridazine is contraindicated in patients taking drugs that inhibit the CYP2D6 isoenzyme or in patients with reduced levels of CYP2D6.

LABORATORY INTERFERENCES

Chlorpromazine and perphenazine (Trilafon) may cause both false-positive and false-negative results in immunological pregnancy tests and falsely elevated bilirubin (with reagent test strips) and urobilinogen (with Ehrlich's reagent test) values. These drugs have also been associated with an abnormal shift in results of the glucose tolerance test, although that shift may reflect the effects of the drugs on the glucose-regulating system. Phenothiazines have been reported to interfere with the measurement of 17-ketosteroids and 17-hydroxycorticosteroids and to produce false-positive results in tests for phenylketonuria.

DOSAGE AND CLINICAL GUIDELINES

Contraindications to the use of DRAs include the following: (1) a history of a serious allergic response; (2) the possible ingestion of a substance that will interact with the antipsychotic to induce CNS depression (e.g., alcohol, opioids, barbiturates, and benzodiazepines) or anticholinergic delirium (e.g., scopolamine and possibly phencyclidine [PCP]); (3) the presence of a severe cardiac abnormality; (4) a high risk for seizures; (5) the presence of narrow-angle glaucoma or prostatic hypertrophy if a drug with high anticholinergic activity is to be used; and (6) the presence or a history of tardive dyskinesia. Antipsychotics should be administered with caution in persons with hepatic disease, because impaired hepatic metabolism may result in high plasma concentrations. The usual assessment should include a CBC with WBC indexes, liver function tests, and electrocardiography (ECG), especially in women older than 40 years of age and men older than 30 years of age. Elderly persons and children are more sensitive to side effects than are young adults, so the dosage of the drug should be adjusted accordingly.

Various patients may respond to widely different dosages of antipsychotics; therefore, there is no set dosage for any given antipsychotic drug. Because of side effects, it is reasonable clinical practice to begin at a low dosage and increase as necessary. It is important to remember that the maximal effects of a particular dosage may not be evident for 4 to 6 weeks. Available preparations and dosages of the DRAs are given in Table 29.17-5.

Table 29.17-5
Dopamine Receptor Antagonists

Name						Adult Dose Range (mg/day)		
Generic or Chemical	Trade	Trade (mg)	Capsules (mg)	Solution	Parenteral	Rectal Suppositories (mg)	Acute	Maintenance
Chlorpromazine	Thorazine	10, 25, 50, 100, 200	30, 75, 150, 200, 300	10 mg/5 mL, 30 mg/mL, 100 mg/mL	25 mg/mL	25, 100	100–1,600 PO 25–400 IM	50–400 PO
Prochlorperazine	Compazine	5, 10, 25	10, 15, 30	5 mg/5 mL	5 mg/mL	2.5, 5, 25	15–200 PO 40–80 IM	15–60 PO
Perphenazine	Trilafon	2, 4, 8, 16	—	16 mg/5 mL	5 mg/mL	—	12–64 PO 15–30 IM	8–24 PO
Trifluoperazine	Stelazine	1, 2, 5, 10	—	10 mg/mL	2 mg/mL	—	4–40 PO 4–10 IM	5–20 PO
Fluphenazine	Prolixin	1, 2.5, 5, 10	—	2.5 mg/5 mL, 5 mg/mL	2.5 mg/mL (IM only)	—	2.5–40.0 PO 5–20 IM	1.0–15.0 PO 12.5–50.0 IM (decanoate or enanthate, weekly or biweekly)
Fluphenazine decanoate	—	—	—	—	2.5 mg/mL	—	—	—
Fluphenazine enanthate	—	—	—	2.5 mg/mL	—	—	—	—
Thioridazine	Mellaril	10, 15, 25, 50, 100, 150, 200	—	25 mg/5 mL, 100 mg/5 mL, 30 mg/mL, 100 mg/mL	—	—	200–800 PO	100–300 PO
Mesoridazine	Serentil	10, 25, 50, 100	—	25 mg/mL	25 mg/mL	—	100–400 PO 25–200 IM	30–150 PO

Pimozide	Orap	2	—	—	—	—	0.5–20	0.5–5.0

IM, intramuscular; PO, oral.

Short-term Treatment

The equivalent of 5 to 20 mg of haloperidol is a reasonable dose for an adult in an acute state. An elderly person may benefit from as little as 1 mg of haloperidol. The administration of more than 25 mg of chlorpromazine in one injection may result in serious hypotension. IM administration results in peak plasma levels in about 30 minutes versus 90 minutes using the oral route. Doses of drugs for IM administration are about half those given by the oral route. In a short-term treatment setting, the person should be observed for 1 hour after the first dose of medication. After that time, most clinicians administer a second dose or a sedative agent (e.g., a benzodiazepine) to achieve effective behavioral control. Possible sedatives include lorazepam (Ativan) (2 mg IM) and amobarbital (50 to 250 mg IM).

Rapid Neuroleptization

Rapid neuroleptization (also called psychotolysis) is the practice of administering hourly IM doses of antipsychotic medications until marked sedation is achieved. However, several research studies have shown that merely waiting several more hours after one dose yields the same clinical improvement as is seen with repeated doses. Nevertheless, clinicians must be careful to keep patients from becoming violent while they are psychotic. Clinicians can help prevent violent episodes by using adjuvant sedatives or by temporarily using physical restraints until the persons can control their behavior.

Early Treatment

A full 6 weeks may be necessary to evaluate the extent of the improvement in psychotic symptoms. However, agitation and excitement usually improve quickly with antipsychotic treatment. About 75 percent of persons with a short history of illness show significant improvement in their psychosis. Psychotic symptoms, both positive and negative, usually continue to improve 3 to 12 months after the initiation of treatment.

About 5 mg of haloperidol or 300 mg of chlorpromazine is a usual effective daily dose. In the past, much higher doses were used, but evidence suggests that it resulted in more side effects without additional benefits. A single daily dose is usually given at bedtime to help induce sleep and to reduce the incidence of adverse effects. However, bedtime dosing for elderly persons may increase their risk of falling if they get out of bed during the night. The sedative effects of typical antipsychotics last only a few hours, in contrast to the antipsychotic effects, which last for 1 to 3 days.

Intermittent Medications

It is common clinical practice to order medications to be given intermittently as needed (PRN). Although this practice may be reasonable during the first few days that a person is hospitalized, the amount of time the person takes antipsychotic drugs, rather than an increase in dosage, is what produces therapeutic improvement. Clinicians on inpatient services may feel pressured by staff members to write PRN antipsychotic orders; such orders should include specific symptoms, how often the drugs should be given, and how many doses can be given each day. Clinicians may choose to use small doses for the PRN doses (e.g., 2 mg of haloperidol) or use a benzodiazepine instead (e.g., 2 mg of lorazepam IM). If PRN doses of an antipsychotic are necessary after the first week of treatment, the clinician may want to consider increasing the standing daily dose of the drug.

Maintenance Treatment

The first 3 to 6 months after a psychotic episode are usually considered a period of stabilization. After that time, the dosage of the antipsychotic can be decreased about 20 percent every 6 months until the minimum effective dosage is found. A person is usually maintained on antipsychotic medications for 1 to 2 years after the first psychotic episode. Antipsychotic treatment is often continued for 5 years after a second psychotic episode, and lifetime maintenance is considered after the third psychotic episode, although attempts to reduce the daily dosage can be made every 6 to 12 months.

Antipsychotic drugs are effective in controlling psychotic symptoms, but persons may report that they prefer being off the drugs because they feel better without them. The clinician must discuss maintenance medication with patients and take into account their wishes, the severity of their illnesses, and the quality of their support systems. It is essential for the clinician to know enough about the patient's life to try to predict upcoming stressors that might require increasing the dosage or closely monitoring compliance.

Long-acting Depot Medications

Long-acting depot preparations may be needed to overcome problems with compliance. IM preparations are typically given once every 1 to 4 weeks.

Two depot preparations, a decanoate and an enanthate, of fluphenazine and a decanoate preparation of haloperidol are available in the United States. The preparations are injected IM into an area of large muscle tissue, from which they are absorbed slowly into the blood. Decanoate preparations can be given less frequently than enanthate preparations because they are absorbed more slowly. Although stabilizing a person on the oral preparation of the specific drugs is not necessary before initiating the depot form, it is good practice to give at least one oral dose of the drug to assess the possibility of an adverse effect, such as severe EPS or an allergic reaction.

It is reasonable to begin with either 12.5 mg (0.5 mL) of fluphenazine preparation or 25 mg (0.5 mL) of haloperidol decanoate. If symptoms emerge in the next 2 to 4 weeks, the person can be treated temporarily with additional oral medications or with additional small depot injections. After 3 to 4 weeks, the depot injection can be increased to a single dose equal to the total of the doses given during the initial period.

A good reason to initiate depot treatment with low doses is that the absorption of the preparations may be faster than usual at the onset of treatment, resulting in frightening episodes of dystonia that eventually discourage compliance with the medication. Some clinicians keep persons drug free for 3 to 7 days before initiating depot treatment and give small doses of the depot preparations (3.125 mg of fluphenazine or 6.25 mg of haloperidol) every few days to avoid those initial problems.

PLASMA CONCENTRATIONS

Genetic differences among persons and pharmacokinetic interactions with other drugs influence the metabolism of the antipsychotics. If a person has not improved after 4 to 6 weeks of treatment, the plasma concentration of the drug should be determined if feasible. After a patient has been on a particular dosage for at least five times the half-life of the drug and thus approaches steady-state concentrations, blood levels may be helpful. It is standard practice to obtain plasma samples at trough levels—just before the daily dose is given, usually at least 12 hours after the previous dose and most commonly 20 to 24 hours after the previous dose. In fact, most antipsychotics have no well-defined dose–response curve. The best-studied drug is haloperidol, which may have a therapeutic window ranging from 2 to 15 ng/mL. Other therapeutic ranges that have been reasonably well documented are 30 to 100 ng/mL for chlorpromazine and 0.8 to 2.4 ng/mL for perphenazine.

Treatment-resistant Persons

Unfortunately, 10 to 35 percent of persons with schizophrenia do not obtain significant benefit from the antipsychotic drugs. Treatment resistance is a failure on at least two adequate trials of antipsychotics from two pharmacological classes. It is useful to determine plasma concentrations for such persons because it is possible that they are slow or rapid metabolizers or are not taking their medication. Clozapine has been conclusively shown to be effective when given to patients who have failed multiple trials of DRAs.

Adjunctive Medications

It is common practice to use DRAs in conjunction with other psychotropic agents, either to treat side effects or to further improve symptoms. Most commonly, this involves the use of lithium or other mood-stabilizing agents, SSRIs, or benzodiazepines. It was once held that antidepressant drugs exacerbated psychosis in patients with schizophrenia. In all likelihood, this observation involved patients with bipolar disorder who were misdiagnosed as having schizophrenia. Abundant evidence suggests that antidepressants in fact improve symptoms of depression in patients with schizophrenia. In some cases, amphetamines can be added to DRAs if patients remain withdrawn and apathetic.

CHOICE OF DRUG

Given their proven efficacy in managing acute psychotic symptoms and the fact that prophylactic administration of antiparkinsonian medication prevents or minimizes acute motor abnormalities, DRAs are still valuable, especially for short-term therapy. There is a considerable cost advantage to a DRA antiparkinsonian regimen compared with monotherapy with a newer antipsychotic agent. Concern about the development of DRA-induced tardive dyskinesia is the major deterrent to long-term use of these drugs, yet it is not clear that SDAs are completely free of this complication. Thus, DRAs still occupy an important role in psychiatric treatment. DRAs are not predictably interchangeable. For reasons that cannot be explained, some patients do better on one drug than another. Choice of a particular DRA should be based on the known adverse effect profile of the drugs. Other than a significant advantage in terms of medication cost, the choice currently would be an SDA. If a DRA is thought to be preferable, a high-potency antipsychotic is favored, even though it may be associated with more neurological adverse effects, mainly because there is a higher incidence of other adverse effects (e.g., cardiac, hypotensive, epileptogenic, sexual, and allergic) with the low-potency drugs. If sedation is a desired goal, either a low-potency antipsychotic can be given in divided doses or a benzodiazepine can be coadministered.

An unpleasant or dysphoric reaction (a subjective sense of restlessness, oversedation, and acute dystonia) to the first dose of an antipsychotic predicts future poor response and noncompliance. Prophylactic use of antiparkinsonian medications may prevent this reaction. In general, clinicians should be vigilant about serious side effects and adverse events (described above) regardless of which drug is used.

29.18 Lamotrigine

Lamotrigine (Lamictal) was developed as a result of screening folate antagonists as anticonvulsants. Lamotrigine proved effective in several animal models of epilepsy, was developed as an antiepileptic drug, and was marketed for the adjunctive treatment of partial seizures in the United States in 1995. Initial, postmarketing, open, clinical experience suggested efficacy in a variety of neurological and psychiatric conditions, coupled with good tolerability (aside from the risk of rash). Later, double-blind, placebo-controlled studies revealed that lamotrigine was useful for some, but not all, of the neurological and psychiatric conditions reported in open studies. Therefore, lamotrigine appeared effective as maintenance treatment for bipolar disorder and was approved for maintenance treatment of bipolar I disorder in 2003. Lamotrigine also appeared to have potential utility in acute bipolar depression, but the magnitude of the effect was too modest to yield consistently superior performance compared with placebo, and hence lamotrigine did not receive approval for the treatment of acute bipolar depression. Similarly, limited data suggested lamotrigine had potential utility in rapid-cycling bipolar disorder. Lamotrigine did not appear to be effective as a main intervention in acute mania. Thus, lamotrigine has emerged as an agent that appears to “stabilize mood from below” in the sense that it may maximally impact the depressive component of bipolar disorders.

PHARMACOLOGICAL ACTIONS

Lamotrigine is completely absorbed, has a bioavailability of 98%, and has a steady-state plasma half-life of 25 hours. However, the rate of metabolism of lamotrigine varies over a sixfold range, depending on which other drugs are administered concomitantly. Dosing is escalated slowly to twice-a-day maintenance dosing. Food does not affect its absorption, and it is 55 percent protein bound in the plasma; 94% of lamotrigine and its inactive metabolites are excreted in the urine. Among the better-delineated biochemical actions of lamotrigine are blockade of voltage-sensitive sodium channels, which in turn modulates release of glutamate and aspartate, and has a slight effect on calcium channels. Lamotrigine modestly increases plasma serotonin concentrations, possibly through inhibition of serotonin reuptake, and is a weak inhibitor of serotonin 5-HT₃ receptors.

THERAPEUTIC INDICATIONS

Bipolar Disorder

Lamotrigine is indicated in the treatment of bipolar disorder and may prolong the time between episodes of depression and mania. It is more effective in lengthening the intervals between depressive episodes than manic episodes. It is also effective as treatment for rapid-cycling bipolar disorder.

Other Indications

There have been reports of therapeutic benefit in the treatment of borderline personality disorder and in the treatment for various pain syndromes.

PRECAUTIONS AND ADVERSE REACTIONS

Lamotrigine is remarkably well tolerated. The absence of sedation, weight gain, and other metabolic effects is noteworthy. The most common adverse effects—dizziness, ataxia, somnolence, headache, diplopia, blurred vision, and nausea—are typically mild. Anecdotal reports of cognitive impairment and joint or back pain are common.

The appearance of a rash, which is common and occasionally very severe, is a source of concern. About 8 percent of patients started on lamotrigine develop a benign maculopapular rash during the first 4 months of treatment, and the drug should be discontinued if a rash develops (see [Color Plate 29.18-1](#)). Even though these rashes are benign, there is concern that in some cases, they may represent early manifestations of Stevens–Johnson syndrome or toxic epidermal necrolysis. Nevertheless, even if lamotrigine is discontinued immediately upon development of rash or other signs of hypersensitivity reaction, such as fever and lymphadenopathy, this may not prevent subsequent development of a life-threatening rash or permanent disfigurement.

Estimates of the rate of serious rash vary, depending on the source of the data. In some studies, the incidence of serious rashes was 0.08 percent in adult patients receiving lamotrigine as initial monotherapy and 0.13 percent in adult patients receiving lamotrigine as adjunctive therapy. German registry data, based on clinical practice, suggest that the risk of rash may be as low as 1 in 5,000 patients. The appearance of any type of rash necessitates immediate discontinuation of drug administration.

It is known that the likelihood of a rash increases if the recommended starting dose and speed of dose increase exceed what is recommended. Concomitant administration of valproic acid also increases risk and should be avoided if possible. If valproate is used, a more conservative dosing regimen is followed. Children and adolescents younger than age 16 years appear to be more susceptible to rash with lamotrigine. If patients miss more than four consecutive days of lamotrigine treatment, they need to restart therapy at the initial starting dose and titrate upward as if they had not already been on the medication.

LABORATORY TESTING

There is no proven correlation between lamotrigine blood concentrations and either antiseizure effects or efficacy in bipolar disorders. Laboratory tests are not useful in predicting the occurrence of adverse events.

DRUG INTERACTIONS

Lamotrigine has significant, well-characterized drug interactions involving other anticonvulsants. The most potentially serious lamotrigine drug interaction involves concurrent use of valproic acid, which doubles serum lamotrigine concentrations. Lamotrigine decreases the plasma concentration of valproic acid by 25 percent. Sertraline (Zoloft) also increases plasma lamotrigine concentrations, but to a lesser extent than does valproic acid. Lamotrigine concentrations are decreased by 40 to 50 percent, with concomitant administration of carbamazepine, phenytoin, or phenobarbital. Combinations of lamotrigine and other anticonvulsants have complex effects on the time of

peak plasma concentration and the plasma half-life of lamotrigine.

LABORATORY INTERFERENCES

Lamotrigine and topiramate do not interfere with any laboratory tests.

DOSAGE AND ADMINISTRATION

In the clinical trials leading to the approval of lamotrigine as a treatment for bipolar disorder, no consistent increase in efficacy was associated with doses above 200 mg per day. Most patients should take between 100 and 200 mg a day. In epilepsy, the drug is administered twice daily, but in bipolar disorder, the total dose can be taken once a day, either in the morning or night, depending on whether the patient finds the drug activating or sedating.

Lamotrigine is available as unscored 25, 100, 150, and 200 mg tablets. The major determinant of lamotrigine dosing is minimization of the risk of rash. Lamotrigine should not be taken by anyone younger than 16 years of age. Because valproic acid markedly slows the elimination of lamotrigine, concomitant administration of these two drugs necessitates a much slower titration (Table 29.18-1). People with renal insufficiency should aim for a lower maintenance dosage. Appearance of any type of rash necessitates immediate discontinuation of lamotrigine administration. Lamotrigine should usually be discontinued gradually over 2 weeks unless a rash emerges, in which case it should be discontinued over 1 to 2 days.

 **Table 29.18-1**
Lamotrigine Dosing (mg/day)

Treatment	Weeks		
	Weeks 1–2	3–4	Weeks 4–5
Lamotrigine monotherapy	25	50	100–200 (500 maximum)
Lamotrigine + carbamazepine	50	100	200–500 (700 maximum)
Lamotrigine + valproate	25 every other day	25	50–200 (200 maximum)

Lamotrigine orally disintegrating tablets (Lamictal ODT) are available for patients who have difficulty swallowing. It is the only antiepileptic treatment that is available in an orally disintegrating formulation. It is available in 25, 50, 100, and 200 mg strengths and matches the dose of lamotrigine tablets. Chewable dispersible tablets of 2, 5, and 25 mg are also available.

29.19 Lithium

The effectiveness of lithium for mania and for the prophylactic treatment of manic–depressive disorder was established in the early 1950s as a result of research done by John F.J. Cade, an Australian psychiatrist. Concerns about toxicity limited initial acceptance of lithium use in the United States, but its use increased gradually in the late 1960s. It was not until 1970 that the Food and Drug Administration (FDA) approved its labeling for the treatment of mania. The only other approved FDA indication came in 1974, when it was accepted as maintenance therapy in patients with a history of mania. For several decades, lithium was the only drug approved for both acute and maintenance treatment. It is also used as an adjunctive medication in the treatment of major depressive disorder.

Lithium (Li), a monovalent ion, is a member of the group IA alkali metals on the periodic table, a group that also includes sodium, potassium, rubidium, cesium, and francium. Lithium exists in nature as both ⁶Li (7.42%) and ⁷Li (92.58%). The latter isotope allows the imaging of lithium by magnetic resonance spectroscopy. Some 300 mg of lithium is contained in 1,597 mg of lithium carbonate (Li₂CO₃). Most lithium used in the United States is obtained from dry lake mining in Chile and Argentina.

