APPENDICES

Preface to 27th Edition

When Hamilton Bailey and McNeil Love published the first edition of their venerated textbook in 1932 the surgical world was a very different place to that of today. There were no antibiotics, no joint replacement, no open heart surgery, no transplantation and many other procedures that we now take for granted had simply not been invented. Medicine as a whole and surgery in particular never stands still. Surgeons continually strive to innovate so that they can tackle conditions and diseases previously thought to be beyond reach. They do this against a background of new discoveries in both the physical and biological sciences. Such breakthroughs make some surgical procedures redundant but others stimulate new approaches. This is seen in all specialties and consequently it is important for textbooks not only to keep pace with new developments but also to ensure that a balanced view is taken of their place in the therapeutic armamentarium. In developing the 27th edition of this much-loved textbook, we have striven to keep this in the forefront of our minds and those of our contributors. Nevertheless, in addition to considering the place of innovation, it is important not to 'throw the baby out with the bathwater'. We have therefore ensured that the basic tenets of surgical practice that have stood the test of time remain where appropriate.

Since the last edition great strides have been made in certain areas and we have ensured that these have been embedded in the book. For instance, in colorectal surgery a tipping point has been reached whereby more elective surgery is performed laparoscopically than by open technique. Similarly, in vascular surgery there has been an explosion in the use of interventional radiology to treat conditions that were previously the sole province of the surgeon. Stenting of aortic aneurysms (EVAR), for instance, is rapidly replacing elective open operations and, in many instances, is being used for treating leaking aneurysms, with a concomitant marked reduction in mortality. Damage control surgery is an increasingly important part of trauma management, in both civilian and conflict settings. Such developments also highlight the important role of the multidisciplinary team and the realisation that modern surgical care can no longer be provided in isolation. This concept is reiterated throughout the book and is also why the importance of human factors is emphasised in the chapter on patient safety, which is a relatively new science of how humans behave physically and psychologically in relation to particular environments. There is no more intense environment than an operating theatre, so how a surgical team interacts is crucial to the outcome for a patient undergoing a surgical procedure. This also applies, of course, outside the operating theatre because multidisciplinary working is now paramount to the delivery of safe and effective patient care. There is no doubt that in recent years regulation of medical practice has become tighter. Whereas in certain jurisdictions some may feel that this has become stifling, there is no doubt that regulation is here to stay. Needless to say, we should all be aware of our responsibilities to patients, both morally and ethically, and, although most need no reminding, the law is continually changing as test cases are brought before the courts. Hence, we draw the attention of the reader to the revamped chapter on ethics and the law, the tenets of which we must all abide by.

Throughout the text, we have also endeavoured to point out where we and our authors think the specialty is moving. Exciting developments are on the horizon. For instance, genome sequencing will have a marked effect on how we practise in certain specialties, none more so than oncology. Robotics is likely to improve many more surgical procedures and tissue engineering will become more commonplace. In order to accommodate these advances, it has been necessary to streamline some of the more established chapters, otherwise the book would become unwieldy. As a consequence, we have ensured that the 'Further reading' list at the end of each chapter has been brought up to date, allowing readers to delve further if they so wish.

We are very conscious that the book is popular throughout the world and consequently we have ensured that those diseases that are prevalent outside Europe and North America are included. Where relevant we have involved experts who are used to dealing with such maladies. The chapter on tropical infections and infestations is such an example.

We have also endeavoured in this edition to be more consistent in its layout, ensuring that we use a similar format for tables, graphs and diagrams. Nevertheless, we have been sure to keep the biographical details of individual scientists and practitioners, which have been beloved of all readers throughout the generations. Similarly, we have retained the section on surgical instruments. Although some are now very much of historical interest, they are part of our heritage and students and indeed established practitioners will, we hope, find these vignettes fascinating. We have been told that the Summary boxes are very much appreciated by both undergraduate and postgraduate students revising, sometimes in

haste, before exams and hence our authors have ensured that these are up to date.

A book as comprehensive as this could never have been completed without the dedication and professionalism of our contributors. They have invariably answered our demands with alacrity and accuracy, appreciating the responsibility that goes with informing the readership of such a respected and established textbook. We are extremely grateful for all their efforts because we are conscious that a textbook such as this can never rest on its laurels. If it is to remain in the higher echelons of surgical tomes it must have the very best contributors and we believe that we have brought together such a cadre in the present edition. This in no way diminishes the contributions of the authors from the previous edition who are no longer involved. They, for a variety of reasons including retirement, have passed on the baton. We are grateful to them for magnanimously stepping down and making way for 'new blood' and none more so than our previous co-editor Professor Christopher Bulstrode. Chris helped revamp the 23rd, 24th, 25th and 26th Editions and these would never have been as successful without his dedicated efforts. Chris's place in the editorial team has been taken by Andrew McCaskie who has streamlined the trauma and orthopaedic sections as well as overseeing other chapters.

Readers of *Bailey & Love* have always been an integral part of the development of the book over the years and the present editorial group relish your feedback, which we know from experience will be forthcoming. Such input is vital if the book is to continue to reach the very high standards expected from each new edition. This has been a labour of love for all of us involved in this edition and we do hope it fulfils your needs, no matter whether you are an undergraduate student exploring the exciting world of surgical practice for the first time, a postgraduate trainee studying for exams or an established consultant who wishes to refresh his or her memory.

We wish you all well in your careers no matter which specialty you choose to practise in and we very much hope that the 27th and indeed subsequent editions of *Bailey & Love* accompany you on your travels through this most rewarding of professions.

Acknowledgements

In this day and age, it is impossible to produce a book like Bailey and Love without the contribution of numerous talented individuals. Although it is impractical to mention all those who have played a part in producing the 27th Edition, it would be remiss not to express our gratitude to the following key players.

Henry Spilberg initiated the new edition as commissioning editor under the supervision of Jo Koster and was very much involved in the early planning. His role was subsequently taken over by Miranda Bromage following his departure for pastures green. Miranda's diligence and experience has been invaluable and we are enormously indebted to her wise counsel. Cherry Allen, as Editorial Assistant has been key in liaising with the editors and the contributors, ensuring manuscripts have been received on time and has been responsible for ensuring the smooth handover of the text to the production team. The latter has been headed by Paul Bennett who has provided an extremely professional service. His and his team's attention to detail has been very much valued and we hope is reflected in a first class product.

Chapter 5, *Surgical infection*, contains some material from '*Surgical infection*' by David J. Leaper. The material has been revised and updated by the current author.

Chapter 7, *Basic surgical skills and anastomoses*, contains some material from '*Basic surgical skills and anastomoses*' by David J. Leaper and William E.G. Thomas. The material has been revised and updated by the current author.

Chapter 9, *Principles of paediatric surgery*, contains some material from '*Principles of paediatric surgery*' by Mark Stringer. The material has been revised and updated by the current author.

Chapter 12, *Surgical ethics and law*, contains some material from '*Surgical ethics*' by Len Doyal. The material has been revised and updated by the current author.

Chapter 14, *Diagnostic imaging*, contains some material from '*Diagnostic imaging*' by the current authors and Gina Allen, which has been revised and updated for this edition.

Chapter 17, *Preoperative care including the high-risk surgical patient*, contains some material from '*Pre operative preparation*' by current authors Medha Vanarase-Pandit and Pierre Foex, and Kevin Tremper, Lisa Leonard and Sarah Barton, and '*Perioperative management of the high-risk patient*' by Mridula Rai, Kevin D. Johnston, Rupert M. Pearse and Richard M. Langford. The material has been revised and updated by the current authors.

Chapter 18, *Anaesthesia and pain relief*, contains some material from '*Anaesthesia and pain relief*' by current author Vivek Mehta, and Richard Langford and Jagannath Halder. The material has been revised and updated by the current authors.

Chapter 20, *Postoperative care*, contains some material from '*Postoperative care*' by Jay Kini, current author Anand Sardesai, and Alistair Pace and Nicholas C.M. Armitage. The material has been revised and updated by the current authors.

Chapter 23, *Early assessment and management of trauma*, contains some material from '*Early assessment and management of trauma*' by Dinesh Nathwani and Joseph Windley. The material has been revised and updated by the current authors.

Chapter 24, *Traumatic brain injury*, contains some material from '*Head injury*' by Richard Stacey and John Leach. The material has been revised and updated by the current authors.

Chapter 25, *Neck and spine*, contains some material from '*Neck and spine*' by Ashley Poynton. The material has been revised and updated by the current authors.

Chapter 26, *Maxillofacial trauma*, contains some material from '*Maxillofacial trauma*' by Charles Perkins. The material has been revised and updated by the current author.

Chapter 28, *Extremity trauma*, contains some material from '*Extremity trauma*' by Parminder Singh. The material has been revised and updated by the current author.

Chapter 31, *History taking and clinical examination in musculoskeletal disease*, contains some material from '*History taking and clinical examination in musculoskeletal disease*' by

Parminder Singh and current author Hemant G. Pandit. The material has been revised and updated by the current authors.

Chapter 32, *Sports medicine and sports injuries*, contains some material from '*Sports medicine and sports injuries*' by D.L. Back and Jay Smith. The material has been revised and updated by the current authors.

Chapter 33, *The spine*, contains some material from '*The spine*' by the current authors and Gavin Bowden, which has been revised and updated for this edition.

Chapter 34, *Upper limb*, contains some material from '*Upper limb – pathology, assessment and management*' by Vinay Takwale, Irfan Khan and Srinath Kamineni. The material has been revised and updated by the current authors.

Chapter 35, *Hip and knee*, contains some material from '*Hip and knee*' by Hermant G. Pandit, Andrew Bernett, current author Vikas Khanduja and Richard N. Villar. The material has been revised and updated by the current authors.

Chapter 36, *Foot and ankle*, contains some material from '*Foot and ankle*' by Mark Davies, Matthew C. Solan and Vikas Khanduja. The material has been revised and updated by the current author.

Chapter 38, *Infection of the bones and joints*, contains some material from '*Infection of the bones and joints*' by the current authors and Philip Bejon, which has been revised and updated for this edition.

Chapter 39, *Paediatric orthopaedics*, contains some material from '*Paediatric orthopaedics*' by the current author and Joanna Hicks, which has been revised and updated for this edition.

Chapter 43, *Cranial neurosurgery*, contains some material from '*Elective Neurosurgery*' by John Leach and Richard Kerr. The material has been revised and updated by the current authors.

Chapter 44, *The eye and orbit*, contains some material from '*The eye and orbit*' by Colm O'Brien, Hugo Henderson and Jonathan Jagger. The material has been revised and updated by the current author.

Chapter 45, *Cleft lip and palate: developmental abnormalities of the face, mouth and jaws*, contains some material from '*Cleft lip and palate: developmental abnormalities of the face, mouth and jaws*' by William P. Smith. The material has been revised and updated by the current author.

Chapter 46, *The ear, nose and sinuses*, contains some material from '*The nose and sinuses*' by Robert W. Ruckley and current author Iain J. Nixon, and '*The ear*' by Grant Bates. The material has been revised and updated by the current authors.

Chapter 47, *Pharynx, larynx and neck*, contains some material from '*Pharynx, larynx and neck*' by Rishi Sharma, Martin Birchall, Jonathan D. Jagger and Hugo W.A. Henderson. The material has been revised and updated by the current author.

Chapter 48, *Oral cavity malignancy*, contains some material from '*Oropharyngeal cancer*' by William P. Smith. The material has been revised and updated by the current author.

Chapter 49, *Disorders of the salivary glands*, contains some material from '*Disorders of the salivary glands*', by William P. Smith. The material has been revised and updated by the current authors.

Chapter 50, *The thyroid glands*, contains some material from '*The thyroid and parathyroid glands*' by Zygmunt H. Krukowski. The material has been revised and updated by the current author.

Chapter 51, *The parathyroid glands*, contains some material from '*The thyroid and parathyroid glands*' by Zygmunt H. Krukowski. The material has been revised and updated by the current author.

Chapter 52, *The adrenal glands and other abdominal endocrine disorders*, contains some material from '*Adrenal glands and other endocrine disorders*' by Matthias Rothmund. The material has been revised and updated by the current author.

Chapter 54, *Cardiac surgery*, contains some material from '*Cardiac surgery*' by current author Jonathan Anderson and Ian Hunt. The material has been revised and updated by the current authors.

Chapter 55, *The thorax*, contains some material from '*The thorax*' by Tom Treasure. The material has been revised and updated by the current authors.

Chapter 56, *Arterial disorders*, contains some material from '*Arterial disorders*' by John A. Murie. The material has been revised and updated by the current author.

Chapter 57, *Venous disorders*, contains some material from '*Venous disorders*' by Peter McCollum, current author Ian Chetter and Kevin Burnand. The material has been revised and updated by the current authors.

Chapter 58, *Lymphatic disorders*, contains some material from '*Lymphatic disorders*' by current author Shervanthi Homer-Vanniasinkam and Andrew Bradbury. The material has been revised and updated by the current authors.

Chapter 59, *History and examination of the abdomen*, contains some material from '*History and examination of the abdomen*', by Mohan de Silva, V. Sitaram and Simon Paterson-Brown. The material has been revised and updated by the current author.

Chapter 60, *Abdominal wall, hernia and umbilicus*, contains some material from '*Hernias, umbilicus and abdominal wall*' by Andrew N. Kingsnorth, Giorgi Giorgobiani and David H. Bennett. The material has been revised and updated by the current authors.

Chapter 61, *The peritoneum, omentum, mesentery and retroperitoneal space*, contains some material from '*The peritoneum, omentum, mesentery and retroperitoneal space*' by Jerry Thompson. The material has been revised and updated by the current author.

Chapter 64, *Bariatric and metabolic surgery*, contains some material from '*Bariatric surgery*' by John Baxter. The material has been revised and updated by the current author.

Chapter 65, *The liver*, contains some material from '*The liver*' by Rahul S. Koti, Sanjeev Kanoria and Brian R. Davidson. The material has been revised and updated by the current authors.

Chapter 69, *The small intestine*, contains some material from '*The small and large intestines*' by current author Gordon Carlson, Jonathan Epstein, Neil J. McC. Mortensen and Shazad Ashraf. The material has been revised and updated by the current authors.

Chapter 70, *The large intestine*, contains some material from '*The small and large intestines*' by Neil J. McC. Mortensen and Shazad Ashraf. The material has been revised and updated by the current authors.

Chapter 71, *Intestinal obstruction*, contains some material from '*Intestinal obstruction*' by Marc Christopher Winslet. The material has been revised and updated by the current author.

Chapter 72, *The vermiform appendix*, contains some material from '*The vermiform appendix*' by P. Ronan O'Connell. The material has been revised and updated by the current author.

Chapter 73, *The rectum*, contains some material from '*The rectum*' by Sue Clark. The material has been revised and updated by the current author.

Chapter 74, *The anus and anal canal*, contains some material from '*The anus and anal canal*' by the current author and Peter Lunniss, which has been revised and updated for this edition.

Chapter 76, *The kidneys and ureters*, contains some material from '*The kidneys and ureters*' by Christopher G. Fowler. The material has been revised and updated by the current author.

Chapter 77, *The urinary bladder*, contains some material from '*The urinary bladder*' by David E. Neal. The material has been revised and updated by the current author.

Chapter 79, *Urethra and penis*, contains some material from '*Urethra and penis*' by Christopher G. Fowler. The material has been revised and updated by the current author.

Chapter 80, *Testis and scrotum*, contains some material from '*Testis and scrotum*' by Christopher G. Fowler. The material has been revised and updated by the current author.

Chapter 81, *Gynaecology*, contains some material from '*Gynaecology*' by Stephen Kennedy and Enda McVeigh. The material has been revised and updated by the current author.

We acknowledge advice, beyond their chapter contribution, from Anand Sardesai in relation to anaesthetics, and Lee Van Rensburg, in relation to trauma.

Sayings of the great

Both Hamilton Bailey and McNeill Love, when medical students, served as clerks to Sir Robert Hutchinson, 1871–1960, who was Consulting Physician to the London Hospital and President of the Royal College of Physicians. They never tired of quoting his 'medical litany', which is appropriate for all clinicians and, perhaps especially, for those who are surgically minded.

From inability to leave well alone;
From too much zeal for what is new and contempt for what is old;
From putting knowledge before wisdom, science before art, cleverness before common sense;
From treating patients as cases; and
From making the cure of a disease more grievous than its endurance,
Good Lord, deliver us.

To which may be added:

The patient is the centre of the medical universe around which all our works revolve and towards which all our efforts trend.

J.B. Murphy, 1857–1916, Professor of Surgery,
Northwestern University, Chicago, IL, USA

To study the phenomenon of disease without books is to sail an uncharted sea, while to study books without patients is not to go to sea at all.

Sir William Osler, 1849–1919,
Professor of Medicine, Oxford, UK

A knowledge of healthy and diseased actions is not less necessary to be understood than the principles of other sciences. By and acquaintance with principles we learn the cause of disease. Without this knowledge a man cannot be a surgeon. … The last part of surgery, namely operations, is a reflection on the healing art; it is a tacit acknowledgement of the insufficiency of surgery. It is like an armed savage who attempts to get that by force which a civilised man would by stratagem.

John Hunter, 1728–1793, Surgeon,
St George's Hospital, London, UK

Investigating Nature you will do well to bear ever in mind that in every question there is the truth, whatever our notions may be. This seems perhaps a very simple consideration; yet it is strange how often it seems to be disregarded. If we had nothing but pecuniary rewards and worldly honours to look to, our profession would not be one to be desired. But in its practice you will find it to be attended with peculiar privileges; second to none in intense interest and pure pleasures. It is our proud office to tend the fleshy tabernacle of the immortal spirit, and our path, if rightly followed, will be guided by unfettered truth and love unfeigned. In the pursuit of this noble and holy calling I wish you all God-speed.

Promoter's address, Graduation in Medicine,
University of Edinburgh, August, 1876, by Lord Lister,
the Founder of Modern Surgery

Surgery has undergone many great transformations during the past fifty years, and many are to be thanked for their contributions – yet when we think of how many remain to be made, it should rather stimulate our inventiveness than fuel our vanity.

Sir Percival Pott, 1714–88, Surgeon,
St Bartholomew's Hospital, London, UK

If you cannot make a diagnosis at least make a decision!
Sir Harry Platt, 1897–1986,
Professor of Orthopaedics, Manchester, and
President of the Royal College of Surgeons England,
London, UK

If the surgeon cuts a vessel and knows the name of that vessel, the situation is serious; if the anaesthetist knows the name of that vessel, the situation is irretrievable.

Maldwyn Morgan 1938–
Anaesthetist, Hammersmith Hospital, London, UK

PART 1

Basic principles

Chapter 1

Metabolic response to injury

Learning objectives

To understand:

- Classical concepts of homeostasis
- Mediators of the metabolic response to injury
- Physiological and biochemical changes that occur during injury and recovery
- Changes in body composition that accompany surgical injury
- Avoidable factors that compound the metabolic response to injury
- Concepts behind optimal perioperative care

BASIC CONCEPTS IN HOMEOSTASIS

In the eighteenth and nineteenth centuries, a series of eminent scientists laid the foundations of our understanding of homeostasis and the response to injury. The classical concepts of homeostasis and the response to injury are:

- 'The stability of the "milieu intérieur" is the primary condition for freedom and independence of existence' (Claude Bernard); i.e. body systems act to maintain internal constancy.
- 'Homeostasis: the coordinated physiological process which maintains most of the steady states of the organism' (Walter Cannon); i.e. complex homeostatic responses involving the brain, nerves, heart, lungs, kidneys and spleen work to maintain body constancy.
- 'There is a circumstance attending accidental injury which does not belong to the disease, namely that the injury done, has in all cases a tendency to produce both the deposition and means of cure' (John Hunter); i.e. responses to injury are, in general, beneficial to the host and allow healing/survival.

In essence, the concept evolved that the constancy of the 'milieu intérieur' allowed for the independence of organisms, that complex homeostatic responses sought to maintain this constancy, and that within this range of responses were the elements of healing and repair. These ideas pertained to normal physiology and mild/moderate injury. In the modern era, such concepts do not account for disease evolution following major injury/sepsis or the injured patient who would have died but for artificial organ support. Such patients exemplify less of the classical homeostatic control system (signal detector–processor–effector regulated by a negative feedback loop) and more of the 'open loop' system, whereby only with medical/surgical resolution of the primary abnormality is a return to classical homeostasis possible.

As a consequence of modern understanding of the metabolic response to injury, elective surgical practice seeks to reduce the need for a homeostatic response by minimising the primary insult (minimal access surgery and 'stress-free' perioperative care). In emergency surgery, where the presence of tissue trauma/sepsis/hypovolaemia often compounds the primary problem, there is a requirement to augment artificially homeostatic responses (resuscitation) and to close the 'open' loop by intervening to resolve the primary insult (e.g. surgical treatment of major abdominal sepsis) and provide organ support (critical care) while the patient comes back to a situation in which homeostasis can achieve a return to normality.

Summary box 1.1

Basic concepts

- Homeostasis is the foundation of normal physiology
- 'Stress-free' perioperative care helps to preserve homeostasis following elective surgery
- Resuscitation, surgical intervention and critical care can return the severely injured patient to a situation in which homeostasis becomes possible once again

Claude Bernard, 1813–1878, Professor of Physiology, The College de France, Paris, France.
Walter Bradford Cannon, 1871–1945, Professor of Physiology, Harvard University Medical School, Boston, MA, USA.
John Hunter, 1728–1793, surgeon, St George's Hospital, London, UK. He is regarded as 'The Father of Scientific Surgery'. To further his knowledge of venereal disease he inoculated himself with syphilis in 1767.

This chapter aims to review the mediators of the stress response, the physiological and biochemical pathway changes associated with surgical injury and the changes in body composition that occur following surgical injury. Emphasis is laid on why knowledge of these events is important to understand the rationale for modern 'stress-free' perioperative and critical care.

THE GRADED NATURE OF THE INJURY RESPONSE

It is important to recognise that the response to injury is graded: the more severe the injury, the greater the response (**Figure 1.1**). This concept not only applies to physiological/metabolic changes but also to immunological changes/sequelae. Thus, following elective surgery of intermediate severity, there may be a transient and modest rise in temperature, heart rate, respiratory rate, energy expenditure and peripheral white cell count. Following major trauma/sepsis, these changes are accentuated, resulting in a systemic inflammatory response syndrome (SIRS), hypermetabolism, marked catabolism, shock and even multiple organ dysfunction (MODS). It is important to recognise that genetic variability plays a key role in determining the intensity of the inflammatory response. Moreover, in certain circumstances, the severity of injury does not lead to a simple dose-dependent metabolic response, but rather leads to quantitatively different responses.

Not only is the metabolic response graded, but it also evolves with time. In particular, the immunological sequelae of major injury evolve from a proinflammatory state driven primarily by the innate immune system (macrophages, neutrophils, dendritic cells) into a compensatory anti-inflammatory response syndrome (CARS) characterised by suppressed immunity and diminished resistance to infection. In patients who develop infective complications, the latter will drive ongoing systemic inflammation, the acute phase response and continued catabolism.

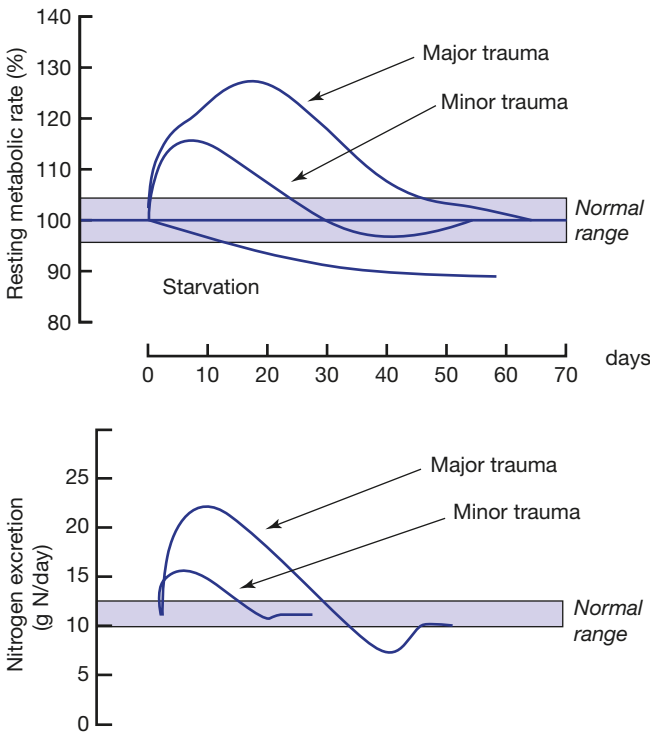

Figure 1.1 Hypermetabolism and increased nitrogen excretion are closely related to the magnitude of the initial injury and show a graded response.

MEDIATORS OF THE METABOLIC RESPONSE TO INJURY

The classical neuroendocrine pathways of the stress response consist of afferent nociceptive neurones, the spinal cord, thalamus, hypothalamus and pituitary (**Figure 1.2**). Corticotrophin-releasing factor (CRF) released from the hypothalamus increases adrenocorticotrophic hormone (ACTH) release from the anterior pituitary. ACTH then acts on the adrenals to increase the secretion of cortisol. Hypothalamic activation of the sympathetic nervous system causes release of adrenaline and also stimulates release of glucagon. Intravenous infusion of a cocktail of these 'counter-regulatory' hormones (glucagon, glucocorticoids and catecholamines) reproduces many aspects of the metabolic response to injury. There are, however, many other players, including alterations in insulin release and sensitivity, hypersecretion of prolactin and growth hormone (GH) in the presence of low circulatory insulin-like growth factor-1 (IGF-1) and inactivation of peripheral thyroid hormones and gonadal function. Of note, GH has direct lipolytic, insulin-antagonising and proinflammatory properties.