PHARMACOLOGICAL ACTIONS

Lithium is rapidly and completely absorbed after oral administration, with peak serum concentrations occurring in 1 to 1.5 hours with standard preparations and in 4 to 4.5 hours with slow-release and controlled-release preparations. Lithium does not bind to plasma proteins, is not metabolized, and is excreted through the kidneys. The plasma half-life is initially 1.3 days, and is 2.4 days after

administration for more than 1 year. The blood–brain barrier permits only slow passage of lithium, which is why a single overdose does not necessarily cause toxicity and why long-term lithium intoxication is slow to resolve. The elimination half-life of lithium is 18 to 24 hours in young adults, but is shorter in children and longer in elderly persons. Renal clearance of lithium is decreased with renal insufficiency. Equilibrium is reached after 5 to 7 days of regular intake. Obesity is associated with higher rates of lithium clearance. The excretion of lithium is complex during pregnancy; excretion increases during pregnancy but decreases after delivery. Lithium is excreted in breast milk and in insignificant amounts in the feces and sweat. Thyroid and renal concentrations of lithium are higher than serum levels.

An explanation for the mood-stabilizing effects of lithium remains elusive. Theories include alterations of ion transport and effects on neurotransmitters and neuropeptides, signal transduction pathways, and second messenger systems.

THERAPEUTIC INDICATIONS

Bipolar I Disorder

Manic Episodes. Lithium controls acute mania and prevents relapse in about 80 percent of persons with bipolar I disorder and in a somewhat smaller percentage of persons with mixed (mania and depression) episodes, rapid-cycling bipolar disorder, or mood changes in encephalopathy. Lithium has a relatively slow onset of action when used and exerts its antimanic effects over 1 to 3 weeks. Thus, a benzodiazepine, dopamine receptor antagonist (DRA), serotonin–dopamine antagonist (SDA), or valproic acid is usually administered for the first few weeks. Patients with mixed or dysphoric mania, rapid cycling, comorbid substance abuse, or organicity respond less well to lithium than those with classic mania.

Bipolar Depression. Lithium has been shown to be effective in the treatment of depression associated with bipolar I disorder, as well as in the role of add-on therapy for patients with severe major depressive disorder. Augmentation of lithium therapy with valproic acid (Depakene) or carbamazepine (Tegretol) is usually well tolerated, with little risk of precipitation of mania.

When a depressive episode occurs in a person taking maintenance lithium, the differential diagnosis should include lithium-induced hypothyroidism, substance abuse, and lack of compliance with the lithium therapy. Possible treatment approaches include increasing the lithium concentration (up to 1 to 1.2 mEq/L); adding supplemental thyroid hormone (e.g., 25 µg a day of liothyronine [Cytomel]), even in the presence of normal findings on thyroid function tests; augmentation with valproate or carbamazepine; the judicious use of antidepressants; or electroconvulsive therapy (ECT). After the acute depressive episode resolves, other therapies should be tapered in favor of lithium monotherapy, if clinically tolerated.

Maintenance. Maintenance treatment with lithium markedly decreases the frequency, severity, and duration of manic and depressive episodes in persons with bipolar I disorder. Lithium provides relatively more effective prophylaxis for mania than for depression, and supplemental antidepressant strategies may be necessary either intermittently or continuously. Lithium maintenance is almost always indicated after the first episode of bipolar I disorder, depression or mania, and should be considered after the first episode for adolescents or for persons who have a family history of bipolar I disorder. Others who benefit from lithium maintenance are those who have poor support systems, had no precipitating factors for the first episode, have a high suicide risk, had a sudden onset of the first episode, or had a first episode of mania. Clinical studies have shown that lithium reduces the incidence of suicide in bipolar I disorder patients sixfold or sevenfold. Lithium is also an effective treatment for persons with severe cyclothymic disorder.

Initiating maintenance therapy after the first manic episode is considered a wise approach based on several observations. First, each episode of mania increases the risk of subsequent episodes. Second, among people responsive to lithium, relapses are 28 times more likely after lithium use is discontinued. Third, case reports describe persons who initially responded to lithium, discontinued taking it, and then had a relapse but no longer responded to lithium in subsequent episodes. Continued maintenance treatment with lithium is often associated with increasing efficacy and reduced mortality. Therefore, an episode of depression or mania that occurs after a relatively short time of lithium maintenance does not necessarily represent treatment failure. However, lithium treatment alone may begin to lose its effectiveness after several years of successful use. If this occurs, then supplemental treatment with carbamazepine or valproate may be useful.

Maintenance lithium dosages can often be adjusted to achieve plasma concentration somewhat lower than that needed for treatment of acute mania. If lithium use is to be discontinued, then the dosage should be slowly tapered. Abrupt discontinuation of lithium therapy is associated with an increased risk of recurrence of manic and depressive episodes.

Major Depressive Disorder

Lithium is effective in the long-term treatment of major depression, but it is not more effective than antidepressant drugs. The most common role for lithium in major depressive disorder is as an adjuvant to antidepressant use in persons who have failed to respond to the antidepressants alone. About 50 to 60 percent of antidepressant nonresponders do respond when lithium, 300 mg three times daily, is added to the antidepressant regimen. In some cases, a response may be seen within days, but most often, several weeks are required to see the efficacy of the regimen. Lithium alone may effectively treat depressed persons who have bipolar I disorder but have not yet had their first manic episode. Lithium has been reported to be effective in persons with major depressive disorder whose disorder has a particularly marked cyclicity.

Schizoaffective Disorder and Schizophrenia

Persons with prominent mood symptoms—either bipolar type or depressive type—with schizoaffective disorder are more likely to respond to lithium than those with predominant psychotic symptoms. Although SDAs and DRAs are the treatments of choice for persons with schizoaffective disorder, lithium is a useful augmentation agent. This is particularly true for persons whose symptoms are resistant to treatment with SDAs and DRAs. Lithium augmentation of an SDA or DRA treatment may be an effective treatment for persons with schizoaffective disorder even in the absence of a prominent mood disorder component. Some persons with schizophrenia who cannot take antipsychotic drugs may benefit from lithium treatment alone.

Other Indications

Over the years, reports have appeared about the use of lithium to treat a wide range of other psychiatric and nonpsychiatric conditions (Tables 29.19-1 and 29.19-2). The effectiveness and safety of lithium for most of these disorders have not been confirmed. Lithium has antiaggressive activity that is separate from its effects on mood. Aggressive outbursts in persons with schizophrenia, violent prison inmates, and children with conduct disorder and aggression, or self-mutilation in persons with mental retardation can sometimes be controlled with lithium.

Table 29.19-1
Psychiatric Uses of Lithium

- Historical
 - Gouty mania
- Well established (FDA approved)
 - Manic episode
 - Maintenance therapy
- Reasonably well established
 - Bipolar I disorder
 - Depressive episode
 - Bipolar II disorder
 - Rapid-cycling bipolar I disorder
 - Cyclothymic disorder
 - Major depressive disorder
 - Acute depression (as an augmenting agent)
 - Maintenance therapy
 - Schizoaffective disorder
- Evidence of benefit in particular groups
 - Schizophrenia
 - Aggression (episodic), explosive behavior, and self-mutilation
 - Conduct disorder in children and adolescents
 - Mental retardation
 - Cognitive disorders
 - Prisoners
- Anecdotal, controversial, unresolved, or doubtful
 - Alcohol and other substance-related disorders
 - Cocaine abuse
 - Substance-induced mood disorder with manic features
- Obsessive-compulsive disorder
- Phobias
- Posttraumatic stress disorder
- ADHD
- Eating disorders
 - Anorexia nervosa
 - Bulimia nervosa
- Impulse-control disorders
 - Kleine-Levin syndrome
- Mental disorders caused by a general medical condition (e.g., mood disorder caused by a general medical condition with manic features)
- Periodic catatonia
- Periodic hypersomnia
- Personality disorders (e.g., antisocial, borderline, emotionally unstable, schizotypal)
- Premenstrual dysphoric disorder
- Sexual disorders
 - Transvestism
 - Exhibitionism
 - Pathological hypersexuality

FDA, Food and Drug Administration; ADHD, attention-deficit/hyperactivity disorder.

 **Table 29.19-2**
Nonpsychiatric Uses of Lithium^a

Historical

- Gout and other uric acid diatheses
- Lithium bromide as anticonvulsant

Neurological

- Epilepsy
- Headache (chronic cluster, hypnic, migraine, particularly cyclic)
- Ménière's disease (not supported by controlled studies)
- Movement disorders
- Huntington's disease
- L-Dopa–induced hyperkinesias
- On–off phenomenon in Parkinson's disease (controlled study found decreased akinesia but development of dyskinesia in a few cases)
- Spasmodic torticollis
- Tardive dyskinesia (not supported by controlled studies, and pseudoparkinsonism has been reported)
- Tourette's disorder
- Pain (facial pain syndrome, painful shoulder syndrome, fibromyalgia)
- Periodic paralysis (hypokalemic and hypermagnesic but not hyperkalemic)

Hematological

- Aplastic anemia
- Cancer—chemotherapy induced, radiotherapy induced
- Neutropenia (one study found increased risk of sudden death in patients with pre-existing cardiovascular disorder)
- Drug-induced neutropenia (e.g., from carbamazepine, antipsychotics, immunosuppressives, and zidovudine)
- Felty's syndrome
- Leukemia

Endocrine

- Thyroid cancer as an adjunct to radioactive iodine
- Thyrotoxicosis
- Syndrome of inappropriate antidiuretic hormone secretion

Cardiovascular

- Antiarrhythmic agent (animal data only)

Dermatological

- Genital herpes (controlled studies support topical and oral use)
- Eczematoid dermatitis
- Seborrheic dermatitis (controlled study supports)

Gastrointestinal

- Cyclic vomiting
- Gastric ulcers
- Pancreatic cholera
- Ulcerative colitis

Respiratory

- Asthma (controlled study did not support)
- Cystic fibrosis

Other

- Bovine spastic paresis

^aAll the uses listed here are experimental and do not have Food and Drug Administration (FDA)–approved labeling. There are conflicting reports about many of these uses—some have negative findings in controlled studies, and a few involve reports of possible adverse effects.

L-Dopa, levodopa.

PRECAUTIONS AND ADVERSE EFFECTS

More than 80 percent of patients taking lithium experience side effects. It is important to minimize the risk of adverse events through monitoring of lithium blood levels and to use appropriate pharmacological interventions to counteract unwanted effects when they occur. The most common adverse effects are summarized in [Table 29.19-3](#). Patient education can play an important role in reducing the incidence and severity of side effects. Patients taking lithium should be advised that changes in the body's water and salt content can affect the amount of lithium excreted, resulting in either increases or decreases in lithium concentrations. Excessive sodium intake (e.g., a dramatic dietary change) lowers lithium concentrations. Conversely, too little sodium (e.g., fad diets) can lead to potentially toxic concentrations of lithium. Decreases in body fluid (e.g., excessive perspiration) can lead to dehydration and lithium intoxication. Patients should report whenever medications are prescribed by another clinician because many commonly used agents can affect lithium concentrations.

Table 29.19-3
Adverse Effects of Lithium

Neurological

Benign, nontoxic: dysphoria, lack of spontaneity, slowed reaction time, memory difficulties

Tremor: postural, occasional extrapyramidal

Toxic: coarse tremor, dysarthria, ataxia, neuromuscular irritability, seizures, coma, death

Miscellaneous: peripheral neuropathy, benign intracranial hypertension, myasthenia gravis–like syndrome, altered creativity, lowered seizure threshold

Endocrine

Thyroid: goiter, hypothyroidism, exophthalmos, hyperthyroidism (rare)

Parathyroid: hyperparathyroidism, adenoma

Cardiovascular

Benign T-wave changes, sinus node dysfunction

Renal

Concentrating defect, morphologic changes, polyuria (nephrogenic diabetes insipidus), reduced GFR, nephrotic syndrome, renal tubular acidosis

Dermatological

Acne, hair loss, psoriasis, rash

Gastrointestinal

Appetite loss, nausea, vomiting, diarrhea

Miscellaneous

Altered carbohydrate metabolism, weight gain, fluid retention

GFR, glomerular filtration rate.

Cardiac Effects

Lithium can cause diffuse slowing, widening of frequency spectrum, and potentiation and disorganization of background rhythm on electrocardiography (ECG). Bradycardia and cardiac arrhythmias may occur, especially in people with cardiovascular disease. Lithium infrequently reveals Brugada syndrome, an inherited, life-threatening heart problem that some people may have without knowing it. It can cause a serious abnormal heartbeat and other symptoms (such as severe dizziness, fainting, shortness of breath) that need medical attention right away. Before starting lithium treatment, clinicians should ask about known heart conditions, unexplained fainting, and family history of problems or sudden unexplained death before age 45.

Gastrointestinal Effects

Gastrointestinal (GI) symptoms—which include nausea, decreased appetite, vomiting, and diarrhea—can be diminished by dividing the dosage, administering the lithium with food, or switching to another lithium preparation. The lithium preparation least likely to cause diarrhea is lithium citrate. Some lithium preparations contain lactose, which can cause diarrhea in lactose-intolerant persons. Persons taking slow-release formulations of lithium who experience diarrhea caused by unabsorbed medication in the lower part of the GI tract may experience less diarrhea than with standard-release preparations. Diarrhea may also respond to antidiarrheal preparations such as loperamide (Imodium, Kaopectate), bismuth subsalicylate (Pepto-Bismol), or diphenoxylate with atropine (Lomotil).

Weight Gain

Weight gain results from a poorly understood effect of lithium on carbohydrate metabolism. Weight gain can also result from lithium-induced hypothyroidism, lithium-induced edema, or excessive consumption of soft drinks and juices to quench lithium-induced thirst.

Neurological Effects

Tremor. A lithium-induced postural tremor may occur that is usually 8 to 12 Hz and is most notable in outstretched hands, especially in the fingers, and during tasks involving fine manipulations. The tremor can be reduced by dividing the daily dosage, using a sustained-release formulation, reducing caffeine intake, reassessing the concomitant use of other medicines, and treating comorbid anxiety. β -Adrenergic receptor antagonists, such as propranolol, 30 to 120 mg a day in divided doses, and primidone (Mysoline), 50 to 250 mg a day, are usually effective in reducing the tremor. In persons with hypokalemia, potassium supplementation may improve the tremor. When a person taking lithium has a severe tremor, the possibility of lithium toxicity should be suspected and evaluated.

Cognitive Effects. Lithium use has been associated with dysphoria, lack of spontaneity, slowed reaction times, and impaired memory. The presence of these symptoms should be noted carefully because they are a frequent cause of noncompliance. The differential diagnosis for such symptoms should include depressive disorders, hypothyroidism, hypercalcemia, other illnesses, and other drugs. Some, but not all, persons have reported that fatigue and mild cognitive impairment decrease with time.

Other Neurological Effects. Uncommon neurological adverse effects include symptoms of mild parkinsonism, ataxia, and dysarthria, although the last two symptoms may also be attributable to lithium intoxication. Lithium is rarely associated with the development of peripheral neuropathy, benign intracranial hypertension (pseudotumor cerebri), findings resembling myasthenia gravis, and increased risk of seizures.

Renal Effect

The most common adverse renal effect of lithium is polyuria with secondary polydipsia. The symptom is particularly a problem in 25 to 35 percent of persons taking lithium who may have a urine output of more than 3 L a day (reference range: 1 to 2 L a day). The polyuria primarily results from lithium antagonism to the effects of antidiuretic hormone, which thus causes diuresis. When polyuria is a significant problem, the person's renal function should be evaluated and followed up with 24-hour urine collections for creatinine clearance determinations. Treatment consists of fluid replacement, the use of the lowest effective dosage of lithium, and single daily dosing of lithium. Treatment can also involve the use of a thiazide or potassium-sparing diuretic—for example, amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium), or amiloride–hydrochlorothiazide (Moduretic). If treatment with a diuretic is initiated, the lithium dosage should be halved, and the diuretic should not be started for 5 days, because the diuretic is likely to increase lithium retention.

The most serious renal adverse effects, which are rare and associated with continuous lithium administration for 10 years or more, involve appearance of nonspecific interstitial fibrosis, associated with gradual decreases in glomerular filtration rate and increases in serum creatinine concentrations, and rarely with renal failure. Lithium is occasionally associated with nephrotic syndrome and features of distal renal tubular acidosis. Another pathological finding in patients with lithium nephropathy is the presence of microcysts. Magnetic resonance imaging (MRI) can be used to demonstrate renal microcysts secondary to chronic lithium nephropathy and therefore avoid renal biopsy. It is prudent for persons taking lithium to check their serum creatinine concentration, urine chemistries, and 24-hour urine volume at 6-month intervals. If creatinine levels do rise, then more frequent monitoring and MRI might be considered.

Thyroid Effects

Lithium causes a generally benign and often transient diminution in the concentrations of circulating thyroid hormones. Reports have attributed goiter (5 percent of persons), benign reversible exophthalmos, hyperthyroidism, and hypothyroidism (7 to 10 percent of persons) to lithium treatment. Lithium-induced hypothyroidism is more common in women (14 percent) than in men (4.5 percent). Women are at highest risk during the first 2 years of treatment. Persons taking lithium to treat bipolar disorder are twice as likely to develop hypothyroidism if they develop rapid cycling. About 50 percent of persons receiving long-term lithium treatment have laboratory abnormalities, such as an abnormal thyrotropin-releasing hormone response, and about 30 percent have elevated concentrations of thyroid-stimulating hormone (TSH). If symptoms of hypothyroidism are present, replacement with levothyroxine (Synthroid) is indicated. Even in the absence of hypothyroid symptoms, some clinicians treat persons with significantly elevated TSH concentrations with levothyroxine. In lithium-treated persons, TSH concentrations should be measured every 6 to 12 months. Lithium-induced hypothyroidism should be considered when evaluating depressive episodes that emerge during lithium therapy.

Cardiac Effects

The cardiac effects of lithium resemble those of hypokalemia on ECG. They are caused by the displacement of intracellular potassium by the lithium ion. The most common changes on the ECG are T-wave flattening or inversion. The changes are benign and disappear after lithium is excreted from the body.

Lithium depresses the pacemaking activity of the sinus node, sometimes resulting in sinus dysrhythmias, heart block, and episodes of syncope. Lithium treatment, therefore, is contraindicated in persons with sick sinus syndrome. In rare cases, ventricular arrhythmias and congestive heart failure have been associated with lithium therapy. Lithium cardiotoxicity is more prevalent in persons on a low-salt diet, those taking certain diuretics or angiotensin-converting enzyme inhibitors (ACEIs), and those with fluid–electrolyte imbalances or any renal insufficiency.

Dermatological Effects

Dermatological effects may be dose dependent. They include acneiform, follicular, and maculopapular eruptions; pretibial ulcerations; and worsening of psoriasis. Occasionally, aggravated psoriasis or acneiform eruptions may force the discontinuation of lithium treatment. Alopecia has also been reported. Persons with many of those conditions respond favorably to changing to another lithium preparation and the usual dermatological measures. Lithium concentrations should be monitored if tetracycline is used for the treatment of acne because it can increase the retention of lithium.

Lithium Toxicity and Overdoses

The early signs and symptoms of lithium toxicity include neurological symptoms, such as coarse tremor, dysarthria, and ataxia; GI symptoms; cardiovascular changes; and renal dysfunction. The later signs and symptoms include impaired consciousness, muscular fasciculations, myoclonus, seizures, and coma. Signs and symptoms of lithium toxicity are outlined in [Table 29.19-4](#). Risk factors include exceeding the recommended dosage, renal impairment, low-sodium diet, drug interaction, and dehydration. Elderly persons are more vulnerable to the effects of increased serum lithium concentrations. The greater the degree and duration of elevated lithium concentrations, the worse the symptoms of lithium toxicity.

 **Table 29.19-4**
Signs and Symptoms of Lithium Toxicity

1. Mild to moderate intoxication (lithium level, 1.5–2.0 mEq/L)	
GI	Vomiting Abdominal pain Dryness of mouth
Neurological	Ataxia Dizziness Slurred speech Nystagmus Lethargy or excitement Muscle weakness
2. Moderate to severe intoxication (lithium level: 2.0–2.5 mEq/L)	
GI	Anorexia Persistent nausea and vomiting
Neurological	Blurred vision Muscle fasciculations Clonic limb movements Hyperactive deep tendon reflexes Choreoathetoid movements Convulsions Delirium Syncope Electroencephalographic changes Stupor Coma Circulatory failure (lowered BP, cardiac arrhythmias, and conduction abnormalities)
3. Severe lithium intoxication (lithium level >2.5 mEq/L)	
	Generalized convulsions Oliguria and renal failure Death

Lithium toxicity is a medical emergency, potentially causing permanent neuronal damage and death. In cases of toxicity ([Table 29.19-5](#)), lithium should be stopped and dehydration treated. Unabsorbed lithium can be removed from the GI tract by ingestion of sodium polystyrene sulfonate (Kayexalate) or polyethylene glycol solution (GoLYTELY), but not activated charcoal. Ingestion of a single large dose may create clumps of medication in the stomach, which can be removed by gastric lavage with a wide-bore tube. The value of forced diuresis is still debated. In severe cases, hemodialysis rapidly removes excessive amounts of serum lithium. Postdialysis serum lithium concentrations may increase as lithium is redistributed from tissues to blood, so repeat dialysis may be needed. Neurological improvement may lag behind clearance of serum lithium by several days because lithium crosses the blood–brain barrier slowly.