Summary box 1.2

Neuroendocrine response to injury/critical illness

The neuroendocrine response to severe injury/critical illness is biphasic:

- **Acute phase** characterised by an actively secreting pituitary and elevated counter-regulatory hormones (cortisol, glucagon, adrenaline). Changes are thought to be beneficial for short-term survival
- **Chronic phase** associated with hypothalamic suppression and low serum levels of the respective target organ hormones. Changes contribute to chronic wasting

The innate immune system (principally macrophages) interacts in a complex manner with the adaptive immune system (T cells, B cells) in co-generating the metabolic response to injury (**Figure 1.2**). Proinflammatory cytokines including interleukin-1 (IL-1), tumour necrosis factor alpha (TNFα), IL-6 and IL-8 are produced within the first 24 hours and act directly on the hypothalamus to cause pyrexia. Such cytokines also augment the hypothalamic stress response and act directly on skeletal muscle to induce proteolysis while inducing acute phase protein production in the liver. Pro-inflammatory cytokines also play a complex role in the development of peripheral insulin resistance. Other important proinflammatory mediators include nitric oxide ([NO]

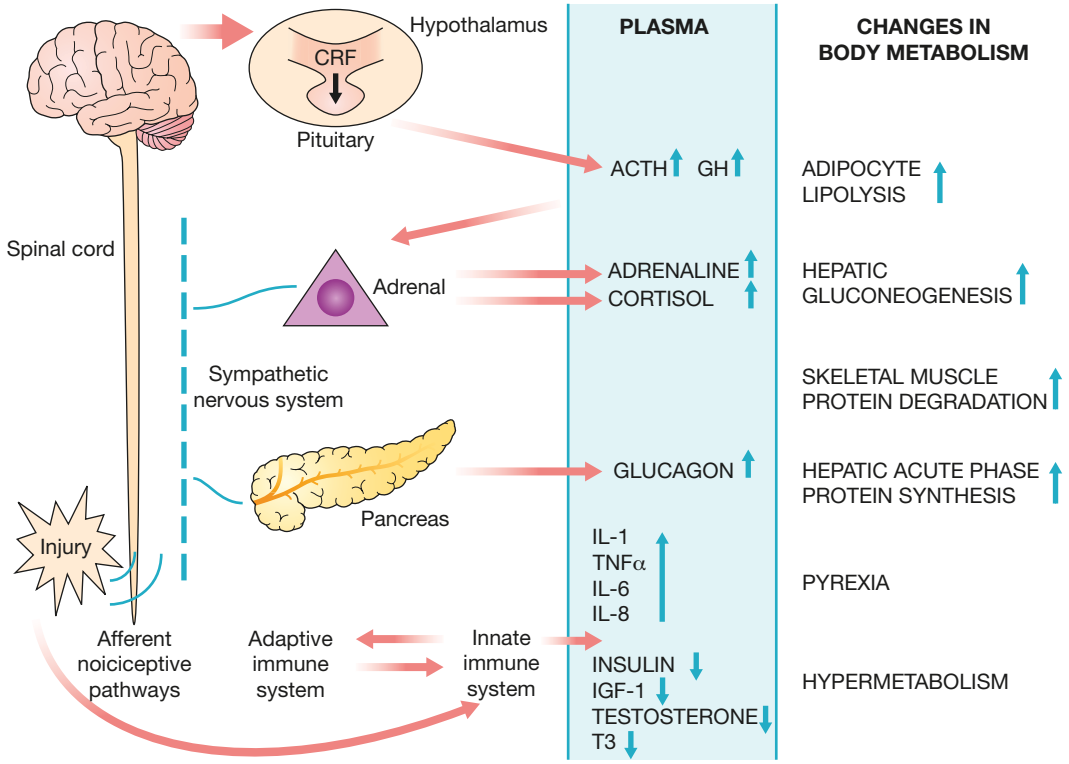

Figure 1.2 The integrated response to surgical injury (first 24–48 hours): there is a complex interplay between the neuroendocrine stress response and the proinflammatory cytokine response of the innate immune system.

via inducible nitric oxide synthetase [iNOS]) and a variety of prostanoids (via cyclooxygenase-2 [Cox-2]). Changes in organ function (e.g. renal hypoperfusion/impairment) may be induced by excessive vasoconstriction via endogenous factors such as endothelin-1.

Within hours of the upregulation of proinflammatory cytokines, endogenous cytokine antagonists enter the circulation (e.g. interleukin-1 receptor antagonist [IL-1Ra] and TNF-soluble receptors [TNF-sR-55 and 75]) and act to control the proinflammatory response. A complex further series of adaptive changes includes the development of a Th2-type counterinflammatory response (regulated by IL-4, -5, -9 and -13 and transforming growth factor beta [TGFβ]) which, if accentuated and prolonged in critical illness, is characterised as the CARS and results in immunosuppression and an increased susceptibility to opportunistic (nosocomial) infection. Within inflamed tissue the duration and magnitude of acute inflammation as well as the return to homeostasis are influenced by a group of local mediators known as specialised proresolving mediators (SPM) that include essential fatty acid-derived lipoxins, resolvins, protectins and maresins. These endogenous resolution agonists orchestrate the uptake and clearance of apoptotic polymorphonuclear neutrophils and microbial particles, reduce proinflammatory cytokines and lipid mediators as well as enhancing the removal of cellular debris in the inflammatory milieu. Thus, both at the systemic level (endogenous cytokine antagonists – see above) and at the local tissue level, the body attempts to limit/resolve inflammation driven dyshomeostasis.

Summary box 1.3

Systemic inflammatory response syndrome following major injury

- Is driven initially by proinflammatory cytokines (e.g. IL-1, IL-6 and TNFα)
- Is followed rapidly by increased plasma levels of cytokine antagonists and soluble receptors (e.g. IL-1Ra, TNF-sR)
- If prolonged or excessive may evolve into a counterinflammatory response syndrome

There are many complex interactions among the neuroendocrine, cytokine and metabolic axes. For example, although cortisol is immunosuppressive at high levels, it acts synergistically with IL-6 to promote the hepatic acute phase response. ACTH release is enhanced by proinflammatory cytokines and the noradrenergic system. The resulting rise in cortisol levels may form a weak feedback loop attempting to limit the proinflammatory stress response. Finally, hyperglycaemia may aggravate the inflammatory response via substrate overflow in the mitochondria, causing the formation of excess oxygen free radicals and also altering gene expression to enhance cytokine production.

At the molecular level, the changes that accompany systemic inflammation are extremely complex. In a recent study using network-based analysis of changes in mRNA expression in leukocytes following exposure to endotoxin, there were changes in the expression of more than 3700 genes

with over half showing decreased expression and the remainder increased expression. The cell surface receptors, signalling mechanisms and transcription factors that initiate these events are also complex, but an early and important player involves the nuclear factor kappa B (NFκB)/*relA* family of transcription factors. A simplified model of current understanding of events within skeletal muscle is shown in **Figure 1.3**.

THE METABOLIC STRESS RESPONSE TO SURGERY AND TRAUMA: THE 'EBB AND FLOW' MODEL

In the natural world, if an animal is injured, it displays a characteristic response, which includes immobility, anorexia and catabolism.

Summary box 1.4

Physiological response to injury

The natural response to injury includes:

- Immobility/rest
- Anorexia
- Catabolism

The changes are designed to aid survival of moderate injury in the absence of medical intervention.

In 1930, Sir David Cuthbertson divided the metabolic response to injury in humans into 'ebb' and 'flow' phases (**Figure 1.4**). The ebb phase begins at the time of injury and lasts for approximately 24–48 hours. It may be attenuated by proper resuscitation, but not completely abolished. The ebb phase is characterised by hypovolaemia, decreased

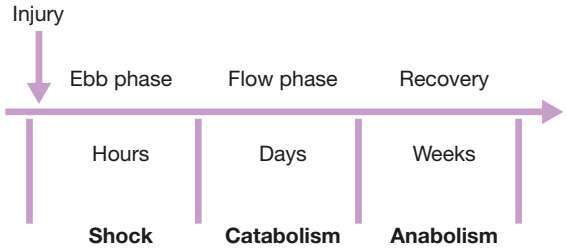

Figure 1.4 Phases of the physiological response to injury (after Cuthbertson 1930).

basal metabolic rate, reduced cardiac output, hypothermia and lactic acidosis. The predominant hormones regulating the ebb phase are catecholamines, cortisol and aldosterone (following activation of the renin–angiotensin system). The magnitude of this neuroendocrine response depends on the degree of blood loss and the stimulation of somatic afferent nerves at the site of injury. The main physiological role of the ebb phase is to conserve both circulating volume and energy stores for recovery and repair.

Following resuscitation, the ebb phase evolves into a hypermetabolic flow phase, which corresponds to SIRS. This phase involves the mobilisation of body energy stores for recovery and repair, and the subsequent replacement of lost or damaged tissue. It is characterised by tissue oedema (from vasodilatation and increased capillary leakage), increased basal metabolic rate (hypermetabolism), increased cardiac output, raised body temperature, leukocytosis, increased oxygen consumption and increased gluconeogenesis. The flow phase may be subdivided into an initial catabolic phase, lasting approximately 3–10 days, followed by an anabolic phase, which may last for weeks if extensive recovery and repair are required following serious injury. During the catabolic phase, the increased production of counter-regulatory hormones (including catecholamines, cortisol, insulin and glucagon) and inflammatory cytokines

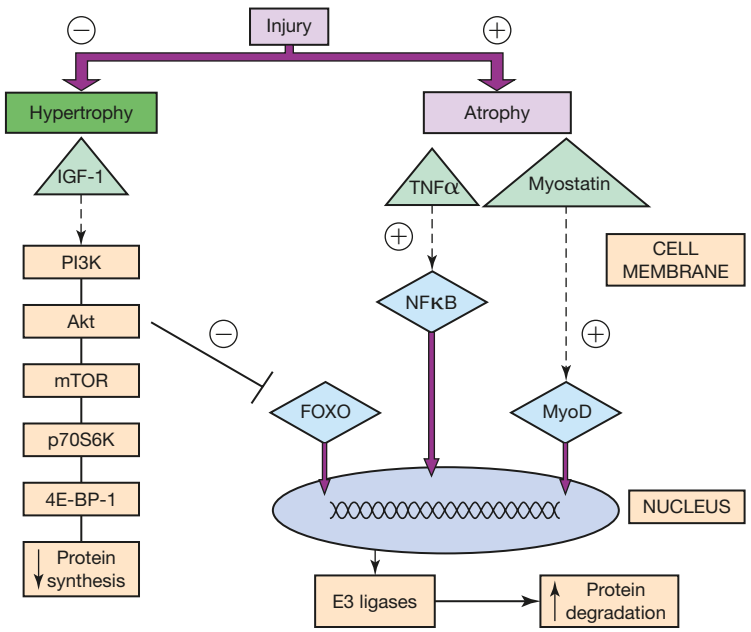

Figure 1.3 The major catabolic and anabolic signalling pathways involved in skeletal muscle homeostasis. FOXO, forkhead box sub-group O; mTOR, mammalian target of rapamycin; MyoD, myogenic differentiation factor D; NFκB, nuclear factor kappa B; PI3K, phosphatidylinositol 3-kinase; p70S6K, p70S6 kinase; TNFα, tumour necrosis factor alpha; 4E-BP-1, eukaryotic initiation translation factor 4E binding protein 1.

Sir David Paton Cuthbertson, 1900–1989, biochemist, Director of the Rowett Research Institute, Glasgow, UK.

(e.g. IL-1, IL-6 and TNFα) results in significant fat and protein mobilisation, leading to significant weight loss and increased urinary nitrogen excretion. The increased production of insulin at this time is associated with significant insulin resistance and, therefore, injured patients often exhibit poor glycaemic control. The combination of pronounced or prolonged catabolism in association with insulin resistance places patients within this phase at increased risk of complications. Obviously, the development of complications will further aggravate the neuroendocrine and inflammatory stress responses, thus creating a vicious catabolic cycle.

Summary box 1.5

Purpose of neuroendocrine changes following injury

The constellation of neuroendocrine changes following injury acts to:

- Provide essential substrates for survival
- Postpone anabolism
- Optimise host defence

These changes may be helpful in the short term, but may be harmful in the long term, especially to the severely injured patient who would otherwise not have survived without medical intervention.

KEY CATABOLIC ELEMENTS OF THE FLOW PHASE OF THE METABOLIC STRESS RESPONSE

There are several key elements of the flow phase that largely determine the extent of catabolism and thus govern the metabolic and nutritional care of the surgical patient. It must be remembered that, during the response to injury, not all tissues are catabolic. Indeed, the essence of this coordinated response is to allow the body to reprioritise limited resources away from peripheral tissues (muscle, adipose tissue, skin) and towards key viscera (liver, immune system) and the wound (**Figure 1.5**).

Hypermetabolism

The majority of trauma patients (except possibly those with extensive burns) demonstrate energy expenditures approximately 15–25% above predicted healthy resting values. The predominant cause appears to be a complex interaction between the central control of metabolic rate and peripheral energy utilisation. In particular, central thermodysregulation (caused by the proinflammatory cytokine cascade), increased sympathetic activity, abnormalities in wound circulation (ischaemic areas produce lactate, which must be metabolised by the adenosine triphosphate [ATP]-consuming hepatic Cori cycle; hyperaemic areas cause an increase in cardiac output), increased protein turnover and nutritional support may all increase patient energy expenditure. Theoretically, patient energy expenditure could rise even higher than observed levels following surgery or trauma, but several features of standard intensive care (including bed rest, paralysis, ventilation and external temperature regulation) counteract the hypermetabolic driving forces of the stress response. Furthermore, the skeletal muscle wasting experienced by patients with prolonged catabolism actually limits the volume of metabolically active tissue (see below).

Summary box 1.6

Hypermetabolism

Hypermetabolism following injury:

- Is mainly caused by an acceleration of energy-dependent metabolic cycles
- Is limited in modern practice on account of elements of routine critical care

Alterations in skeletal muscle protein metabolism

Muscle protein is continually synthesised and broken down with a turnover rate in humans of 1–2% per day, and with a greater amplitude of changes in protein synthesis (± twofold) than breakdown (± 0.25-fold) during the diurnal cycle. Under normal circumstances, synthesis equals breakdown and muscle bulk remains constant. Physiological stimuli that promote net muscle protein accretion include feeding (especially extracellular amino acid concentration) and exercise. Paradoxically, during exercise, skeletal muscle

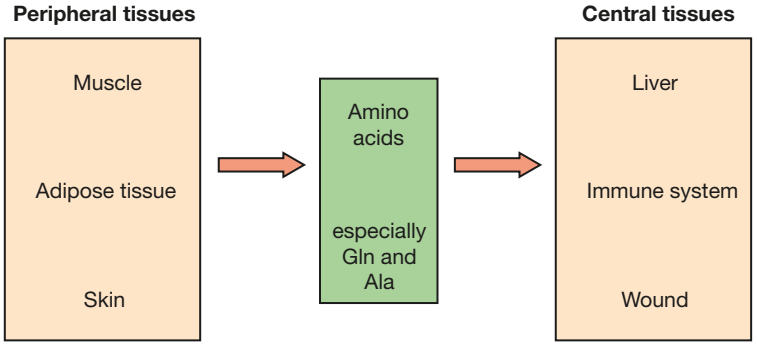

Figure 1.5 During the metabolic response to injury, the body reprioritises protein metabolism away from peripheral tissues and towards key central tissues such as the liver, immune system and wounds. One of the main reasons why the reutilisation of amino acids derived from muscle proteolysis leads to net catabolism is that the increased glutamine and alanine efflux from muscle is derived, in part, from the irreversible degradation of branched chain amino acids. Ala, alanine; Gln, glutamine.

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology, and later of Biochemistry, Washington University Medical School, St Louis, MI, USA and his wife **Gerty Theresa Cori**, 1896–1957, who was also Professor of Biochemistry at the Washington University Medical School. In 1947 the Coris were awarded a share of the Nobel Prize for Physiology or Medicine 'for their discovery of how glycogen is catalytically converted'.

protein synthesis is depressed, but it increases again during rest and feeding.

During the catabolic phase of the stress response, muscle wasting occurs as a result of an increase in muscle protein degradation (via enzymatic pathways), coupled with a decrease in muscle protein synthesis. The major site of protein loss is peripheral skeletal muscle, although nitrogen losses also occur in the respiratory muscles (predisposing the patient to hypoventilation and chest infections) and in the gut (reducing gut motility). Cardiac muscle appears to be mostly spared. Under extreme conditions of catabolism (e.g. major sepsis), urinary nitrogen losses can reach 14–20 g/day; this is equivalent to the loss of 500 g of skeletal muscle per day. It is remarkable that muscle catabolism cannot be inhibited fully by providing artificial nutritional support as long as the stress response continues. Indeed, in critical care, it is now recognised that 'hyperalimentation' represents a metabolic stress in itself, and that nutritional support should be at a modest level to attenuate rather than replace energy and protein losses.

The predominant mechanism involved in the wasting of skeletal muscle is the ATP-dependent ubiquitin–proteasome pathway (**Figure 1.6**), although the lysosomal cathepsins and the calcium–calpain pathway play facilitatory and accessory roles.

Clinically, a patient with skeletal muscle wasting will experience asthenia, increased fatigue, reduced functional ability, decreased quality of life and an increased risk of morbidity and mortality. In critically ill patients, muscle weakness may be further worsened by the development of critical illness myopathy, a multifactorial condition that is associated with impaired excitation–contraction coupling at the level of the sarcolemma and the sarcoplasmic reticulum membrane.

Summary box 1.7

Skeletal muscle wasting

- Provides amino acids for the metabolic support of central organs/tissues
- Is mediated at a molecular level mainly by activation of the ubiquitin–proteasome pathway
- Can result in immobility and contribute to hypostatic pneumonia and death if prolonged and excessive

Alterations in hepatic protein metabolism: the acute phase protein response

The liver and skeletal muscle together account for >50% of daily body protein turnover. Skeletal muscle has a large mass but a low turnover rate (1–2% per day), whereas the liver has a relatively small mass (1.5 kg) but a much higher protein turnover rate (10–20% per day). Hepatic protein synthesis is divided roughly 50:50 between renewal of structural proteins and synthesis of export proteins. Albumin is the major export protein produced by the liver and is renewed at the rate of about 10% per day. The transcapillary escape rate (TER) of albumin is about ten times the rate of synthesis, and short-term changes in albumin concentration are most probably due to increased vascular permeability. Albumin TER may be increased three-fold following major injury/sepsis.

In response to inflammatory conditions, including surgery, trauma, sepsis, cancer or autoimmune conditions, circulating peripheral blood mononuclear cells secrete a range of proinflammatory cytokines, including IL-1, IL-6 and TNFα.

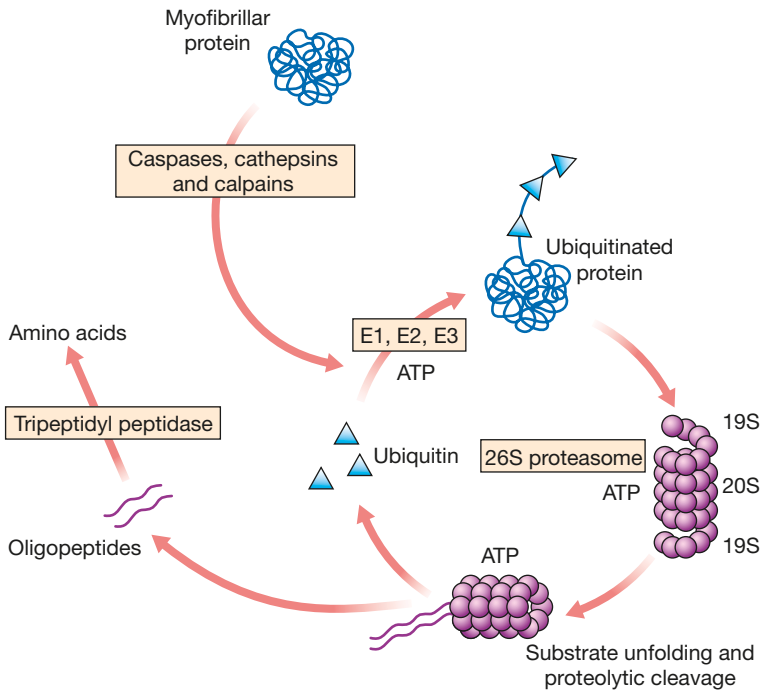

Figure 1.6 The intercellular effector mechanisms involved in degrading myofibrillar protein into free amino acids. The ubiquitin–proteasome pathway is a complex multistep process, which requires adenosine triphosphate and results in the tagging of specific proteins with ubiquitin for degradation of proteasome. E1, ubiquitin-activating enzyme; E2, ubiquitin-conjugating enzyme; E3, ubiquitin ligase.

These cytokines, in particular IL-6, promote the hepatic synthesis of positive acute phase proteins, e.g. fibrinogen and C-reactive protein (CRP). The acute phase protein response (APPR) represents a 'double-edged sword' for surgical patients as it provides proteins important for recovery and repair, but only at the expense of valuable lean tissue and energy reserves.

In contrast to the positive acute phase reactants, the plasma concentrations of other liver export proteins (the negative acute phase reactants) fall acutely following injury, e.g. albumin. However, rather than representing a reduced hepatic synthesis rate, the fall in plasma concentration of negative acute phase reactants is thought principally to reflect increased transcapillary escape, secondary to an increase in microvascular permeability (see above). Thus, increased hepatic synthesis of positive acute phase reactants is not compensated for by reduced synthesis of negative reactants.

Summary box 1.8

Hepatic acute phase response

The hepatic acute phase response represents a reprioritisation of body protein metabolism towards the liver and is characterised by:

- **Positive** reactants (e.g. CRP): plasma concentration ↑
- **Negative** reactants (e.g. albumin): plasma concentration ↓

Insulin resistance

Following surgery or trauma, postoperative hyperglycaemia develops as a result of increased glucose production combined with decreased glucose uptake in peripheral tissues. Decreased glucose uptake is a result of insulin resistance which is transiently induced within the stressed patient. Suggested mechanisms for this phenomenon include the action of proinflammatory cytokines and the decreased responsiveness of insulin-regulated glucose transporter proteins. The degree of insulin resistance is proportional to the magnitude of the injurious process. Following routine upper abdominal surgery, insulin resistance may persist for approximately 2 weeks.

Postoperative patients with insulin resistance behave in a similar manner to individuals with type II diabetes mellitus. The mainstay of management of insulin resistance is intravenous insulin infusion. Insulin infusions may be used in either an intensive approach (i.e. sliding scales are manipulated to normalise the blood glucose level) or a conservative approach (i.e. insulin is administered when the blood glucose level exceeds a defined limit and discontinued when the level falls). While some studies of postoperatively ventilated patients in the intensive care unit (ICU) have suggested that maintenance of normal glucose levels using intensive insulin therapy can significantly reduce both morbidity and mortality, others have not. The risks of adverse events following significant hypoglycaemia as a consequence of intensive insulin therapy have led most ICUs to adopt a more conventional approach to glycaemic control. It should be noted that diabetic patients whose glycaemic control has been poor prior to their critical illness pose a particular challenge.

CHANGES IN BODY COMPOSITION FOLLOWING INJURY

The average 70-kg male can be considered to consist of fat (13 kg) and fat-free mass (or lean body mass: 57 kg). In such an individual, the lean tissue is composed primarily of protein (12 kg), water (42 kg) and minerals (3 kg) (**Figure 1.7**). The protein mass can be considered as two basic compartments, skeletal muscle (4 kg) and non-skeletal muscle (8 kg), which includes the visceral protein mass. The water mass (42 litres) is divided into intracellular (28 litres) and extracellular (14 litres) spaces. Most of the mineral mass is contained in the bony skeleton.

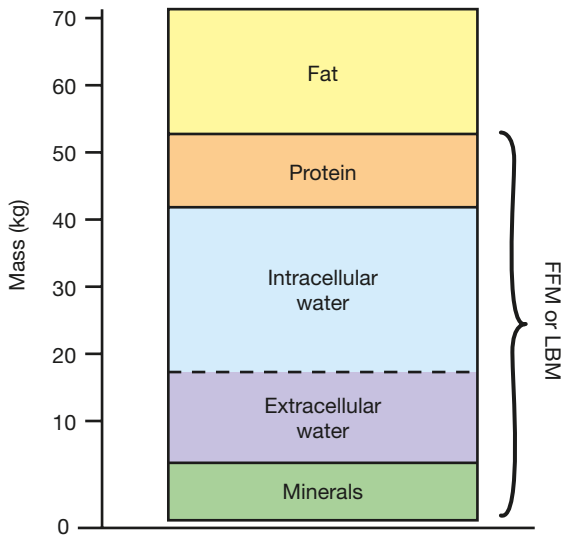

Figure 1.7 The chemical body composition of a normal 70-kg male. FFM, fat-free mass; LBM, lean body mass.

The main labile energy reserve in the body is fat, and the main labile protein reserve is skeletal muscle. While fat mass can be reduced without major detriment to function, loss of protein mass results not only in skeletal muscle wasting, but also in depletion of visceral protein status. Within lean issue, each 1 g of nitrogen is contained within 6.25 g of protein, which is contained in approximately 36 g of wet weight tissue. Thus, the loss of 1 g of nitrogen in urine is equivalent to the breakdown of 36 g of wet weight lean tissue. Protein turnover in the whole body is of the order of 150–200 g per day. A normal human ingests about 70–100 g protein per day, which is metabolised and excreted in urine as ammonia and urea (i.e. approximately 14 g N/day). During total starvation, urinary loss of nitrogen is rapidly attenuated by a series of adaptive changes. Loss of body weight follows a similar course (**Figure 1.8**), thus accounting for the survival of hunger strikers for a period of 50–60 days. Following major injury, and particularly in the presence of ongoing septic complications, this adaptive change fails to occur, and there is a state of 'autocannibalism', resulting in continuing urinary nitrogen losses of 10–20 g N/day (equivalent to 500 g of wet weight lean tissue

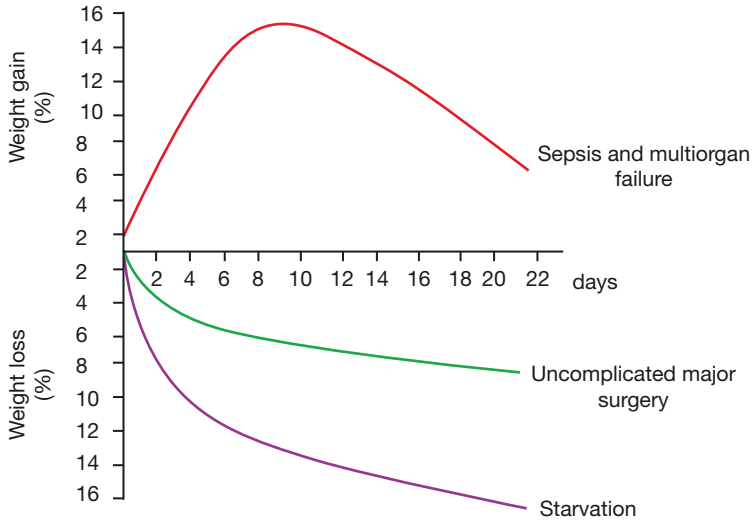

Figure 1.8 Changes in body weight that occur in serious sepsis, after uncomplicated surgery and in total starvation.

per day). As with total starvation, once loss of body protein mass has reached 30–40% of the total, survival is unlikely.

Critically ill patients admitted to the ICU with severe sepsis or major blunt trauma undergo massive changes in body composition (**Figure 1.8**). Body weight increases immediately on resuscitation with an expansion of extracellular water by 6–10 litres within 24 hours. Thereafter, even with optimal metabolic care and nutritional support, total body protein will diminish by 15% in the next 10 days, and body weight will reach negative balance as the expansion of the extracellular space resolves. In marked contrast, it is now possible to maintain body weight and nitrogen equilibrium following major elective surgery. This can be achieved by blocking the neuroendocrine stress response with epidural analgesia/other related techniques and providing early oral/enteral feeding. Moreover, the early fluid retention phase can be avoided by careful intraoperative management of fluid balance, with avoidance of excessive administration of intravenous saline.

Summary box 1.9

Changes in body composition following major surgery/critical illness

- Catabolism leads to a **decrease** in fat mass and skeletal muscle mass
- Body weight may paradoxically **increase** because of expansion of extracellular fluid space

AVOIDABLE FACTORS THAT COMPOUND THE RESPONSE TO INJURY

As noted previously, the main features of the metabolic response are initiated by the immune system, cardiovascular system, sympathetic nervous system, ascending reticular formation and limbic system. However, the metabolic stress response may be further exacerbated by anaesthesia, dehydration, starvation (including preoperative fasting), sepsis, acute medical illness or even severe psychological stress (**Figure 1.9**). Attempts to limit or control these factors can be beneficial to the patient.

Summary box 1.10

Avoidable factors that compound the response to injury

- Continuing haemorrhage
- Hypothermia
- Tissue oedema
- Tissue underperfusion
- Starvation
- Immobility

Volume loss

During simple haemorrhage, pressor receptors in the carotid artery and aortic arch, and volume receptors in the wall of the left atrium, initiate afferent nerve input to the central nervous system (CNS), resulting in the release of both aldosterone and antidiuretic hormone (ADH). Pain can also stimulate ADH release. ADH acts directly on the kidney to cause fluid retention. Decreased pulse pressure stimulates the juxtaglomerular apparatus in the kidney and directly activates the renin–angiotensin system, which in turn increases aldosterone release.

Aldosterone causes the renal tubule to reabsorb sodium (and consequently also conserve water). ACTH release also augments the aldosterone response. The net effects of ADH and aldosterone result in the natural oliguria observed after surgery and conservation of sodium and water in the extracellular space. The tendency towards water and salt retention is exacerbated by resuscitation with saline-rich fluids. Salt and water retention can result in not only peripheral oedema, but also visceral oedema (e.g. in the stomach). Such visceral oedema has been associated with reduced gastric emptying, delayed resumption of food intake and prolonged hospital

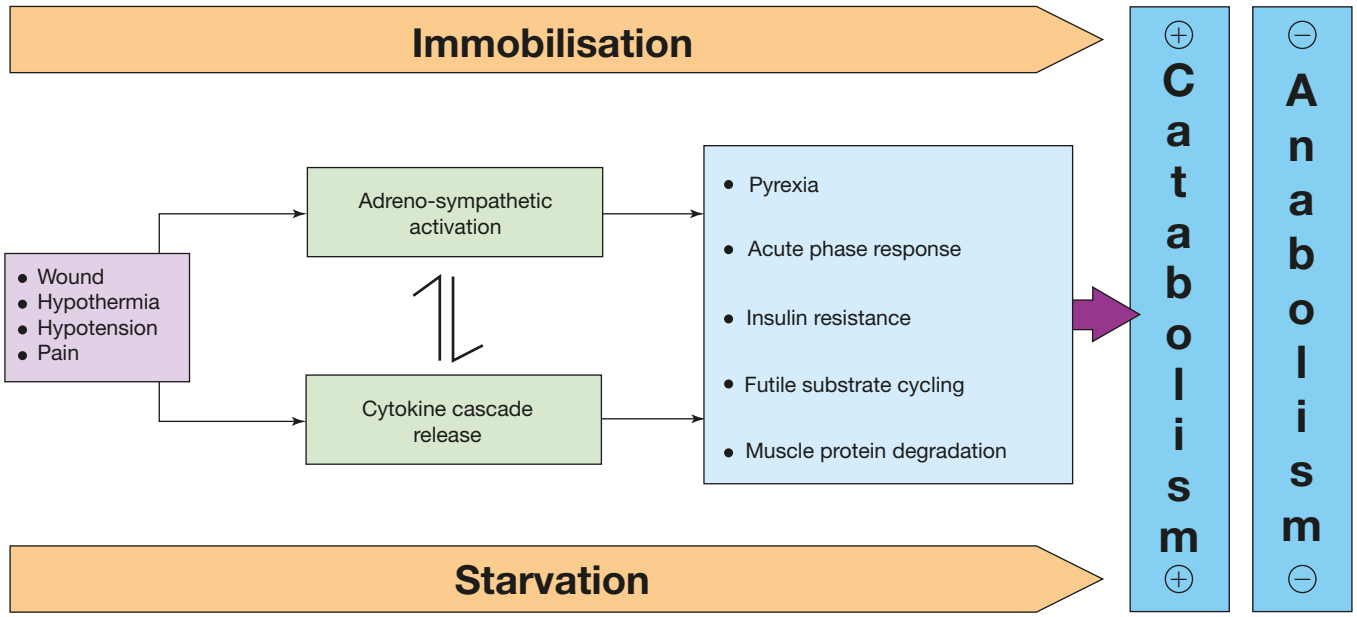

Figure 1.9 Factors that exacerbate the metabolic response to surgical injury include hypothermia, uncontrolled pain, starvation, immobilisation, sepsis and medical complications.

stay. Careful limitation of intraoperative administration of balanced crystalloids so that there is no net weight gain following elective surgery has been proven to reduce postoperative complications and length of stay.

Hypothermia

Hypothermia results in increased elaboration of adrenal steroids and catecholamines. When compared with normothermic controls, even mild hypothermia results in a two- to three-fold increase in postoperative cardiac arrhythmias and increased catabolism. Randomised trials have shown that maintaining normothermia by an upper body forced-air heating cover reduces wound infections, cardiac complications and bleeding and transfusion requirements.

Tissue oedema

During systemic inflammation, fluid, plasma proteins, leukocytes, macrophages and electrolytes leave the vascular space and accumulate in the tissues. This can diminish the alveolar diffusion of oxygen and may lead to reduced renal function. Increased capillary leak is mediated by a wide variety of mediators including cytokines, prostanoids, bradykinin and nitric oxide. Vasodilatation implies that intravascular volume decreases, which induces shock if inadequate resuscitation is not undertaken. Meanwhile, intracellular volume decreases, and this provides part of the volume necessary to replenish intravascular and extravascular extracellular volume.

Systemic inflammation and tissue underperfusion

The vascular endothelium controls vasomotor tone and microvascular flow, and regulates trafficking of nutrients and biologically active molecules. When endothelial activation is excessive, compromised microcirculation and subsequent cellular hypoxia contribute to the risk of organ failure. Maintaining normoglycaemia with insulin infusion during critical illness has been proposed to protect the endothelium, probably, in part, via inhibition of excessive iNOS-induced NO release.

Starvation

During starvation, the body is faced with an obligate need to generate glucose to sustain cerebral energy metabolism (100 g of glucose per day). This is achieved in the first 24 hours by mobilising glycogen stores and thereafter by hepatic gluconeogenesis from amino acids, glycerol and lactate. The energy metabolism of other tissues is sustained by mobilising fat from adipose tissue. Such fat mobilisation is mainly dependent on a fall in circulating insulin levels. Eventually, accelerated loss of lean tissue (the main source of amino acids for hepatic gluconeogenesis) is reduced as a result of the liver converting free fatty acids into ketone bodies, which can serve as a substitute for glucose for cerebral energy metabolism. Provision of 2 litres of intravenous 4% dextrose/0.18% sodium chloride as maintenance intravenous fluids for surgical patients who are fasted provides 80 g of glucose per day and has a significant protein-sparing effect. Avoiding unnecessary fasting in the first instance and early oral/enteral/parenteral nutrition form the platform for avoiding loss of body mass as a result of the varying degrees of starvation observed in surgical patients. Modern guidelines on fasting prior to anaesthesia allow intake of clear fluids up to 2 hours before surgery. Administration of a carbohydrate drink at this time reduces perioperative anxiety and thirst and decreases postoperative insulin resistance.

Immobility

Immobility has long been recognised as a potent stimulus for inducing muscle wasting. Inactivity impairs the normal meal-derived amino acid stimulation of protein synthesis in skeletal muscle. Avoidance of unnecessary bed rest and active early mobilisation are essential measures to avoid muscle wasting as a consequence of immobility.

CONCEPTS BEHIND ENHANCED RECOVERY AFTER SURGERY

Current understanding of the metabolic response to surgical injury and the mediators involved has led to a reappraisal of traditional perioperative care. There is now a strong scientific rationale for avoiding unmodulated exposure to stress, prolonged fasting and excessive administration of intravenous (saline) fluids (**Figure 1.10**). The widespread adoption of minimal access (laparoscopic) surgery is a key change in surgical practice that can reduce the magnitude of surgical injury and enhance the rate of patients' return to homeostasis and recovery. It is also important to realise that modulating the stress/inflammatory response at the time of surgery may have long-term sequelae over periods of months or longer. For example, β-blockers and statins have been shown to improve long-term survival after major surgery. It has been suggested that these effects may be due to suppression of innate immunity at the time of surgery. Equally, in 'open' surgery the use of epidural analgesia to reduce pain, block the cortisol stress response and attenuate postoperative insulin resistance may, via effects on the body's protein economy, favourably affect many of the patient-centred outcomes that are important to postoperative recovery. Due to the reduction in wound size and tissue trauma, it should be noted that epidural analgesia is no longer recommended for laparoscopic surgery. Patient controlled analgesia is usually sufficient. Adjuncts such as 'one shot' spinal diamorphine and/or a 6–12-hour infusion of intravenous lidocaine have been suggested to be opiate sparing, to improve gut function and enhance overall recovery.

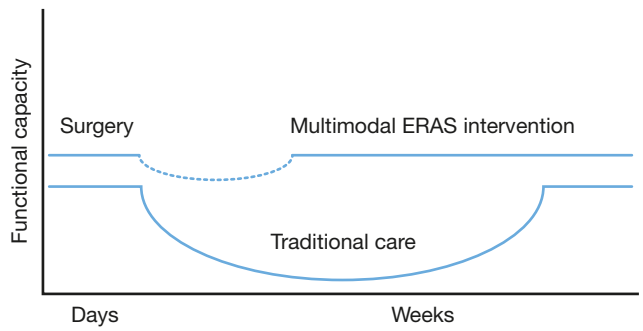

Figure 1.10 Enhanced recovery after surgery (ERAS) programmes can be modulated by multimodal enhanced recovery programmes (optimal nutritional and metabolic care to minimise the stress response).

Summary box 1.11

A proactive approach to prevent unnecessary aspects of the surgical stress response

- Minimal access techniques
- Blockade of afferent painful stimuli (e.g. epidural analgesia, spinal analgesia, wound catheters)
- Minimal periods of starvation
- Early mobilisation

Chapter 2

Shock and blood transfusion

Learning objectives

To understand:

- The pathophysiology of shock and ischaemia–reperfusion injury
- The different patterns of shock and the principles and priorities of resuscitation
- Appropriate monitoring and end points of resuscitation
- Use of blood and blood products, the benefits and risks of blood transfusion

INTRODUCTION

Shock is the most common and therefore the most important cause of death of surgical patients. Death may occur rapidly due to a profound state of shock, or be delayed due to the consequences of organ ischaemia and reperfusion injury. It is important therefore that every surgeon understands the pathophysiology, diagnosis and priorities in management of shock and haemorrhage.

SHOCK

Shock is a systemic state of low tissue perfusion that is inadequate for normal cellular respiration. With insufficient delivery of oxygen and glucose, cells switch from aerobic to anaerobic metabolism. If perfusion is not restored in a timely fashion, cell death ensues.

Pathophysiology

Cellular

As perfusion to the tissues is reduced, cells are deprived of oxygen and must switch from aerobic to anaerobic metabolism. The product of anaerobic respiration is not carbon dioxide but lactic acid. When enough tissue is underperfused, the accumulation of lactic acid in the blood produces a systemic metabolic acidosis.

As glucose within cells is exhausted, anaerobic respiration ceases and there is failure of sodium/potassium pumps in the cell membrane and intracellular organelles. Intracellular lysosomes release autodigestive enzymes and cell lysis ensues. Intracellular contents, including potassium, are released into the blood stream.

Microvascular

As tissue ischaemia progresses, changes in the local milieu result in activation of the immune and coagulation systems. Hypoxia and acidosis activate complement and prime neutrophils, resulting in the generation of oxygen free radicals and cytokine release. These mechanisms lead to injury of the capillary endothelial cells. These, in turn, further activate the immune and coagulation systems. Damaged endothelium loses its integrity and becomes 'leaky'. Spaces between endothelial cells allow fluid to leak out and tissue oedema ensues, exacerbating cellular hypoxia.

Systemic

CARDIOVASCULAR

As preload and afterload decrease, there is a compensatory baroreceptor response resulting in increased sympathetic activity and release of catecholamines into the circulation. This results in tachycardia and systemic vasoconstriction (except in sepsis – see below).

RESPIRATORY

The metabolic acidosis and increased sympathetic response result in an increased respiratory rate and minute ventilation to increase the excretion of carbon dioxide (and so produce a compensatory respiratory alkalosis).

RENAL

Decreased perfusion pressure in the kidney leads to reduced filtration at the glomerulus and a decreased urine output. The renin–angiotensin–aldosterone axis is stimulated, resulting in further vasoconstriction and increased sodium and water reabsorption by the kidney.

ENDOCRINE

As well as activation of the adrenal and renin–angiotensin systems, vasopressin (antidiuretic hormone) is released from the hypothalamus in response to decreased preload and results in vasoconstriction and resorption of water in the renal collecting system. Cortisol is also released from the adrenal cortex, contributing to the sodium and water resorption and sensitising cells to catecholamines.

Ischaemia–reperfusion syndrome

During the period of systemic hypoperfusion, cellular and organ damage progresses due to the direct effects of tissue hypoxia and local activation of inflammation. Further injury occurs once normal circulation is restored to these tissues. The acid and potassium load that has built up can lead to direct myocardial depression, vascular dilatation and further hypotension. The cellular and humoral elements activated by the hypoxia (complement, neutrophils, microvascular thrombi) are flushed back into the circulation where they cause further endothelial injury to organs such as the lungs and the kidneys. This leads to acute lung injury, acute renal injury, multiple organ failure and death. Reperfusion injury can currently only be attenuated by reducing the extent and duration of tissue hypoperfusion.

Classification of shock

There are numerous ways to classify shock, but the most common and most clinically applicable is one based on the initiating mechanism.

All states are characterised by systemic tissue hypoperfusion, and different states may coexist within the same patient.

Summary box 2.1

Classification of shock

- Hypovolaemic shock
- Cardiogenic shock
- Obstructive shock
- Distributive shock
- Endocrine shock

Hypovolaemic shock

Hypovolaemic shock is due to a reduced circulating volume. Hypovolaemia may be due to haemorrhagic or non-haemorrhagic causes. Non-haemorrhagic causes include poor fluid intake (dehydration), excessive fluid loss due to vomiting, diarrhoea, urinary loss (e.g. diabetes), evaporation, or 'third-spacing' where fluid is lost into the gastrointestinal tract and interstitial spaces, as for example in bowel obstruction or pancreatitis.

Hypovolaemia is probably the most common form of shock, and to some degree is a component of all other forms of shock. Absolute or relative hypovolaemia must be excluded or treated in the management of the shocked state, regardless of cause.

Cardiogenic shock

Cardiogenic shock is due to primary failure of the heart to pump blood to the tissues. Causes of cardiogenic shock include myocardial infarction, cardiac dysrhythmias, valvular heart disease, blunt myocardial injury and cardiomyopathy. Cardiac insufficiency may also be due to myocardial depression caused by endogenous factors (e.g. bacterial and humoral agents released in sepsis) or exogenous factors, such as pharmaceutical agents or drug abuse. Evidence of venous hypertension with pulmonary or systemic oedema may coexist with the classical signs of shock.

Obstructive shock

In obstructive shock there is a reduction in preload due to mechanical obstruction of cardiac filling. Common causes of obstructive shock include cardiac tamponade, tension pneumothorax, massive pulmonary embolus or air embolus. In each case, there is reduced filling of the left and/or right sides of the heart leading to reduced preload and a fall in cardiac output.

Distributive shock

Distributive shock describes the pattern of cardiovascular responses characterising a variety of conditions, including septic shock, anaphylaxis and spinal cord injury. Inadequate organ perfusion is accompanied by vascular dilatation with hypotension, low systemic vascular resistance, inadequate afterload and a resulting abnormally high cardiac output.

In anaphylaxis, vasodilatation is due to histamine release, while in high spinal cord injury there is failure of sympathetic outflow and adequate vascular tone (neurogenic shock). The cause in sepsis is less clear but is related to the release of bacterial products (endotoxin) and the activation of cellular and humoral components of the immune system. There is maldistribution of blood flow at a microvascular level with arteriovenous shunting and dysfunction of cellular utilization of oxygen.

In the later phases of septic shock there is hypovolaemia from fluid loss into interstitial spaces and there may be concomitant myocardial depression, complicating the clinical picture (*Table 2.1*).

Endocrine shock

Endocrine shock may present as a combination of hypovolaemic, cardiogenic or distributive shock. Causes of endocrine shock include hypo- and hyperthyroidism and adrenal insufficiency. Hypothyroidism causes a shock state similar to that of neurogenic shock due to disordered vascular and cardiac responsiveness to circulating catecholamines. Cardiac output falls due to low inotropy and bradycardia. There may also be an associated cardiomyopathy. Thyrotoxicosis may cause a high-output cardiac failure.

Adrenal insufficiency leads to shock due to hypovolaemia and a poor response to circulating and exogenous catecholamines. Adrenal insufficiency may be due to pre-existing Addison's disease or be a relative insufficiency due to a pathological disease state, such as systemic sepsis.

Thomas Addison, 1799–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1849.

TABLE 2.1 Cardiovascular and metabolic characteristics of shock.

	Hypovolaemia	Cardiogenic	Obstructive	Distributive
Cardiac output Vascular resistance	Low High	Low High	Low High	High Low
Venous pressure	Low	High	High	Low
Mixed venous saturation Base deficit	Low High	Low High	Low High	High High

Severity of shock

Compensated shock

As shock progresses, the body's cardiovascular and endocrine compensatory responses reduce flow to non-essential organs to preserve preload and flow to the lungs and brain. In compensated shock, there is adequate compensation to maintain central blood volume and preserve flow to the kidneys, lungs and brain. Apart from a tachycardia and cool peripheries (vasoconstriction, circulating catecholamines), there may be no other clinical signs of hypovolaemia.

However, this cardiovascular state is only maintained by reducing perfusion to the skin, muscle and gastrointestinal tract. There is a systemic metabolic acidosis and activation of humoral and cellular elements within the underperfused organs. Although clinically occult, this state will lead to multiple organ failure and death if prolonged, due to the ischaemia–reperfusion effect described above under **Ischaemia–reperfusion syndrome**. Patients with occult hypoperfusion (metabolic acidosis despite normal urine output and cardiorespiratory vital signs) for more than 12 hours have a significantly higher mortality, infection rate and incidence of multiple organ failure (see below, **Multiple organ failure**).

Decompensation

Further loss of circulating volume overloads the body's compensatory mechanisms and there is progressive renal, respiratory and cardiovascular decompensation. In general, loss of around 15% of the circulating blood volume is within normal compensatory mechanisms. Blood pressure is usually well maintained and only falls after 30–40% of circulating volume has been lost.

Mild shock

Initially there is tachycardia, tachypnoea, a mild reduction in urine output and the patient may exhibit mild anxiety. Blood pressure is maintained although there is a decrease in pulse pressure. The peripheries are cool and sweaty with prolonged capillary refill times (except in septic distributive shock).

Moderate shock

As shock progresses, renal compensatory mechanisms fail, renal perfusion falls and urine output dips below 0.5 mL/kg per hour. There is further tachycardia, and now the blood pressure starts to fall. Patients become drowsy and mildly confused.

Severe shock

In severe shock, there is profound tachycardia and hypotension. Urine output falls to zero and patients are unconscious with laboured respiration.

Pitfalls

The classic cardiovascular responses described (*Table 2.2*) are not seen in every patient. It is important to recognise the limitations of the clinical examination and to recognise patients who are in shock despite the absence of classic signs.

CAPILLARY REFILL

Most patients in hypovolaemic shock will have cool, pale peripheries, with prolonged capillary refill times. However, the actual capillary refill time varies so much in adults that it is not a specific marker of whether a patient is shocked, and patients with short capillary refill times may be in the early stages of shock. In distributive (septic) shock, the peripheries will be warm and capillary refill will be brisk, despite profound shock.

TACHYCARDIA

Tachycardia may not always accompany shock. Patients who are on beta-blockers or who have implanted pacemakers are unable to mount a tachycardia. A pulse rate of 80 in a fit young adult who normally has a pulse rate of 50 is very abnormal. Furthermore, in some young patients with penetrating trauma, where there is haemorrhage but little tissue damage, there may be a paradoxical bradycardia rather than tachycardia accompanying the shocked state.

TABLE 2.2 Clinical features of shock.

	Compensated	Mild	Moderate	Severe
Lactic acidosis	+	++	++	+++
Urine output	Normal	Normal	Reduced	Anuric
Conscious level	Normal	Mild anxiety	Drowsy	Comatose
Respiratory rate	Normal	Increased	Increased	Laboured
Pulse rate	Mild increase	Increased	Increased	Increased
Blood pressure	Normal	Normal	Mild hypotension	Severe hypotension

BLOOD PRESSURE

It is important to recognise that hypotension is one of the last signs of shock. Children and fit young adults are able to maintain blood pressure until the final stages of shock by dramatic increases in stroke volume and peripheral vasoconstriction. These patients can be in profound shock with a normal blood pressure.

Elderly patients who are normally hypertensive may present with a 'normal' blood pressure for the general population but be hypovolaemic and hypotensive relative to their usual blood pressure. Beta-blockers or other medications may prevent a tachycardic response. The diagnosis of shock may be difficult unless one is alert to these pitfalls.

Consequences

Unresuscitatable shock

Patients who are in profound shock for a prolonged period of time become 'unresuscitatable'. Cell death follows from cellular ischaemia and the ability of the body to compensate is lost. There is myocardial depression and loss of responsiveness to fluid or inotropic therapy. Peripherally there is loss of the ability to maintain systemic vascular resistance and further hypotension ensues. The peripheries no longer respond appropriately to vasopressor agents. Death is the inevitable result.

This stage of shock is the combined result of the severity of the insult and delayed, inadequate or inappropriate resuscitation in the earlier stages of shock. Conversely, when patients present in this late stage, and have minimal responses to maximal therapy, it is important that the futility of treatment is recognised and valuable resources are not wasted.

Multiple organ failure

As techniques of resuscitation have improved, more and more patients are surviving shock. Where intervention is timely and the period of shock is limited, patients may make a rapid, uncomplicated recovery. However the result of prolonged systemic ischaemia and reperfusion injury is end-organ damage and multiple organ failure.

Multiple organ failure is defined as two or more failed organ systems. There is no specific treatment for multiple organ failure. Management is supporting of organ systems, with ventilation, cardiovascular support and haemofiltration/dialysis until there is recovery of organ function. Multiple organ failure currently carries a mortality of 60%; thus, prevention is vital by early aggressive identification and reversal of shock.

Summary box 2.2

Effects of organ failure

- Lung: Acute respiratory distress syndrome
- Kidney: Acute renal insufficiency
- Clotting: Coagulopathy
- Cardiac: Cardiovascular failure

RESUSCITATION

Immediate resuscitation manoeuvres for patients presenting in shock are to ensure a patent airway and adequate oxygenation and ventilation. Once 'airway' and 'breathing' are assessed and controlled, attention is directed to cardiovascular resuscitation.

Conduct of resuscitation

Resuscitation should not be delayed in order to definitively diagnose the source of the shocked state. However, the timing and nature of resuscitation will depend on the type of shock and the timing and severity of the insult. Rapid clinical examination will provide adequate clues to make an appropriate first determination, even if a source of bleeding or sepsis is not immediately identifiable. If there is initial doubt about the cause of shock, it is safer to assume the cause is hypovolaemia and begin with fluid resuscitation, and then assess the response.

In patients who are actively bleeding (major trauma, aortic aneurysm rupture, gastrointestinal haemorrhage), it is counterproductive to institute high-volume fluid therapy without controlling the site of haemorrhage. Increasing blood pressure merely increases bleeding from the site while fluid therapy cools the patient and dilutes available coagulation factors. Thus operative haemorrhage control should not be delayed and resuscitation should proceed in parallel with surgery.

Conversely, a patient with bowel obstruction and hypovolaemic shock must be adequately resuscitated before undergoing surgery otherwise the additional surgical injury and hypovolaemia induced during the procedure will exacerbate the inflammatory activation and increase the incidence and severity of end-organ insult.

Fluid therapy

In all cases of shock, regardless of classification, hypovolaemia and inadequate preload must be addressed before other therapy is instituted. Administration of inotropic or chronotropic agents to an empty heart will rapidly and permanently deplete the myocardium of oxygen stores and dramatically reduce diastolic filling and therefore coronary perfusion. Patients will enter the unresuscitatable stage of shock as the myocardium becomes progressively more ischaemic and unresponsive to resuscitative attempts.

First-line therapy, therefore, is intravenous access and administration of intravenous fluids. Access should be through short, wide-bore catheters that allow rapid infusion of fluids as necessary. Long, narrow lines, such as central venous catheters, have too high a resistance to allow rapid infusion and are more appropriate for monitoring than fluid replacement therapy.