 **Table 29.19-5**

Management of Lithium Toxicity

1. Contact personal physician or go to a hospital emergency department.
2. Lithium should be discontinued
3. Vital signs and a neurological examination with complete formal mental status examination.
4. Lithium level, serum electrolytes, renal function tests, and ECG
5. Emesis, gastric lavage, and absorption with activated charcoal.
6. For any patient with a serum lithium level greater than 4.0 mEq/L, hemodialysis

ECG, electrocardiography.

Adolescents

The serum lithium concentrations for adolescents are similar to those for adults. Weight gain and acne associated with lithium use can be particularly troublesome to adolescents.

Elderly Persons

Lithium is a safe and effective drug for elderly persons. However, the treatment of elderly persons taking lithium may be complicated by the presence of other medical illnesses, decreased renal function, special diets that affect lithium clearance, and generally increased sensitivity to lithium. Elderly persons should initially be given low dosages, their dosages should be switched less frequently than those of younger persons, and a longer time must be allowed for renal excretion to equilibrate with absorption before lithium can be assumed to have reached its steady-state concentrations.

Pregnant Women

Lithium should not be administered to pregnant women in the first trimester because of the risk of birth defects. The most common malformations involve the cardiovascular system, most commonly Ebstein's anomaly of the tricuspid valves. The risk of Ebstein's malformation in lithium-exposed fetuses is one in 1,000, which is 20 times the risk in the general population. The possibility of fetal cardiac anomalies can be evaluated with fetal echocardiography. The teratogenic risk of lithium (4 to 12 percent) is higher than that for the general population (2 to 3 percent) but appears to be lower than that associated with the use of valproate or carbamazepine. A woman who continues to take lithium during pregnancy should use the lowest effective dosage. The maternal lithium concentration must be monitored closely during pregnancy, and especially after pregnancy, because of the significant decrease in renal lithium excretion as renal function returns to normal in the first few days after delivery. Adequate hydration can reduce the risk of lithium toxicity during labor. Lithium prophylaxis is recommended for all women with bipolar disorder as they enter the postpartum period. Lithium is excreted into breast milk and should be taken by a nursing mother only after careful evaluation of potential risks and benefits. Signs of lithium toxicity in infants include lethargy, cyanosis, abnormal reflexes, and sometimes hepatomegaly.

Miscellaneous Effects

Lithium should be used with caution in diabetic persons, who should monitor their blood glucose concentrations carefully to avoid diabetic ketoacidosis. Benign, reversible leukocytosis is commonly associated with lithium treatment. Dehydrated, debilitated, and medically ill persons are most susceptible to adverse effects and toxicity.

DRUG INTERACTIONS

Lithium drug interactions are summarized in [Table 29.19-6](#).

 **Table 29.19-6**
Drug Interactions with Lithium

Drug Class	Reaction
Antipsychotics	Case reports of encephalopathy, worsening of extrapyramidal adverse effects, and neuroleptic malignant syndrome; inconsistent reports of altered red blood cell and plasma concentrations of lithium, antipsychotic drug, or both
Antidepressants	Occasional reports of a serotonin-like syndrome with potent serotonin reuptake inhibitors
Anticonvulsants	No significant pharmacokinetic interactions with carbamazepine or valproate; reports of neurotoxicity with carbamazepine; combinations helpful for treatment resistance
NSAIDs	May reduce renal lithium clearance and increase serum concentration; toxicity reported (exception is aspirin)
Diuretics	
Thiazides	Well-documented reduced renal lithium clearance and increased serum concentration; toxicity reported
Potassium sparing	
Loop	Limited data; may increase lithium concentration
Osmotic (mannitol, urea)	Lithium clearance unchanged (some case reports of increased lithium concentration)
Xanthine (aminophylline, caffeine, theophylline)	Increase renal lithium clearance and decrease lithium concentration
Carbonic anhydrase inhibitors (acetazolamide)	Increase renal lithium clearance
ACEIs	Reports of reduced lithium clearance, increased concentrations, and toxicity
Calcium channel inhibitors	Case reports of neurotoxicity; no consistent pharmacokinetic interactions
Miscellaneous	
Succinylcholine, pancuronium	Reports of prolonged neuromuscular blockade
Metronidazole	Increased lithium concentration
Methyldopa	Few reports of neurotoxicity
Sodium bicarbonate	Increased renal lithium clearance
Iodides	Additive antithyroid effects
Propranolol	Used for lithium tremor; possible slight increase in lithium concentration

NSAID, nonsteroidal anti-inflammatory drug; ACEI, angiotensin-converting enzyme inhibitor.

Lithium is commonly used in conjunction with DRAs. This combination is typically effective and safe. However, coadministration of higher dosages of a DRA and lithium may result in a synergistic increase in the symptoms of lithium-induced neurological side effects and neuroleptic extrapyramidal symptoms. In rare instances, encephalopathy has been reported with this combination.

The coadministration of lithium and carbamazepine, lamotrigine, valproate, and clonazepam may increase lithium concentrations and

aggravate lithium-induced neurological adverse effects. Treatment with the combination should be initiated at slightly lower dosages than usual, and the dosages should be increased gradually. Changes from one to another treatment for mania should be made carefully, with as little temporal overlap between the drugs as possible.

Most diuretics (e.g., thiazide and potassium sparing) can increase lithium concentrations; when treatment with such a diuretic is stopped, the clinician may need to increase the person's daily lithium dosage. Osmotic and loop diuretics, carbonic anhydrase inhibitors, and xanthines (including caffeine) may reduce lithium concentrations to below therapeutic concentrations. Whereas ACEIs may cause an increase in lithium concentrations, the AT₁ angiotensin II receptor inhibitors losartan (Cozaar) and irbesartan (Avapro) do not alter lithium concentrations. A wide range of nonsteroidal anti-inflammatory drugs (NSAIDs) can decrease lithium clearance, thereby increasing lithium concentrations. These drugs include indomethacin (Indocin), phenylbutazone (Azolid), diclofenac (Voltaren), ketoprofen (Orudis), oxyphenbutazone (Oxalid), ibuprofen (Motrin, Advil), piroxicam (Feldene), and naproxen (Naprosyn). Aspirin and sulindac (Clinoril) do not affect lithium concentrations.

The coadministration of lithium and quetiapine (Seroquel) may cause somnolence but is otherwise well tolerated. The coadministration of lithium and ziprasidone (Geodon) may modestly increase the incidence of tremor. The coadministration of lithium and calcium channel inhibitors should be avoided because of potentially fatal neurotoxicity.

A person taking lithium who is about to undergo ECT should discontinue taking lithium 2 days before beginning ECT to reduce the risk of delirium.

LABORATORY INTERFERENCES

Lithium does not interfere with any laboratory tests, but lithium-induced alterations include an increased white blood cell count, decreased serum thyroxine, and increased serum calcium. Blood collected in a lithium–heparin anticoagulant tube will produce falsely elevated lithium concentrations.

DOSAGE AND CLINICAL GUIDELINES

Initial Medical Workup

All patients should have a routine laboratory workup and physical examination before being started on lithium. The laboratory tests should include serum creatinine concentration (or a 24-hour urine creatinine if the clinician has any reason to be concerned about renal function), electrolytes, thyroid function (TSH, T₃ [triiodothyronine], and T₄ [thyroxine]), a complete blood count (CBC), ECG, and a pregnancy test in women of childbearing age.

Dosage Recommendations

Lithium formulations include immediate-release 150, 300, and 600 mg lithium carbonate capsules (Eskalith and generic), 300 mg lithium carbonate tablets (Lithotabs), 450 mg controlled-release lithium carbonate capsules (Eskalith CR and Lithonate), and 8 mEq/5 mL of lithium citrate syrup.

The starting dosage for most adults is 300 mg of the regular-release formulation three times daily. The starting dosage for elderly persons or persons with renal impairment should be 300 mg once or twice daily. After stabilization, dosages between 900 and 1,200 mg a day usually produce a therapeutic plasma concentration of 0.6 to 1 mEq/L, and a daily dose of 1,200 to 1,800 mg usually produces a therapeutic concentration of 0.8 to 1.2 mEq/L. Maintenance dosing can be given either in two or three divided doses of the regular-release formulation or in a single dosage of the sustained-release formulation equivalent to the combined daily dosage of the regular-release formulation. The use of divided doses reduces gastric upset and avoids single high-peak lithium concentrations. Discontinuation of lithium should be gradual to minimize the risk of early recurrence of mania and to permit recognition of early signs of recurrence.

Laboratory Monitoring

The periodic measurement of serum lithium concentration is an essential aspect of patient care, but it should always be combined with sound clinical judgment. A laboratory report listing the therapeutic range as 0.5 to 1.5 mEq/L may lull a clinician into disregarding early signs of lithium intoxication in patients whose levels are less than 1.5 mEq/L. Clinical toxicity, especially in elderly persons, has been well documented within this so-called therapeutic range.

Regular monitoring of serum lithium concentrations is essential. Lithium levels should be obtained every 2 to 6 months except when there are signs of toxicity, during dosage adjustments, and in persons suspected to be noncompliant with the prescribed dosages. Under these circumstances, levels may be done weekly. Baseline ECG studies are essential, and should be repeated annually.

When obtaining blood for lithium levels, patients should be at steady-state lithium dosing (usually after 5 days of constant dosing), preferably using a twice-daily or thrice-daily dosing regimen, and the blood sample must be drawn 12 hours (\pm 30 minutes) after a given dose. Lithium concentrations 12 hours postdose in persons treated with sustained-release preparations are generally about 30% higher than the corresponding concentrations obtained from those taking the regular-release preparations. Because available data are based on a sample population following a multiple-dosage regimen, regular-release formulations given at least twice daily should be used for initial determination of the appropriate dosages. Factors that may cause fluctuations in lithium measurements include dietary sodium intake, mood state, activity level, body position, and use of an improper blood sample tube.

Laboratory values that do not seem to correspond to clinical status may result from the collection of blood in a tube with a lithium–heparin anticoagulant (which can give results falsely elevated by as much as 1 mEq/L) or aging of the lithium ion–selective electrode (which can cause inaccuracies of up to 0.5 mEq/L). After the daily dose has been set, it is reasonable to change to the sustained-release formulation given once daily.

Effective serum concentrations for mania are 1.0 to 1.5 mEq/L, a level associated with 1,800 mg a day. The recommended range for maintenance treatment is 0.4 to 0.8 mEq/L, which is usually achieved with a daily dose of 900 to 1,200 mg. A small number of persons will not achieve therapeutic benefit with a lithium concentration of 1.5 mEq/L, yet will have no signs of toxicity. For such persons, titration of the lithium dosage to achieve a concentration above 1.5 mEq/L may be warranted. Some patients can be maintained at concentrations below 0.4 mEq/L. There may be considerable variation from patient to patient, so it is best to follow the maxim “treat the patient, not the laboratory results.” The only way to establish an optimal dose for a patient may be through trial and error.

Package inserts (U.S.) for lithium products list effective serum concentrations for mania between 1.0 and 1.5 mEq/L (usually achieved with 1,800 mg of lithium carbonate daily) and for long-term maintenance between 0.6 and 1.2 mEq/L (usually achieved with 900 to 1,200 mg of lithium carbonate daily). The dose–blood level relationship may vary considerably from patient to patient. The likelihood of achieving a response at levels above 1.5 mEq/L is usually outweighed greatly by the increased risk of toxicity, although rarely a patient may both require and tolerate a higher-than-usual blood concentration.

What constitutes the lower end of the therapeutic range remains a matter of debate. A prospective 3-year study found patients who maintained a concentration between 0.4 and 0.6 mEq/L (mean 0.54) were 2.6 times more likely to relapse than those who maintained between 0.8 and 1.0 mEq/L (mean 0.83). However, the higher blood concentrations produced more adverse effects and were less well tolerated.

If there is no response after 2 weeks at a concentration that is beginning to cause adverse effects, then the person should taper off lithium over 1 to 2 weeks and other mood-stabilizing drugs should be tried.

Patient Education

Lithium has a narrow therapeutic index, and many factors can upset the balance between lithium concentrations that are well tolerated and therapeutic, and those that produce side effects or toxicity. It is thus imperative that persons taking lithium be educated about signs and symptoms of toxicity, factors that affect lithium levels, how and when to obtain laboratory testing, and the importance of regular communication with the prescribing physician. Lithium concentrations can be disrupted by common factors such as excessive sweating from ambient heat or exercise or use of widely prescribed agents such as ACEIs or nonsteroidal anti-inflammatory drugs (NSAIDs). Patients may stop taking their lithium because they are feeling well or because they are experiencing side effects. They should be advised against discontinuing or modifying their lithium regimen. [Table 29.19-7](#) lists some important instructions for patients.

Table 29.19-7 **Instructions to Patients Taking Lithium**

Lithium can be remarkably effective in treating your disorder. If not used appropriately and not monitored closely, it can be ineffective and potentially harmful. It is important to keep the following instructions in mind.

Dosing

Take lithium exactly as directed by your doctor—never take more or less than the prescribed dose.

Do not stop taking without speaking to your doctor.

If you miss a dose, take it as soon as possible. If it is within 4 hours of the next dose, skip the missed dose (about 6 hours in the case of extended-release or slow-release preparations). Never double up doses.

Blood Tests

Comply with the schedule of recommended regular blood tests.

Despite their inconvenience and discomfort, your lithium blood levels, thyroid function, and kidney status need to be monitored as long as you take lithium.

When going to have lithium levels checked, you should have taken your last lithium dose 12 hours earlier.

Use of Other Medications

Do not start any prescription or over-the-counter medications without telling your doctor.

Even drugs such as ibuprofen (Advil, Motrin) and naproxen (Aleve) can significantly increase lithium levels.

Diet and Fluid Intake

Avoid sudden changes in your diet or fluid intake. If you do go on a diet, your doctor may need to increase the frequency of blood tests.

Caffeine and alcohol act as diuretics and can lower your lithium concentrations.

During treatment with lithium, it is recommended that you drink about 2 or 3 quarts of fluid daily and use normal amounts of salt.

Inform your doctor if you start or stop a low-salt diet.

Recognizing Potential Problems

If you engage in vigorous exercise or have an illness that causes sweating, vomiting, or diarrhea, consult your doctor because these might affect lithium levels.

Nausea, constipation, shakiness, increased thirst, frequency of urination, weight gain, or swelling of the extremities should be reported to your doctor.

Blurred vision, confusion, loss of appetite, diarrhea, vomiting, muscle weakness, lethargy, shakiness, slurred speech, dizziness, loss of balance, inability to urinate, or seizures could indicate severe toxicity and should prompt immediate medical attention.

29.20 Melatonin Agonists: Ramelteon and Melatonin

There are two melatonin receptor agonists commercially available in the United States: (1) melatonin, a dietary supplement available in various preparations in health food stores, and not under Food and Drug Administration (FDA) regulations; (2) and ramelteon (Rozerem), an FDA-approved drug for the treatment of insomnia characterized by difficulties with sleep onset. Both exogenous melatonin and ramelteon are thought to exert their effects by interaction with central melatonin receptors.

RAMELTEON

Ramelteon (Rozerem) is a melatonin receptor agonist used to treat sleep-onset insomnia. Unlike the benzodiazepines, ramelteon has no appreciable affinity for the γ -aminobutyric acid (GABA) receptor complex.

Pharmacological Actions

Ramelteon essentially mimics melatonin's sleep-promoting properties and has high affinity for melatonin MT1 and MT2 receptors in the brain. These receptors are thought to be critical in the regulation of the body's sleep-wake cycle.

Ramelteon is rapidly absorbed and eliminated over a dose range of 4 to 64 mg. Maximum plasma concentration (C_{max}) is reached approximately 45 minutes after administration, and the elimination half-life is 1 to 2.6 hours. The total absorption of ramelteon is at least 84%, but extensive first-pass metabolism results in a bioavailability of approximately 2%. Ramelteon is metabolized primarily through the cytochrome P450 (CYP)1A2 pathway and eliminated principally in urine. Repeated once-daily dosing does not appear to result in accumulation, likely because of the compound's short half-life.

Therapeutic Indications

Ramelteon was approved by the FDA for the treatment of insomnia characterized by difficulty with sleep onset. Potential off-label use is centered on application in circadian rhythm disorders, predominantly jet lag, delayed sleep phase syndrome, and shift work sleep disorder.

Clinical trials and animal studies have failed to demonstrate evidence of rebound insomnia or withdrawal effects.

Precautions and Adverse Events

Headache is the most common side effect of ramelteon. Other adverse effects may include somnolence, fatigue, dizziness, worsening insomnia, depression, nausea, and diarrhea. The drug should not be used in patients with severe hepatic impairment. It is also not recommended in patients with severe sleep apnea or severe chronic obstructive pulmonary disease. Prolactin levels may be increased in women. The drug should be used with caution, if at all, in nursing mothers and pregnant women.

Ramelteon has been found to sometimes decrease blood cortisol and testosterone and to increase prolactin. Female patients should be monitored for cessation of menses and of galactorrhea, decreased libido, and fertility problems. The safety and effectiveness of ramelteon in children has not been established.

Drug Interactions

CYP1A2 is the major isozyme involved in the hepatic metabolism of ramelteon. Accordingly, fluvoxamine (Luvox) and other CYP1A2 inhibitors may increase side effects of ramelteon.

Ramelteon should be administered with caution in patients taking CYP1A2 inhibitors, strong CYP3A4 inhibitors such as ketoconazole, and strong CYP2C inhibitors such as fluconazole (Diflucan). No clinically meaningful interactions were found when ramelteon was coadministered with omeprazole, theophylline, dextromethorphan, midazolam, digoxin, and warfarin.

Dosing and Clinical Guidelines

The usual dose of ramelteon is 8 mg within 30 minutes of going to bed. It should not be taken with or immediately after high-fat meals.

MELATONIN

Melatonin (*N*-acetyl-5-methoxytryptamine) is a hormone produced mainly at night in the pineal gland. Ingested melatonin can reach and bind to melatonin-binding sites in the brains of mammals, and produce somnolence when used at high doses. Melatonin is available as a dietary supplement and is not a medication. Few well-controlled clinical trials have been conducted to determine its effectiveness in treating such conditions as insomnia, jet lag, and sleep disturbances related to shift work.

Pharmacological Actions

Melatonin's secretion is stimulated by the dark and inhibited by the light. It is naturally synthesized from the amino acid tryptophan, which is converted to serotonin and finally converted to melatonin. The suprachiasmatic nuclei (SCN) of the hypothalamus have melatonin receptors, and melatonin may have a direct action on SCN to influence circadian rhythms, which are relevant for jet lag and sleep disturbances. In addition to the pineal gland, melatonin is also produced in the retina and gastrointestinal tract.

Melatonin has a very short half-life of 0.5 to 6 minutes. Plasma concentrations are a function of the dose administered and the endogenous rhythm. Approximately 90 percent of melatonin is cleared through first-pass metabolism by way of the CYP1A1 and CYP1A2 pathways. Elimination occurs principally in urine.

Exogenous melatonin interacts with the melatonin receptors that suppress neuronal firing and promote sleep. There does not appear to be a dose-response relationship between exogenous melatonin administrations and sleep effects.

Therapeutic Indications

Melatonin is not regulated by the FDA. Individuals have used exogenous melatonin to address sleep difficulties (insomnia, circadian rhythm disorders), cancer (breast, prostate, colorectal), seizures, depression, anxiety, and seasonal affective disorder. Some studies suggest that exogenous melatonin may have some antioxidant effects and antiaging properties.

Precautions and Adverse Reactions

Adverse events associated with melatonin include fatigue, dizziness, headache, irritability, and somnolence. Disorientation, confusion, sleepwalking, vivid dreams, and nightmares have also been observed, often with effects resolving after melatonin administration was suspended.

Melatonin may reduce fertility in both men and women. In men, exogenous melatonin reduces sperm motility, and long-term administration has been shown to inhibit testicular aromatase levels. In women, exogenous melatonin may inhibit ovarian function and for that reason it has been evaluated as a contraceptive, but with inconclusive results.

Drug Interactions

As a dietary supplement preparation, exogenous melatonin is not regulated by the FDA and has not been subjected to the same type of drug interaction studies that were performed for ramelteon. Caution is suggested in coadministering melatonin with blood thinners (e.g., warfarin [Coumadin], aspirin, and heparin), antiseizure medications, and medications that lower blood pressure.

Laboratory Interference

Melatonin is not known to interfere with any commonly used clinical laboratory tests.

Dosage and Administration

Over-the-counter melatonin is available in the following formulations: 1, 2.5, 3, and 5 mg capsules; 1 mg/4 mL liquid; 0.5 and 3 mg lozenges; 2.5 mg sublingual tablets; and 1, 2, and 3 mg timed-release tablets.