Type of fluids

There is continuing debate over which resuscitation fluid is best for the management of shock. There is no ideal resuscitation fluid, and it is more important to understand how and when to administer it. In most studies of shock resuscitation

there is no overt difference in response or outcome between crystalloid solutions (normal saline, Hartmann's solution, Ringer's lactate) or colloids (albumin or commercially available products). Furthermore, there is less volume benefit to the administration of colloids than had previously been thought, with only 1.3 times more crystalloid than colloid administered in blinded trials. On balance, there is little evidence to support the administration of colloids, which are more expensive and have worse side-effect profiles.

Most importantly, the oxygen carrying capacity of crystalloids and colloids is zero. If blood is being lost, the ideal replacement fluid is blood, although crystalloid therapy may be required while awaiting blood products.

Hypotonic solutions (dextrose etc.) are poor volume expanders and should not be used in the treatment of shock unless the deficit is free water loss (e.g. diabetes insipidus) or patients are sodium overloaded (e.g. cirrhosis).

Dynamic fluid response

The shock status can be determined dynamically by the cardiovascular response to the rapid administration of a fluid bolus. In total, 250–500 mL of fluid is rapidly given (over 5–10 minutes) and the cardiovascular responses in terms of heart rate, blood pressure and central venous pressure are observed. Patients can be divided into 'responders', 'transient responders' and 'non-responders'.

Responders have an improvement in their cardiovascular status that is sustained. These patients are not actively losing fluid but require filling to a normal volume status.

Transient responders have an improvement, but this then reverts to the previous state over the next 10–20 minutes. These patients have moderate ongoing fluid losses (either overt haemorrhage or further fluid shifts reducing intravascular volume).

Non-responders are severely volume depleted and are likely to have major ongoing loss of intravascular volume, usually through persistent uncontrolled haemorrhage.

Vasopressor and inotropic support

Vasopressor or inotropic therapy is not indicated as first-line therapy in hypovolaemia. As discussed above, administration of these agents in the absence of adequate preload rapidly leads to decreased coronary perfusion and depletion of myocardial oxygen reserves.

Vasopressor agents (phenylephrine, noradrenaline) are indicated in distributive shock states (sepsis, neurogenic shock) where there is peripheral vasodilatation, and a low systemic vascular resistance, leading to hypotension despite a high cardiac output. Where the vasodilatation is resistant to catecholamines (e.g. absolute or relative steroid deficiency) vasopressin may be used as an alternative vasopressor.

In cardiogenic shock, or where myocardial depression has complicated a shock state (e.g. severe septic shock with low cardiac output), inotropic therapy may be required to increase cardiac output and therefore oxygen delivery. The inodilator dobutamine is the agent of choice.

Monitoring

The **minimum** standard for monitoring of the patient in shock is continuous heart rate and oxygen saturation monitoring, frequent non-invasive blood pressure monitoring and hourly urine output measurements. Most patients will need more aggressive invasive monitoring, including central venous pressure and invasive blood pressure monitoring.

Summary box 2.3

Monitoring for patients in shock

Minimum

- ECG
- Pulse oximetry
- Blood pressure
- Urine output

Additional modalities

- Central venous pressure
- Invasive blood pressure
- Cardiac output
- Base deficit and serum lactate

Cardiovascular

Cardiovascular monitoring at minimum should include continuous heart rate (ECG), oxygen saturation and pulse waveform and non-invasive blood pressure. Patients whose state of shock is not rapidly corrected with a small amount of fluid should have central venous pressure monitoring and continuous blood pressure monitoring through an arterial line.

CENTRAL VENOUS PRESSURE

There is no 'normal' central venous pressure (CVP) for a shocked patient, and reliance cannot be placed on an individual pressure measurement to assess volume status. Some patients may require a CVP of 5 cmH_2O, whereas some may require a CVP of 15 cmH_2O or higher. Further, ventricular compliance can change from minute to minute in the shocked state, and CVP is a poor reflection of end diastolic volume (preload).

CVP measurements should be assessed dynamically as response to a fluid challenge (see above). A fluid bolus (250–500 mL) is infused rapidly over 5–10 minutes.

The normal CVP response is a rise of 2–5 cmH_2O which gradually drifts back to the original level over 10–20 minutes. Patients with no change in their CVP are empty and require further fluid resuscitation. Patients with a large, sustained rise in CVP have high preload and an element of cardiac insufficiency or volume overload.

Alexis Frank Hartmann, 1898–1964, paediatrician, St Louis, MO, USA, described the solution; should not be confused with the name of Henri Albert Charles Antoine Hartmann, French surgeon, who described the operation that goes by his name.
Sidney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, UK.

CARDIAC OUTPUT

Cardiac output monitoring allows assessment of not only the cardiac output but also the systemic vascular resistance and, depending on the technique used, end diastolic volume (preload) and blood volume. Use of invasive cardiac monitoring with pulmonary artery catheters is becoming less frequent as new non-invasive monitoring techniques, such as Doppler ultrasound, pulse waveform analysis and indicator dilution methods, provide similar information without many of the drawbacks of more invasive techniques.

Measurement of cardiac output, systemic vascular resistance and preload can help distinguish the types of shock present (hypovolaemia, distributive, cardiogenic), especially when they coexist. The information provided guides fluid and vasopressor therapy by providing real-time monitoring of the cardiovascular response.

Measurement of cardiac output is desirable in patients who do not respond as expected to first-line therapy, or who have evidence of cardiogenic shock or myocardial dysfunction. Early consideration should be given to instituting cardiac output monitoring for patients who require vasopressor or inotropic support.

Systemic and organ perfusion

Ultimately, the goal of treatment is to restore cellular and organ perfusion. Ideally, therefore, monitoring of organ perfusion should guide the management of shock. The best measure of organ perfusion and the best monitor of the adequacy of shock therapy remains the urine output. However, this is an hourly measure and does not give a minute-to-minute view of the shocked state. The level of consciousness is an important marker of cerebral perfusion, but brain perfusion is maintained until the very late stages of shock, and hence is a poor marker of adequacy of resuscitation (*Table 2.3*).

Currently, the only clinical indicators of perfusion of the gastrointestinal tract and muscular beds are the global measures of lactic acidosis (lactate and base deficit) and the mixed venous oxygen saturation.

BASE DEFICIT AND LACTATE

Lactic acid is generated by cells undergoing anaerobic respiration. The degree of lactic acidosis, as measured by serum lactate level and/or the base deficit, is sensitive for both diagnosis of shock and monitoring the response to therapy. Patients with a base deficit over 6 mmol/L have a much higher morbidity and mortality than those with no metabolic acidosis. Furthermore, the length of time in shock with an increased base deficit is important, even if all other vital signs have returned to normal (see occult hypoperfusion below under **End points of resuscitation**).

These parameters are measured from arterial blood gas analyses, and therefore the frequency of measurements is limited and they do not provide minute-to-minute data on systemic perfusion or the response to therapy. Nevertheless, the base deficit and/or lactate should be measured routinely in these patients until they have returned to normal levels.

MIXED VENOUS OXYGEN SATURATION

The percentage saturation of oxygen returning to the heart from the body is a measure of the oxygen delivery and extraction by the tissues. Accurate measurement is via analysis of blood drawn from a long central line placed in the right atrium. Estimations can be made from blood drawn from lines in the superior vena cava, but these values will be slightly higher than those of a mixed venous sample (as there is relatively more oxygen extraction from the lower half of the body). Normal mixed venous oxygen saturation levels are 50–70%. Levels below 50% indicate inadequate oxygen delivery and increased oxygen extraction by the cells. This is consistent with hypovolaemic or cardiogenic shock.

High mixed venous saturations (>70%) are seen in sepsis and some other forms of distributive shock. In sepsis, there is disordered utilisation of oxygen at the cellular level, and arteriovenous shunting of blood at the microvascular level. Therefore, less oxygen is presented to the cells, and those cells cannot utilise what little oxygen is presented. Thus, venous blood has a higher oxygen concentration than normal.

TABLE 2.3 Monitors for organ/systemic perfusion.

	Clinical	Investigational
Systemic perfusion		Base deficit
		Lactate
		Mixed venous oxygen saturation
Organ perfusion		
Muscle	–	Near-infrared spectroscopy
		Tissue oxygen electrode
Gut	–	Sublingual capnometry
		Gut mucosal pH
		Laser Doppler flowmetry
Kidney	Urine output	–
Brain	Conscious level	Tissue oxygen electrode
		Near-infrared spectroscopy

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the Doppler principle in 1842.

Patients who are septic should therefore have mixed venous oxygen saturations above 70%; below this level, they are not only in septic shock but also in hypovolaemic or cardiogenic shock. Although the S_vO_2 level is in the 'normal' range, it is low for the septic state, and inadequate oxygen is being supplied to cells that cannot utilise oxygen appropriately. This must be corrected rapidly. Hypovolaemia should be corrected with fluid therapy, and low cardiac output due to myocardial depression or failure should be treated with inotropes (dobutamine), to achieve a mixed venous saturation greater than 70% (normal for the septic state).

New methods for monitoring regional tissue perfusion and oxygenation are becoming available, the most promising of which are muscle tissue oxygen probes, near-infrared spectroscopy and sublingual capnometry. While these techniques provide information regarding perfusion of specific tissue beds, it is as yet unclear whether there are significant advantages over existing measurements of global hypoperfusion (base deficit, lactate).

End points of resuscitation

It is much easier to know when to start resuscitation than when to stop. Traditionally, patients have been resuscitated until they have a normal pulse, blood pressure and urine output. However, these parameters are monitoring organ systems whose blood flow is preserved until the late stages of shock. A patient therefore may be resuscitated to restore central perfusion to the brain, lungs and kidneys and yet continue to underperfuse the gut and muscle beds. Thus, activation of inflammation and coagulation may be ongoing and lead to reperfusion injury when these organs are finally perfused, and ultimately multiple organ failure.

This state of normal vital signs and continued underperfusion is termed 'occult hypoperfusion'. With current monitoring techniques, it is manifested only by a persistent lactic acidosis and low mixed venous oxygen saturation. The time spent by patients in this hypoperfused state has a dramatic effect on outcome. Patients with occult hypoperfusion for more than 12 hours have two to three times the mortality of patients with a limited duration of shock.

Resuscitation algorithms directed at correcting global perfusion end points (base deficit, lactate, mixed venous oxygen saturation) rather than traditional end points have been shown to improve mortality and morbidity in high-risk surgical patients. However, it is clear that, despite aggressive regimes, some patients cannot be resuscitated to normal parameters within 12 hours by fluid resuscitation alone. More research is underway to identify the pathophysiology behind this and investigate new therapeutic options.

HAEMORRHAGE

Haemorrhage must be recognised and managed aggressively to reduce the severity and duration of shock and avoid death and/or multiple organ failure. Haemorrhage is treated by arresting the bleeding – not by fluid resuscitation or blood transfusion. Although necessary as supportive measures to maintain organ perfusion, attempting to resuscitate patients who have ongoing haemorrhage will lead to physiological exhaustion (coagulopathy, acidosis and hypothermia) and subsequently death.

Pathophysiology

Haemorrhage leads to a state of hypovolaemic shock. The combination of tissue trauma and hypovolaemic shock leads to the development of an endogenous coagulopathy called acute traumatic coagulopathy (ATC). Up to 25% of trauma patients develop ATC within minutes of injury and it is associated with a four-fold increase in mortality. It is likely that ATC exists whenever there is the combination of shock and tissue trauma (e.g. major surgery). ATC is a component of trauma-induced coagulopathy (TIC), which is ultimately multifactorial (**Figure 2.1**).

Ongoing bleeding with fluid and red blood cell resuscitation leads to a dilution of coagulation factors which worsens the coagulopathy. In addition, the acidosis induced by the hypoperfused state leads to decreased function of the coagulation proteases, resulting in coagulopathy and further haemorrhage. The reduced tissue perfusion includes reduced blood supply to muscle beds. Underperfused muscle is unable to generate heat and hypothermia ensues. Coagulation functions poorly at low temperatures and there is further haemorrhage, further hypoperfusion and worsening acidosis and hypothermia. These three factors result in a downward spiral leading to physiological exhaustion and death (**Figure 2.1**).

Medical therapy has a tendency to worsen this effect. Intravenous blood and fluids are cold and exacerbate hypothermia. Further heat is lost by opening body cavities during surgery. Surgery usually leads to further bleeding and many crystalloid fluids are themselves acidic (e.g. normal saline has a pH of 6.7). Every effort must therefore be made to rapidly identify and stop haemorrhage, and to avoid (preferably) or limit physiological exhaustion from coagulopathy, acidosis and hypothermia.

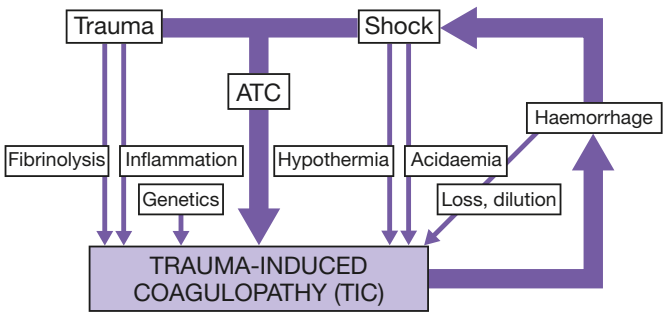

Figure 2.1 Trauma-induced coagulopathy.

Definitions

Revealed and concealed haemorrhage

Haemorrhage may be revealed or concealed. Revealed haemorrhage is obvious external haemorrhage, such as exsanguination from an open arterial wound or from massive haematemesis from a duodenal ulcer.

Concealed haemorrhage is contained within the body cavity and must be suspected, actively investigated and controlled. In

trauma, haemorrhage may be concealed within the chest, abdomen, pelvis, retroperitoneum or in the limbs with contained vascular injury or associated with long-bone fractures. Examples of non-traumatic concealed haemorrhage include occult gastrointestinal bleeding or ruptured aortic aneurysm.

Primary, reactionary and secondary haemorrhage

Primary haemorrhage is haemorrhage occurring immediately due to an injury (or surgery). Reactionary haemorrhage is delayed haemorrhage (within 24 hours) and is usually due to dislodgement of a clot by resuscitation, normalisation of blood pressure and vasodilatation. Reactionary haemorrhage may also be due to technical failure, such as slippage of a ligature.

Secondary haemorrhage is due to sloughing of the wall of a vessel. It usually occurs 7–14 days after injury and is precipitated by factors such as infection, pressure necrosis (such as from a drain) or malignancy.

Surgical and non-surgical haemorrhage

Surgical haemorrhage is due to a direct injury and is amenable to surgical control (or other techniques such as angioembolisation). Non-surgical haemorrhage is the general ooze from all raw surfaces due to coagulopathy and cannot be stopped by surgical means (except packing). Treatment requires correction of the coagulation abnormalities.

Degree and classification

The adult human has approximately 5 litres of blood (70 mL/kg children and adults, 80 mL/kg neonates). Estimation of the amount of blood that has been lost is difficult, inaccurate and usually underestimates the actual value.

External haemorrhage is obvious, but it may be difficult to estimate the actual volume lost. In the operating room, blood collected in suction apparatus can be measured and swabs soaked in blood weighed.

The haemoglobin level is a poor indicator of the degree of haemorrhage because it represents a concentration and not an absolute amount. In the early stages of rapid haemorrhage, the haemoglobin concentration is unchanged (as whole blood is lost). Later, as fluid shifts from the intracellular and interstitial spaces into the vascular compartment, the haemoglobin and haematocrit levels will fall.

The amount of haemorrhage can be classified into classes 1–4 based on the estimated blood loss required to produce certain physiological compensatory changes (*Table 2.4*). Although conceptually useful, there is variation across ages (the young compensate well, the old very poorly), variation among individuals (e.g. athletes versus the obese) and variation due to confounding factors (e.g. concomitant medications, pain).

Treatment should therefore be based upon the degree of hypovolaemic shock according to vital signs, preload assessment, base deficit and, most importantly, the dynamic response to fluid therapy. Patients who are 'non-responders' or 'transient responders' are still bleeding and must have the site of haemorrhage identified and controlled.

TABLE 2.4 Traditional classification of haemorrhagic shock.

	Class			
	1	2	3	4
Blood volume lost as percentage of total	<15%	15–30%	30–40%	>40%

Management

Identify haemorrhage

External haemorrhage may be obvious, but the diagnosis of concealed haemorrhage may be more difficult. Any shock should be assumed to be hypovolaemic until proven otherwise and, similarly, hypovolaemia should be assumed to be due to haemorrhage until this has been excluded.

Immediate resuscitative manoeuvres

Direct pressure should be placed over the site of external haemorrhage. Airway and breathing should be assessed and controlled as necessary. Large-bore intravenous access should be instituted and blood drawn for cross-matching (see **Cross-matching** below). Emergency blood should be requested if the degree of shock and ongoing haemorrhage warrants this.

Identify the site of haemorrhage

Once haemorrhage has been considered, the site of haemorrhage must be rapidly identified. Note this is not to identify the exact location definitively, but rather to define the next step in haemorrhage control (operation, angioembolisation, endoscopic control).

Clues may be in the history (previous episodes, known aneurysm, non-steroidal therapy for gastrointestinal [GI] bleeding) or examination (nature of blood – fresh, melaena; abdominal tenderness, etc.). For shocked trauma patients, the external signs of injury may suggest internal haemorrhage, but haemorrhage into a body cavity (thorax, abdomen) must be excluded with rapid investigations (chest and pelvis x-ray, abdominal ultrasound or diagnostic peritoneal aspiration).

Investigations for blood loss must be appropriate to the patient's physiological condition. Rapid bedside tests are more appropriate for profound shock and exsanguinating haemorrhage than investigations such as computed tomography (CT) which take time. Patients who are not actively bleeding can have a more methodical, definitive work-up.

Haemorrhage control

The bleeding, shocked patient must be moved rapidly to a place of haemorrhage control. This will usually be in the operating room but may be the angiography or endoscopy suite. These patients require surgical and anaesthetic support and full monitoring and equipment must be available.

Haemorrhage control must be achieved rapidly to prevent the patient entering the triad of coagulopathy–acidosis–hypothermia and physiological exhaustion. There should be no unnecessary investigations or procedures prior to haemorrhage

control to minimise the duration and severity of shock. This includes prolonged attempts to volume resuscitate the patient prior to surgery, which will result in further hypothermia and clotting factor dilution until the bleeding is stopped. Attention should be paid to correction of coagulopathy with blood component therapy to aid surgical haemorrhage control.

Surgical intervention may need to be limited to the minimum necessary to stop bleeding and control sepsis. More definitive repairs can be delayed until the patient is haemodynamically stable and physiologically capable of sustaining the procedure. This concept of tailoring the operation to match the patient's physiology and staged procedures to prevent physiological exhaustion is called 'damage control surgery' – a term borrowed from the military which ensures continued functioning of a damaged ship above conducting complete repairs which would prevent rapid return to battle.

Once haemorrhage is controlled, patients should be aggressively resuscitated, warmed and coagulopathy corrected. Attention should be paid to fluid responsiveness and the end points of resuscitation to ensure that patients are fully resuscitated and to reduce the incidence and severity of organ failure.

Summary box 2.4

Damage control surgery

- Arrest haemorrhage
- Control sepsis
- Protect from further injury
- Nothing else

Damage control resuscitation

These concepts have been combined into a new paradigm for the management of trauma patients with active haemorrhage called damage control resuscitation (DCR). The four central strategies of DCR are:

1 Anticipate and treat acute traumatic coagulopathy.
2 Permissive hypotension until haemorrhage control.
3 Limit crystalloid and colloid infusion to avoid dilutional coagulopathy.
4 Damage control surgery to control haemorrhage and preserve physiology.

Damage control resuscitation strategies have been shown to reduce mortality and morbidity in patients with exsanguinating trauma and may be applicable in other forms of acute haemorrhage.

TRANSFUSION

The transfusion of blood and blood products has become commonplace since the first successful transfusion in 1818. Although the incidence of severe transfusion reactions and infections is now very low, in recent years it has become apparent that there is an immunological price to be paid from the transfusion of heterologous blood, leading to increased morbidity and decreased survival in certain population groups (trauma, malignancy). Supplies are also limited, and therefore the use of blood and blood products must always be judicious and justifiable for clinical need (*Table 2.5*).

TABLE 2.5 History of blood transfusion.

1492	Pope Innocent VIII suffers a stroke and receives a blood transfusion from three 10-year-old boys (paid a ducat each). All three boys died, as did the pope later that year
1665	Richard Lower in Oxford conducts the first successful canine transfusions
1667	Jean-Baptiste Denis reports successful sheep–human transfusions
1678	Animal–human transfusions are banned in France because of the poor results
1818	James Blundell performs the first successful documented human transfusion in a woman suffering post-partum haemorrhage. She received blood from her husband and survived
1901	Karl Landsteiner discovers the ABO system
1914	The Belgian physician Albert Hustin performed the first non-direct transfusion, using sodium citrate as an anticoagulant
1926	The British Red Cross instituted the first blood transfusion service in the world
1939	The Rhesus system was identified and recognised as the major cause of transfusion reactions

Blood and blood products

Blood is collected from donors who have been previously screened before donating, to exclude any donor whose blood may have the potential to harm the patient, or to prevent possible harm that donating a unit of blood may have on the donor. In the UK, up to 450 mL of blood is drawn, a maximum of three times each year. Each unit is tested for evidence of hepatitis B, hepatitis C, HIV-1, HIV-2 and syphilis. Donations are leukodepleted as a precaution against variant Creutzfeldt–Jakob disease (this may also reduce the immunogenicity of the transfusion). The ABO and rhesus D blood groups are determined, as well as the presence of irregular red cell antibodies. The blood is then processed into subcomponents.

Whole blood

Whole blood is now rarely available in civilian practice because it has been seen as an inefficient use of the limited resource. However, whole blood transfusion has significant advantages over packed cells as it is coagulation factor rich and, if fresh, more metabolically active than stored blood.

Hans Gerhard Creutzfeldt, 1885–1946, neurologist, Kiel, Germany.
Alfons Maria Jakob, 1884–1931, neurologist, Hamburg, Germany.
Karl Landsteiner, 1868–1943, Professor of Pathological Anatomy, University of Vienna, Austria. In 1909 he classified the human blood groups into A, B, AB and O. For this he was awarded the Nobel Prize for Physiology or Medicine in 1930.

Packed red cells

Packed red blood cells are spun-down and concentrated packs of red blood cells. Each unit is approximately 330 mL and has a haematocrit of 50–70%. Packed cells are stored in a SAG-M solution (saline–adenine–glucose–mannitol) to increase shelf life to 5 weeks at 2–6°C. (Older storage regimes included storage in CPD: citrate–phosphate–dextrose solutions, which have a shelf life of 2–3 weeks.)

Fresh-frozen plasma

Fresh-frozen plasma (FFP) is rich in coagulation factors and is removed from fresh blood and stored at −40 to −50°C with a 2-year shelf life. It is the first-line therapy in the treatment of coagulopathic haemorrhage (see below under **Management of coagulopathy**). Rhesus D-positive FFP may be given to a rhesus D-negative woman although it is possible for seroconversion to occur with large volumes owing to the presence of red cell fragments, and Rh-D immunisation should be considered.

Cryoprecipitate

Cryoprecipitate is a supernatant precipitate of FFP and is rich in factor VIII and fibrinogen. It is stored at −30°C with a 2-year shelf life. It is given in low fibrinogen states or factor VIII deficiency.

Platelets

Platelets are supplied as a pooled platelet concentrate and contain about 250×10^9/L. Platelets are stored on a special agitator at 20–24°C and have a shelf life of only 5 days. Platelet transfusions are given to patients with thrombocytopenia or with platelet dysfunction who are bleeding or undergoing surgery.

Patients are increasingly presenting on antiplatelet therapy such as aspirin or clopidogrel for reduction of cardiovascular risk. Aspirin therapy rarely poses a problem but control of haemorrhage on the more potent platelet inhibitors can be extremely difficult. Patients on clopidogrel who are actively bleeding and undergoing major surgery may require almost continuous infusion of platelets during the course of the procedure. Arginine vasopressin or its analogues (DDAVP) have also been used in this patient group, although with limited success.

Prothrombin complex concentrates

Prothrombin complex concentrates (PCC) are highly purified concentrates prepared from pooled plasma. They contain factors II, IX and X. Factor VII may be included or produced separately. It is indicated for the emergency reversal of anticoagulant (warfarin) therapy in uncontrolled haemorrhage.

Autologous blood

It is possible for patients undergoing elective surgery to predonate their own blood up to 3 weeks before surgery for retransfusion during the operation. Similarly, during surgery blood can be collected in a cell-saver which washes and collects red blood cells which can then be returned to the patient.

Indications for blood transfusion

Blood transfusions should be avoided if possible, and many previous uses of blood and blood products are now no longer considered appropriate. The indications for blood transfusion are as follows:

- Acute blood loss, to replace circulating volume and maintain oxygen delivery;
- Perioperative anaemia, to ensure adequate oxygen delivery during the perioperative phase;
- Symptomatic chronic anaemia, without haemorrhage or impending surgery.

Transfusion trigger

Historically, patients were transfused to achieve a haemoglobin >10 g/dL. This has now been shown not only to be unnecessary but also to be associated with an increased morbidity and mortality compared with lower target values. A haemoglobin level of 6 g/dL is acceptable in patients who are not actively bleeding, not about to undergo major surgery and are not symptomatic. There is some controversy as to the optimal haemoglobin level in some patient groups, such as those with cardiovascular disease, sepsis and traumatic brain injury. Although, conceptually, a higher haemoglobin level improves oxygen delivery, there is little clinical evidence at this stage to support higher levels in these groups (*Table 2.6*).

TABLE 2.6 Perioperative red blood cell transfusion criteria.

Haemoglobin level (g/dL)	Indications
<6	Probably will benefit from transfusion
6–8	Transfusion unlikely to be of benefit in the absence of bleeding or impending surgery
>8	No indication for transfusion in the absence of other risk factors

Blood groups and cross-matching

Human red cells have on their cell surface many different antigens. Two groups of antigens are of major importance in surgical practice – the ABO and rhesus systems.

ABO system

These proteins are strongly antigenic and are associated with naturally occurring antibodies in the serum. The system consists of three allelic genes – A, B and O – which control synthesis of enzymes that add carbohydrate residues to cell surface glycoproteins. A and B genes add specific residues while the O gene is an amorph and does not transform the glycoprotein. The system allows for six possible genotypes although there are only four phenotypes. Naturally occurring antibodies are found in the serum of those lacking the corresponding antigen (*Table 2.7*).

Blood group O is the universal donor type as it contains no antigens to provoke a reaction. Conversely, group AB individuals are 'universal recipients' and can receive any ABO blood type because they have no circulating antibodies.

TABLE 2.7 ABO blood group system.

Phenotype	Genotype	Antigens	Antibodies	Frequency (%)
O	OO	O	Anti-A, anti-B	46
A	AA or AO	A	Anti-B	42
B	BB or BO	B	Anti-A	9
AB	AB	AB	None	3

Rhesus system

The rhesus D (Rh(D)) antigen is strongly antigenic and is present in approximately 85% of the population in the UK. Antibodies to the D antigen are not naturally present in the serum of the remaining 15% of individuals, but their formation may be stimulated by the transfusion of Rh-positive red cells, or acquired during delivery of a Rh(D)-positive baby.

Acquired antibodies are capable, during pregnancy, of crossing the placenta and, if present in a Rh(D)-negative mother, may cause severe haemolytic anaemia and even death (hydrops fetalis) in a Rh(D)-positive fetus *in utero*. The other minor blood group antigens may be associated with naturally occurring antibodies, or may stimulate the formation of antibodies on relatively rare occasions.

Transfusion reactions

If antibodies present in the recipient's serum are incompatible with the donor's cells, a transfusion reaction will result. This usually takes the form of an acute haemolytic reaction. Severe immune-related transfusion reactions due to ABO incompatibility result in potentially fatal complement-mediated intravascular haemolysis and multiple organ failure. Transfusion reactions from other antigen systems are usually milder and self-limiting.

Febrile transfusion reactions are non-haemolytic and are usually caused by a graft-versus-host response from leukocytes in transfused components. Such reactions are associated with fever, chills or rigors. The blood transfusion should be stopped immediately. This form of transfusion reaction is rare with leukodepleted blood.

Cross-matching

To prevent transfusion reactions, all transfusions are preceded by ABO and rhesus typing of both donor and recipient blood to ensure compatibility. The recipient's serum is then mixed with the donor's cells to confirm ABO compatibility and to test for rhesus and any other blood group antigen–antibody reaction.

Full cross-matching of blood may take up to 45 minutes in most laboratories. In more urgent situations, 'type specific' blood is provided which is only ABO/rhesus matched and can be issued within 10–15 minutes. Where blood must be given emergently, group O (universal donor) blood is given (O– to females, O+ to males).

When blood transfusion is prescribed and blood is administered, it is essential that the correct patient receives the correct transfusion. Two healthcare personnel should check the patient details against the prescription and the label of the donor blood. In addition, the donor blood serial number should also be checked against the issue slip for that patient. Provided these principles are strictly adhered to the number of severe and fatal ABO incompatibility reactions can be minimised.

Complications of blood transfusion

Complications from blood transfusion can be categorised as those arising from a single transfusion and those related to massive transfusion.

Complications from a single transfusion

Complications from a single transfusion include:

- incompatibility haemolytic transfusion reaction;
- febrile transfusion reaction;
- allergic reaction;
- infection:
  - bacterial infection (usually due to faulty storage);
  - hepatitis;
  - HIV;
  - malaria;
- air embolism;
- thrombophlebitis;
- transfusion-related acute lung injury (usually from FFP).

Complications from massive transfusion

Complications from massive transfusion include:

- coagulopathy;
- hypocalcaemia;
- hyperkalaemia;
- hypokalaemia;
- hypothermia.

In addition, patients who receive repeated transfusions over long periods of time (e.g. patients with thalassaemia) may develop iron overload. (Each transfused unit of red blood cells contains approximately 250 mg of elemental iron.)

Management of coagulopathy

Correction of coagulopathy is not necessary if there is no active bleeding and haemorrhage is not anticipated (not due for surgery). However, coagulopathy following or during massive transfusion should be anticipated and managed aggressively. Prevention of dilutional coagulopathy is central to the damage control resuscitation of patients who are actively bleeding.

This is the prime reason for delivering balanced transfusion regimes matching red blood cell packs with plasma and platelets. Based on moderate evidence, when red cells are transfused for active haemorrhage, it is best to match each red cell unit with one unit of FFP and one of platelets (1:1:1). This will reduce the incidence and severity of subsequent dilutional coagulopathy. Crystalloids and colloids should be avoided for the same reason.

The balanced transfusion approach cannot, however, correct coagulopathy. Therefore, coagulation should be monitored routinely, either with point-of-care testing (thromboelastometry) or with laboratory tests (fibrinogen, clotting times). Underlying coagulopathies should be treated in addition to the administration of 1:1:1 balanced transfusions.

There are pharmacological adjuncts to blood component therapy. The antifibrinolytic tranexamic acid is the most commonly administered. It is usually administered empirically to bleeding patients because effective point-of-care tests of fibrinolysis are not yet routinely available. There is little evidence to support the use of other coagulation factor concentrates at this time.

Blood substitutes

Blood substitutes are an attractive alternative to the costly process of donating, checking, storing and administering blood, especially given the immunogenic and potential infectious complications associated with transfusion.

There are several oxygen-carrying blood substitutes under investigation in experimental animal or early clinical trials. Blood substitutes are either biomimetic or abiotic. Biomimetic substitutes mimic the standard oxygen-carrying capacity of the blood and are haemoglobin based. Abiotic substitutes are synthetic oxygen carriers and are currently primarily perfluorocarbon based.

Haemoglobin is seen as the obvious candidate for developing an effective blood substitute. Various engineered molecules are under clinical trials, and are based on human, bovine or recombinant technologies. Second-generation perfluorocarbon emulsions are also showing potential in clinical trials.

Chapter 3

Wounds, healing and tissue repair

Learning objectives

To understand:

- Normal healing and how it can be adversely affected
- How to manage wounds of different types, of different structures and at different sites
- Aspects of disordered healing that lead to chronic wounds
- The variety of scars and their treatment
- How to differentiate between acute and chronic wounds

INTRODUCTION

Wound healing is a mechanism whereby the body attempts to restore the integrity of the injured part. This falls far short of tissue regeneration by pluripotent cells, seen in some amphibians, and is often detrimental, as seen in the problems created by scarring, such as adhesions, keloids, contractures and cirrhosis of the liver. Several factors may influence healing. However, a clean incised wound in a healthy person where there is no skin loss will follow a set pattern as outlined below.

Summary box 3.1

Factors influencing healing of a wound

- Site of the wound
- Structures involved
- Mechanism of wounding
  - Incision
  - Crush
  - Crush avulsion
- Contamination (foreign bodies/bacteria)[a]
- Loss of tissue
- Other local factors
  - Vascular insufficiency (arterial or venous)
  - Previous radiation
  - Pressure
- Systemic factors
  - Malnutrition or vitamin and mineral deficiencies
  - Disease (e.g. diabetes mellitus)
  - Medications (e.g. steroids)
  - Immune deficiencies (e.g. chemotherapy, acquired immunodeficiency syndrome [AIDS])
  - Smoking

[a] In explosions, the contamination may consist of tissue such as bone from another individual.

NORMAL WOUND HEALING

This is variously described as taking place in three or four phases, the most commonly agreed being:

1. the inflammatory phase;
2. the proliferative phase;
3. the remodelling phase (maturing phase).

Occasionally, a haemostatic phase is referred to as occurring before the inflammatory phase, or a destructive phase following inflammation consisting of the cellular cleansing of the wound by macrophages (**Figure 3.1**).

The inflammatory phase begins immediately after wounding and lasts 2–3 days. Bleeding is followed by vasoconstriction and thrombus formation to limit blood loss. Platelets stick to the damaged endothelial lining of vessels, releasing adenosine diphosphate (ADP), which causes thrombocytic aggregates to fill the wound. When bleeding stops, the platelets then release several cytokines from their alpha granules. These are platelet-derived growth factor (PDGF), platelet factor IV and transforming growth factor beta (TGFβ). These attract inflammatory cells such as polymorphonuclear leukocytes (PMN) and macrophages. Platelets and the local injured tissue release vasoactive amines, such as histamine, serotonin and prostaglandins, which increase vascular permeability, thereby aiding infiltration of these inflammatory cells. Macrophages remove devitalised tissue and microorganisms while regulating fibroblast activity in the proliferative phase of healing. The initial framework for structural support of cells is provided by fibrin produced by fibrinogen. A more historical (Latin) description of this phase is described in four words: *rubor* (redness), *tumor* (swelling), *calor* (heat) and *dolor* (pain).

The proliferative phase lasts from the third day to the third week, consisting mainly of fibroblast activity with the production of collagen and ground substance (glycosaminogly-

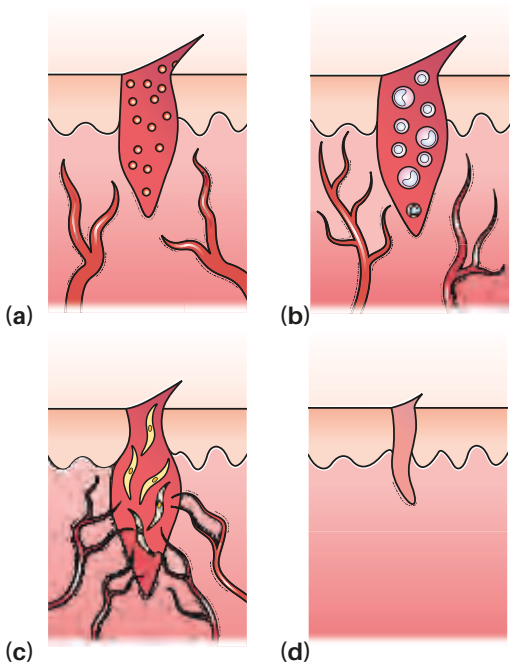

Figure 3.1 The phases of healing. **(a)** Early inflammatory phase with platelet-enriched blood clot and dilated vessels. **(b)** Late inflammatory phase with increased vascularity and increase in polymorphonuclear leukocytes and lymphocytes (round cells). **(c)** Proliferative phase with capillary buds and fibroblasts. **(d)** Mature contracted scar.

cans and proteoglycans), the growth of new blood vessels as capillary loops (angioneogenesis) and the re-epithelialisation of the wound surface. Fibroblasts require vitamin C to produce collagen. The wound tissue formed in the early part of this phase is called granulation tissue. In the latter part of this phase, there is an increase in the tensile strength of the wound due to increased collagen, which is at first deposited in a random fashion and consists of type III collagen. This proliferative phase with its increase of collagen deposition is associated with wound contraction, which can considerably reduce the surface area of a wound over the first 3 weeks of healing.

The remodelling phase is characterised by maturation of collagen (type I replacing type III until a ratio of 4:1 is achieved). There is a realignment of collagen fibres along the lines of tension, decreased wound vascularity, and wound contraction due to fibroblast and myofibroblast activity. This maturation of collagen leads to increased tensile strength in the wound which is maximal at the 12th week post injury and represents approximately 80% of the uninjured skin strength.

NORMAL HEALING IN SPECIFIC TISSUES

Bone

The phases are as above, but periosteal and endosteal proliferation leads to the formation of callus, which is immature bone consisting of osteoid (mineralised by hydroxyapatite and laid down by osteoblasts). In the remodelling phase, cortical structure and the medullary cavity are restored. If fracture ends are accurately opposed and rigidly fixed, callus formation is minimal and primary healing occurs. If a gap exists, then secondary healing may lead to delayed union, non-union or malunion.

Nerve

Distal to the wound, Wallerian degeneration occurs. Proximally, the nerve suffers traumatic degeneration as far as the last node of Ranvier. The regenerating nerve fibres are attracted to their receptors by neurotrophism, which is mediated by growth factors, hormones and other extracellular matrix trophins. Nerve regeneration is characterised by profuse growth of new nerve fibres which sprout from the cut proximal end. Overgrowth of these, coupled with poor approximation, may lead to neuroma formation.

Tendon

Although repair follows the normal pattern of wound healing, there are two main mechanisms whereby nutrients, cells and new vessels reach the severed tendon. These are intrinsic, which consists of vincular blood flow and synovial diffusion, and extrinsic, which depends on the formation of fibrous adhesions between the tendon and the tendon sheath. The random nature of the initial collagen produced means that the tendon lacks tensile strength for the first 3–6 weeks. Active mobilisation prevents adhesions limiting range of motion, but the tendon must be protected by splintage in order to avoid rupture of the repair.

ABNORMAL HEALING

Some of the adverse influences on wound healing are listed in *Summary box 3.1*. Delayed healing may result in loss of function or poor cosmetic outcome. The aim of treatment is to achieve healing by primary intention and so reduce the inflammatory and proliferative responses.

Summary box 3.2

Classification of wound closure and healing

- Primary intention
  - Wound edges opposed
  - Normal healing
  - Minimal scar
- Secondary intention
  - Wound left open
  - Heals by granulation, contraction and epithelialisation
  - Increased inflammation and proliferation
  - Poor scar
- Tertiary intention (also called delayed primary intention)
  - Wound initially left open
  - Edges later opposed when healing conditions favourable

Augustus Volney Waller, 1816–1870, general practitioner of Kensington, London, UK (1842–1851), subsequently worked as a physiologist in Bonn, Germany; Paris, France; Birmingham, UK; and Geneva, Switzerland.
Louis Antoine Ranvier, 1835–1922, physician and histologist who was a professor in the College of France, Paris, France, described these nodes in 1878.

Healing by primary intention is also known as healing by first intention. This occurs when there is apposition of the wound edges and minimal surrounding tissue trauma that causes least inflammation and leaves the best scar. Delayed primary intention healing occurs when the wound edges are not opposed immediately, which may be necessary in contaminated or untidy wounds. The inflammatory and proliferative phases of healing are well established when delayed closure of the wound is carried out. This is also called healing by tertiary intention in some texts and will result in a less satisfactory scar than would result after healing by primary intention. Secondary healing or healing by secondary intention occurs in wounds that are left open and allowed to heal by granulation, contraction and epithelialisation.

TYPES OF WOUNDS – TIDY VERSUS UNTIDY

The site injured, the structures involved in the injury and the mechanism of injury (e.g. incision or explosion) all influence healing and recovery of function. This has led to the management of wounds based upon their classification into tidy and untidy (*Table 3.1* and **Figure 3.2**).

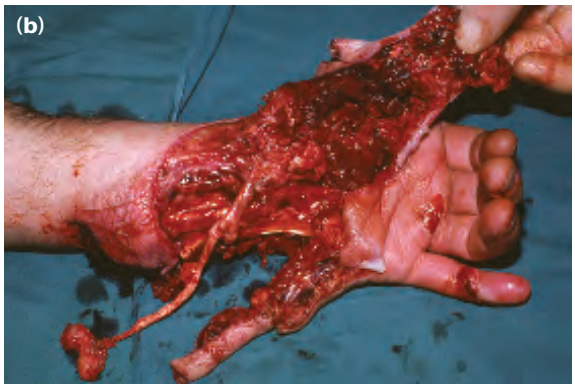

Figure 3.2 **(a)** Tidy incised wound on the finger. **(b)** Untidy avulsed wound on the hand.

The surgeon's aim is to convert untidy to tidy by removing all contaminated and devitalised tissue.

Primary repair of all structures (e.g. bone, tendon, vessel and nerve) may be possible in a tidy wound, but a contaminated wound with dead tissue requires debridement on one or several occasions before definitive repair can be carried out (the concept of 'second look' surgery). This is especially true in injuries caused by explosions, bullets or other missiles, where the external wound itself may appear much smaller than the wider extent of the injured tissues deep to the surface. Multiple debridements are often required after crushing injuries in road traffic accidents or in natural disasters such as earthquakes, where fallen masonry causes widespread muscle damage and compartment syndromes (see Compartment syndromes below). Any explosion where there are multiple victims at the same site or where there has been a suicide-related explosion will carry the risk of tissue and viral contamination. Appropriate tests for hepatitis viruses and human immunodeficiency virus (HIV) are required.

TABLE 3.1 Tidy versus untidy wounds.

Tidy	Untidy
Incised	Crushed or avulsed
Clean	Contaminated
Healthy tissues	Devitalised tissues
Seldom tissue loss	Often tissue loss

MANAGING THE ACUTE WOUND

The surgeon must remember to examine the whole patient according to acute trauma life support (ATLS) principles. A stab wound in the back can be missed just as easily in the reality of the accident and emergency room as in a fictitious detective novel. The wound itself should be examined, taking into consideration the site and the possible structures damaged (**Figure 3.3**). It is essential to assess movement and sensation while

Figure 3.3 Facial trauma – apparent tissue loss but none found after careful matching.

The term '**debridement**' was introduced by the great French surgeon in Napoleon's army, Dominique Jean Larrey (1766–1842). He used it to describe the removal of bullets, bits of cloth, loose bits of bone and soft tissue.

watching for pain and listening to the patient. Tetanus cover should be noted and appropriate treatment carried out.

A bleeding wound should be elevated and a pressure pad applied. Clamps should not be put on vessels blindly because nerve damage is likely and vascular anastomosis is rendered impossible.

In order to facilitate examination, adequate analgesia and/or anaesthesia (local, regional or general) are required. General anaesthesia is often needed in children. With limb injuries, particularly those of the hand, a tourniquet should be used in order to facilitate visualisation of all structures. Due care should be taken with tourniquet application, avoiding uneven pressure and noting the duration of tourniquet time.

After assessment, a thorough debridement is essential. Abrasions, 'road rash' (following a fall from a motorbike) and explosions all cause dirt tattooing and require the use of a scrubbing brush or even excision under magnification. A wound should be explored and debrided to the limit of blood staining. Devitalised tissue must be excised until bleeding occurs, with the obvious exceptions of nerves, vessels and tendons. These may survive with adequate revascularisation subsequently or after being covered with viable tissue such as that brought in by skin or muscle flaps.

The use of copious saline irrigation or pulsed jet lavage (where the instrumentation is available) can be less destructive than knife or scissors when debriding. However, it has been suggested that pulsed jet lavage can implant dirt into a deeper plane and care should be taken to avoid this complication. Muscle viability is judged by the colour, bleeding pattern and contractility. In a tidy wound, repair of all damaged structures may be attempted. Repair of nerves under magnification (loupes or microscope) using 8/0 or 10/0 monofilament nylon is usual. Vessels such as the radial or ulnar artery may be repaired using similar techniques. Tendon repairs, particularly those in the hand, benefit from early active mobilisation because this minimises adhesions between the tendon and the tendon sheath (see above under **Tendon** for extrinsic tendon healing mechanism).

Skin cover by flap or graft may be required as skin closure should always be without tension and should allow for the oedema typically associated with injury and the inflammatory phase of healing. A flap brings in a new blood supply and can be used to cover tendon, nerve, bone and other structures that would not provide a suitable vascular base for a skin graft. A skin graft has no inherent blood supply and is dependent on the recipient site for nutrition.

SOME SPECIFIC WOUNDS

Bites

Most bites involve either puncture wounds or avulsions. Bites from small animals are common in children (**Figure 3.4**) and require cleansing and treatment according to the principles outlined in *Summary box 3.3*, usually under general anaesthetic.

Injuries to the ear, tip of nose and lower lip are most usually seen in victims of human bites. A boxing-type injury of the metacarpophalangeal joint may result from a perforating contact with the teeth of a victim. Anaerobic and aerobic organism prophylaxis is required as bite wounds typically have high virulent bacterial counts.

Figure 3.4 Dog bite in a child.

Summary box 3.3

Managing the acute wound

- Cleansing
- Exploration and diagnosis
- Debridement
- Repair of structures
- Replacement of lost tissues where indicated
- Skin cover if required
- Skin closure without tension
- All of the above with careful tissue handling and meticulous technique

Puncture wounds

Wounds caused by sharp objects should be explored to the limit of tissue blood staining. Needle-stick injuries should be treated according to the well-published protocols because of hepatitis and HIV risks. X-ray examination should be carried out in order to rule out retained foreign bodies in the depth of the wound.

Haematoma

If large, painful or causing neural deficit, a haematoma may require release by incision or aspiration. In the gluteal or thigh region, there may be an associated disruption of fat in the form of a fat fracture, which results in an unsightly groove but intact skin. An untreated haematoma may also calcify and therefore require surgical exploration if symptomatic.

Degloving

Degloving occurs when the skin and subcutaneous fat are stripped by avulsion from the underlying fascia, leaving neurovascular structures, tendon or bone exposed. A degloving injury may be open or closed. An obvious example of an open degloving is a ring avulsion injury with loss of finger

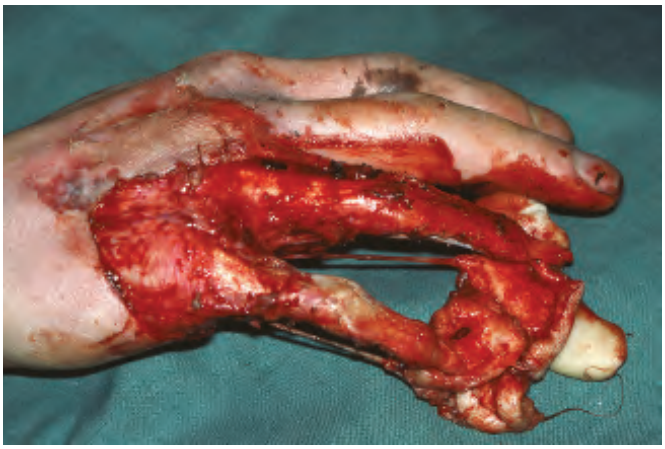

Figure 3.5 Degloving hand injury.

Figure 3.6 Degloving buttock injury.

skin (Figure 3.5). A closed degloving may be a rollover injury, typically caused by a motor vehicle over a limb. Such an injury will extend far further than expected, and much of the limb skin may be non-viable (Figure 3.6). Examination under anaesthetic is required with a radical excision of all non-bleeding skin, as judged by bleeding dermis. Fluoroscein can be administered intravenously while the patient is anaesthetised. Under ultraviolet light, viable (perfused) skin will show up as a fluorescent yellowish green colour, and the non-viable skin for excision is clearly mapped out. However, the main objection to this method is that of possible anaphylactic shock due to fluoroscein sensitivity. Most surgeons therefore rely upon serial excision until punctate dermal bleeding is obvious. Split-skin grafts can be harvested from the degloved non-viable skin and meshed (Figure 3.7) to cover the raw areas resulting from debridement.

Compartment syndromes

Compartment syndromes typically occur in closed lower limb injuries. They are characterised by severe pain, pain on passive movement of the affected compartment muscles, distal sensory disturbance and, finally, by the absence of pulses distally (a late sign). They can occur with an open injury if the wound does not extend into the affected compartment.

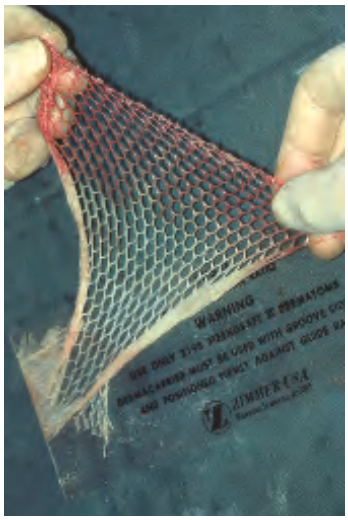

Figure 3.7 Meshed split-skin graft.

Compartment pressures can be measured using a pressure monitor and a catheter placed in the muscle compartment. If pressures are constantly greater than 30 mmHg or if the above clinical signs are present, then fasciotomy should be performed. Fasciotomy involves incising the deep muscle fascia and is best carried out via longitudinal incisions of skin, fat and fascia (Figure 3.8). The muscle will then be seen bulging out through the fasciotomy opening. The lower limb can be decompressed via two incisions, each being lateral to the subcutaneous border of the tibia. This gives access to the two posterior compartments and to the peroneal and anterior compartments of the leg. In crush injuries that present several days after the event, a late fasciotomy can be dangerous because dead muscle produces myoglobin which, if suddenly released into the blood stream, causes myoglobinuria with glomerular blockage and renal failure. In the late treatment of lower limb injuries, therefore, it may be safer to amputate the limb once viable and non-viable tissues have been demarcated.

High-pressure injection injuries

The use of high-pressure devices in cleaning, degreasing and painting can cause extensive closed injuries through

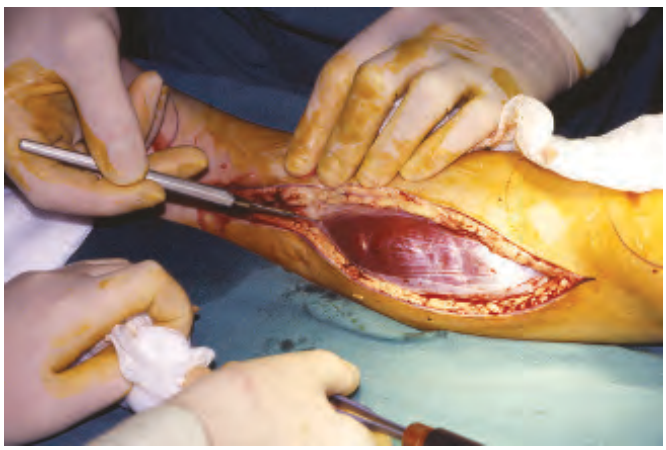

Figure 3.8 Fasciotomy of the lower leg.

small entry wounds. The liquid injected spreads along fascial planes, a common site being from finger to forearm. The tissue damage is dependent upon the toxicity of the substance and the injection pressure. Treatment is surgical, with wide exposure, removal of the toxic substance and thorough debridement. Preoperative x-rays may be helpful where air or lead-based paints can be seen. It should be noted that amputation rates following high-pressure injection injuries are reported as being over 45%. Delayed or conservative treatment is therefore inappropriate.

CHRONIC WOUNDS

A chronic wound may be defined as one that fails to heal in the expected time for a wound of that type, which is usually less than 3 weeks. Delays in healing can occur at any phase but most often occur in the inflammatory phase.

Leg ulcers

In resource-rich countries, the most common chronic wounds are leg ulcers. An ulcer can be defined as a break in the epithelial continuity. A prolonged inflammatory phase leads to overgrowth of granulation tissue, and attempts to heal by scarring leave a fibrotic margin. Necrotic tissue, often at the ulcer centre, is called slough. The more common aetiologies are listed in *Summary box 3.4*.