Standard recommendations are to take the desired melatonin dose at bedtime, but some evidence from clinical trials suggests that dosing up to 2 hours before habitual bedtime may produce greater improvement in sleep onset.

Agomelatine (Valdoxan)

Agomelatine is structurally related to melatonin and is used in Europe as a treatment for major depressive disorder. It acts as an agonist at melatonin (MT₁ and MT₂) receptors. It also acts as a serotonin antagonist. Analysis of agomelatine clinical trial data raised serious questions about the efficacy and safety of the drug. The drug is not being marketed in the United States.

29.21 Mirtazapine

Mirtazapine (Remeron) is unique among drugs used to treat major depression in that it increases both norepinephrine and serotonin through a mechanism other than reuptake blockade (as in the case of tricyclic agents or SSRIs) or monoamine oxidase inhibition (as in the case of phenelzine or tranylcypromine). Mirtazapine is also more likely to reduce rather than cause nausea and diarrhea, the result of its effects on serotonin 5-HT₃ receptors. Characteristic side effects include increased appetite and sedation.

PHARMACOLOGIC ACTIONS

Mirtazapine is administered orally and is rapidly and completely absorbed. It has a half-life of about 30 hours. Peak concentration is achieved within 2 hours of ingestion, and steady state is reached after 6 days. Plasma clearance may be slowed up to 30 percent in persons with impaired hepatic function, up to 50 percent in those with impaired renal function, up to 40 percent slower in elderly men, and up to 10 percent slower in elderly women.

The mechanism of action of mirtazapine is antagonism of central presynaptic α_2 -adrenergic receptors and blockade of postsynaptic serotonin 5-HT₂ and 5-HT₃ receptors. The α_2 -adrenergic receptor antagonism causes increased firing of norepinephrine and serotonin neurons. The potent antagonist of serotonin 5-HT₂ and 5-HT₃ receptors serves to decrease anxiety, relieve insomnia, and stimulate appetite. Mirtazapine is a potent antagonist of histamine H₁ receptors and is a moderately potent antagonist at α_1 -adrenergic and muscarinic-cholinergic receptors.

THERAPEUTIC INDICATIONS

Mirtazapine is effective for the treatment of depression. It is highly sedating, making it a reasonable choice for use in depressed patients with severe or long-standing insomnia. Some patients find the residual daytime sedation associated with initiation of treatment to be quite pronounced. However, the more extreme sedating properties of the drug generally lessen over the first week of treatment. Combined with

the tendency to sometimes cause a ravenous appetite, mirtazapine is well suited for depressed patients with melancholic features such as insomnia, weight loss, and agitation. Elderly depressed patients in particular are good candidates for mirtazapine; young adults are more likely to object to this side effect profile.

Mirtazapine's blockade of 5-HT₃ receptors, a mechanism associated with medications used to combat the severe gastrointestinal side effects of cancer chemotherapy agents, has led to the use of the drug in a similar role. In this population, sedation and stimulation of appetite clearly could be seen as being beneficial instead of unwelcome side effects.

Mirtazapine is often combined with SSRIs or venlafaxine to augment antidepressant response or counteract serotonergic side effects of those drugs, particularly nausea, agitation, and insomnia. Mirtazapine has no significant pharmacokinetic interactions with other antidepressants.

PRECAUTIONS AND ADVERSE REACTIONS

Somnolence, the most common adverse effect of mirtazapine, occurs in more than 50 percent of persons (Table 29.21-1). Persons starting mirtazapine should thus exercise caution when driving or operating dangerous machinery and even when getting out of bed at night. This adverse effect is why mirtazapine is almost always given before sleep. Mirtazapine potentiates the sedative effects of other CNS depressants, so potentially sedating prescription or over-the-counter drugs and alcohol should be avoided during use of mirtazapine. Mirtazapine also causes dizziness in 7 percent of persons. It does not appear to increase the risk for seizures. Mania or hypomania occurred in clinical trials at a rate similar to that of other antidepressant drugs.

 **Table 29.21-1**
Adverse Reactions Reported with Mirtazapine

Event	Patients (%)
Somnolence	54
Dry mouth	25
Increased appetite	17
Constipation	13
Weight gain	12
Dizziness	7
Myalgias	5
Disturbing dreams	4

Mirtazapine increases appetite in about one-third of patients. Mirtazapine may also increase serum cholesterol concentration to 20 percent or more above the upper limit of normal in 15 percent of persons and increase triglycerides to 500 mg/dL or more in 6 percent of persons. Elevations of alanine transaminase levels to more than three times the upper limit of normal were seen in 2 percent of mirtazapine-treated persons as opposed to 0.3 percent of placebo control subjects.

In limited premarketing experience, the absolute neutrophil count dropped to 500/mm³ or less within 2 months of the onset of use in 0.3 percent of persons, some of whom developed symptomatic infections. This hematologic condition was reversible in all cases and was more likely to occur when other risk factors for neutropenia were present. Increases in the frequency of neutropenia have not, however, been reported during the extensive postmarketing period. Persons who develop fever, chills, sore throat, mucous membrane ulceration, or other signs of infection should nevertheless be evaluated medically. If a low white blood cell count is found, mirtazapine should be immediately discontinued, and the infectious disease status should be followed closely.

A small number of persons experience orthostatic hypotension while taking mirtazapine. Although no data exist regarding the effects on fetal development, mirtazapine should be used with caution during pregnancy.

Mirtazapine use by pregnant women has not been studied, but because the drug may be excreted in breast milk, it should not be taken by nursing mothers. Because of the risk of agranulocytosis associated with mirtazapine use, persons should be attuned to signs of infection. Because of the sedating effects of mirtazapine, persons should determine the degree to which they are affected before engaging in driving or other potentially dangerous activities.

DRUG INTERACTIONS

Mirtazapine can potentiate the sedation of alcohol and benzodiazepines. Mirtazapine should not be used within 14 days of use of an MAOI.

LABORATORY INTERFERENCES

No laboratory interferences have yet been described for mirtazapine.

DOSAGE AND ADMINISTRATION

Mirtazapine is available in 15-, 30-, and 45-mg scored tablets. Mirtazapine is also available in 15-, 30-, and 45-mg orally disintegrating tablets for persons who have difficulty swallowing pills. If persons fail to respond to the initial dose of 15 mg of mirtazapine before sleep, the dose may be increased in 15-mg increments every 5 days to a maximum of 45 mg before sleep. Lower dosages may be necessary in elderly persons or persons with renal or hepatic insufficiency.

29.22 Monoamine Oxidase Inhibitors

Introduced in the late 1950s, MAOIs were the first class of approved antidepressant drugs. The first of these drugs, isoniazid, was intended to be used as a treatment for tuberculosis, but its antidepressant properties were discovered by chance when some treated patients experienced elevation of mood during treatment. Despite their effectiveness, prescription of MAOIs as first-line agents has always been limited by concern about the development of potentially lethal hypertension and the consequent need for a restrictive diet. Use of MAOIs declined further after the introduction of the SSRIs and other new agents. They are now mainly relegated to use in treatment-resistant cases. Thus, the second-line status of MAOIs has less to do with considerations of efficacy than with concerns for safety. The currently available MAOIs include phenelzine (Nardil), isocarboxazid (Marplan), tranylcypromine (Parnate), rasagiline (Azilect), moclobemide (Manerix), and selegiline (Eldepryl).

Two subsequent advances in the field of antidepressant MAOIs involve the introduction of a selective reversible inhibitor of MAO_A (RIMA), moclobemide (Manerix), in the early 1990s into most countries except the United States, and in 2005, the introduction of a transdermal delivery form of selegiline (Emsam) in the United States that is used for the treatment of parkinsonism. Other RIMA agents, including brofaromine (Consonar) and befloxatone, have not been submitted for registration despite favorable outcomes in clinical trials.

PHARMACOLOGIC ACTIONS

Phenelzine, tranylcypromine, and isocarboxazid are readily absorbed after oral administration and reach peak plasma concentrations within 2 hours. Whereas their plasma half-lives are in the range of 2 to 3 hours, their tissue half-lives are considerably longer. Because they irreversibly inactivate MAOs, the therapeutic effect of a single dose of irreversible MAOIs may persist for as long as 2 weeks. The RIMA moclobemide is rapidly absorbed and has a half-life of 0.5 to 3.5 hours. Because it is a reversible inhibitor, moclobemide has a much briefer clinical effect after a single dose than do irreversible MAOIs.

The MAO enzymes are found on the outer membranes of mitochondria, where they degrade cytoplasmic and extraneuronal monoamine neurotransmitters such as norepinephrine, serotonin, dopamine, epinephrine, and tyramine. MAOIs act in the CNS, the sympathetic nervous system, the liver, and the GI tract. There are two types of MAOs, MAO_A and MAO_B. MAO_A primarily metabolizes norepinephrine, serotonin, and epinephrine; dopamine and tyramine are metabolized by both MAO_A and MAO_B.

The structures of phenelzine and tranylcypromine are similar to those of amphetamine and have similar pharmacologic effects in that they increase the release of dopamine and norepinephrine with attendant stimulant effects on the brain.

THERAPEUTIC INDICATIONS

MAOIs are used for treatment of depression. Some research indicates that phenelzine is more effective than tricyclic antidepressants (TCAs) in depressed patients with mood reactivity, extreme sensitivity to interpersonal loss or rejection, prominent anergia, hyperphagia, and hypersomnia—a constellation of symptoms conceptualized as atypical depression. Evidence also suggests that MAOIs are more effective than TCAs as a treatment for bipolar depression.

Patients with panic disorder and social phobia respond well to MAOIs. MAOIs have also been used to treat bulimia nervosa, posttraumatic stress disorder (PTSD), anginal pain, atypical facial pain, migraine, attention-deficit/hyperactivity disorder (ADHD), idiopathic orthostatic hypotension, and depression associated with traumatic brain injury.

PRECAUTIONS AND ADVERSE REACTIONS

The most frequent adverse effects of MAOIs are orthostatic hypotension, insomnia, weight gain, edema, and sexual dysfunction. Orthostatic hypotension can lead to dizziness and falls. Thus, cautious upward tapering of the dosage should be used to determine the maximum tolerable dosage. Treatment for orthostatic hypotension includes avoidance of caffeine; intake of 2 L of fluid per day; addition of dietary salt or adjustment of antihypertensive drugs (if applicable); support stockings; and in severe cases, treatment with fludrocortisone (Florinef), a mineralocorticoid, 0.1 to 0.2 mg a day. Orthostatic hypotension associated with tranylcypromine use can usually be relieved by dividing the daily dosage.

Insomnia can be treated by dividing the dose, not giving the medication after dinner, and using trazodone (Desyrel) or a benzodiazepine hypnotic if necessary. Weight gain, edema, and sexual dysfunction often do not respond to any treatment and may warrant switching to another agent. When switching from one MAOI to another, the clinician should taper and stop use of the first drug for 10 to 14 days before beginning use of the second drug.

Paresthesias, myoclonus, and muscle pains are occasionally seen in persons treated with MAOIs. Paresthesias may be secondary to MAOI-induced pyridoxine deficiency, which may respond to supplementation with pyridoxine, 50 to 150 mg orally each day. Occasionally, persons complain of feeling drunk or confused, perhaps indicating that the dosage should be reduced and then increased gradually. Reports that the hydrazine MAOIs are associated with hepatotoxic effects are relatively uncommon. MAOIs are less cardiotoxic and less epileptogenic than are the tricyclic and tetracyclic drugs.

The most common adverse effects of the RIMA moclobemide are dizziness, nausea, and insomnia or sleep disturbance. RIMAs cause fewer GI adverse effects than do SSRIs. Moclobemide does not have adverse anticholinergic or cardiovascular effects, and it has not been reported to interfere with sexual function.

MAOIs should be used with caution by persons with renal disease, cardiovascular disease, or hyperthyroidism. MAOIs may alter the dosage of a hypoglycemic agent required by persons with diabetes. MAOIs have been particularly associated with induction of mania in persons in the depressed phase of bipolar I disorder and triggering of a psychotic decompensation in persons with schizophrenia. MAOIs are contraindicated during pregnancy, although data on their teratogenic risk are minimal. MAOIs should not be taken by nursing women because the drugs can pass into the breast milk.

Tyramine-Induced Hypertensive Crisis

The most worrisome side effect of MAOIs is the tyramine-induced hypertensive crisis. The amino acid tyramine is normally transformed via GI metabolism. However, MAOIs inactivate GI metabolism of dietary tyramine, thus allowing intact tyramine to enter the circulation. A hypertensive crisis may subsequently occur as a result of a powerful pressor effect of the amino acid. Tyramine-containing foods should be avoided for 2 weeks after the last dose of an irreversible MAOI to allow resynthesis of adequate concentrations of MAO enzymes.

Accordingly, foods rich in tyramine (Table 29.22-1) or other sympathomimetic amines, such as ephedrine, pseudoephedrine (Sudafed), or dextromethorphan (Trocal), should be avoided by persons who are taking irreversible MAOIs. Patients should be advised to continue the

dietary restrictions for 2 weeks after they stop MAOI treatment to allow the body to resynthesize the enzyme. Bee stings may cause a hypertensive crisis. In addition to severe hypertension, other symptoms may include headache, stiff neck, diaphoresis, nausea, and vomiting. A patient with these symptoms should seek immediate medical treatment.

Table 29.22-1
Tyramine-Rich Foods to be Avoided in Planning Monoamine Oxidase Inhibitor Diets

High Tyramine Content* (≥2 mg of tyramine a serving)
Cheese: English Stilton, blue cheese, white (3 yr old), extra old, old cheddar, Danish blue, mozzarella, cheese snack spreads
Fish, cured meats, sausage; pâtés and organs, salami, mortadella, air-dried sausage
Alcoholic beverages [‡] : Liqueurs and concentrated after-dinner drinks
Marmite (concentrated yeast extract)
Sauerkraut (Kraus)
Moderate Tyramine Content* (0.5–1.99 mg of tyramine a serving)
Cheese: Swiss Gruyere, muenster, feta, parmesan, gorgonzola, blue cheese dressing, Black Diamond
Fish, cured meats, sausage, pâtés and organs: Chicken liver (5 days old); bologna; aged sausage, smoked meat; salmon mousse
Alcoholic beverages: Beer and ale (12 oz per bottle)—Amstel, Export Draft, Blue Light, Guinness Extra Stout, Old Vienna, Canadian, Miller Light, Export, Heineken, Blue Wines (per 4 oz glass)—Rioja (red wine)
Low Tyramine Content* (0.01 to >0.49 mg of tyramine a serving)
Cheese: Brie, Camembert, Cambozola with or without rind
Fish, cured meat, sausage, organs, and pâtés; pickled herring; smoked fish; kielbasa sausage; chicken liver; liverwurst (<2 days old)
Alcoholic beverages: Red wines, sherry, scotch [‡]
Others: Banana or avocado (ripe or not), banana peel

*Any food left out to age or spoil can spontaneously develop tyramine through fermentation.

[‡]Alcohol can produce profound orthostasis interacting with monoamine oxidase inhibitors (MAOIs) but cannot produce direct hypotensive reactions.

[§]White wines, gin, and vodka have no tyramine content.

Table by Jonathan M. Himmelhoch, MD.

An MAOI-induced hypertensive crisis should be treated with α -adrenergic antagonists—for example, phentolamine (Regitine) or chlorpromazine (Thorazine). These drugs lower blood pressure within 5 minutes. IV furosemide (Lasix) can be used to reduce fluid load, and a β -adrenergic receptor antagonist can control tachycardia. A sublingual 10-mg dose of nifedipine (Procardia) can be given and repeated after 20 minutes. MAOIs should not be used by persons with thyrotoxicosis or pheochromocytoma.

The risk of tyramine-induced hypertensive crises is relatively low for persons who are taking RIMAs, such as moclobemide and befloxatone. These drugs have relatively little inhibitory activity for MAO_B, and because they are reversible, normal activity of existing MAO_A returns within 16 to 48 hours of the last dose of a RIMA. Therefore, the dietary restrictions are less stringent for RIMAs, applying only to foods containing high concentrations of tyramine, which need be avoided for 3 days after the last dose of a RIMA. A reasonable dietary recommendation for persons taking RIMAs is to avoid eating tyramine-containing foods 1 hour before and 2 hours after taking a RIMA.

Spontaneous, nontyramine-induced hypertensive crisis is a rare occurrence, usually shortly after the first exposure of an MAOI. Persons experiencing such a crisis should avoid MAOIs altogether.

Withdrawal

Abrupt cessation of regular doses of MAOIs may cause a self-limited discontinuation syndrome consisting of arousal, mood disturbances, and somatic symptoms. To avoid these symptoms when discontinuing use to an MAOI, dosages should be gradually tapered over several weeks.

Overdose

There is often an asymptomatic period of 1 to 6 hours after an MAOI overdose before the occurrence of the symptoms of toxicity. MAOI overdose is characterized by agitation that can progress to coma with hyperthermia, hypertension, tachypnea, tachycardia, dilated pupils, and hyperactive deep tendon reflexes. Involuntary movements may be present, particularly in the face and the jaw. Acidification of the urine markedly hastens the excretion of MAOIs, and dialysis can be of some use. Phentolamine or chlorpromazine may be useful if hypertension is a problem. Moclobemide alone in overdosage causes relatively mild and reversible symptoms.

DRUG INTERACTIONS

The major drug–drug interactions involving MAOIs are listed in Table 29.22-2. Most antidepressants as well as precursor agents should be avoided. Persons should be instructed to tell any other physicians or dentists who are treating them that they are taking an MAOI. MAOIs may potentiate the action of CNS depressants, including alcohol and barbiturates. MAOIs should not be coadministered with serotonergic drugs, such as SSRIs and clomipramine (Anafranil), because this combination can trigger a serotonin syndrome. Use of lithium or tryptophan with an irreversible MAOI may also induce a serotonin syndrome. Initial symptoms of a serotonin syndrome can include tremor, hypertonicity, myoclonus, and autonomic signs, which can then progress to hallucinosis, hyperthermia, and even death. Fatal reactions have occurred when MAOIs were combined with meperidine (Demerol) or fentanyl (Sublimaze).

Table 29.22-2
Drugs to be Avoided During Monoamine Oxidase Inhibitor Treatment (Part of Listing)

Never Use

Antiasthmatics
Antihypertensives (methyldopa, guanethidine, reserpine)
Buspirone
Levodopa
Opioids (especially meperidine, dextromethorphan, propoxyphene, tramadol; morphine or codeine may be less dangerous.)
Cold, allergy, or sinus medications containing dextromethorphan or sympathomimetics
SSRIs, clomipramine, venlafaxine, sibutramine
Sympathomimetics (amphetamines, cocaine, methylphenidate, dopamine, epinephrine, norepinephrine, isoproterenol, ephedrine, pseudoephedrine, phenylpropanolamine)
L-Tryptophan

Use Carefully

Anticholinergics
Antihistamines
Disulfiram
Bromocriptine
Hydralazine
Sedative-hypnotics
Terpin hydrate with codeine
Tricyclics and tetracyclics (avoid clomipramine)

MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.

When switching from an irreversible MAOI to any other type of antidepressant drug, persons should wait at least 14 days after the last dose of the MAOI before beginning use of the next drug to allow replenishment of the body's MAOs. When switching from an antidepressant to an irreversible MAOI, persons should wait 10 to 14 days (or 5 weeks for fluoxetine [Prozac]) before starting use of the MAOI to avoid drug-drug interactions. In contrast, MAO activity recovers completely 24 to 48 hours after the last dose of a RIMA.

The effects of the MAOIs on hepatic enzymes are poorly studied. Tranylcypromine inhibits CYP2C19. Moclobemide inhibits CYP2D6, CYP2C19, and CYP1A2 and is a substrate for 2C19.

Cimetidine (Tagamet) and fluoxetine significantly reduce the elimination of moclobemide. Modest doses of fluoxetine and moclobemide administered concurrently may be well tolerated, with no significant pharmacodynamic or pharmacokinetic interactions.

LABORATORY INTERFERENCES

MAOIs may lower blood glucose concentrations. MAOIs artificially raise urinary metanephrine concentrations and may cause a false-positive test result for pheochromocytoma or neuroblastoma. MAOIs have been reported to be associated with a minimal false elevation in thyroid function test results.

DOSAGE AND CLINICAL GUIDELINES

There is no definitive rationale for choosing one irreversible MAOI over another. Table 29.22-3 lists MAOI preparations and typical dosages. Phenelzine use should begin with a test dose of 15 mg on the first day. The dosage can be increased to 15 mg three times daily during the first week and increased by 15 mg a day each week thereafter until the dosage of 90 mg a day, in divided doses, is reached by the end of the fourth week. Tranylcypromine and isocarboxazid use should begin with a test dosage of 10 mg and may be increased to 10 mg three times daily by the end of the first week. Many clinicians and researchers have recommended upper limits of 50 mg a day for isocarboxazid and 40 mg a day for tranylcypromine. Administration of tranylcypromine in multiple small daily doses may reduce its hypotensive effects.