A chronic ulcer, unresponsive to dressings and simple treatments, should be biopsied to rule out neoplastic change, a squamous cell carcinoma known as a Marjolin's ulcer being the most common. Effective treatment of any leg ulcer depends on treating the underlying cause, and diagnosis is therefore vital. Arterial and venous circulation should be assessed, as should sensation throughout the lower limb. Surgical treatment is only indicated if non-operative treatment has failed or if the patient suffers from intractable pain. Meshed skin grafts **(Figure 3.7)** are more successful than sheet grafts and have the advantage of allowing mobilisation, as any tissue exudate can escape through the mesh. It should be stressed that the recurrence rate is high in venous ulceration, and patient compliance with a regime of hygiene, elevation and elastic compression is essential.

Summary box 3.4

Aetiology of leg ulcers

- Venous disease leading to local venous hypertension (e.g. varicose veins)
- Arterial disease, either large vessel (atherosclerosis) or small vessel (diabetes)
- Arteritis associated with autoimmune disease (rheumatoid arthritis, lupus, etc.)
- Trauma – could be self-inflicted
- Chronic infection – tuberculosis/syphilis
- Neoplastic – squamous or basal cell carcinoma, sarcoma

Pressure sores

These can be defined as tissue necrosis with ulceration due to prolonged pressure. Less preferable terms are bed sores, pressure ulcers and decubitus ulcers. They should be regarded as preventable but occur in approximately 5% of all hospitalised patients (range 3–12% in published literature). There is a higher incidence in paraplegic patients, in the elderly and in the severely ill patient. The most common sites are listed in *Summary box 3.5*.

A staging system for description of pressure sores devised by the American National Pressure Ulcer Advisory Panel is shown in *Table 3.2*.

Summary box 3.5

Pressure sore frequency in descending order

- Ischium
- Greater trochanter
- Sacrum
- Heel
- Malleolus (lateral then medial)
- Occiput

TABLE 3.2 Staging of pressure sores.

Stage	Description
1	Non-blanchable erythema without a breach in the epidermis
2	Partial-thickness skin loss involving the epidermis and dermis
3	Full-thickness skin loss extending into the subcutaneous tissue but not through underlying fascia
4	Full-thickness skin loss through fascia with extensive tissue destruction, maybe involving muscle, bone, tendon or joint

If external pressure exceeds the capillary occlusive pressure (over 30 mmHg), blood flow to the skin ceases, leading to tissue anoxia, necrosis and ulceration **(Figure 3.9)**. Prevention

Figure 3.9 Pressure ulcer.

Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

is obviously the best treatment, with good skin care, special pressure dispersion cushions or foams, the use of low air loss and air-fluidised beds and urinary or faecal diversion in selected cases. Pressure sore awareness is vital, and the bed-bound patient should be turned at least every 2 hours, with the wheelchair-bound patient being taught to lift themselves off their seat for 10 seconds every 10 minutes. It should be stressed that the most important treatment is to treat the cause of the pressure sore and that surgical treatment is a last resort often doomed to failure if the cause persists.

Surgical management of pressure sores follows the same principles involved in acute wound treatment (*Summary box 3.4*). The patient must be well motivated, clinically stable with good nutrition and adhere to the preventative measures advised postoperatively. Preoperative management of the pressure sore involves adequate debridement, and the use of vacuum-assisted closure (VAC) may help to provide a suitable wound for surgical closure (see below). The aim is to fill the dead space and to provide durable sensate skin. Large skin flaps that include muscle are best and, occasionally, an intact sensory innervated area can be included (e.g. extensor fascia lata flap with lateral cutaneous nerve of the thigh). If possible, use a flap that can be advanced further if there is recurrence and that does not interfere with the planning of neighbouring flaps that may be used in the future.

Vacuum-assisted closure

This is now more correctly known as negative pressure wound closure. Applying intermittent negative pressure of approximately −125 mmHg appears to hasten debridement and the formation of granulation tissue in chronic wounds and ulcers. A foam dressing is cut to size to fit the wound. A perforated wound drain is placed over the foam, and the wound is sealed with a transparent adhesive film. A vacuum is then applied to the drain (**Figure 3.10**). Negative pressure may act by decreasing oedema, by removing interstitial fluid and by increasing blood flow. As a result, bacterial counts decrease and cell proliferation increases, thereby creating a suitable bed for graft or flap cover.

Figure 3.10 Vacuum-assisted closure dressing of a large wound.

NECROTISING SOFT-TISSUE INFECTIONS

These are rare but often fatal. They are most commonly polymicrobial infections with Gram-positive aerobes (*Staphylococcus aureus*, *S. pyogenes*), Gram-negative anaerobes (*Escherichia coli*, *Pseudomonas*, *Clostridium*, *Bacteroides*) and beta-haemolytic *Streptococcus*. There is usually a history of trauma or surgery with wound contamination. Sometimes, the patient's own defence mechanisms may be deficient. These infections are characterised by sudden presentation and rapid progression. The fact that deeper tissues are involved often leads to a late or missed diagnosis (**Figure 3.11**). Clinical signs are shown in *Summary box 3.6*.

There are two main types of necrotising infections: clostridial (gas gangrene) and non-clostridial (streptococcal gangrene and necrotising fasciitis). The variant of necrotising fasciitis with toxic shock syndrome results from *Streptococcus pyogenes* and is often called the 'flesh-eating bug' in this situation. Treatment consists of appropriate antibiotics with wide surgical excision. Tissue biopsies are essential for histological

Summary box 3.6

Signs and symptoms of necrotising infections

- Unusual pain
- Oedema beyond area of erythema
- Crepitus
- Skin blistering
- Fever (often absent)
- Greyish drainage ('dishwater pus')
- Pink/orange skin staining
- Focal skin gangrene (late sign)
- Shock, coagulopathy and multiorgan failure

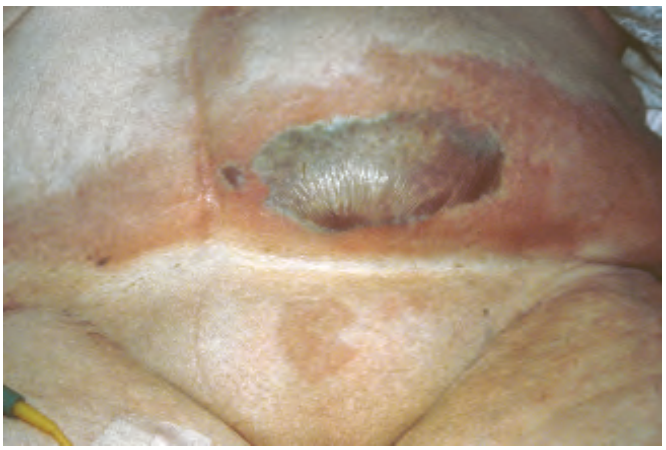

Figure 3.11 Necrotising fasciitis of the anterior abdominal wall.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

diagnosis and culture to obtain appropriate antibiotic sensitivity information. The raw areas resulting from excision often require skin grafting. Treatment is surgical excision, with tissue biopsies being sent for culture and diagnosis. Wide raw areas requiring skin grafting often result.

SCARS

The maturation phase of wound healing has been discussed above and represents the formation of what is described as a scar. The immature scar becomes mature over a period lasting a year or more, but it is at first pink, hard, raised and often itchy. The disorganised collagen fibres become aligned along stress lines with their strength being in their weave rather than in their amount (this has been compared with steel wool being slowly woven into a cable). As the collagen matures and becomes denser, the scar becomes almost acellular as the fibroblasts and blood vessels reduce. The external appearance of the scar becomes paler, while the scar becomes softer, flattens and its itchiness diminishes. Most of these changes occur over the first three months but a scar will continue to mature for one to two years. Tensile strength will continue to increase but would not be expected to exceed 60–80% that of normal skin.

Scars are often described as being atrophic, hypertrophic and keloid. An atrophic scar is pale, flat and stretched in appearance, often appearing on the back and in areas of tension. It is easily traumatised as the epidermis and dermis are thinned. Excision and resuturing may only rarely improve such a scar.

A hypertrophic scar is defined as excessive scar tissue that does not extend beyond the boundary of the original incision or wound. It results from a prolonged inflammatory phase of wound healing and from unfavourable scar siting (i.e. across the lines of skin tension). In the face, these are known as the lines of facial expression.

A keloid scar is defined as excessive scar tissue that extends beyond the boundaries of the original incision or wound (**Figure 3.12**). Its aetiology is unknown, but it is associated with elevated levels of growth factor, deeply pigmented skin, an inherited tendency and certain areas of the body (e.g. a triangle whose points are the xiphisternum and each shoulder tip).

The histology of both hypertrophic and keloid scars shows excess collagen with hypervascularity, but this is more marked in keloids where there is more type III collagen.

The treatment of both hypertrophic and keloid scars is difficult and is summarised in *Summary box 3.7*.

Hypertrophic scars improve spontaneously with time, whereas keloid scars do not.

Summary box 3.7

Treatment of hypertrophic and keloid scars

- Pressure – local moulds or elasticated garments
- Silicone gel sheeting (mechanism unknown)
- Intralesional steroid injection (triamcinolone)
- Excision and steroid injections[a]
- Excision and postoperative radiation (external beam or brachytherapy)[a]
- Intralesional excision (keloids only)
- Laser – to reduce redness (which may resolve in any event)
- Vitamin E or palm oil massage (unproven)

[a]All excisions are associated with high rates of recurrence.

AVOIDABLE SCARRING

If an acute wound has been managed correctly (see *Summary box 3.3*), most of the problems described above should not occur. However, the surgeon should always stress to the patient that there will be a scar of some description after wounding, be it planned or accidental. A dirt-ingrained (tattooed) scar is usually preventable by proper initial scrubbing and cleansing of the wound (**Figure 3.13**). Late treatment may require excision of the scar or pigment destruction by laser.

Mismatched or misaligned scars result from a failure to recognise normal landmarks, such as the lip vermilion/white roll interface, eyelid and nostril free margins and hair lines such as

Figure 3.12 Multiple keloid scars.

Figure 3.13 Dirt-ingrained scar.

Laser is an acronym for **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation. A laser is an intense beam of monochromatic light.

those relating to eyebrows and moustache. Treatment consists of excision and resuturing.

Poorly contoured scars can be stepped, grooved or pincushioned. Most are caused by poor alignment of deep structures such as muscle or fat, but trapdoor or pincushioned scars are often unavoidable unless the almost circumferential wound can be excised initially. Late treatment consists of scar excision and correct alignment of deeper structures or, as in the case of a trapdoor scar, an excision of the scar margins and repair using W or Z-plasty techniques.

Suture marks may be minimised by using monofilament sutures that are removed early (3–5 days). Sutures inserted under tension will leave marks. Wounds can be strengthened post suture removal by the use of sticky strips. Fine sutures (6/0 or smaller) placed close to the wound margins tend to leave less scarring. Subcuticular suturing avoids suture marks either side of the wound or incision.

CONTRACTURES

Where scars cross joints or flexion creases, a tight web may form restricting the range of movement at the joint. This may be referred to as a contracture and can cause hyperextension or hyperflexion deformity (**Figure 3.14**). In the neck, it may interfere with head extension (**Figure 3.15**). Treatment may be simple involving, multiple Z-plasties (**Figure 3.16**), or more complex, requiring the inset of grafts or flaps. Splintage and intensive physiotherapy are often required postoperatively.

Figure 3.14 Burn contractures showing hyperextended fingers and hyperflexed elbow.

Figure 3.15 Post-traumatic (chainsaw) midline neck contracture.

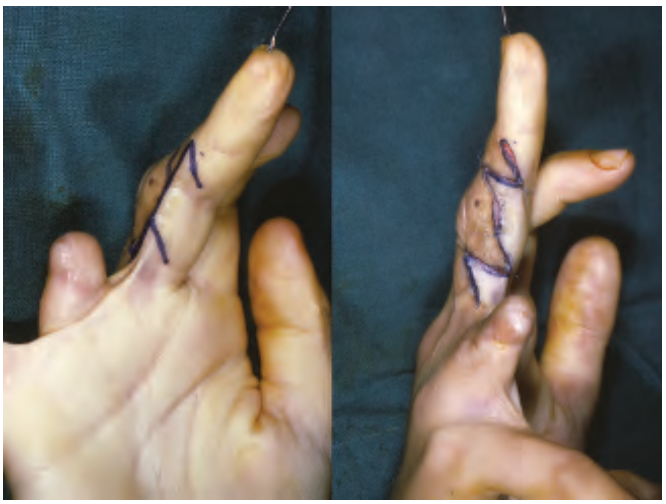

Figure 3.16 Multiple Z-plasty release of finger contracture.

Chapter 4

Tissue engineering and regeneration

Learning objectives

To understand:

- The potential opportunities afforded by tissue engineering and regenerative medicine
- The nature of stem cells, including somatic and adult stem cells, embryonic stem cells, fetal stem cells and induced pluripotent stem cells
- The role and range of scaffolds for tissue engineering
- The different approaches for seeding scaffolds and bioreactor technology
- The main safety issues and current limitations to clinical application

INTRODUCTION

Tissue engineering and regenerative medicine are relatively new but rapidly expanding multidisciplinary fields of clinical medicine, which have the potential to revolutionise the treatment of a wide range of human diseases. The ability of tissues to undergo spontaneous repair and regeneration is highly variable but in many cases very limited. Bone, for example, is one of the few tissues able to undergo effective regeneration, so long as the defective tissue is not too extensive. Adjacent cartilage, on the other hand, in common with most tissues, has little or no propensity for spontaneous regeneration, in terms of quality and quantity, following injury or arthritic disease. The limited ability of tissues to repair themselves has driven the desire to develop cell therapy and tissue engineering approaches to repair or replace diseased and damaged tissues. In most cases this involves the implantation of cells and tissues that have been expanded *in vitro* (outside the body), either as a cell therapy or with cells seeded into natural or synthetically based tissue scaffolds. However, cells (with or without expansion) and cellularised or cell-free scaffolds may also be implanted into areas of tissue injury with the aim of promoting *in vivo* (inside the body) regeneration and repair of tissues. This chapter provides a brief overview of tissue engineering and regenerative therapy, highlighting the opportunities, challenges and likely future directions.

OPPORTUNITIES

The potential impact of tissue engineering and regenerative therapies is so far-reaching that practising surgeons should be aware of the opportunities afforded to improve radically the management of patients. Stem cell therapy has the potential to provide treatment for a wide range of diseases, including spinal cord injury and neurodegenerative conditions, cardiovascular disease, degenerative retinal conditions, type I diabetes and diseases of the musculoskeletal system. The field of tissue engineering is of particular relevance to surgeons because many of the potential future clinical applications are for conditions where surgeons are closely involved in assessment and treatment (*Table 4.1*). Selected examples include

TABLE 4.1 Examples of tissues created by tissue engineering and conditions they may be used to treat.

Tissue	Conditions treated
Skin	Burns and skin defects after excision or trauma
Cardiac muscle	Heart failure
Heart valves	Congenital and acquired valvular heart disease
Cartilage	Degenerative and traumatic joint disorders
Trachea and bronchus	Congenital and acquired stenosis and resection for malignancy
Bladder	Congenital bladder malformation, and cystectomy
Anal/bladder sphincter	Incontinence
Pancreatic islets	Insulin-dependent diabetes
Large blood vessels	Atheromatous, aneurysmal and traumatic arterial disease
Oesophagus	Benign stenosis, and resection for malignancy
Small intestine	Intestinal failure after surgical resection for Crohn's disease, cancer or ischaemia

repair or replacement of injured or diseased cartilage, skin, pancreatic islets, bladder, intestine, heart tissue, arteries, larynx and bronchus. A longer-term goal in tissue engineering is the replacement of diseased whole organs such as the liver and kidney, although the technical challenges here are enormous.

Surgeons are integral to many of the multidisciplinary research teams currently undertaking translational research in the field and will play a vital role in the future delivery and assessment of many of the treatments based on tissue engineering and regenerative therapy. In addition to its direct therapeutic application, tissue engineering also has the potential to provide *in vitro* tissues that can be used to model human disease and to test therapeutic drugs for efficacy and toxicity. It is important to emphasise, however, that while the potential benefit of cell therapy and tissue engineering is undeniable, there are many technical, regulatory and safety issues to be addressed for it to have wide clinical impact.

Summary box 4.1

Tissue engineering and regenerative therapies have potential to provide:

- Treatment for a wide range of diseases
- Clinical applications in surgical assessment and treatment
- Models to test therapeutic efficacy and toxicity

THE KEY AREAS OF UNDERPINNING SCIENCE

Advances in both the biological and physical sciences underpin the fields of tissue engineering and regenerative therapy (**Figure 4.1**). In the biological sciences, new discoveries in stem cell biology have been key, particularly an understanding of the different types of stem cell, and how these can be derived and directed *in vitro* to differentiate into specialised cell types. In material sciences, major advances in the manufacture of scaffolds, on which to seed cells or to encourage specific interaction with host cells, have been key. In particular, design goals relate to scaffolds that possess both the physical and the biological characteristics that allow cells to create tissues, and potentially even organs, for therapeutic purposes. Key also have been engineering advances in the development of the many different types of bioreactors that provide an appropriate physical environment for growing engineered tissues *in vitro*, outside the body in the laboratory.

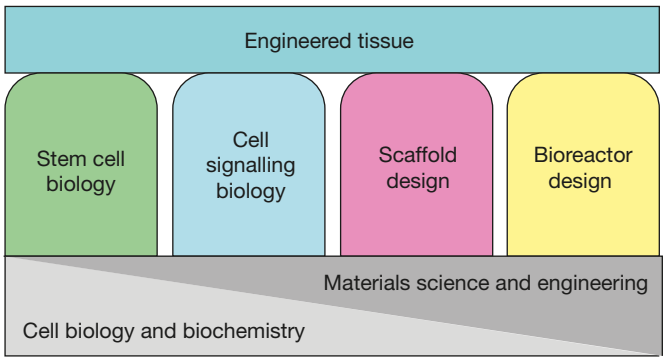

Figure 4.1 Underpinning science in tissue engineering and cell therapy.

There is considerable commercial interest in tissue engineering and regenerative therapy and this is contributing to the rapid pace of development in these areas. Notwithstanding the potential offered by these therapies, it should be emphasised that the whole field is still at a relatively early stage of development. While there are examples where tissue engineering and regenerative therapies have already been introduced into clinical practice (e.g. for repair of damaged cartilage), most potential regenerative therapies have not yet entered routine surgical practice, as there are considerable barriers to be overcome before this translational step can be achieved.

SOURCE OF CELLS FOR TISSUE ENGINEERING

Both fully differentiated cells (somatic cells) and stem cells are being used for tissue engineering and regenerative therapy, but most of the focus is on the use of stem cells, particularly somatic stem cells (SSCs) such as mesenchymal stem cells, and induced pluripotent stem cells (iPSCs). The major features of the different cell types are listed in *Table 4.2*.

Somatic cells

Fully differentiated specialised cells (somatic cells) obtained from normal tissues have been used for tissue engineering and

TABLE 4.2 Cells used in tissue engineering and regenerative therapy.

Cell type	Somatic cells	SSCs	hESCs	Fetal cells	iPSCs
Ease of availability	Limited	Good	Moderate	Moderate	Good
Expansion *in vitro*	Limited	Good	Excellent	Good	Excellent
Pluripotency	No	Limited	Excellent	Limited	Excellent
Ethical concerns	No	No	Yes	Yes	Yes*
Risk of malignancy	None	Low	Moderate	Moderate	Moderate
Autologous	Yes	Yes	No	No	Yes
Likely future use	Limited	High	Limited	Limited	High

hESCs, human embryonic stem cells; iPSCs, induced pluripotent stem cells; SSCs, somatic stem cells. *Note iPSCs avoid some of the ethical issues associated with hESCs.

regenerative therapy with some degree of success. For example, skin has been engineered using cultured epithelial cells grown *in vitro* and used to treat patients with burn injuries. Chondrocytes have been isolated, expanded *in vitro*, and implanted into areas of deficient cartilage in a procedure called autologous chondrocyte implantation. Bladder wall has also been engineered using a combination of smooth muscle cells and uroepithelial cells expanded *in vitro* and grown on a scaffold before reimplantation. Such tissues can be grown using cells obtained from the intended recipient by tissue biopsy (autologous cells) or using cells obtained from deceased unrelated donors (allogeneic cells). The major advantage of the former source is that after implantation they are not rejected by the recipient's immune system and hence there is no requirement for immunosuppression (see Chapter 82 for a description of immunosuppressive agents and their side effects).

For other indications, the use of fully differentiated specialised cells is not practical in most situations because such cells are not readily available in sufficient numbers and they have only limited proliferative ability *in vitro*, which means their numbers cannot be readily expanded to sufficient levels. To overcome these limitations, the major focus in the field of cell therapy has been on the use of stem cells.

Stem cells

Stem cells are undifferentiated or non-specialised cells that are able, through cell division, to renew themselves indefinitely. Crucially, they are also able, when provided with the appropriate stimuli, to differentiate into one or more of the different types of specialised cell found in tissues and organs. Because of their unique ability to undergo self-renewal when cultured *in vitro* and to be directed to differentiate into specialised cell types, they have enormous potential for use as cell-based therapies. There are several different types of stem cell with different characteristics, all of which have potential uses in regenerative medicine.

Stem cells can be classified according to whether they are derived from the early embryo (embryonic stem cells), tissues from the fetus (fetal stem cells), later in development (adult or somatic stem cells) or whether they are derived by reprogramming adult specialised cells to become pluripotent stem cells (iPSCs).

Adult tissue resident or somatic stem cells (SSCs)

Stem cells resident in the different tissues and organs are responsible for providing replacements for specialised cells that have reached the end of their functional lifespan either through natural attrition or because of damage and disease. In certain tissues and organs, notably the bone marrow and gut, stem cells regularly divide and differentiate into specialised cells to replace senescent or damaged cells in the blood and the gastrointestinal mucosa, respectively. Stem cells in other organs, such as the heart or central nervous system, are less able to effect repair or replacement. SSCs have the capacity to differentiate into a limited number of specialised cell types (i.e. they are multipotent). Among the best characterised types of SSCs are haematopoeitic stem cells, mesenchymal stem or stromal cells (MSCs), endothelial progenitor cells and neural stem cells. While haematopoeitic stem cells are widely used for treatment of haematological malignancies, the somatic stem cell type that has been most widely used for tissue engineering and regenerative therapy is the MSC.

Mesenchymal stem and stromal cells

MSCs are multipotent stromal cells that can be sourced from a variety of tissues, including bone marrow, adipose tissue and umbilical cord. Morphologically they resemble fibroblasts. They are adherent to plastic, express certain cell surface markers (CD105, CD73 and CD90), and do not express the cell surface markers associated with haematopoietic stem cells (such as CD34 and CD45). MSCs were initially shown to have the ability to be directed to differentiate into a variety of specialised cell types of the mesodermal lineages, including osteoblasts, chondrocytes, adipocytes, tenocytes and myocytes **(Figure 4.2)**. Recent studies suggest that they may also be directed into cells of the ectoderm and endoderm lineages.

Of further clinical importance, MSCs have potent trophic and anti-inflammatory properties, attributable to their ability to produce growth factors (including vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF), hepatocyte growth factor (HGF)), and prostaglandin E2. MSCs for therapeutic use can be isolated from bone marrow (iliac crest aspiration) or from subcutaneous fat (liposuction) which is less invasive and gives a high yield of MSCs. In both cases, MSCs are isolated *in vitro* on the basis of their adherence to plastic. They can then be used either immediately, or after expansion of their numbers by *in vitro* culture. Alternatively, MSCs can be differentiated into the desired lineage *in vitro* by addition of suitable growth factors and chemicals.

The relative ease of cell acquisition has meant that autologous MSCs have been used clinically in a variety of settings such as treatment of burns and to repair defects in cartilage. More clinical evidence is required in terms of efficacy and mechanism of action, as it is not entirely clear whether a given clinical effect resulting from MSC administration is attributable to their ability to contribute directly to tissue regeneration, or due to immunomodulatory and paracrine effects resulting from their ability to release trophic mediators that promote tissue repair by recipient cells **(Figure 4.2)**.

Embryonic stem cells (ESCs)

In the embryo, stem cells are able to give rise to all of the different cell types of the body (i.e. they are totipotent). ESCs are obtained from the inner cell mass of the early human blastocyst (days 4–5 after fertilisation) using embryos that have been created through *in vitro* fertilisation for treatment of infertility, and are surplus to those needed for reimplantation. The technique for isolating and growing hESCs in culture was developed by James Thompson at the University of Wisconsin, Madison, USA in 1998.