Table 29.22-3

Typical Dosage Forms and Recommended Dosages for Currently Available Monoamine Oxidase Inhibitors

Drug	Usual Dose (mg/day)	Maximum Dose (mg/day)	Dosage (Oral) Formulation
Isocarboxazid (Marplan)	20–40	60	10-mg tablets
Phenelzine (Nardil)	30–60	90	15-mg tablets
Tranylcypromine (Parnate)	20–60	60	10-mg tablets
Rasagiline	0.5–1.0	1.0	0.5- or 1.0-mg tablets
Selegiline (Eldepryl)	10	30	5-mg tablets
Moclobemide (Manerix)	300–600	600	100- or 150-mg tablets

Even though coadministration of MAOIs with TCAs, SSRIs, or lithium is generally contraindicated, these combinations have been used successfully and safely to treat patients with refractory depression. However, they should be used with extreme caution.

Hepatic transaminase serum concentrations should be monitored periodically because of the potential for hepatotoxicity, especially with phenelzine and isocarboxazid. Elderly persons may be more sensitive to MAOI adverse effects than are younger adults. MAO activity increases with age, so MAOI dosages for elderly persons are the same as those required for younger adults. The use of MAOIs for children has had minimal study.

Studies have suggested that transdermal selegiline has antidepressant properties. Although selegiline is a type B inhibitor at low doses, it becomes less selective as the dose is increased.

29.23 Nefazodone and Trazodone

Nefazodone (Serzone) and Trazodone (Desyrel, Olepto) are mechanistically and structurally related drugs approved as treatments for depression. Nefazodone (Serzone) is an analog of trazodone. When nefazodone was introduced in 1995, there were expectations that it would become widely used because it did not cause the sexual side effects and sleep disruption associated with the selective SSRIs. Although it was devoid of these side effects, it was nevertheless found to produce problematic sedation, nausea, dizziness, and visual disturbances. Consequently, nefazodone was never extensively adopted in clinical practice. This fact, as well as reports of rare cases of sometimes fatal hepatotoxicity, led the original manufacturer to discontinue production of branded nefazodone in 2004. Generic nefazodone remains available in the United States.

Trazodone received Food and Drug Administration (FDA) approval in 1981 as a treatment for major depressive disorder (MDD). Its novel triazolopyridine chemical structure distinguished it from the TCAs, and clinical trials suggested improved safety and tolerability compared with TCAs. There were high expectations that it would replace the older drugs as a mainstay of treatment for depression. However, the extreme sedation associated with trazodone, even at subtherapeutic doses, limited the clinical effectiveness of the drug. However, its soporific properties made trazodone a favorite alternative to standard hypnotics as a sleep-inducing agent. Unlike conventional sleeping pills, trazodone is not a controlled substance.

In 2010, the FDA approved an extended-release, once-daily formulation (Olepto) as a treatment for MDD in adults. In the trial leading to the approval of the extended-release formulation, the most common adverse events were somnolence or sedation, dizziness, constipation, and blurred vision. Surprisingly, only 4 percent of patients in the trazodone group discontinued treatment because of somnolence or sedation.

NEFAZODONE

Pharmacologic Actions

Nefazodone is rapidly and completely absorbed but is then extensively metabolized so that the bioavailability of active compounds is about 20 percent of the oral dose. Its half-life is 2 to 4 hours. Steady-state concentrations of nefazodone and its principal active metabolite, hydroxynefazodone, are achieved within 4 to 5 days. Metabolism of nefazodone in elderly persons, especially women, is about half of that seen in younger persons, so lowered doses are recommended for elderly persons. An important metabolite of nefazodone is meta-chlorophenylpiperazine (mCPP), which has some serotonergic effects and may cause migraine, anxiety, and weight loss.

Although nefazodone is an inhibitor of serotonin uptake and, more weakly, of norepinephrine reuptake, its antagonism of serotonin 5-HT_A receptors is thought to produce its antianxiety and antidepressant effects. Nefazodone is also a mild antagonist of the α_1 -adrenergic receptors, which predisposes some persons to orthostatic hypotension but is not sufficiently potent to produce priapism.

Therapeutic Indications

Nefazodone is effective for the treatment of major depression. The usual effective dosage is 300 to 600 mg a day. In direct comparison with SSRIs, nefazodone is less likely to cause inhibition of orgasm or decreased sexual desire. Nefazodone is also effective for treatment of panic disorder and panic with comorbid depression or depressive symptoms, generalized anxiety disorder, and premenstrual dysphoric disorder and for management of chronic pain. It is not effective for the treatment of OCD. Nefazodone increases rapid eye movement (REM) sleep and increases sleep continuity. Nefazodone is also of use in patients with PTSD and chronic fatigue syndrome. It may also be effective in patients who have been treatment resistant to other antidepressant drugs.

Precautions and Adverse Reactions

The most common reasons for discontinuing nefazodone use are sedation, nausea, dizziness, insomnia, weakness, and agitation. Many patients report no specific side effect but describe a vague sense of feeling medicated. Nefazodone also causes visual trails, in which patients see an afterimage when looking at moving objects or when moving their heads quickly.

A major safety concern with the use of nefazodone is severe elevation of hepatic enzymes, and, in some instances, liver failure. Accordingly, serial hepatic function tests need to be done when patients are treated with nefazodone. Hepatic effects can be seen early in treatment and are more likely to develop when nefazodone is combined with other drugs metabolized in the liver.

Some patients taking nefazodone may experience a decrease in blood pressure that can cause episodes of postural hypotension. Nefazodone should therefore be used with caution by persons with underlying cardiac conditions or history of stroke or heart attack, dehydration, or hypovolemia or by persons being treated with antihypertensive medications. Patients switched from SSRIs to nefazodone may experience an increase in side effects, possibly because nefazodone does not protect against SSRI withdrawal symptoms. One of its metabolites, mCPP, may actually intensify these discontinuation symptoms. Patients have survived nefazodone overdoses in excess of 10 g, but deaths have been reported when it has been combined with alcohol. Nausea, vomiting, and somnolence are the most common signs of toxicity.

The effects of nefazodone in human mothers are not as well understood as those of the SSRIs, mainly because of the paucity of its clinical use. Nefazodone should therefore be used during pregnancy only if the potential benefit to the mother outweighs the potential risks to the fetus. It is not known whether nefazodone is excreted in human breast milk. Therefore, it should be used with caution by lactating mothers. The nefazodone dosage should be lowered in persons with severe hepatic disease, but no adjustment is necessary for persons with renal disease (Table 29.23-1).

Table 29.23-1
Adverse Reactions Reported with Nefazodone (300–600 mg a Day)

Reaction	Patients (%)
Headache	36
Dry mouth	25
Somnolence	25
Nausea	22
Dizziness	17
Constipation	14
Insomnia	11
Weakness	11
Lightheadedness	10
Blurred vision	9
Dyspepsia	9
Infection	8
Confusion	7
Scotomata	7

Drug Interactions and Laboratory Interferences

Nefazodone should not be given concomitantly with MAOIs. In addition, nefazodone has particular drug–drug interactions with the triazolobenzodiazepines triazolam (Halcion) and alprazolam (Xanax) because of the inhibition of CYP3A4 by nefazodone. Potentially elevated levels of each of these drugs can develop after administration of nefazodone, but the levels of nefazodone are generally not affected. The dose of triazolam should be lowered by 75 percent, and the dose of alprazolam should be lowered by 50 percent when given concomitantly with nefazodone.

Nefazodone may slow the metabolism of digoxin; therefore, digoxin levels should be monitored carefully in persons taking both medications. Nefazodone also slows the metabolism of haloperidol (Haldol) so that the dosage of haloperidol should be reduced in persons taking both medications. Addition of nefazodone may also exacerbate the adverse effects of lithium carbonate (Eskalith).

There are no known laboratory interferences associated with nefazodone.

Dosage and Clinical Guidelines

Nefazodone is available in 50-, 200-, and 250-mg unscored tablets and 100- and 150-mg scored tablets. The recommended starting dosage of nefazodone is 100 mg twice a day, but 50 mg twice a day may be better tolerated, especially by elderly persons. To limit the development of adverse effects, the dosage should be slowly raised in increments of 100 to 200 mg a day at intervals of no less than 1 week per increase. The optimal dosage is 300 to 600 mg daily in two divided doses. However, some studies report that nefazodone is effective when taken once a day, especially at bedtime. Geriatric persons should receive dosages about two-thirds of the usual nongeriatric dosages, with a maximum of 400 mg a day. Similar to other antidepressants, clinical benefit of nefazodone usually appears after 2 to 4 weeks of treatment. Patients with premenstrual syndrome are treated with a flexible dosage that averages about 250 mg a day.

TRAZODONE

Pharmacologic Actions

Trazodone is readily absorbed from the GI tract and reaches peak plasma levels in about 1 hour. It has a half-life of 5 to 9 hours. Trazodone is metabolized in the liver, and 75 percent of its metabolites are excreted in the urine.

Trazodone is a weak inhibitor of serotonin reuptake and a potent antagonist of serotonin 5-HT_{2A} and 5-HT_{2C} receptors. The active metabolite of trazodone is mCPP, which is an agonist at 5-HT_{2C} receptors and has a half-life of 14 hours. mCPP has been associated with migraine, anxiety, and weight loss. The adverse effects of trazodone are partially mediated by α_1 -adrenergic receptor antagonism.

Therapeutic Indications

Depressive Disorders. The main indication for the use of trazodone is MDD. There is a clear dose–response relationship, with dosages of 250 to 600 mg a day being necessary for trazodone to have therapeutic benefit. Trazodone increases total sleep time, decreases the number and the duration of nighttime awakenings, and decreases the amount of REM sleep. Unlike tricyclic drugs, trazodone does not decrease stage 4 sleep. Trazodone is thus useful for depressed persons with anxiety and insomnia.

Insomnia. Trazodone is a first-line agent for the treatment of insomnia because of its marked sedative qualities and favorable effects on sleep architecture (see above) combined with its lack of anticholinergic effects. Trazodone is effective for insomnia caused by depression or use of drugs. When used as a hypnotic, the usual initial dosage is 25 to 100 mg at bedtime.

Erectile Disorder. Trazodone is associated with an increased risk of priapism. Trazodone can potentiate erections resulting from sexual stimulation. It has thus been used to prolong erectile time and turgidity in some men with erectile disorder. The dosage for this indication is 150 to 200 mg a day. Trazodone-triggered priapism (an erection lasting more than 3 hours with pain) is a medical emergency. The use of trazodone for treatment of male erectile dysfunction has diminished considerably since the introduction of phosphodiesterase (PDE)-5 agents (see Chapter 25).

Other Indications. Trazodone may be useful in low dosages (50 mg a day) for controlling severe agitation in children with developmental disabilities and elderly persons with dementia. At dosages above 250 mg a day, trazodone reduces the tension and apprehension associated with generalized anxiety disorder. It has been used to treat depression in patients with schizophrenia. Trazodone may have a beneficial effect on insomnia and nightmares in persons with PTSD.

Precautions and Adverse Reactions

The most common adverse effects associated with trazodone are sedation, orthostatic hypotension, dizziness, headache, and nausea. Some

persons experience dry mouth or gastric irritation. The drug is not associated with anticholinergic adverse effects, such as urinary retention, weight gain, and constipation. A few case reports have noted an association between trazodone and arrhythmias in persons with preexisting premature ventricular contractions or mitral valve prolapse. Neutropenia, usually not of clinical significance, may develop, which should be considered if persons have fever or sore throat.

Trazodone may cause significant orthostatic hypotension 4 to 6 hours after a dose is taken, especially if taken concurrently with antihypertensive agents or if a large dose is taken without food. Administration of trazodone with food slows absorption and reduces the peak plasma concentration, thus reducing the risk of orthostatic hypotension.

Because suicide attempts often involve ingestion of sleeping pills, it is important to be familiar with the symptoms and treatment of trazodone overdose. Patients have survived trazodone overdoses of more than 9 g. Symptoms of overdose include lethargy, vomiting, drowsiness, headache, orthostasis, dizziness, dyspnea, tinnitus, myalgias, tachycardia, incontinence, shivering, and coma. Treatment consists of emesis or lavage and supportive care. Forced diuresis may enhance elimination. Treat hypotension and sedation as appropriate.

Trazodone causes priapism, prolonged erection in the absence of sexual stimuli, in one of every 10,000 men. Trazodone-induced priapism usually appears in the first 4 weeks of treatment but may occur as late as 18 months into treatment. It can appear at any dose. In such cases, trazodone use should be discontinued, and another antidepressant should be used. Painful erections or erections lasting more than 1 hour are warning signs that warrant immediate discontinuation of the drug and medical evaluation. The first step in the emergency management of priapism is intracavernosal injection of an α_1 -adrenergic agonist pressor agent, such as metaraminol (Aramine) or epinephrine. In about one-third of reported cases, surgical intervention was required. In some cases, permanent impairment of erectile function or impotence resulted.

The use of trazodone is contraindicated in pregnant and nursing women. Trazodone should be used with caution in persons with hepatic and renal diseases.

Drug Interactions

Trazodone potentiates the CNS depressant effects of other centrally acting drugs and alcohol. Concurrent use of trazodone and antihypertensives may cause hypotension. No cases of hypertensive crisis have been reported when trazodone has been used to treat MAOI-associated insomnia. Trazodone can increase levels of digoxin and phenytoin. Trazodone should be used with caution in combination with warfarin. Drugs that inhibit CYP3A4 can increase levels of trazodone's major metabolite, mCPP, leading to an increase in side effects.

Laboratory Interferences

No known laboratory interferences are associated with the administration of trazodone.

Dosage and Clinical Guidelines

Trazodone is available in 50-, 100-, 150-, and 300-mg tablets. Once-a-day dosing is as effective as divided dosing and reduces daytime sedation. The usual starting dose is 50 mg before sleep. The dosage can be increased in increments of 50 mg every 3 days if sedation or orthostatic hypotension does not become a problem. The therapeutic range for trazodone is 200 to 600 mg a day in divided doses. Some reports indicate that dosages of 400 to 600 mg a day are required for maximal therapeutic effects; other reports indicate that 250 to 400 mg a day is sufficient. The dosage may be titrated up to 300 mg a day; then the person can be evaluated for the need for further dosage increases on the basis of the presence or the absence of signs of clinical improvement.

Once-daily trazodone is available as bisectable tablets of 150 mg or 300 mg. The starting dosage of the extended-release formulation is 150 mg once daily. It may be increased by 75 mg per day every 3 days. The maximum dosage is 375 mg per day. Dosing should be at the same time every day in the late evening, preferably at bedtime, on an empty stomach. Tablets should be swallowed whole or broken in half along the score line.

29.24 Opioid Receptor Agonists

Opioid receptor agonists are a structurally diverse group of compounds that are used for pain management. These drugs are also called narcotics. Although highly effective as analgesics, they often cause dependence and are frequently diverted for recreational use. Commonly used opioid agonists for pain relief include morphine, hydromorphone (Dilaudid), codeine, meperidine (Demerol), oxycodone (OxyContin),

buprenorphine (Buprenex), hydrocodone (Robidone), tramadol (Ultram), and fentanyl (Durogesic). Heroin is used as a street drug. Methadone is used both for pain management and for treatment of opiate addiction. This chapter focuses on the μ -opioid receptor agonists that are most likely to be used in the treatment of psychiatric disorders instead of pain management.

It is now recognized that the pharmacology of the opioid system is complex. There are multiple types of opioid receptors, with μ - and κ -opioid receptors representing functionally opposing endogenous systems (Table 29.24-1). All of the compounds above, which represent the most extensively used narcotic analgesics, are agonists at μ -opioid receptors. However, analgesic effects also result from antagonist effects on the κ -opioid receptor. Buprenorphine has mixed receptor effects, being primarily a μ -opioid receptor agonist as well as a κ -opioid antagonist.

Table 29.24-1
 μ - and κ -Opiate Receptors

Receptor	Agonist Effects	Antagonist Effects
Mu (μ)	Analgesia Euphoria Antidepressant Anxiety	Anxiety Hostility
Kappa (κ)	Analgesia Dysphoria Depression Stress-induced anxiety	Antidepressant

There is growing interest in the use of some drugs that act on opioid receptors as alternative treatments for a subpopulation of patients with refractory depression, as well as treatment for cutting behavior in patients with borderline personality disorder.

Consideration of such off-label use is tempered by the well-known fact that ongoing, regular use of opioids produces dependence and tolerance and may lead to maladaptive use, functional impairment, and withdrawal symptoms. The prevalence of opioid use, abuse, and dependence, particularly in regard to prescription opioids, has risen in recent years.

Before using opioid receptor agonists with patients who have failed on multiple conventional therapeutic agents, screen carefully for history of drug abuse, document the rationale for off-label use, establish treatment ground rules, obtain written consent, consult with primary care physician, and monitor closely. Avoid replacing “lost” prescriptions and providing early prescription renewals.

PHARMACOLOGIC ACTIONS

Methadone and buprenorphine are absorbed rapidly from the GI tract. Hepatic first-pass metabolism significantly affects the bioavailability of each of the drugs but in markedly different ways. For methadone, hepatic enzymes reduce the bioavailability of an oral dosage by about half, an effect that is easily managed with dosage adjustments.

For buprenorphine, first-pass intestinal and hepatic metabolism eliminates oral bioavailability almost completely. When used in opioid detoxification, buprenorphine is given sublingually in either a liquid or a tablet formulation.

The peak plasma concentrations of oral methadone are reached within 2 to 6 hours, and the plasma half-life initially is 4 to 6 hours in opioid-naïve persons and 24 to 36 hours after steady dosing of any type of opioid. Methadone is highly protein bound and equilibrates widely throughout the body, which ensures little postdosage variation in steady-state plasma concentrations.

Elimination of a sublingual dosage of buprenorphine occurs in two phases: an initial phase with a half-life of 3 to 5 hours and a terminal phase with a half-life of more than 24 hours. Buprenorphine dissociates from its receptor binding site slowly, which permits an every-other-day dosing schedule.

Methadone acts as pure agonists at μ -opioid receptors and has negligible agonist or antagonist activity at κ - or δ -opioid receptors. Buprenorphine is a partial agonist at μ -receptors, a potent antagonist at κ -receptors, and neither an agonist nor an antagonist at δ -receptors.

THERAPEUTIC INDICATIONS

Methadone

Methadone is used for short-term detoxification (7 to 30 days), long-term detoxification (up to 180 days), and maintenance (treatment beyond 180 days) of opioid-dependent individuals. For these purposes, it is only available through designated clinics called methadone maintenance treatment programs (MMTPs) and in hospitals and prisons. Methadone is a schedule II drug, which means that its administration is tightly governed by specific federal laws and regulations.

Enrollment in a methadone program reduces the risk of death by 70 percent; reduces illicit use of opioids and other substances of abuse; reduces criminal activity; reduces the risk of infectious diseases of all types, most importantly HIV and hepatitis B and C infection; and in pregnant women, reduces the risk of fetal and neonatal morbidity and mortality. The use of methadone maintenance frequently requires lifelong treatment.

Some opioid-dependence treatment programs use a stepwise detoxification protocol in which a person addicted to heroin switches first to the strong agonist methadone; then to the weaker agonist buprenorphine; and finally to maintenance on an opioid receptor antagonist, such as naltrexone (ReVia). This approach minimizes the appearance of opioid withdrawal effects, which, if they occur, are mitigated with clonidine (Catapres). However, compliance with opioid receptor antagonist treatment is poor outside of settings using intensive cognitive-behavioral techniques. In contrast, noncompliance with methadone maintenance precipitates opioid withdrawal symptoms, which serve to reinforce the use of methadone and make cognitive-behavioral therapy less than essential. Thus, some well-motivated, socially integrated former heroin addicts are able to use methadone for years without participation in a psychosocial support program.

Data pooled from many reports indicate that methadone is more effective when taken at dosages in excess of 60 mg a day. The analgesic effects of methadone are sometimes used in the management of chronic pain when less addictive agents are ineffective.

Pregnancy. Methadone maintenance, combined with effective psychosocial services and regular obstetric monitoring, significantly improves obstetric and neonatal outcomes for women addicted to heroin. Enrollment of a heroin-addicted pregnant woman in such a maintenance program reduces the risk of malnutrition, infection, preterm labor, spontaneous abortion, preeclampsia, eclampsia, abruptio placenta, and septic thrombophlebitis.

The dosage of methadone during pregnancy should be the lowest effective dosage, and no withdrawal to abstinence should be attempted during pregnancy. Methadone is metabolized more rapidly in the third trimester, which may necessitate higher dosages. To avoid potentially sedating postdose peak plasma concentrations, the daily dose can be administered in two divided doses during the third trimester. Methadone treatment has no known teratogenic effects.

Neonatal Methadone Withdrawal Symptoms. Withdrawal symptoms in newborns frequently include tremor, a high-pitched cry, increased muscle tone and activity, poor sleep and eating, mottling, yawning, perspiration, and skin excoriation. Convulsions that require aggressive anticonvulsant therapy may also occur. Withdrawal symptoms may be delayed in onset and prolonged in neonates because of

their immature hepatic metabolism. Women taking methadone are sometimes counseled to initiate breastfeeding as a means of gently weaning their infants from methadone dependence, but they should not breastfeed their babies while still taking methadone.

Buprenorphine

The analgesic effects of buprenorphine are sometimes used in the management of chronic pain when less addictive agents are ineffective. Because buprenorphine is a partial agonist rather than a full agonist at the μ -receptor and is a weak antagonist at the κ -receptor, this agent produces a milder withdrawal syndrome and has a wider margin of safety than the full μ -agonist compounds generally used in treatment. Buprenorphine has a ceiling effect beyond which dose increases prolong the duration of action of the drug without further increasing the agonist effects. Because of this, buprenorphine has a high clinical safety profile, with limited respiratory depression, therefore decreasing the likelihood of lethal overdose. Buprenorphine does have the capacity to cause typical side effects associated with opioids, including sedation, nausea and vomiting, constipation, dizziness, headache, and sweating. A relevant pharmacokinetic consideration when using buprenorphine is the fact that it requires hepatic conversion to become analgesic (*N*-dealkylation catalyzed by CYP3A4). This may explain why some patients do not benefit from buprenorphine. Genetics, grapefruit juice, and many medications (including fluoxetine and fluvoxamine) can reduce a person's ability to metabolize buprenorphine into its bioactive form.

To reduce the likelihood of abusing buprenorphine via the IV route, buprenorphine has been combined with the narcotic antagonist naloxone for sublingual administration. Because naloxone is poorly absorbed by the sublingual route, when the combination drug is taken sublingually, there is no effect of the naloxone on the efficacy of buprenorphine. If an opioid-dependent individual injects the combination medication, the naloxone precipitates a withdrawal reaction, therefore reducing the likelihood of illicit injection use of the sublingual preparation.

Inducting and stabilizing a patient on buprenorphine is analogous to inducting and stabilizing a patient on methadone except that, as a partial agonist, buprenorphine has the potential to cause precipitated withdrawal in patients who have recently taken full agonist opioids. Thus, a patient must abstain from the use of short-acting opioids for 12 to 24 hours before starting buprenorphine and from longer acting opioids such as methadone for 24 to 48 hours or longer. The physician must assess the patient clinically and determine that the patient is in mild to moderate opioid withdrawal with objectively observable withdrawal signs before initiating buprenorphine.

In most instances, a relatively low dose of buprenorphine (2 to 4 mg) can then be administered with additional doses given in 1 to 2 hours if withdrawal signs persist. The goal for the first 24 hours is to suppress withdrawal signs and symptoms, and the total 24-hour dose to do so can range from 2 to 16 mg on the first day. In subsequent days, the dose can be adjusted upward or downward to resolve withdrawal fully and, as with methadone, to achieve an absence of craving, adequate tolerance to prevent reinforcement from the use of other opioids, and ultimately abstinence from other opioids while minimizing side effects. Dose-ranging studies have demonstrated that dosages of 6 to 16 mg per day are associated with improved treatment outcomes compared with lower doses of buprenorphine (1 to 4 mg). Sometimes patients seem to need dosages higher than 16 mg per day, although there is no evidence for any benefit of dosages beyond 32 mg per day. For the treatment of opioid dependence, a dose of approximately 4 mg of sublingual buprenorphine is the equivalent of a daily dose of 40 mg of oral methadone. It has also been demonstrated that daily, alternate-day, or three-times-per-week administration has equivalent effects in suppressing the symptoms of opioid withdrawal in dependent individuals. The combination tablet is recommended for most clinical purposes, including induction and maintenance. The buprenorphine mono should be used only for pregnant patients or for patients who have a documented anaphylactic reaction to naloxone.

Newer forms of buprenorphine delivery, including a transdermal skin patch, a long-acting depot intramuscular injection that provides therapeutic plasma levels for several weeks, and subcutaneous buprenorphine implants that may provide therapeutic plasma levels for 6 months, are being investigated. The last two delivery systems could obviate the need for taking medications daily while virtually eliminating the risk of medication nonadherence.

Tramadol

There are multiple reports of tramadol's antidepressant effects, both as monotherapy and augmentation agent in treatment-resistant depression. Clinical and experimental data suggest that tramadol has an inherent antidepressant-like activity. Tramadol has a complex pharmacology. It is a weak μ -opioid receptor agonist, a 5-HT releasing agent, a DA-releasing agent, a 5-HT_{2C} receptor antagonist, an norepinephrine reuptake inhibitor, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, a nicotinic acetylcholine receptor antagonist, a TRPV1 receptor agonist and an M1 and M3 muscarinic acetylcholine receptor antagonist. Consistent with the evidence of its antidepressant effects is the fact that tramadol has a close structural similarity to the antidepressant venlafaxine.

Both venlafaxine and tramadol inhibit norepinephrine/serotonin reuptake and inhibit the reserpine-induced syndrome completely. Both compounds also have an analgesic effect on chronic pain. Venlafaxine may have an opioid component, and naloxone reverses the antipain effect of venlafaxine. Nonopioid activity is demonstrated by the fact that its analgesic effect is not fully antagonized by the μ -opioid receptor antagonist naloxone. Indicative of their structural similarities, venlafaxine may cause false-positive results on liquid chromatography tests to detect urinary tramadol levels.

Another relevant property of tramadol is its relatively long half-life, which reduces the potential for misuse. Its habituating effects are found to be much less than other opiate agonists, but abuse, withdrawal, and dependence are risks. Tramadol requires metabolism to become analgesic: individuals who are CYP2D6 "poor metabolizers" or use drugs that are CYP2D6 inhibitors reduce the efficacy of tramadol (the same is true of codeine).

PRECAUTIONS AND ADVERSE REACTIONS

The most common adverse effects of opioid receptor agonists are lightheadedness, dizziness, sedation, nausea, constipation, vomiting, perspiration, weight gain, decreased libido, inhibition of orgasm, and insomnia or sleep irregularities. Opioid receptor agonists are capable of inducing tolerance as well as producing physiologic and psychological dependence. Other CNS adverse effects include depression, sedation, euphoria, dysphoria, agitation, and seizures. Delirium has been reported in rare cases. Occasional non-CNS adverse effects include peripheral edema, urinary retention, rash, arthralgia, dry mouth, anorexia, biliary tract spasm, bradycardia, hypotension, hypoventilation, syncope, antidiuretic hormone-like activity, pruritus, urticaria, and visual disturbances. Menstrual irregularities are common in women, especially in the first 6 months of use. Various abnormal endocrine laboratory indexes of little clinical significance may also be seen.

Most persons develop tolerance to the pharmacologic adverse effects of opioid agonists during long-term maintenance, and relatively few adverse effects are experienced after the induction period.

Overdosage

The acute effects of opioid receptor agonist overdosage include sedation, hypotension, bradycardia, hypothermia, respiratory suppression, miosis, and decreased GI motility. Severe effects include coma, cardiac arrest, shock, and death. The risk of overdosage is greatest in the induction stage of treatment and in persons with slow drug metabolism caused by preexisting hepatic insufficiency. Deaths have been caused during the first week of induction by methadone dosages of only 50 to 60 mg a day.

The risk of overdosage with buprenorphine appears to be lower than with methadone. However, deaths have been caused by use of buprenorphine in combination with benzodiazepines.

Withdrawal Symptoms

Abrupt cessation of methadone use triggers withdrawal symptoms within 3 to 4 days, which usually reach peak intensity on the sixth day. Withdrawal symptoms include weakness, anxiety, anorexia, insomnia, gastric distress, headache, sweating, and hot and cold flashes. The withdrawal symptoms usually resolve after 2 weeks. However, a protracted methadone abstinence syndrome is possible that may include restlessness and insomnia.

The withdrawal symptoms associated with buprenorphine are similar to, but less marked than, those caused by methadone. In particular, buprenorphine is sometimes used to ease the transition from methadone to opioid receptor antagonists or abstinence because of the relatively mild withdrawal reaction associated with discontinuation of buprenorphine.

DRUG-DRUG INTERACTIONS

Opioid receptor agonists can potentiate the CNS-depressant effects of alcohol, barbiturates, benzodiazepines, other opioids, low-potency dopamine receptor antagonists, tricyclic and tetracyclic drugs, and MAOIs. Carbamazepine (Tegretol), phenytoin (Dilantin), barbiturates, rifampin (Rimactane, Rifadin), and heavy long-term consumption of alcohol may induce hepatic enzymes, which may lower the plasma concentration of methadone or buprenorphine and thereby precipitate withdrawal symptoms. In contrast, however, hepatic enzyme induction may increase the plasma concentration of active levomethadyl metabolites and cause toxicity.

Acute opioid withdrawal symptoms may be precipitated in persons on methadone maintenance therapy who take pure opioid receptor antagonists such as naltrexone, nalmefene (Revex), and naloxone (Narcan); partial agonists such as buprenorphine; or mixed agonist-antagonists such as pentazocine (Talwin). These symptoms may be mitigated by use of clonidine, a benzodiazepine, or both.

Competitive inhibition of methadone or buprenorphine metabolism after short-term use of alcohol or administration of cimetidine (Tagamet), erythromycin, ketoconazole (Nizoral), fluoxetine (Prozac), fluvoxamine (Luvox), loratadine (Claritin), quinidine (Quinidex), and alprazolam (Xanax) may lead to higher plasma concentrations or a prolonged duration of action of methadone or buprenorphine. Medications that alkalinize the urine may reduce methadone excretion.

Methadone maintenance may also increase plasma concentrations of desipramine (Norpramin, Pertofrane) and fluvoxamine. Use of methadone may increase zidovudine (Retrovir) concentrations, which increases the possibility of zidovudine toxicity at otherwise standard dosages. Moreover, in vitro human liver microsome studies demonstrate competitive inhibition of methadone demethylation by several protease inhibitors, including ritonavir (Norvir), indinavir (Crixivan), and saquinavir (Invirase). The clinical relevance of this finding is unknown.

Fatal drug-drug interactions with the MAOIs are associated with use of the opioids fentanyl (Sublimaze) and meperidine (Demerol) but not with use of methadone, levomethadyl, or buprenorphine.

Tramadol may interact with drugs that inhibit serotonin reuptake. Such combinations can trigger seizures and serotonin syndrome. These events may also develop during tramadol monotherapy, either at routine or excessive doses. Risk of interactions is increased when tramadol is combined with virtually all classes of antidepressants and with drugs that lower the seizure threshold, especially the antidepressant bupropion.

LABORATORY INTERFERENCES

Methadone and buprenorphine can be tested for separately in urine toxicology to distinguish them from other opioids. No known laboratory interferences are associated with the use of methadone or buprenorphine.

DOSAGE AND CLINICAL GUIDELINES

Methadone

Methadone is supplied in 5-, 10-, and 40-mg dispersible scored tablets; 40-mg scored wafers; 5-mg/5-mL, 10-mg/5-mL, and 10-mg/mL solutions; and a 10-mg/mL parenteral form. In maintenance programs, methadone is usually dissolved in water or juice, and dose administration is directly observed to ensure compliance. For induction of opioid detoxification, an initial methadone dose of 15 to 20 mg will usually suppress craving and withdrawal symptoms. However, some individuals may require up to 40 mg a day in single or divided doses. Higher dosages should be avoided during induction of treatment to reduce the risk of acute toxicity from overdose.

Over several weeks, the dosage should be raised to at least 70 mg a day. The maximum dosage is usually 120 mg a day, and higher dosages require prior approval from regulatory agencies. Dosages above 60 mg a day are associated with much more complete abstinence from use of illicit opioids than are dosages less than 60 mg a day.

The duration of treatment should not be predetermined but should be based on response to treatment and assessment of psychosocial factors. All studies of methadone maintenance programs endorse long-term treatment (i.e., several years) as more effective than short-term programs (i.e., less than 1 year) for prevention of relapse into opioid abuse. In actual practice, however, a minority of programs are permitted by policy or approved by insurers to provide even 6 months of continuous maintenance treatment. Moreover, some programs actually encourage withdrawal from methadone in less than 6 months after induction. This is quite ill conceived because more than 80 percent of persons who terminate methadone maintenance treatment eventually return to illicit drug use within 2 years. In programs that offer both maintenance and withdrawal treatments, the overwhelming majority of participants enroll in the maintenance treatment.

Buprenorphine

Buprenorphine is supplied as a 0.3-mg/mL solution in 1-mL ampules. Sublingual tablet formulations of buprenorphine containing buprenorphine only or buprenorphine combined with naloxone in a 4:1 ratio are used for opioid maintenance treatment. Buprenorphine is not used for short-term opioid detoxification. Maintenance dosages of 8 to 16 mg thrice weekly have effectively reduced heroin use. Physicians must be trained and certified to carry out this therapy in their private offices. There are a number of approved training programs in the United States.

Tramadol

There are no controlled trials establishing the appropriate dosing schedule for tramadol when used for conditions other than pain. Tramadol is available in many formulations. These range from capsules (regular and extended release) to tablets (regular, extended release, chewable tablets) that can be taken sublingually, suppositories and injectable ampules. It also comes as tablets and capsules containing acetaminophen or aspirin. Doses in case reports of treatment for depression or OCD range from 50 to 200 mg a day and involve short-term use. The long-term use of tramadol in the treatment of psychiatric disorders has not been studied.

29.25 Opioid Receptor Antagonists: Naltrexone, Nalmefene, and Naloxone

Naltrexone (Revia, Depade) and naloxone (Narcan) are competitive opioid antagonists. They bind to opioid receptors without causing their activation. Because these drugs induce opioid withdrawal effects in people using full opioid agonists, these drugs are classified as opioid antagonists.

Naltrexone is the most widely used of these drugs. It has a relatively long half-life, is orally effective, is not associated with dysphoria, and is administered once daily. Naloxone, which predated naltrexone to treat narcotic overdose, became less widely used for preventing relapse to opiate use in detoxified opiate addicts. Since its introduction, naltrexone has been tried for the treatment of a wide range of psychiatric disorders, including, among others, eating disorders, autism, self-injurious behavior, cocaine dependence, gambling, and alcoholism. Naltrexone was approved for the treatment of alcohol dependence in 1994. A number of generic formulations are also available. An extended-release, once-a-month injectable suspension (Vivitrol) was also approved in 2006. Nalmefene (Revex) is indicated for the complete or partial reversal of opioid drug effects and in the management of known or suspected opioid overdose. An oral formulation of nalmefene is available in some countries but not in the United States. Nalmefene (Revex) is an opioid receptor antagonist that is sometimes used in the management of alcohol dependence.

PHARMACOLOGICAL ACTIONS

Oral opioid receptor antagonists are rapidly absorbed from the gastrointestinal (GI) tract, but because of first-pass hepatic metabolism, only 60 percent of a dose of naltrexone and 40 to 50 percent of a dose of nalmefene reach the systemic circulation unchanged. Peak concentrations of naltrexone and its active metabolite, 6- β -naltrexol, are achieved within 1 hour of ingestion. The half-life of naltrexone is 1 to 3 hours and the half-life of 6- β -naltrexol is 13 hours. Peak concentrations of nalmefene are achieved in about 1 to 2 hours, and the half-life is 8 to 10 hours. Clinically, a single dose of naltrexone effectively blocks the rewarding effects of opioids for 72 hours. Traces of 6- β -naltrexol may linger for up to 125 hours after a single dose.

Naltrexone and nalmefene are competitive antagonists of opioid receptors. Understanding the pharmacology of opioid receptors can explain the difference in adverse effects caused by naltrexone and nalmefene. Opioid receptors in the body are typed pharmacologically as μ , κ , or δ . Whereas activation of the κ - and δ -receptors is thought to reinforce opioid and alcohol consumption centrally, activation of μ -receptors is more closely associated with central and peripheral antiemetic effects. Because naltrexone is a relatively weak antagonist of κ - and δ -receptors and a potent μ -receptor antagonist, dosages of naltrexone that effectively reduce opioid and alcohol consumption also strongly block μ -receptors and therefore may cause nausea. Nalmefene, in contrast, is an equally potent antagonist of all three opioid receptor types, and dosages of nalmefene that effectively reduce opioid and alcohol consumption have no particularly increased effect on μ -receptors. Thus, nalmefene is associated clinically with few GI adverse effects.

Naloxone has the highest affinity for the μ -receptor but is a competitive antagonist at the μ -, κ -, and δ -receptors.

Whereas the effects of opioid receptor antagonists on opioid use are easily understood in terms of competitive inhibition of opioid receptors, the effects of opioid receptor antagonists on alcohol dependence are less straightforward and probably relate to the fact that the desire for and the effects of alcohol consumption appear to be regulated by several neurotransmitter systems, both opioid and nonopioid.

THERAPEUTIC INDICATIONS

The combination of a cognitive-behavioral program plus use of opioid receptor antagonists is more successful than either the cognitive-behavioral program or use of opioid receptor antagonists alone. Naltrexone is used as a screening test to ensure that the patient is opioid-free before the induction of therapy with naltrexone (see “Naloxone Challenge Test” in Table 29.25-1).

 **Table 29.25-1**
Naloxone (Narcan) Challenge Test

The naloxone challenge test should not be performed in a patient showing clinical signs or symptoms of opioid withdrawal or in a patient whose urine contains opioids. The naloxone challenge test may be administered by either the intravenous (IV) or the subcutaneous route.

IV challenge: After appropriate screening of the patient, 0.8 mg of naloxone should be drawn into a sterile syringe. If the IV route of administration is selected, 0.2 mg of naloxone should be injected, and while the needle is still in the patient's vein, the patient should be observed for 30 seconds for evidence of withdrawal signs or symptoms. If there is no evidence of withdrawal, the remaining 0.6 mg of naloxone should be injected and the patient observed for an additional 20 minutes for signs and symptoms of withdrawal.

Subcutaneous challenge: If the subcutaneous route is selected, 0.8 mg should be administered subcutaneously and the patient observed for signs and symptoms of withdrawal for 20 minutes.

Conditions and technique for observation of patient: During the appropriate period of observation, the patient's vital signs should be monitored, and the patient should be monitored for signs of withdrawal. It is also important to question the patient carefully. The signs and symptoms of opioid withdrawal include, but are not limited to, the following:

Withdrawal signs: Stuffiness or running nose, tearing, yawning, sweating, tremor, vomiting, or piloerection

Withdrawal symptoms: Feeling of temperature change, joint or bone and muscle pain, abdominal cramps, and formication (feeling of bugs crawling under skin)

Interpretation of the challenge: Warning—the elicitation of the enumerated signs or symptoms indicates a potential risk for the subject, and naltrexone should not be administered. If no signs or symptoms of withdrawal are observed, elicited, or reported, naltrexone may be administered. If there is any doubt in the observer's mind that the patient is not in an opioid-free state or is in continuing withdrawal, naltrexone should be withheld for 24 hours and the challenge repeated.

Opioid Dependence

Patients in detoxification programs are usually weaned from potent opioid agonists such as heroin over a period of days to weeks, during which emergent adrenergic withdrawal effects are treated as needed with clonidine (Catapres). A serial protocol is sometimes used in which potent agonists are gradually replaced by weaker agonists followed by mixed agonist-antagonists and then finally by pure antagonists. For example, an abuser of the potent agonist heroin would switch first to the weaker agonist methadone (Dolophine), then to the partial agonist buprenorphine (Buprenex) or levomethadyl acetate (ORLAAM)—commonly called LAAM—and finally, after a 7- to 10-day washout period, to a pure antagonist, such as naltrexone or nalmefene. However, even with gradual detoxification, some persons continue to experience mild adverse effects or opioid withdrawal symptoms for the first several weeks of treatment with naltrexone.

As the opioid receptor agonist potency diminishes, so do the adverse consequences of discontinuing the drug. Thus, because there are no pharmacological barriers to discontinuation of pure opioid receptor antagonists, the social environment and frequent cognitive-behavioral intervention become extremely important factors supporting continued opioid abstinence. Because of poorly tolerated adverse symptoms, most persons not simultaneously enrolled in a cognitive-behavioral program stop taking opioid receptor antagonists within 3 months. Compliance with the administration of an opioid receptor antagonist regimen can also be increased with participation in a well-conceived voucher program.

Issues of medication compliance should be a central focus of treatment. If a person with a history of opioid addiction stops taking a pure opioid receptor antagonist, the person's risk of relapse into opioid abuse is exceedingly high because reintroduction of a potent opioid agonist would yield a very rewarding subjective "high." In contrast, compliant persons do not develop tolerance to the therapeutic benefits of naltrexone even if it is administered continuously for 1 year or longer. Individuals may undergo several relapses and remissions before achieving long-term abstinence.