ESCs have much greater proliferative ability than MSCs and, as already noted, can differentiate into all types of specialised cells, unlike MSCs. However, their use has major

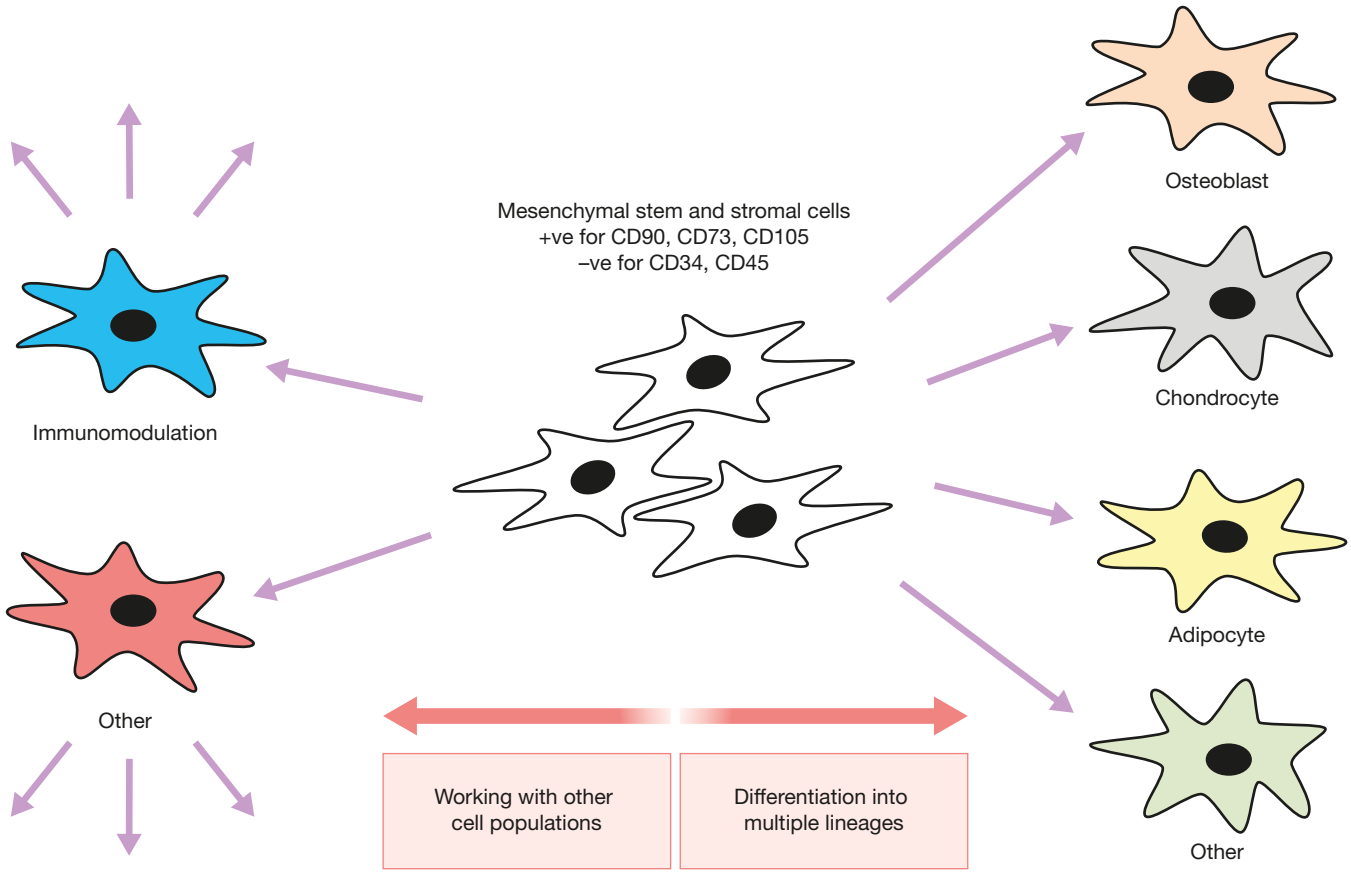

Figure 4.2 Proposed characteristics of mesenchymal stem and stromal cells relevant to tissue engineering and regenerative medicine.

limitations, one of which is ethical. The surplus embryos used for derivation of ESCs would otherwise be discarded, but because they need to be destroyed to obtain ESCs the approach has raised major ethical and political debate. The dominant view in many countries, including the UK, is that the potential therapeutic benefits of ESCs justify their use but there are very strict guidelines for their derivation, and to date their clinical use has been very limited. Cells from ESCs would be allogeneic and therefore be at risk of immunological rejection. It would, in principle, be possible to produce ESCs that were autologous for an intended recipient by the process of somatic cell nuclear transfer, i.e. transferring the nucleus from a somatic cell of the intended recipient into an oocyte that has had its nucleus removed. The transferred somatic cell nucleus, containing the human leukocyte antigen (HLA) genes and all of the other genetic information from the donor, is turned into a pluripotent stem cell that can be used as cell therapy for the donor of the nucleus.

Fetal stem cells

Stem cells can also be obtained from the blood, bone marrow and other tissues of aborted fetuses (fetal stem cells). These proliferate *in vitro* as efficiently as ESCs and are pluripotent. They have been used as cell therapy in a variety of clinical settings, including Parkinson's disease, diabetes and spinal cord injury. In some studies they showed early promise but the magnitude of any clinical benefits is controversial. The use of fetal stem cells also poses ethical challenges, although perhaps not to the extent seen with ESCs.

Induced pluripotent stem cells (iPSCs)

The discovery in 2006 by Shinya Yamanaka, building on the earlier work of John Gurdon, that certain types of specialised adult cells could be reprogrammed using genetic manipulation to become embryonic-like iPSCs was a major breakthrough. Using retroviral or lentiviral transfection to introduce a combination of transcription factors (OCT3/4, SOX2, and either Kruppel-like factor and C-MYC (together designated the OSKM reprogramming factors) or NANOG and LIN28), it was shown that specialised somatic cells can be reprogrammed to become stem cells. Moreover, iPSCs proliferate *in vitro* as efficiently as ESCs and are pluripotent, thereby circumventing concerns about the use of human embryos. Importantly, the development of iPSCs also means that, at least in principle, an intended recipient of stem cell therapy can themselves provide a source of stem cells (e.g. from a skin biopsy or blood sample) that can then be directed to differentiate into the desired specialised cell type for therapy; because such cells would be autologous they would not provoke an immunological rejection response (**Figure 4.3**). Alternatively, iPSCs could be obtained from a number of volunteer donors selected on the basis of their

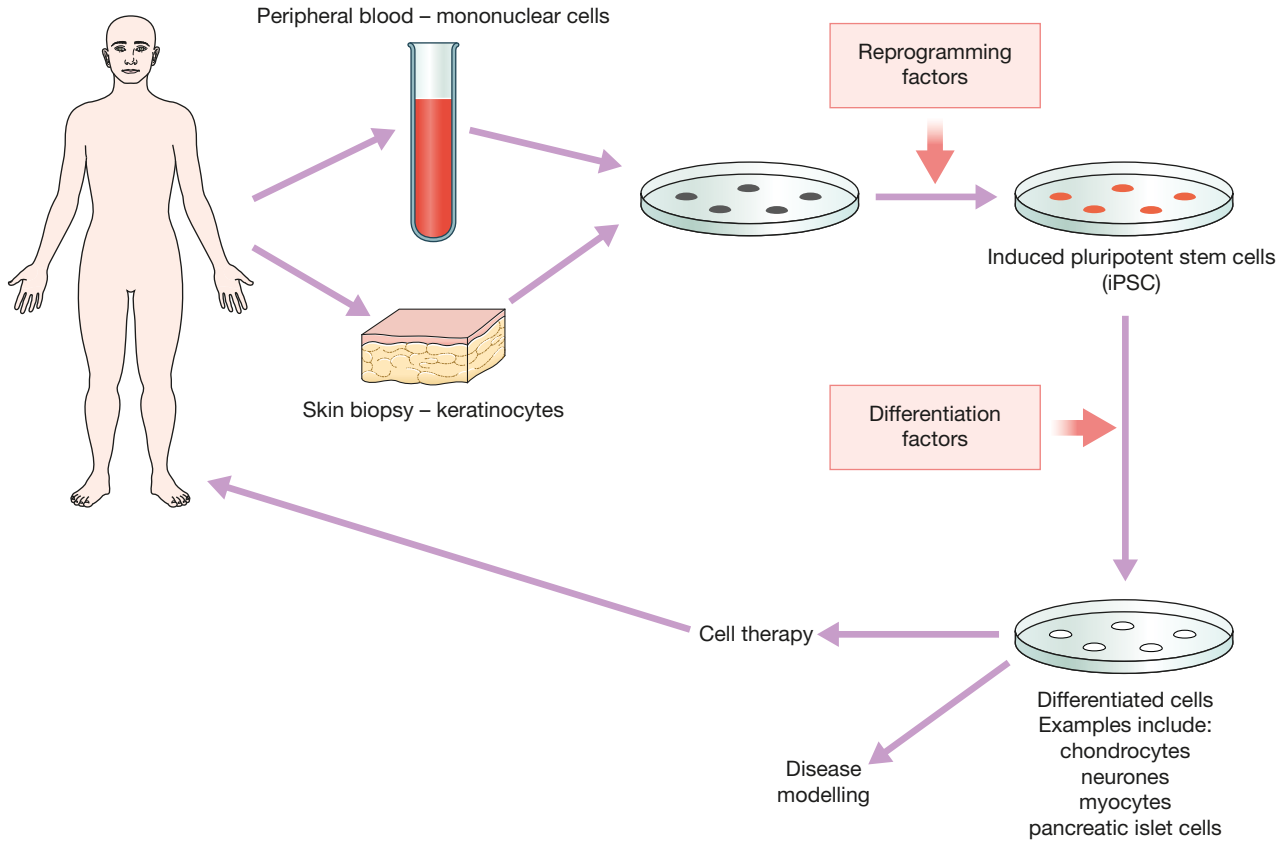

Figure 4.3 Schematic diagram showing the principles of iPSC therapy. Mononuclear cells from peripheral blood or keratinocytes from a skin biopsy are cultured *in vitro* and then reprogrammed to become iPSC by addition of reprogramming factors. The iPSC are then expanded, and selected differentiation factors added to promote differentiation of iPSCs into the desired specialised cell type for use as therapy.

HLA type and stored to create a national or international tissue bank of iPSCs. Lines of iPSCs could then be chosen from the bank to provide a fully or partially matched cell transplant for recipients, eliminating or reducing the need for immunosuppression to prevent immunological rejection.

One of the problems of reprogramming somatic cells to become iPSCs using retroviruses is that genomic integration of the virus may lead to activation of oncogenic genes, causing tumorigenesis. To reduce this risk, non-retroviral vectors have been used (such as adenovirus and Sandai virus vectors, that do not insert their own genes into the host cell genome), or plasmids, episomal vectors and synthetic RNA. There has also been much recent progress in identifying combinations of small molecules, growth factors and chemicals that mimic the effect of viral transfection with transcription factors and obviate the need for viral vectors altogether. The production process from sourcing cells (e.g. skin fibroblasts or peripheral blood mononuclear cells) to obtaining an adequate number of validated iPSCs may take several weeks.

In vitro differentiation of stem cells to specialised tissue cells

There is an enormous research effort aimed at better understanding the factors responsible for cell fate decisions, and establishing effective and reproducible protocols that can be used to differentiate stem cells *in vitro* into the desired type of specialised cell. Typically such protocols use culture in chemically defined media containing cocktails of small molecules that stimulate or inhibit key signalling pathways, along with cytokines, growth factors and chemicals. Many protocols include the addition of critical amounts of Activin, bone-morphogenetic protein-4 (BMP4) and fibroblast growth factor-2 (FGF2) at specific time points during culture, but protocols vary widely. For example, exposure of iPSCs to a combination of retinoic acid and BMP4 promotes differentiation along the ectoderm and then the keratinocyte lineage. Alternatively, culture of iPSCs on a Matrigel® scaffold in defined media supplemented with ascorbic acid and exposed sequentially to a glycogen synthase kinase (GSK) inhibitor followed by an inhibitor of Wnt signalling promotes the development of immature cardiomyocytes.

It is becoming increasingly clear that exposure to certain biomaterials and the physical attributes of a scaffold, including its surface characteristics, also promote stem cell differentiation along a particular lineage. Mechanical stress also influences cell fate decisions.

Protocols for differentiation often promote stem cells to differentiate in steps through intermediate stages that mirror normal *in vivo* development. In other words, sequential exposure to different factors is used first to differentiate ESCs or

iPSCs into either endoderm, mesoderm or ectoderm lineages, followed by further differentiation into the specific lineage desired. After stem cells have been subjected to *in vitro* differentiation, it is essential that the purity of the differentiated cells and the absence of undifferentiated stem cells are confirmed, to reduce the risk of tumour transmission. The cells must also be fully phenotyped and their function confirmed before they are used for therapeutic purposes.

SCAFFOLDS FOR TISSUE ENGINEERING

The complex anatomical arrangement of the different cell types in tissues and organs is absolutely integral to their normal function, and the importance of structural integrity is evident in many diseases where deranged tissue structure and tissue remodelling is associated with a failure in function. Stem cells and their progeny are able, when cultured under conventional tissue culture conditions, to form cell sheets or small three-dimensional collections of cells (organoids), but they are not able under such conditions spontaneously to assume the complex anatomical relationships seen in normal tissues. To do so they need to be provided with an appropriate scaffold that gives physical support and shape to the engineered tissue, mimicking extracellular matrix. This allows cells to attach, and delivers the cell signals necessary to guide the cell growth, migration and differentiation to form a functional tissue. Tissue engineering typically utilises rigid or semi-rigid scaffolds (usually three-dimensional) that are porous (**Figure 4.4**) and act as templates on which to seed donor cells and guide them to restore a functional tissue or organ that can then be implanted in the recipient. Scaffolds may be derived from intact human tissue (natural scaffolds) or from engineered implantable biomaterials (artificial scaffolds). The general requirements that a scaffold must provide are listed in *Table 4.3*, and the choice of scaffolds that best fulfils the requirements for tissue engineering will depend on the nature of the tissue to be engineered.

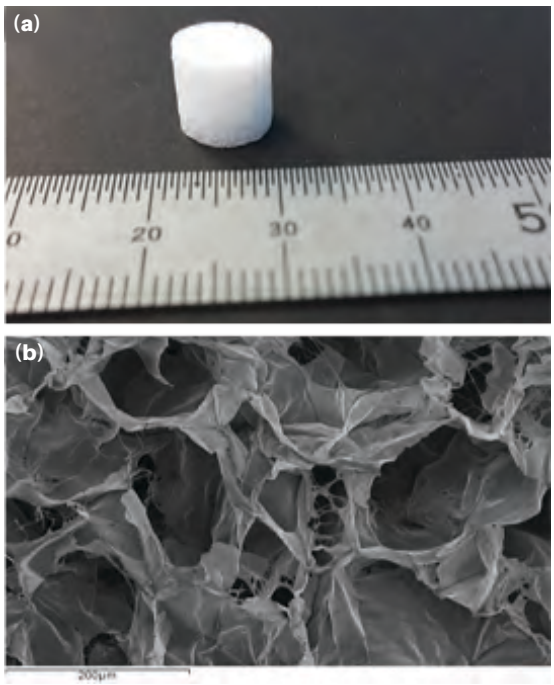

Figure 4.4 An example of a porous scaffold in research development, manufactured using collagen. **(a)** Macroscopic view of collagen scaffold. **(b)** Overview of a scanning electron microscopy (SEM) image that shows the structure of collagen scaffold (courtesy of Prof S Best and Prof R Cameron, University of Cambridge).

TABLE 4.3 Requirements of a scaffold used in tissue engineering.

Provide structural support for cells
Allow cells to attach, migrate and proliferate
Enable oxygen, nutrients and regulatory factors access to all cells
Deliver signals to promote cell migration and proliferation
Biocompatible, non-immunogenic and ideally biodegradable

Summary box 4.2

Regenerative scaffolds can:

- Provide physical support and shape to the engineered tissue
- Guide cell growth, migration and differentiation
- Be natural or artificial

Natural scaffolds

Natural scaffolds may be obtained by treatment of human (or other animal) tissues or organs to remove the resident cell types, leaving behind the extracellular matrix that preserves the intricate architecture of the tissue or organ, onto which to seed new cells. Natural scaffolds not only act as a physical scaffold that allows the natural architecture of the tissue to be preserved, but they may also provide key cell signals that guide the growth and differentiation of the cells used to repopulate the scaffold. Typically, natural scaffolds are obtained either by immersing tissues in detergent or perfusing them with detergent via the arterial tree. This effectively destroys most or all of the cellular elements of the tissue or organ but leaves the collagen-rich extracellular matrix largely intact. Variable protocols have been used successfully to achieve decellurisation, and the optimal approach probably varies according to the type of tissue or organ being used to create the scaffold. The use of natural scaffolds may be particularly suited to certain applications where deceased donor tissue is relatively easy to source, for example to engineer lengths of trachea. The use of natural scaffolds to engineer whole organs such as the kidney or liver has the advantage that the extremely intricate three-dimensional structure of the organ is preserved and this would be extremely challenging to achieve using engineered biocompatible materials. Moreover, decellularised organ scaffolds provide an opportunity to repopulate the scaffold with autologous cells derived from the potential recipient to create an organ that is not susceptible to immunological rejection, thereby avoiding the need for immunosuppressive drugs and their attendant side effects. However, a significant

disadvantage of using decellularised scaffolds to engineer whole organs is the need to use a whole human organ for each organ to be engineered; the availability of such organs is likely to be limited.

Summary box 4.3

Natural scaffolds:

- Can be prepared by removal of the resident cell types from tissue, for example with detergent
- Consist of tissue extracellular matrix, which can preserve intricate anatomical structures

Artificial scaffolds

The materials used to create artificial scaffolds are highly variable, and new materials are being developed continually. Different scaffold characteristics are required for engineering different types of tissue but all scaffolds need to be biocompatible and in most settings they should be biodegradable and bioreabsorbable. Scaffolds encompass both natural and synthetic materials. Natural materials used include various polysaccharides, collagen, fibrin, gelatin and cellulose, while synthetic materials include various synthetic polymers such as polylactide (PLA) and polyglycolide (PGA), and graphene. Bioactive ceramics such as calcium phosphates (e.g. hydroxyapatite) and bioactive glasses have been widely used for skeletal repair. Synthetic biodegradable polymers are commonly used and have the advantage that they can be produced under standard conditions that ensure reproducible physical characteristics. Scaffolds can also be fabricated using a blend of natural and synthetic components to optimise their performance.

Most artificial scaffolds are fabricated with a porous three-dimensional structure, and a wide variety of designs are in use. The application of computational design and three-dimensional printing technology has revolutionised the development of artificial scaffolds. Hydrogel scaffolds composed of cross-linked hydrophilic polymers are also increasingly used in tissue engineering because of their favourable physical and chemical characteristics. They are able to absorb very large amounts of aqueous fluid while maintaining their three-dimensional shape and structural integrity. They are fabricated from naturally occurring (e.g. collagen and fibrin) or artificial (egg PLA) cross-linked polymers and can be impregnated with growth factors to promote cellularisation.

Electrospinning technology is being utilised increasingly to produce scaffolds composed of fibres with a diameter at the nanoscale level. The fibres can be spun using blends of different synthetic polymers or blends of synthetic and natural polymers, depending on the desired characteristics of the scaffold. Scaffolds based on microspheres have also been utilised. Recent developments in materials science have led to the creation of increasingly complex and innovative artificial scaffolds for tissue engineering, including composite materials (e.g. combining ceramics with polymers to gain the advantages of each), and the production of so called 'smart scaffolds' having biomimetic properties that provide biophysical cues or cellular signals to instruct and guide cell behaviour.

Historically, a limitation of traditional artificial scaffolds is that they do not incorporate a vasculature that can be used in the potential recipient to restore the vascular integrity of the transplanted tissue or organ. However, recent innovations that allow a vascular network to be created by three-dimensional printing suggest that this limitation may be overcome. Such technology also allows the design and production of scaffolds that have the structural properties (e.g. pore size and diffusion characteristics) needed to provide the necessary cues for cell differentiation and migration. Artificial scaffolds can be engineered to incorporate molecules that aid retention of particular cell growth factors, including angiogenic growth factors such as vascular endothelial growth factor (VEGF), to provide a local environment conducive to the growth of a functional tissue construct.

Summary box 4.4

Artificial scaffolds include:

- Natural materials, synthetic polymers, bioactive ceramics and glasses
- New or 'smart' materials that have biomimetic properties

Approaches to cell seeding of scaffolds and bioreactors

Cellularisation of scaffolds can be achieved *in vitro* (outside the body) by a variety of methods and the most appropriate seeding system may to some extent depend on the type of tissue being engineered (*Table 4.4*). This is a rapidly developing area and it is only possible here to outline the principles of different approaches to cell seeding. The aim is to achieve a rapid seeding of viable cells with high seeding efficiency and uniform and effective penetration of cells into the scaffold. Some systems incorporate mechanisms to deliver mechanical stress or electrical stimulation to promote cellularisation.

The most simple but possibly least effective method is static cell seeding, where a concentrated cell suspension is placed in direct contact with the scaffold. The seeding efficiency and penetration of cells into the scaffold are generally low, although scaffolds can be coated with various agents to increase the efficiency of cell attachment.

Dynamic cell seeding techniques include a range of systems in which either the scaffold is rotated in the medium containing the cells or both the scaffold and cell suspension are rotated together. Rotation in some systems occurs at

TABLE 4.4 Approaches for seeding cells into scaffolds.

Static cell seeding
Dynamic cell seeding
Magnetic cell seeding
Pressure and vacuum seeding
Photopolymerised hydrogels
Bioreactor perfusion systems

a sufficiently high speed to generate centrifugal forces. Dynamic seeding techniques increase seeding efficiency, shorten the duration of the culture period needed and may help penetration of cells into the scaffold.

Magnetic cell seeding makes use of magnetic forces to direct cells into the scaffold. Essentially, the cells are first labelled, either by using supramagnetic microbeads coated with a ligand that specifically binds to molecules on the cell surface or by culturing them with cationic liposomes that contain supramagnetic ferrous particles. Magnets are then used to attract the cells into the scaffold. This enables rapid seeding of the scaffold but a potential concern is that the magnetic particles used may have adverse effects.

Photopolymerised hydrogel scaffolds offer a completely different approach to cell seeding. Essentially, the cells are suspended in an aqueous monomer solution and ultraviolet light is used to promote polymerisation of the hydrogel scaffold. Alternatively, to increase cell adherence to the surface of polymerised hydrogel scaffolds, an arginine–glycine–aspartic acid adhesion peptide can be incorporated.

Another approach to cell seeding uses differential pressure or vacuum seeding systems to force cells into the pores of the scaffold. Again this reduces the time needed to seed cells but the pressures used may potentially reduce cell viability.

Finally, one of the more complex approaches to cell seeding is to use scaffold perfusion systems. These may take the form of bioreactor perfusion systems for tissue engineering, or whole organ perfusion systems in the case of decellularised organ scaffolds.

CHALLENGES TO ENGINEERING TISSUE *IN VITRO*

There are many technical challenges to successful engineering of tissues *in vitro*. Delivery of adequate oxygen and nutrients uniformly to three-dimensional tissue constructs is problematic, as is ensuring that the varying nutritional and growth requirements of different cell types grown simultaneously are met.

The difficulties of tissue engineering vary considerably according to the nature of the tissue or organ being engineered. Flat tissues such as skin, cornea and cartilage present fewer problems than complex tubular structures such as trachea, bronchus and blood vessels. Hollow organs, such as bladder and gut, present a much greater challenge, and complex solid organs such as the liver and kidney present the greatest challenge of all. Obtaining adequate numbers of differentiated cells, maintaining their viability and ensuring that they maintain their function and do not revert to undesirable cell types are all important challenges.

IMPLANTATION OF ENGINEERED TISSUE

Irrespective of the nature of the engineered scaffold and the cell types used to populate it, after it is implanted it will only effect successful repair if it becomes fully integrated into adjacent normal tissue and can be remodelled appropriately in the recipient. An important consideration that is often not addressed sufficiently is that many tissues in the body, notably tissues in the musculoskeletal system and the cardiovascular system, are subject to considerable mechanical stress. Engineered tissues are not subjected to relevant mechanical stresses during their fabrication *in vitro* and their behaviour in response to mechanical loading after implantation is a major determinant of their ability to perform successfully. The development of innovative high-resolution three-dimensional imaging techniques to evaluate engineered tissue before and after implantation is key to refining the design of engineered tissues and assessing their functional integration after implantation.

SAFETY CONCERNS

The major safety concerns of cell-based therapy and tissue engineering are listed in *Table 4.5*. One of the most serious concerns is that of tumour formation and malignant transformation. The risk of tumour formation varies according to the cell type used, the genetic modification strategy used to transform the stem cells, the site of transplantation and whether the cells are autologous or allogeneic. The direct risk of tumour formation by the transplanted cells relates specifically to ESCs and iPSCs and there appears to be little risk with SSCs. The ability of stem cells to form teratomas is one of the hallmarks of pluripotency, and the risk of this happening following stem cell therapy may be reduced by ensuring that only cells that have been fully differentiated *in vitro* and not those that are still pluripotent are used for therapy. The risk of malignancy may also be reduced by the choice of *in vitro* strategy used to differentiate stem cells prior to use: use of viral vectors that do not integrate into the genome or of non-viral approaches to differentiation reduces the risk of malignant transformation. There is also interest in developing techniques for directly reprogramming somatic cells to adopt the function of a different cell type without having to make them first revert back to the pluripotent state – so-called transdifferentiation.

Another major concern is that of transmitting infection. It is essential that if allogeneic stem cells are used they are screened to exclude infection and that cells and engineered tissues are prepared according to Good Manufacturing Practice (GMP) guidelines to avoid bacterial infection during in vitro culture prior to use. As already noted, if allogeneic stem cells are used for tissue engineering and regenerative therapy they may be susceptible to graft rejection, and immunosuppressive therapy may be necessary.

TABLE 4.5 Risks of cell-based therapy.

Tumour formation
Genetic and epigenetic abnormalities
Transmission of infection
Poor viability and loss of function
Differentiation to undesired cell-types
Rejection (allogeneic cells)
Side effects of immunosuppression (allogeneic cells)

FUTURE DIRECTIONS

Tissue engineering and regenerative strategies hold out great hope for effectively repairing or replacing tissues in a wide number of human diseases. The field is moving rapidly, underpinned by new developments in stem cells and scaffold design. The use of mesenchymal stem and stromal cell based therapies and iPSC based therapies is likely to dominate, in conjunction with improved bioactive scaffold designs that can be reproducibly manufactured and seeded, sometimes with multiple cell types, by sophisticated bioreactors that incorporate dynamic culture systems.

It is likely that patient stratification will further refine therapy options. The ability to phenotype, to genotype and to profile patients at a molecular level will allow more detailed characterisation of patient subgroups and staging of disease. This would refine the surgical approach to many diseases, including regenerative procedures.

Over the next decade it is likely that major advances will be made in the clinical translation of tissue engineering and regenerative therapies across a broad range of applications. Numerous clinical studies are currently being undertaken, many with promising early results, and the number of studies is set to rise considerably. However, caution is required and there are many examples where engineered tissues have failed to live up to their early promise. The pace of development is so rapid that regulatory authorities will have difficulty keeping up.

It is important that the clinical use of tissue engineering is subject to rigorous evaluation, and that novel developments are only used in the context of appropriate clinical trials where the potential benefits and limitations are fully examined before they are introduced into routine clinical practice. The field is becoming increasingly commercialised and the cost and practicality of regenerative therapies, especially personalised autologous therapies, will need to be addressed.

Chapter 5

Surgical infection

Learning objectives

To understand:
- The characteristics of the common surgical pathogens and their sensitivities
- The factors that determine whether a wound will become infected
- The classification of sources of infection and their severity
- The clinical presentation of surgical infections
- The indications for and choice of prophylactic antibiotics
- The spectrum of commonly used antibiotics in surgery and the principles of therapy

To learn:
- Koch's postulates
- The management of abscesses

To appreciate:
- The importance of aseptic and antiseptic techniques and delayed primary or secondary closure in contaminated wounds

To be aware of:
- The causes of reduced resistance to infection (host response)

To know:
- The definitions of infection, particularly at surgical sites
- What basic precautions to take to avoid surgically relevant hospital acquired infections

HISTORY OF SURGICAL INFECTION

Surgical infection, particularly surgical site infection (SSI), has always been a major complication of surgery and trauma and has been documented for 4000–5000 years. The Egyptians had some concepts about infection, as they were able to prevent putrefaction using their skills in mummification. Their medical papyruses also describe the use of salves and antiseptics to prevent SSIs. This 'prophylaxis' had also been known earlier by the Assyrians, although less well documented. It was described again independently by the Greeks. The Hippocratic teachings described the use of antimicrobials, such as wine and vinegar, which were widely used to irrigate open, infected wounds before delayed primary or secondary wound closure. A belief common to all these civilisations, and indeed even later to the Romans, was that, whenever pus was localised in an infected wound, it needed to be drained.