Persons taking opioid receptor antagonists should also be warned that sufficiently high dosages of opioid agonists can overcome the receptor antagonism of naltrexone or nalmefene, which may lead to hazardous and unpredictable levels of receptor activation (see "Precautions and Adverse Reactions").

Rapid Detoxification

To avoid the 7- to 10-day period of opioid abstinence generally recommended before use of opioid receptor antagonists, rapid detoxification protocols have been developed. Continuous administration of adjunct clonidine—to reduce the adrenergic withdrawal symptoms—and adjunct benzodiazepines, such as oxazepam (Serax)—to reduce muscle spasms and insomnia—can permit use of oral opioid receptor antagonists on the first day of opioid cessation. Detoxification can thus be completed within 48 to 72 hours, at which point opioid receptor antagonist maintenance is initiated. Moderately severe withdrawal symptoms may be experienced on the first day, but they taper off rapidly thereafter.

Because of the potential hypotensive effects of clonidine, the blood pressure (BP) of persons undergoing rapid detoxification must be closely monitored for the first 8 hours. Outpatient rapid detoxification settings must therefore be adequately prepared to administer emergency care.

The main advantage of rapid detoxification is that the transition from opioid abuse to maintenance treatment occurs over just 2 or 3 days. The completion of detoxification in as little time as possible minimizes the risk that the person will relapse into opioid abuse during the detoxification protocol.

Alcohol Dependence

Opioid receptor antagonists are also used as adjuncts to cognitive-behavioral programs for treatment of alcohol dependence. Opioid receptor antagonists reduce alcohol craving and alcohol consumption, and they ameliorate the severity of relapses. The risk of relapse into heavy consumption of alcohol attributable to an effective cognitive-behavioral program alone may be halved with concomitant use of opioid receptor antagonists.

The newer agent nalmefene has a number of potential pharmacological and clinical advantages over its predecessor naltrexone for treatment of alcohol dependence. Whereas naltrexone may cause reversible transaminase elevations in persons who take dosages of 300 mg a day (which is six times the recommended dosage for treatment of alcohol and opioid dependence [50 mg a day]), nalmefene has not been associated with any hepatotoxicity. Clinically effective dosages of naltrexone are discontinued by 10 to 15 percent of persons because of adverse effects, most commonly nausea. In contrast, discontinuation of nalmefene because of an adverse event is rare at the clinically effective dosage of 20 mg a day and in the range of 10 percent at excessive dosages—that is, 80 mg a day. Because of its pharmacokinetic

profile, a given dosage of nalmefene may also produce a more sustained opioid antagonist effect than does naltrexone.

The efficacy of opioid receptor antagonists in reducing alcohol craving may be augmented with a selective serotonin reuptake inhibitor, although data from large trials are needed to assess this potential synergistic effect more fully.

PRECAUTIONS AND ADVERSE REACTIONS

Because opioid receptor antagonists are used to maintain a drug-free state after opioid detoxification, great care must be taken to ensure that an adequate washout period elapses—at least 5 days for a short-acting opioid such as heroin and at least 10 days for longer-acting opioids such as methadone—after the last dose of opioids and before the first dose of an opioid receptor antagonist is taken. The opioid-free state should be determined by self-report and urine toxicology screens. If any question persists of whether opioids are in the body despite a negative urine screen result, then a *naloxone challenge test* should be performed. Naloxone challenge is used because its opioid antagonism lasts less than 1 hour, but those of naltrexone and nalmefene may persist for more than 24 hours. Thus, any withdrawal effects elicited by naloxone will be relatively short lived (see “Dosage and Clinical Guidelines”). Symptoms of acute opioid withdrawal include drug craving, feeling of temperature change, musculoskeletal pain, and GI distress. Signs of opioid withdrawal include confusion, drowsiness, vomiting, and diarrhea. Naltrexone and nalmefene should not be taken if naloxone infusion causes any signs of opioid withdrawal except as part of a supervised rapid detoxification protocol.

A set of adverse effects resembling a vestigial withdrawal syndrome tends to affect up to 10 percent of persons who take opioid receptor antagonists. Up to 15 percent of persons taking naltrexone may experience abdominal pain, cramps, nausea, and vomiting, which may be limited by transiently halving the dosage or altering the time of administration. Adverse central nervous system effects of naltrexone, experienced by up to 10 percent of persons, include headache, low energy, insomnia, anxiety, and nervousness. Joint and muscle pains may occur in up to 10 percent of persons taking naltrexone, as may rash.

Naltrexone may cause dosage-related hepatic toxicity at dosages well in excess of 50 mg a day; 20 percent of persons taking 300 mg a day of naltrexone may experience serum aminotransferase concentrations 3 to 19 times the upper limit of normal. The hepatocellular injury of naltrexone appears to be a dose-related toxic effect rather than an idiosyncratic reaction. At the lowest dosages of naltrexone required for effective opioid antagonism, hepatocellular injury is not typically observed. However, naltrexone dosages as low as 50 mg a day may be hepatotoxic in persons with underlying liver disease, such as persons with cirrhosis of the liver caused by chronic alcohol abuse. Serum aminotransferase concentrations should be monitored monthly for the first 6 months of naltrexone therapy and thereafter on the basis of clinical suspicion. Hepatic enzyme concentrations usually return to normal after discontinuation of naltrexone therapy.

If analgesia is required while a dose of an opioid receptor antagonist is pharmacologically active, opioid agonists should be avoided in favor of benzodiazepines or other nonopioid analgesics. Persons taking opioid receptor antagonists should be instructed that low dosages of opioids will have no effect but larger dosages could overcome the receptor blockade and suddenly produce symptoms of profound opioid overdose, with sedation possibly progressing to coma or death. Use of opioid receptor antagonists is contraindicated in persons who are taking opioid agonists, small amounts of which may be present in over-the-counter antiemetic and antitussive preparations; in persons with acute hepatitis or hepatic failure; and in persons who are hypersensitive to the drugs.

Because naltrexone is transported across the placenta, opioid receptor antagonists should only be taken by pregnant women if a compelling need outweighs the potential risks to the fetus. It is not known whether opioid receptor antagonists are distributed into breast milk.

Opioid receptor antagonists are relatively safe drugs, and ingestion of high doses of opioid receptor antagonists should be treated with supportive measures combined with efforts to decrease GI absorption.

Because buprenorphine has a high affinity and slow displacement from the opioid receptors, nalmefene may not completely reverse buprenorphine-induced respiratory depression.

DRUG INTERACTIONS

Many drug interactions involving opioid receptor antagonists have been discussed earlier, including those with opioid agonists associated with drug abuse as well as those involving antiemetics and antitussives. Because of its extensive hepatic metabolism, naltrexone may affect or be affected by other drugs that influence hepatic enzyme levels. However, the clinical importance of these potential interactions is not known.

One potentially hepatotoxic drug that has been used in some cases with opioid receptor antagonists is disulfiram (Antabuse). Although no adverse effects were observed, frequent laboratory monitoring is indicated when such combination therapy is contemplated. Opioid receptor antagonists have been reported to potentiate the sedation associated with use of thioridazine (Mellaril), an interaction that probably applies equally to all low-potency dopamine receptor antagonists.

Intravenous nalmefene has been administered after benzodiazepines, inhalational anesthetics, muscle relaxants, and muscle relaxant antagonists administered in conjunction with general anesthetics without any adverse reactions. Care should be taken when using flumazenil (Romazicon) and nalmefene together because both of these agents have been shown to induce seizures in preclinical studies.

LABORATORY INTERFERENCES

The potential for a false-positive urine for opiates using less specific urine screens such as enzyme-multiplied immunoassay technique (EMIT) may exist, given that naltrexone and nalmefene are derivatives of oxymorphone. Thin-layer, gas-liquid, and high-pressure liquid chromatographic methods used for the detection of opiates in the urine are not interfered with by naltrexone.

DOSAGE AND CLINICAL GUIDELINES

To avoid the possibility of precipitating an acute opioid withdrawal syndrome, several steps should be taken to ensure that the person is opioid free. Within a supervised detoxification setting, at least 5 days should elapse after the last dose of short-acting opioids, such as heroin, hydromorphone (Dilaudid), meperidine (Demerol), or morphine, and at least 10 days should elapse after the last dose of longer-acting opioids, such as methadone, before opioid antagonists are initiated. Briefer periods off opioids have been used in rapid detoxification protocols. To confirm that opioid detoxification is complete, urine toxicological screens should demonstrate no opioid metabolites. However, an individual may have a negative urine opioid screen result, yet still be physically dependent on opioids and thus susceptible to antagonist-induced withdrawal effects. Therefore, after the urine screen result is negative, a naloxone challenge test is recommended unless an adequate period of opioid abstinence can be reliably confirmed by observers (Table 29.25-1).

The initial dosage of naltrexone for treatment of opioid or alcohol dependence is 50 mg a day, which should be achieved through gradual introduction, even when the naloxone challenge test result is negative. Various authorities begin with 5, 10, 12.5, or 25 mg and titrate up to the 50-mg dosage over a period ranging from 1 hour to 2 weeks while constantly monitoring for evidence of opioid withdrawal. When a daily dose of 50 mg is well tolerated, it may be averaged over a week by giving 100 mg on alternate days or 150 mg every third day. Such schedules may increase compliance. The corresponding therapeutic dosage of nalmefene is 20 mg a day divided into two equal doses. Gradual titration of nalmefene to this daily dose is probably a wise strategy, although clinical data on dosage strategies for nalmefene are not yet available.

To maximize compliance, it is recommended that family members directly observe ingestion of each dose. Random urine tests for opioid

receptor antagonists and their metabolites as well as for ethanol or opioid metabolites should also be taken. Opioid receptor antagonists should be continued until the person is no longer considered psychologically at risk for relapse into opioid or alcohol abuse. This generally requires at least 6 months but may take longer, particularly if there are external stresses.

Nalmefene is available as a sterile solution for intravenous, intramuscular, and subcutaneous administration in two concentrations, containing 100 µg or 1.0 mg of nalmefene free base per milliliter. The 100 µg/mL concentration contains 110.8 µg of nalmefene hydrochloride and the 1.0 mg/mL concentration contains 1.108 mg of nalmefene hydrochloride per milliliter. Both concentrations contain 9.0 mg of sodium chloride per milliliter and the pH is adjusted to 3.9 with hydrochloric acid. Pharmacodynamic studies have shown that nalmefene has a longer duration of action than naloxone at fully reversing opiate activity.

Rapid Detoxification

Rapid detoxification has been standardized using naltrexone, although nalmefene would be expected to be equally effective with fewer adverse effects. In rapid detoxification protocols, the addicted person stops opioid use abruptly and begins the first opioid-free day by taking clonidine, 0.2 mg, orally every 2 hours for nine doses, to a maximum dose of 1.8 mg, during which time the BP is monitored every 30 to 60 minutes for the first 8 hours. Naltrexone, 12.5 mg, is administered 1 to 3 hours after the first dose of clonidine. To reduce muscle cramps and later insomnia, a short-acting benzodiazepine, such as oxazepam, 30 to 60 mg, is administered simultaneously with the first dose of clonidine, and half of the initial dose is readministered every 4 to 6 hours as needed. The maximum daily dosage of oxazepam should not exceed 180 mg. The person undergoing rapid detoxification should be accompanied home by a reliable escort. On the second day, similar doses of clonidine and the benzodiazepine are administered but with a single dose of naltrexone, 25 mg, taken in the morning. Relatively asymptomatic persons may return home after 3 to 4 hours. Administration of the daily maintenance dose of 50 mg of naltrexone is begun on the third day, and the dosages of clonidine and the benzodiazepine are gradually tapered off over 5 to 10 days.

29.26 Phosphodiesterase-5 Inhibitors

Phosphodiesterase (PDE)-5 inhibitors, such as sildenafil (Viagra), which was developed in 1998, revolutionized the treatment of the major sexual dysfunction affecting men—erectile disorder. Two congeners have since come on the market—vardenafil (Levitra) and tadalafil (Cialis). All have a similar method of action and have changed people's expectations of sexual functioning. Although indicated only for the treatment of male erectile dysfunction, there is anecdotal evidence of these drugs being effective in women. They are also being misused as recreational drugs to enhance sexual performance. These drugs have been used by more than 20 million men around the world.

The development of sildenafil provided important information about the physiology of erection. Sexual stimulation causes the release of the neurotransmitter nitric oxide (NO), which increases the synthesis of cyclic guanosine monophosphate (cGMP), causing smooth muscle relaxation in the corpus cavernosum that allows blood to flow into the penis and results in turgidity and tumescence. The concentration of cGMP is regulated by the enzyme PDE-5, which, when inhibited, allows cGMP to increase and enhance erectile function. Because sexual stimulation is required to cause the release of NO, PDE-5 inhibitors have no effect in the absence of such stimulation, an important point to understand when providing information to patients about their use. The congeners vardenafil and tadalafil work in the same way, by inhibiting PDE-5, thus allowing an increase in cGMP and enhancing the vasodilatory effects of NO. For this reason, these drugs are sometimes referred to as NO enhancers.

PHARMACOLOGICAL ACTIONS

All three substances are fairly rapidly absorbed from the gastrointestinal tract, with maximum plasma concentrations reached in 30 to 120 minutes (median, 60 minutes) in the fasting state. Because it is lipophilic, concomitant ingestion of a high-fat meal delays the rate of absorption by up to 60 minutes and reduces the peak concentration by one quarter. These drugs are principally metabolized by the CYP3A4 system, which may lead to clinically significant drug–drug interactions, not all of which have been documented. Excretion of 80 percent of the dose is via feces, and another 13 percent is eliminated in the urine. Elimination is reduced in persons older than age 65 years, which results in plasma concentrations 40 percent higher than in persons age 18 to 45 years. Elimination is also reduced in the presence of severe renal or hepatic insufficiency.

The mean half-lives of sildenafil and vardenafil are 3 to 4 hours, and that of tadalafil is about 18 hours. Tadalafil can be detected in the bloodstream 5 days after ingestion, and because of its long half-life, it has been marketed as effective for up to 36 hours—the so-called weekend pill. The onset of sildenafil occurs about 30 minutes after ingestion on an empty stomach; tadalafil and vardenafil act somewhat more quickly.

Clinicians need to be aware of the important clinical observation that these drugs do not by themselves create an erection. Rather, the mental state of sexual arousal brought on by erotic stimulation must first lead to activity in the penile nerves, which then release NO into the cavernosum, triggering the erectile cascade, the resulting erection being prolonged by the NO enhancers. Thus, full advantage may be taken of a sexually exciting stimulus, but the drug is not a substitute for foreplay and emotional arousal.

THERAPEUTIC INDICATIONS

Erectile dysfunctions have traditionally been classified as organic, psychogenic, or mixed. Over the past 20 years, the prevailing view of the cause of erectile dysfunction has shifted away from psychological causes toward organic causes. The latter include diabetes mellitus, hypertension, hypercholesterolemia, cigarette smoking, peripheral vascular disease, pelvic or spinal cord injury, pelvic or abdominal surgery (especially prostate surgery), multiple sclerosis, peripheral neuropathy, and Parkinson's disease. Erectile dysfunction is often induced by alcohol, nicotine, and other substances of abuse and by prescription drugs.

These drugs are effective regardless of the baseline severity of erectile dysfunction, race, or age. Among those responding to sildenafil are men with coronary artery disease, hypertension, other cardiac disease, peripheral vascular disease, diabetes mellitus, depression, coronary artery bypass graft surgery, radical prostatectomy, transurethral resection of the prostate, spina bifida, and spinal cord injury, as well as persons taking antidepressants, antipsychotics, antihypertensives, and diuretics. However, the response rate is variable.

Sildenafil has been reported to reverse selective serotonin reuptake inhibitor-induced anorgasmia in men. There are anecdotal reports of sildenafil having a therapeutic effect on sexual inhibition in women as well.

PRECAUTIONS AND ADVERSE REACTIONS

A major potential adverse effect associated with use of these drugs is myocardial infarction (MI). The U.S. Food and Drug Administration (FDA) distinguished the risk of MI caused directly by these drugs from that caused by underlying conditions such as hypertension, atherosclerotic heart disease, diabetes mellitus, and other atherogenic conditions. The FDA concluded that when used according to the approved labeling, the drugs do not by themselves confer an increased risk of death. However, there is increased oxygen demand and stress placed on the cardiac muscle by sexual intercourse. Thus, coronary perfusion may be severely compromised, and cardiac failure may occur as a result. For that reason, any person with a history of MI, stroke, renal failure, hypertension, or diabetes mellitus and any person older than the age of 70 years should discuss plans to use these drugs with an internist or a cardiologist. The cardiac evaluation should specifically address exercise tolerance and the use of nitrates.

Use of PDE-5 inhibitors is contraindicated in persons who are taking organic nitrates in any form. Also, amyl nitrate (poppers), a popular substance of abuse used by homosexual men to enhance the intensity of orgasm, should not be used with any of the erection-enhancing drugs. The combination of organic nitrates and PDE inhibitors can cause a precipitous lowering of blood pressure and can reduce coronary perfusion to the point of causing MI and death.

Adverse effects are dose dependent, occurring at higher rates with higher dosages. The most common adverse effects are headache, flushing, and stomach pain. Other less common adverse effects include nasal congestion, urinary tract infection, abnormal vision (colored tinge [usually blue], increased sensitivity to light, or blurred vision), diarrhea, dizziness, and rash. No cases of priapism were reported in premarketing trials. Supportive management is indicated in cases of overdose. Tadalafil has been associated with back and muscle pain in about 10 percent of patients.

Recently, there have been 50 reports and 14 verified cases of a serious condition in men taking sildenafil called nonarteritic anterior ischemic optic neuropathy. This is an eye ailment that causes restriction of blood flow to the optic nerve and can result in permanent vision loss. The first symptoms appear within 24 hours after use of sildenafil and include blurred vision and some degree of vision loss. The incidence of this effect is very rare—1 in 1 million. In the reported cases, many patients had preexisting eye problems that may have increased their risk, and many had a history of heart disease and diabetes, which may indicate vulnerability in these men to endothelial damage.

In addition to vision problems, in 2010, a warning of possible hearing loss was reported based on 29 incidents of the problem since introduction of these drugs. Hearing loss usually occurs within hours or days of using the drug and in some cases is both unilateral and temporary.

No data are available on the effects on human fetal growth and development or testicular morphologic or functional changes. However, because these drugs are not considered an essential treatment, they should not be used during pregnancy.

TREATMENT OF PRIAPISM

Phenylephrine (Neo-Synephrine) is the drug of choice and first-line treatment of priapism because the drug has almost pure α -agonist effects and minimal β activity. In short-term priapism (less than 6 hours), especially for drug-induced priapism, intracavernosal injection of phenylephrine can be used to cause detumescence. A mixture of 1 ampule of phenylephrine (1 mL/1,000 μ g) should be diluted with an additional 9 mL of normal saline. Using a 29-gauge needle, 0.3 to 0.5 mL should be injected into the corpora cavernosa, with 10 to 15 minutes between injections. Vital signs should be monitored, and compression should be applied to the area of injection to help prevent hematoma formation.

Phenylephrine can also be used orally, 10 to 20 mg every 4 hours as needed, but it may not be as effective or act as rapidly as the injectable route.

DRUG INTERACTIONS

The major route of PDE-5 metabolism is through CYP3A4, and the minor route is through CYP2C9. Inducers or inhibitors of these enzymes will therefore affect the plasma concentration and half-life of sildenafil. For example, 800 mg of cimetidine (Tagamet), a nonspecific CYP inhibitor, increases plasma sildenafil concentrations by 56 percent, and erythromycin (E-mycin) increases plasma sildenafil concentrations by 182 percent. Other, stronger inhibitors of CYP3A4 include ketoconazole (Nizoral), itraconazole (Sporanox), and mibefradil (Posicor). In contrast, rifampicin, a CYP3A4 inducer, decreases plasma concentrations of sildenafil.

LABORATORY INTERFERENCES

No laboratory interferences have been described.

DOSAGE AND CLINICAL GUIDELINES

Sildenafil is available as 25-, 50-, and 100-mg tablets. The recommended dose of sildenafil is 50 mg taken by mouth 1 hour before intercourse. However, sildenafil may take effect within 30 minutes. The duration of the effect is usually 4 hours, but in healthy young men, the effect may persist for 8 to 12 hours. Based on effectiveness and adverse effects, the dose should be titrated between 25 and 100 mg. Sildenafil is recommended for use no more than once a day. The dosing guidelines for use by women, an off-label use, are the same as those for men.

Increased plasma concentrations of sildenafil may occur in persons older than 65 years of age and those with cirrhosis or severe renal

impairment or using CYP3A4 inhibitors. A starting dose of 25 mg should be used in these circumstances.

An investigational nasal spray formulation of sildenafil has been developed that acts within 5 to 15 minutes of administration. This formulation is highly water soluble, and it is rapidly absorbed directly into the bloodstream. Such a formulation would permit more ease of use.

Vardenafil is supplied in 2.5-, 5-, 10-, and 20-mg tablets. The initial dose is usually 10 mg taken with or without food about 1 hour before sexual activity. The dose can be increased to a maximum of 20 mg or decreased to 5 mg based on efficacy and side effects. The maximum dosing frequency is once per day. As with sildenafil, dosages may have to be adjusted in patients with hepatic impairment or in patients using certain CYP3A4 inhibitors. A 10 mg orally disintegrating form of vardenafil (Staxyn) is available. It is placed on the tongue approximately 60 minutes before sexual activity and should not be used more than once a day.

Tadalafil is available in 2.5-, 5-, or 20-mg tablets for oral administration. The recommended dose of tadalafil is 10 mg before sexual activity, which may be increased to 20 mg or decreased to 5 mg depending on efficacy and side effects. Once-a-day use of the 2.5- or 5-mg pill is acceptable for most patients. Similar cautions apply as mentioned earlier in patients with hepatic impairment and in those taking concomitant potent inhibitors of CYP3A4. As with other PDE-5 inhibitors, concomitant use of nitrates in any form is contraindicated.

29.27 Selective Serotonin–Norepinephrine Reuptake Inhibitors

There are currently four serotonin–norepinephrine reuptake inhibitors (SNRIs) approved for use in the United States: venlafaxine (Effexor and Effexor XR), desvenlafaxine succinate (DVS; Pristiq), duloxetine (Cymbalta), and levomilnacipran (Fetzima). A fifth SNRI, milnacipran (Savella), available in other countries as an antidepressant, has U.S. Food and Drug Administration (FDA) approval in the United States as a treatment for fibromyalgia. The term SNRI reflects the belief that the therapeutic effects of these medications are mediated by concomitant blockade of neuronal serotonin (5-HT) and norepinephrine uptake transporters. The SNRIs are also sometimes referred to as dual reuptake inhibitors, a broader functional class of antidepressant medications that includes tricyclic antidepressants (TCAs) such as clomipramine (Anafranil) and, to a lesser extent, imipramine (Tofranil) and amitriptyline (Elavil). What distinguishes the SNRIs from TCAs is their relative lack of affinity for other receptors, especially muscarinic, histaminergic, and the families of α - and β -adrenergic receptors. This distinction is an important one because the SNRIs have a more favorable tolerability profile than the older dual reuptake inhibitors.

VENLAFAXINE AND DESVENLAFAXINE

Therapeutic Indications

Venlafaxine is approved for treatment of four disorders: major depressive disorder, generalized anxiety disorder, social anxiety disorder, and panic disorder. Major depressive disorder is currently the only FDA-approved indication for DVS.

Depression. The FDA does not recognize any class of antidepressant as being more effective than any other. This does not mean that differences do not exist, but no study to date has sufficiently demonstrated such superiority. It has been argued that direct modulation of serotonin and norepinephrine may convey greater antidepressant effects than are exerted by medications that selectively enhance only noradrenergic or serotonergic neurotransmission. This greater therapeutic benefit could result from an acceleration of postsynaptic adaptation to increased neuronal signaling; simultaneous activation of two pathways for intracellular signal transduction; additive effects on the activity of relevant genes such as brain-derived neurotrophic factor; or, quite simply, broader coverage of depressive symptoms. Clinical evidence supporting this hypothesis first emerged in a pair of studies conducted by the Danish University Antidepressant Group, which found an advantage for the dual reuptake inhibitor clomipramine compared with the selective serotonin reuptake inhibitors (SSRIs) citalopram (Celexa) and paroxetine (Paxil). Another report, which compared the results of a group of patients prospectively treated with the combination of the TCAs desipramine (Norpramin) and fluoxetine (Prozac) with a historical comparison group treated with desipramine alone, provided additional support. A meta-analysis of 25 inpatient studies comparing the efficacy of TCAs and SSRIs yielded the strongest evidence. Specifically, although the TCAs were found to have a modest overall advantage, superiority versus SSRIs was almost entirely explained by the studies that used the TCAs that are considered to be dual reuptake inhibitors—clomipramine, amitriptyline, and imipramine. Meta-analyses of head-to-head studies suggest that venlafaxine has the potential to induce higher rates of remission in depressed patients than do the SSRIs. This difference of the venlafaxine advantage is about 6 percent. DVS has not been extensively compared with other classes of antidepressants with respect to efficacy.

Generalized Anxiety Disorder. The extended-release formulation of venlafaxine is approved for treatment of generalized anxiety disorder. In clinical trials lasting 6 months, dosages of 75 to 225 mg a day were effective in treating insomnia, poor concentration, restlessness, irritability, and excessive muscle tension related to generalized anxiety disorder.

Social Anxiety Disorder. The extended-release formulation of venlafaxine is approved for treatment of social anxiety disorder. Its efficacy was established in 12-week studies.

Other Indications. Case reports and uncontrolled studies have indicated that venlafaxine may be beneficial in the treatment of obsessive-compulsive disorder, panic disorder, agoraphobia, social phobia, attention-deficit/hyperactivity disorder, and patients with a dual diagnosis of depression and cocaine dependence. It has also been used in chronic pain syndromes with good effect.

Precautions and Adverse Reactions

Venlafaxine has a safety and tolerability profile similar to that of the more widely prescribed SSRI class. Nausea is the most frequently reported treatment-emergent adverse effect associated with venlafaxine and DVS therapy. Initiating therapy at lower dosages may also attenuate nausea. When extremely problematic, treatment-induced nausea can be controlled by prescribing a selective 5-HT₃ antagonist or mirtazapine (Remeron).

Venlafaxine and DVS therapy is associated with sexual side effects, predominantly decreased libido and a delay to orgasm or ejaculation. The incidence of these side effects may exceed 30 to 40 percent when there is direct, detailed assessment of sexual function.

Other common side effects include headache, insomnia, somnolence, dry mouth, dizziness, constipation, asthenia, sweating, and nervousness. Although several side effects are suggestive of anticholinergic effects, these drugs have no affinity for muscarinic or nicotinic receptors. Thus, noradrenergic agonism is likely to be the culprit.

Higher-dose venlafaxine therapy is associated with an increased risk of sustained elevations of blood pressure (BP). Experience with the instant-release (IR) formulation in studies of depressed patients indicated that sustained hypertension was dose related, increasing from 3 to 7 percent at doses of 100 to 300 mg per day and to 13 percent at doses greater than 300 mg per day. In this dataset, venlafaxine therapy did not adversely affect BP control of patients taking antihypertensives and actually lowered mean values of patients with elevated BP readings before therapy. In controlled studies of the extended-release formulation, venlafaxine therapy resulted in only approximately 1 percent greater risk of high BP when compared with placebo. Arbitrarily capping the upper dose of venlafaxine used in these studies thus greatly attenuated concerns about elevated BP. When higher doses of the extended-release formulation are used, however, monitoring of BP is recommended.

Venlafaxine and DVS are commonly associated with a discontinuation syndrome. This syndrome is characterized by the appearance of a constellation of adverse effects during a rapid taper or abrupt cessation, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances. It is recommended that, whenever possible, a slow taper schedule should be used when longer-term treatment must be stopped. On occasion, substituting a few doses of the sustained-release formulation of fluoxetine may help to bridge this transition.

There were no overdose fatalities in premarketing trials of venlafaxine, although electrocardiographic changes (e.g., prolongation of QT interval, bundle branch block, QRS interval prolongation), tachycardia, bradycardia, hypotension, hypertension, coma, serotonin syndrome, and seizures were reported. Fatal overdoses have been documented subsequently, typically involving venlafaxine ingestion in combination with other drugs, alcohol, or both.

Information concerning use of venlafaxine and DVS by pregnant and nursing women is not available at this time. Venlafaxine and DVS are excreted in breast milk. Clinicians should carefully weigh the risks and benefits of venlafaxine use by pregnant and nursing women.

Drug Interactions

Venlafaxine is metabolized in the liver primarily by the CYP2D6 isoenzyme. Because the parent drug and principal metabolite are essentially equipotent, medications that inhibit this isoenzyme usually do not adversely affect therapy. Venlafaxine is itself a relatively weak inhibitor of CYP2D6, although it can increase levels of substrates, such as desipramine or risperidone (Risperdal). In vitro and in vivo studies have shown venlafaxine to cause little or no inhibition of CYP1A2, CYP2C9, CYP2C19, and CYP3A4.

Venlafaxine is contraindicated in patients taking monoamine oxidase inhibitors (MAOIs) because of the risk of a pharmacodynamic interaction (i.e., serotonin syndrome). An MAOI should not be started for at least 7 days after stopping venlafaxine. Few data are available regarding the combination of venlafaxine with atypical neuroleptics, benzodiazepines, lithium (Eskalith), and anticonvulsants; therefore, clinical judgment should be exercised when combining medications.

Laboratory Interferences

Data are not currently available on laboratory interferences with venlafaxine.

Dosage and Administration

Venlafaxine is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets and 37.5-, 75-, and 150-mg extended-release capsules. The tablets and the extended-release capsules are equally potent, and persons stabilized with one can switch to an equivalent dosage of the other. Because the immediate-release tablets are rarely used due to their tendency to cause nausea and the need for multiple daily doses, the dosage recommendations that follow refer to use of the extended-release capsules.

In depressed persons, venlafaxine demonstrates a dose–response curve. The initial therapeutic dosage is 75 mg a day given once a day. However, most persons are started at a dosage of 37.5 mg for 4 to 7 days to minimize adverse effects, particularly nausea. A convenient starter kit for the drug contains a 1-week supply of both the 37.5- and 75-mg strengths. If a rapid titration is preferred, the dosage can be raised to 150 mg per day after day 4. As a rule, the dosage can be raised in increments of 75 mg a day every 4 or more days. Although the recommended upper dosage of the extended-release preparation (venlafaxine XR) is 225 mg per day, it is approved by the FDA for use at dosages up to 375 mg a day. The dosage of venlafaxine should be halved in persons with significantly diminished hepatic or renal function. If discontinued, venlafaxine use should be gradually tapered over 2 to 4 weeks to avoid withdrawal symptoms.

There are minor differences in the doses used for major depression, generalized anxiety disorder, and social anxiety disorder. In the treatment of these disorders, for example, a dose–response effect has not been found. In addition, lower mean dosages are typically used, with most patients taking 75 to 150 mg per day.

DVS is available as 50- and 100-mg extended-release tablets. The therapeutic dose for most patients is 50 mg a day. Although some patients may need higher doses, in clinical trials, no greater therapeutic benefit was noted when the dose was increased. At higher doses, adverse event and discontinuation rates were increased.

DULOXETINE

Pharmacological Actions

Duloxetine is formulated as a delayed-release capsule to reduce the risk of severe nausea associated with the drug. It is well absorbed, but there is a 2-hour delay before absorption begins. Peak plasma concentrations occur 6 hours after ingestion. Food delays the time to achieve maximum concentrations from 6 to 10 hours and reduces the extent of absorption by about 10 percent. Duloxetine has an elimination half-life of about 12 hours (range, 8 to 17 hours). Steady-state plasma concentrations occur after 3 days. Elimination is mainly through the isozymes CYP2D6 and CYP1A2. Duloxetine undergoes extensive hepatic metabolism to numerous metabolites. About 70 percent of the drug appears in the urine as metabolites and about 20 percent is excreted in the feces. Duloxetine is 90 percent protein bound.

Therapeutic Indications

Depression. In contrast to venlafaxine, a small number of studies have compared duloxetine with the SSRIs. Although these studies are suggestive of some advantage in efficacy, their findings are limited by the use of fixed, low starting doses of paroxetine and fluoxetine, but dosages of duloxetine in some studies were as high as 120 mg per day. Any inferences on whether duloxetine is superior to the SSRIs in any aspect of treatment for depression thus await more evidence from properly designed trials.

Neuropathic Pain Associated with Diabetes and Stress Urinary Incontinence. Duloxetine is the first drug to be approved by the FDA as a treatment for neuropathic pain associated with diabetes. The drug has been studied for its effects on physical symptoms, including pain, in depressed patients, but these effects have not been compared with those seen with other widely used agents such as venlafaxine and the TCAs. Duloxetine is currently awaiting approval as a treatment for stress urinary incontinence, the inability to voluntarily control bladder voiding, which is the most frequent type of incontinence in women. The action of duloxetine in the treatment of stress urinary incontinence is associated with its effects in the sacral spinal cord, which in turn increase the activity of the striated urethral sphincter. Duloxetine will be marketed under the name Yentreve for this indication.

Precautions and Adverse Reactions. The most common adverse reactions are nausea, dry mouth, dizziness, constipation, fatigue, decreased appetite, anorexia, somnolence, and increased sweating. Nausea was the most common side effect that led to treatment discontinuation in clinical trials. The true incidence of sexual dysfunction is unknown; the long-term effects on body weight are also unknown. In clinical trials, treatment with duloxetine was associated with mean increases in BP averaging 2 mm Hg systolic and 0.5 mm Hg diastolic versus placebo. No studies have compared the BP effects of venlafaxine and duloxetine at equivalent therapeutic doses.

Close monitoring is suggested when using duloxetine in patients who have or are at risk for diabetes. Duloxetine has been shown to increase blood sugar and hemoglobin A1C levels during long-term treatment.

Patients with substantial alcohol use should not be treated with duloxetine because of possible hepatic effects. It also should not be prescribed for patients with hepatic insufficiency and end-stage renal disease or for patients with uncontrolled narrow-angle glaucoma.

Abrupt discontinuation of duloxetine should be avoided because it may produce a discontinuation syndrome similar to that of venlafaxine. A gradual dose reduction is recommended.

Clinicians should avoid the use of duloxetine by pregnant and nursing women unless the potential benefits justify the potential risks.

Drug Interactions

Duloxetine is a moderate inhibitor of CYP450 enzymes.

Laboratory Interferences

Data are not currently available on laboratory interferences with duloxetine.

Dosage and Administration

Duloxetine is available in 20-, 30-, and 60-mg tablets. The recommended therapeutic, and maximum, dosage is 60 mg per day. The 20- and 30-mg doses are useful for either initial therapy or for twice-daily use as strategies to reduce side effects. In clinical trials, dosages of up to 120 mg per day were studied, but no consistent advantage in efficacy was noted at doses higher than 60 mg per day. Duloxetine thus does not appear to demonstrate a dosage–response curve. However, there were difficulties in tolerability with single doses above 60 mg. Accordingly, when dosages of 80 and 120 mg per day were used, they were administered as 40 or 60 mg twice daily. Because of limited clinical experience with duloxetine, it remains to be seen to what extent dosages above 60 mg per day will be necessary and whether this will actually require divided doses to make the drug tolerable.

MILNACIPRAN AND LEVOMILNACIPRAN

Milnacipran is only FDA approved for the treatment of fibromyalgia. Although some countries have approved milnacipran for general use as an antidepressant, efficacy is not as well established. Compared with venlafaxine, milnacipran is approximately five times more potent for inhibition of norepinephrine uptake than for 5-HT reuptake inhibition. Milnacipran has a half-life of approximately 8 hours and shows linear pharmacokinetics between doses of 50 and 250 mg per day. Metabolized in the liver, milnacipran has no active metabolites. Milnacipran is primarily excreted by the kidneys.

Milnacipran is available as 12.5-, 25-, 50-, and 100-mg tablets. The standard recommended milnacipran dose is as follows: day 1, 12.5 mg once daily; days 2 and 3, 12.5 mg twice daily; days 4 to 7, 25 mg twice daily; and day 7 and beyond, 50 mg twice daily.

Levomilnacipran was approved in 2013 by the FDA as a treatment for major depressive disorder (MOD) in adults. Levomilnacipran is an active enantiomer of the racemic drug milnacipran. In vitro studies have shown that it has greater potency for norepinephrine reuptake inhibition than for serotonin reuptake inhibition and does not directly affect the uptake of dopamine or other neurotransmitters. It is taken once daily as a sustained-release formulation. In clinical trials, doses of 40 mg, 80 mg, or 120 mg improved symptoms compared with placebo.

The most common adverse reactions in the placebo-controlled trials were nausea, constipation, hyperhidrosis, increased heart rate, erectile dysfunction, tachycardia, vomiting, and palpitations. Rates of adverse events were generally consistent across the 40 to 120 mg dose range. The only dose-related adverse events were urinary hesitation and erectile dysfunction.

29.28 Selective Serotonin Reuptake Inhibitors

Fluoxetine (Prozac), the first selective serotonin reuptake inhibitor (SSRI) marketed in the United States, rapidly captured the favor of both clinicians and the general public as reports emerged of dramatic patient responses to treatment of depression. Patients no longer experienced such side effects as dry mouth, constipation, sedation, orthostatic hypotension, and tachycardia, common side effects associated with the earlier antidepressant drugs—the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). It was also significantly safer when taken in overdose than any previously available antidepressant. A significant effect of fluoxetine's popularity was that it helped ameliorate the long-standing stigma of depression and its treatment.

Fluoxetine was followed by other SSRIs. These include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and vilazodone (Viibryd). These drugs are all equally effective in treating depression but some are approved by the U.S. Food and Drug Administration (FDA) for multiple indications, such as major depression, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), premenstrual dysphoric disorder (PMDD), panic disorder, and social phobia (social anxiety disorder) (Table 29.28-1). Note that fluvoxamine is not FDA approved as an antidepressant, a fact that is due to a marketing decision. It is considered an antidepressant in other countries.

^cMarketed as Sarafem.

^dParoxetine-controlled release is approved for premenstrual dysphoric disorder.

Although all SSRIs are equally effective, there are meaningful differences in pharmacodynamics, pharmacokinetics, and side effects, differences that might affect clinical responses among individual patients. This would explain why some patients have better clinical responses to a particular SSRI than another. The SSRIs have proven more problematic in terms of some side effects than the original clinical trials suggested. Quality-of-life–associated adverse effects such as nausea, sexual dysfunction, and weight gain sometimes mitigate the therapeutic benefits of the SSRIs. There can also be distressing withdrawal symptoms when SSRIs are stopped abruptly. This is especially true with paroxetine, but also occurs when other SSRIs with short half-lives are stopped.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics

A significant difference among the SSRIs is their broad range of serum half-lives. Fluoxetine has the longest half-life: 4 to 6 days; its active metabolite has a half-life of 7 to 9 days. The half-life of sertraline is 26 hours, and its less active metabolite has a half-life of 3 to 5 days. The half-lives of the other three, which do not have metabolites with significant pharmacological activity, are 35 hours for citalopram, 27 to 32 hours for escitalopram, 21 hours for paroxetine, and 15 hours for fluvoxamine. As a rule, the SSRIs are well absorbed after oral administration and have their peak effects in the range of 3 to 8 hours. Absorption of sertraline may be slightly enhanced by food.

There are also differences in plasma protein–binding percentages among the SSRIs, with sertraline, fluoxetine, and paroxetine being the most highly bound and escitalopram being the least bound.

All SSRIs are metabolized in the liver by the CYP450 enzymes. Because the SSRIs have such a wide therapeutic index, it is rare that other drugs produce problematic increases in SSRI concentrations. The most important drug–drug interactions involving the SSRIs occur as a result of the SSRIs inhibiting the metabolism of the coadministered medication. Each of the SSRIs possesses a potential for slowing or blocking the metabolism of many drugs (Table 29.28-2). Fluvoxamine is the most problematic of the drugs in this respect. It has a marked effect on several of the CYP enzymes. Examples of clinically significant interactions include fluvoxamine and theophylline (Slo-Bid, Theo-Dur) through CYP1A2 interaction; fluvoxamine and clozapine (Clozaril) through CYP1A2 inhibition; and fluvoxamine with alprazolam (Xanax) or

clonazepam (Klonopin) through CYP3A4 inhibition. Fluoxetine and paroxetine also possess significant effects on the CYP2D6 isozyme, which may interfere with the efficacy of opiate analogs, such as codeine and hydrocodone, by blocking the conversion of these agents to their active form. Thus, coadministration of fluoxetine and paroxetine with an opiate interferes with its analgesic effects. Sertraline, citalopram, and escitalopram are least likely to complicate treatment because of interactions.

Table 29.28-2
CYP450 Inhibitory Potential of Commonly Prescribed Antidepressants

Low or minimal	Bupropion (Wellbutrin) Mirtazapine (Remeron) Nefazodone (Serzone) Paroxetine (Paxil) Sertraline (Zoloft) Venlafaxine	Paroxetine Venlafaxine (Effexor)	Fluvoxamine Mirtazapine Nefazodone Venlafaxine	Citalopram Escitalopram Mirtazapine Paroxetine Venlafaxine

CYP, cytochrome P450.

The pharmacokinetics of vilazodone (5 to 80 mg) are dose proportional. Steady-state plasma levels are achieved in about 3 days. Elimination of vilazodone is primarily by hepatic metabolism with a terminal half-life of approximately 25 hours.

Pharmacodynamics