Galen recognised that this localisation of infection (suppuration) in wounds inflicted in the gladiatorial arena often heralded recovery, particularly after drainage (*pus bonum et laudabile*). Sadly, this dictum of laudable pus was misunderstood by many later healers, who thought that it was the production of pus that was desirable. Until well into the Middle Ages, some practitioners promoted suppuration in wounds by the application of noxious substances, including faeces, in the misguided belief that healing could not occur without pus formation. Theodoric of Cervia, Ambroise Paré and Guy de Chauliac observed that clean wounds, closed primarily, could heal without infection or suppuration.

An understanding of the causes of infection came in the nineteenth century. Microbes had been seen under the

Hippocrates was a Greek Physician, and by common consent 'The Father of Medicine'. He was born on the Greek island of Cos off Turkey about 460 BC and probably died in 375 BC.

Galen, 130–200, Roman physician, commenced practice as Surgeon to the Gladiators at Pergamum (now Bregama in Turkey) and later became personal physician to the Emperor Marcus Aurelius and to two of his successors. He was a prolific writer on many subjects, amongst them anatomy, medicine, pathology and philosophy. His work affected medical thinking for 15 centuries after his death. (Gladiator is Latin for 'swordsman'.)

Theodoric of Cervia. Theodoric, 1210–1298, Bishop of Cervia, published a book on surgery ca. 1267.

Ambroise Paré, 1510–1590, French military surgeon, also worked at the Hotel Dieu, Paris, France.

Guy de Chauliac, ?1298–1368, physician and chaplain to Pope Clement VI at Avignon, France and the author of *Chirurgia Magna*, which was published about 1363.

microscope, but Koch laid down the first definition of infective disease (Koch's postulates). Koch's postulates do not cover every eventuality though. Organisms of low virulence may not cause disease in normal hosts but may be responsible for disease in immunocompromised hosts. Some hosts may develop subclinical disease and yet still be a carrier of the organism capable of infecting others. Also, not every organism that causes disease can be grown in culture, the commonly quoted one being *Mycobacterium leprae* which causes leprosy.

Summary box 5.1

Koch's postulates proving whether a given organism is the cause of a given disease

- It must be found in every case
- It should be possible to isolate it from the host and grow it in culture
- It should reproduce the disease when injected into another healthy host
- It should be recovered from an experimentally infected host

The Austrian obstetrician Ignac Semmelweis showed that puerperal sepsis could be reduced from over 10% to under 2% by the simple act of hand washing between cases, particularly between postmortem examinations and the delivery suite. He was ignored by his contemporaries and died at the age of 47 in an insane asylum before the value of his work was accepted two decades later with the recognition that infections were caused by microbes.

Louis Pasteur recognised through his germ theory that microorganisms were responsible for infecting humans and causing disease. Joseph Lister applied this knowledge to the reduction of colonising organisms in compound fractures by using antiseptics. The principles of antiseptic surgery were soon enhanced with aseptic surgery at the turn of the twentieth century. As well as killing the bacteria on the skin before surgical incision (antiseptic technique), the conditions under which the operation was performed were kept free of bacteria (aseptic technique). This technique is still employed in modern operating theatres.

The concept of a 'magic bullet' (*Zauberkugel*) that could kill microbes but not their host became a reality with the discovery of sulphonamide chemotherapy in the mid-twentieth century. The discovery of the antibiotic penicillin is attributed to Alexander Fleming in 1928, but it was not isolated for clinical use until 1941, by Florey and Chain. The first patient to receive penicillin was Police Constable Alexander in Oxford. He scratched his mouth while pruning roses and developed abscesses of the face and eyes leading to a severe staphylococcal bacteraemia. He responded to treatment and made a partial recovery before the limited batch of penicillin ran out, following which he relapsed and died. Since then there has been a proliferation of antibiotics with broad-spectrum activity and antibiotics today remain the mainstay of antimicrobial therapy.

Many staphylococci today have become resistant to penicillin. Often bacteria develop resistance through the acquisition of β-lactamases, which break up the β-lactam ring present in the molecular structure of many antibiotics. The acquisition of extended spectrum β-lactamases (ESBLs) is an increasing concern in some gram-negative organisms that cause urinary tract infections because it is difficult to find an antibiotic effective against them. In addition, there is increasing concern about the rising resistance of many other bacteria to antibiotics, in particular the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) and glycopeptide-resistant enterococci (GRE), which are also relevant in general surgical practice.

The introduction of antibiotics for prophylaxis and for treatment, together with advances in anaesthesia and critical care medicine, has made possible surgery that would not previously have been considered. Faecal peritonitis is no longer inevitably fatal, and incisions made in the presence of such contamination can heal primarily without infection in over 90% of patients with appropriate antibiotic therapy. Despite this, it is common practice in many countries to delay wound closure in patients in whom the wound is known to be contaminated or dirty. Waiting for the wound to granulate and then performing a delayed primary or secondary closure may be considered a better option in such cases.

Summary box 5.2

Advances in the control of infection in surgery

- Aseptic operating theatre techniques have enhanced the use of antiseptics
- Antibiotics have reduced postoperative infection rates after elective and emergency surgery
- Delayed primary, or secondary, closure remains useful in heavily contaminated wounds

Surgical site infection in patients who have contaminated wounds, who are immunosuppressed or who are undergoing prosthetic surgery is now the exception rather than the rule since the introduction of prophylactic antibiotics. The evidence for this is of the highest level. The use of prophylactic

Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his 'Postulates' in 1882.
Ignac Semmelweis, 1818–1865, Professor of Obstetrics, Budapest, Hungary.
Louis Pasteur, 1822–1895, French chemist, bacteriologist and immunologist, Professor of Chemistry at the Sorbonne, Paris, France.
Joseph Lister (Lord Lister), 1827–1912, Professor of Surgery, Glasgow, Scotland (1860–1869), Edinburgh, Scotland (1869–1877) and King's College Hospital, London (1877–1892).
Sir Alexander Fleming, 1881–1955, Professor of Bacteriology, St Mary's Hospital, London, England, discovered *Penicillium notatum* in 1928.
Howard Walter Florey (Lord Florey of Adelaide), 1898–1968, Professor of Pathology, the University of Oxford, Oxford, England.
Sir Ernst Boris Chain, Professor of Biochemistry, Imperial College, London, England. Fleming, Florey and Chain shared the 1945 Nobel Prize for Physiology or Medicine for their work on penicillin.
Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

antibiotics in clean, non-prosthetic surgery is of less value as infection rates are low and the indiscriminate use of antibiotics simply encourages the emergence of resistant strains of bacteria.

MICROBIOLOGY OF SURGICAL INFECTION

Common bacteria causing surgical infection

Streptococci

Streptococci form chains and are Gram positive on staining (**Figure 5.1**). The most important is the β-haemolytic *Streptococcus*, which resides in the pharynx of 5–10% of the population. In the Lancefield A–G carbohydrate antigens classification, it is the group A *Streptococcus*, also called *Streptococcus pyogenes*, that is the most pathogenic. It has the ability to spread, causing cellulitis, and to cause tissue destruction through the release of enzymes such as streptolysin, streptokinase and streptodornase.

Streptococcus faecalis is an enterococcus in Lancefield group D. It is often found in synergy with other organisms, as are the γ-haemolytic *Streptococcus* and *Peptostreptococcus*, which is an anaerobe.

Both *Streptococcus pyogenes* and *Streptococcus faecalis* may be involved in wound infection after large bowel surgery, but the α-haemolytic *Streptococcus viridans* is not associated with wound infections.

All the streptococci remain sensitive to penicillin and erythromycin. The cephalosporins are a suitable alternative in patients who are allergic to penicillin.

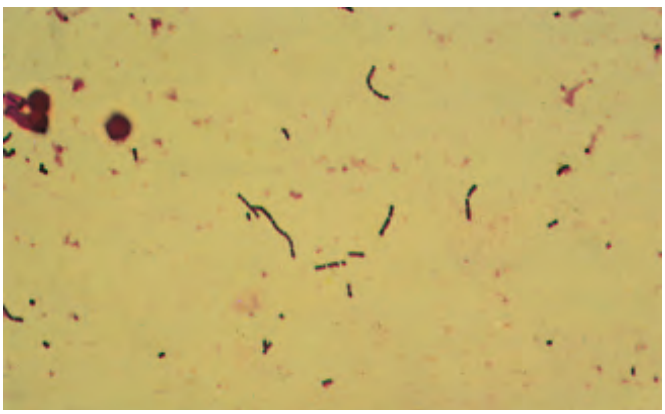

Figure 5.1 Streptococci.

Staphylococci

Staphylococci form clumps and are Gram positive (**Figure 5.2**). *Staphylococcus aureus* is the most important pathogen in this group and is found in the nasopharynx of up to 15% of the population. It can cause suppuration in wounds and around implanted prostheses. Some strains are resistant to many common antibiotics (especially methicillin resistant *Staphylococcus aureus*, MRSA) and so are difficult to treat. MRSA can be found in the nose of asymptomatic carriers amongst both patients and hospital workers, a potential source of infection after surgery. In parts of northern Europe, the prevalence of MRSA infections has been kept at very low levels using 'search and destroy' methods, which use screening techniques to look for MRSA in patients before they come in to hospital for elective surgery so that any carriers can be treated before their admission for surgery. Local policies on the management of MRSA depend on the prevalence of MRSA, the type of hospital, the clinical specialty and the availability of facilities. Widespread swabbing, ward closures, isolation of patients and disinfection of wards by deep cleaning all have to be carefully considered.

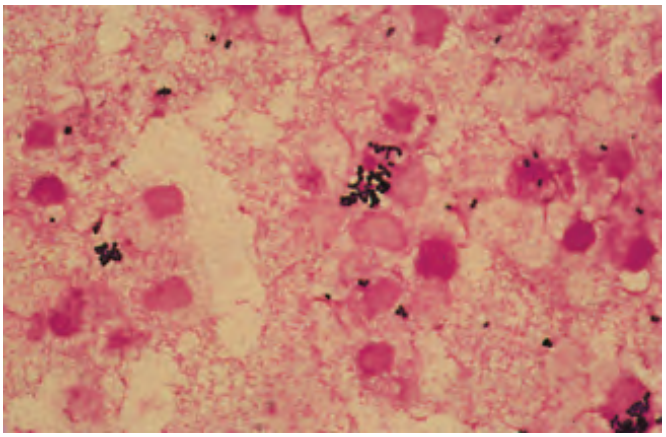

Figure 5.2 Staphylococcal pus.

Staphylococcal infections are usually suppurative and localised. Most hospital *Staphylococcus aureus* strains are now β-lactamase producers and so are resistant to penicillin, but many strains remain sensitive to flucloxacillin, vancomycin, aminoglycosides and some cephalosporins. There are several novel and innovative antibiotics becoming available that have high activity against resistant strains. Some have the advantage of good oral activity (linezolid), some have a wide spectrum (teicoplanin), some have good activity in bacteraemia (daptomycin) but all are relatively expensive, and some have side effects involving marrow, hepatic and renal toxicity. Their use is justified but needs to be controlled by tight local policies and guidelines that involve clinical microbiologists.

Staphylococcus epidermidis (previously *Staphylococcus albus*), also known as coagulase-negative staphylococcus, was regarded as a non-pathogenic commensal organism commonly found on the skin, but is now recognised as a major threat in vascular and orthopaedic prosthetic surgery and in indwelling vascular cannulas/catheters. The bacteria form biofilms which adhere to prosthetic surfaces and limit the effectiveness of antibiotics.

Clostridia

Clostridial organisms are gram-positive, obligate anaerobes, which produce resistant spores (**Figure 5.3**). *Clostridium perfringens* is the cause of gas gangrene, and *C. tetani* causes tetanus after implantation into tissues or a wound.

Clostridium difficile is the cause of pseudomembranous colitis, where destruction of the normal colonic bacterial flora by

Rebecca Graighill Lancefield, 1895–1981, American bacteriologist, classified streptococci in 1933.

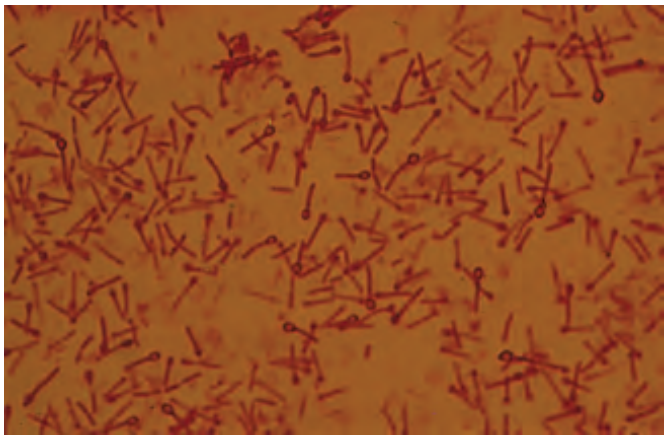

Figure 5.3 *Clostridium tetani* (drumstick spores).

antibiotic therapy allows an overgrowth of the normal gut commensal *C. diff* to pathological levels. Any antibiotic may cause this phenomenon, although the quinolones such as ciprofloxacin seem to be the highest risk, especially in elderly or immunocompromised patients. In its most severe form, the colitis may lead to perforation and the need for emergency colectomy with an associated high mortality. Treatment involves resuscitation and antibiotic therapy with metronidazole or vancomycin. The fibrinous exudate is typical and differentiates the colitis from other inflammatory diseases; laboratory recognition of the toxin is an early accurate diagnostic test.

Aerobic gram-negative bacilli

These bacilli are normal inhabitants of the large bowel. *Escherichia coli* and *Klebsiella* spp. are lactose fermenting; *Proteus* is non-lactose fermenting. Most organisms in this group act in synergy with *Bacteroides* to cause SSIs after bowel operations (in particular, appendicitis, diverticulitis and peritonitis). *Escherichia coli* is a major cause of urinary tract infection, although most aerobic gram-negative bacilli can be involved, particularly in relation to urinary catheterisation. There is increasing concern about the development of extended spectrum β-lactamases (ESBLs) in many of this group of bacteria, which confer resistance to many antibiotics, particularly cephalosporins.

Pseudomonas spp. tend to colonise burns and tracheostomy wounds, as well as the urinary tract. Once *Pseudomonas* has colonised wards and intensive care units, it may be difficult to eradicate. Surveillance of cross-infection is important in outbreaks. Hospital strains become resistant to β-lactamase as resistance can be transferred by plasmids. Wound infections need antibiotic therapy only when there is progressive or spreading infection with systemic signs. The aminoglycosides and the quinolones are effective, but some cephalosporins and penicillin may not be. Many of the carbapenems (e.g. meropenem) are useful in severe infections.

Bacteroides

Bacteroides are non-spore-bearing, strict anaerobes that colonise the large bowel, vagina and oropharynx. *Bacteroides fragilis* is the principal organism that acts in synergy with aerobic gram-negative bacilli to cause SSIs, including intra-abdominal abscesses after colorectal or gynaecological surgery. They are sensitive to the imidazoles (e.g. metronidazole) and some cephalosporins (e.g. cefotaxime).

Sources of infection

The infection of a wound can be defined as the invasion of organisms into tissues following a breakdown of local and systemic host defences, leading to either cellulitis, lymphangitis, abscess formation or bacteraemia. The infection of most surgical wounds is referred to as superficial surgical site infection (SSSI). The other categories include deep SSI (infection in the deeper musculofascial layers) and organ space infection (such as an abdominal abscess after an anastomotic leak).

Pathogens resist host defences by releasing toxins, which favour their spread, and this is enhanced in anaerobic or frankly necrotic wound tissue. *Clostridium perfringens*, which is responsible for gas gangrene, releases proteases such as hyaluronidase, lecithinase and haemolysin, which allow it to spread through the tissues. Resistance to antibiotics can be acquired by previously sensitive bacteria by transfer through plasmids.

The human body harbours approximately 10^{14} organisms. They can be released into tissues before, during or after surgery, contamination being most severe when a hollow viscus perforates (e.g. faecal peritonitis following a diverticular perforation). Any infection that follows surgery may be termed endogenous or exogenous, depending on the source of the bacterial contamination. Endogenous organisms are present on or in the patient at the time of surgery, whereas exogenous organisms come from outside the patient. In modern hospital practice, endogenous organisms colonising the patient are by far the most common source of infection.

Summary box 5.3

Classification of sources of infection

- Endogenous: present in or on the host e.g. SSSI following contamination of the wound from a perforated appendix
- Exogenous: acquired from a source outside the body such as the operating theatre (inadequate air filtration, poor antisepsis) or the ward (e.g. poor hand-washing compliance). The cause of hospital acquired infection (HAI)

Microorganisms are normally prevented from causing infection in tissues by intact epithelial surfaces, most notably the skin. These surfaces are broken down by trauma or surgery. In addition to these mechanical barriers, there are other protective mechanisms, which can be divided into:

- **chemical**: low gastric pH;
- **humoral**: antibodies, complement and opsonins;
- **cellular**: phagocytic cells, macrophages, polymorphonuclear cells and killer lymphocytes.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia, Zurich, Switzerland and The Rush Medical College, Chicago, IL, USA.

All of these natural mechanisms may be compromised by surgical intervention and treatment.

The chance of developing an SSI after surgery is also determined by the pathogenicity of the organisms present and by the size of the bacterial inoculum. The more virulent the organism or the larger the extent of bacterial contamination, the more likely is wound infection to occur. Host factors are also important, so a less virulent organism or a lower level of wound contamination may still result in a wound infection if the host response is impaired (see *Summary box 5.5*). Devitalised tissue, excessive dead space or haematoma, all the results of poor surgical technique, increase the chances of infection. The same applies to foreign materials of any kind, including sutures and drains. If there is a silk suture in tissue, the critical number of organisms needed to start an infection is reduced logarithmically. Silk should not be used to close skin as it causes suture abscesses for this reason. These principles are important to an understanding of how best to prevent infection in surgical practice.

Summary box 5.4

Factors that determine whether a wound will become infected

- Host response
- Virulence and inoculum of infective agent
- Vascularity and health of tissue being invaded (including local ischaemia as well as systemic shock)
- Presence of dead or foreign tissue
- Presence of antibiotics during the 'decisive period'

The decisive period

There is up to a 4-hour interval before bacterial growth becomes established enough to cause an infection after a breach in the tissues, whether caused by trauma or surgery. This interval is called the 'decisive period' and strategies aimed at preventing infection from taking a hold become ineffective after this time period. It is therefore logical that prophylactic antibiotics should be given to cover this period and that they could be decisive in preventing an infection from developing, before bacterial growth takes a hold. The tissue levels of antibiotics during the period when bacterial contamination is likely to occur should be above the minimum inhibitory concentration (MIC_{90}) for the expected pathogens.

Reduced resistance to infection

Reduced resistance to infection has several causes, particularly those that impair the inflammatory response. Host response is weakened by malnutrition, which can be recognised clinically, and most easily, as recent rapid weight loss that can be present even in the presence of obesity. Metabolic diseases such as diabetes mellitus, uraemia and jaundice, disseminated malignancy and acquired immmune deficiency syndrome (AIDS) are other contributors to infection and a poor healing response, as are iatrogenic causes including the immunosuppression caused by radiotherapy, chemotherapy or steroids (**Figures 5.4 and 5.5**).

Summary box 5.5

Risk factors for increased risk of wound infection

- Malnutrition (obesity, weight loss)
- Metabolic disease (diabetes, uraemia, jaundice)
- Immunosuppression (cancer, AIDS, steroids, chemotherapy and radiotherapy)
- Colonisation and translocation in the gastrointestinal tract
- Poor perfusion (systemic shock or local ischaemia)
- Foreign body material
- Poor surgical technique (dead space, haematoma)

When enteral feeding is suspended during the perioperative period, and particularly with underlying disease such as cancer, immunosuppression, shock or sepsis, bacteria (particularly aerobic gram-negative bacilli) tend to colonise the normally sterile upper gastrointestinal tract. They may then translocate to the mesenteric nodes and cause the release of endotoxins (lipopolysaccharide in bacterial cell walls), which

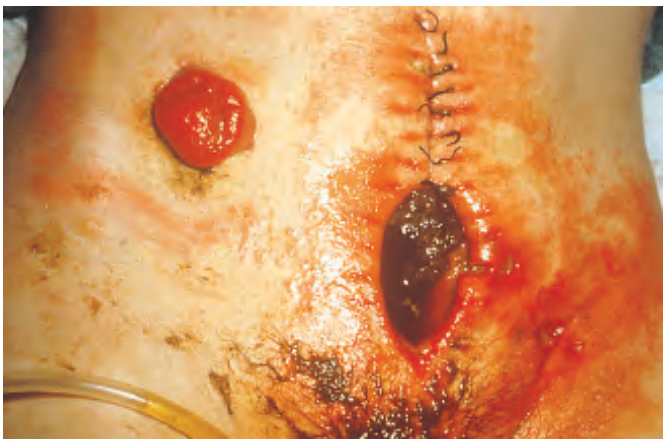

Figure 5.4 Major wound infection and delayed healing presenting as a faecal fistula in a patient with Crohn's disease on steroid treatment.

Figure 5.5 Delayed healing relating to infection in a patient on high-dose steroids.

can be one cause of a harmful systemic inflammatory response through the excessive release of proinflammatory cytokines and activation of macrophages (**Figure 5.6**). In the circumstances of reduced host resistance to infection, microorganisms that are not normally pathogenic may start to behave as pathogens. This is known as opportunistic infection. Opportunistic infection with fungi is an example, particularly when prolonged and changing antibiotic regimes have been used.

PRESENTATION OF SURGICAL INFECTION

Major and minor surgical site infection (SSI)

Infection acquired from the environment or the staff following surgery or admission to hospital is termed hospital acquired infection (HAI). There are four main groups: respiratory infections (including ventilator-associated pneumonia), urinary tract infections (mostly related to urinary catheters), bacteraemia (mostly related to indwelling vascular catheters) and SSIs.

A major SSI is defined as a wound that either discharges significant quantities of pus spontaneously or needs a secondary procedure to drain it (**Figure 5.7**). The patient may have systemic signs such as tachycardia, pyrexia and a raised white cell count.

Summary box 5.6

Major wound infections

- Significant quantity of pus
- Delayed return home
- Patients are systemically ill

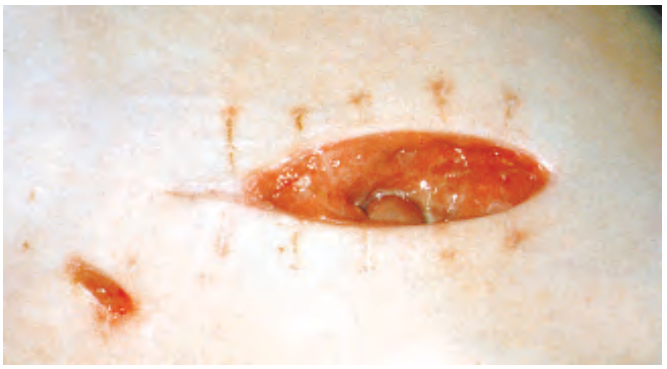

Figure 5.7 Major wound infection with superficial skin dehiscence.

Minor wound infections may discharge pus or infected serous fluid but are not associated with excessive discomfort, systemic signs or delay in return home (**Figure 5.8**). The differentiation between major and minor and the definition of SSI is important in audits and clinical trials of antibiotic prophylaxis. There are scoring systems for the severity of wound infection, which are particularly useful in surveillance and research. Examples are the Southampton (*Table 5.1*) and ASEPSIS systems (*Table 5.2*).

Accurate surveillance can only be achieved using trained, unbiased and blinded assessors. Most include surveillance for a 30-day postoperative period. The US Centers for Disease Control (CDC) definition insists on a 30-day follow-up period for non-prosthetic surgery and 1 year after implanted hip and knee surgery.

Figure 5.8 Minor wound infection that settled spontaneously without antibiotics.

Localised infection

ABSCESS

An abscess presents all the clinical features of acute inflammation originally described by Celsus: *calor* (heat), *rubor* (redness), *dolor* (pain) and *tumor* (swelling). To these can be added *functio laesa* (loss of function: if it hurts, the infected part is not used). Abscesses usually follow a puncture wound of some kind, which may have been forgotten, as well as surgery, but can be metastatic in all tissues following bacteraemia.

Aulus Aurelius Cornelius Celsus, 25 BC–50 AD, Roman surgeon and the author of *De Re Medico Libri Octo*.

TABLE 5.1 Southampton wound grading system.

Grade	Appearance
0	Normal healing
I	Normal healing with mild bruising or erythema
Ia	Some bruising
Ib	Considerable bruising
Ic	Mild erythema
II	Erythema plus other signs of inflammation
IIa	At one point
IIb	Around sutures
IIc	Along wound
IId	Around wound
III	Clear or haemoserous discharge
IIIa	At one point only (≤2 cm)
IIIb	Along wound (>2 cm)
IIIc	Large volume
IIId	Prolonged (>3 days)
Major complication	
IV	Pus
IVa	At one point only (≤2 cm)
IVb	Along wound (>2 cm)
V	Deep or severe wound infection with or without tissue breakdown; haematoma requiring aspiration

TABLE 5.2 The ASEPSIS wound score.

Criterion	Points
Additional treatment	0
Antibiotics for wound infection	10
Drainage of pus under local anaesthesia	5
Debridement of wound under general anaesthesia	10
Serous discharge[a]	Daily 0–5
Erythema[a]	Daily 0–5
Purulent exudate[a]	Daily 0–10
Separation of deep tissues[a]	Daily 0–10
Isolation of bacteria from wound	10
Stay as inpatient prolonged over 14 days as result of wound infection	5

[a] Scored for 5 of the first 7 days only, the remainder being scored if present in the first 2 months.

Pyogenic organisms, predominantly *Staphylococcus aureus*, cause tissue necrosis and suppuration. Pus is composed of dead and dying white blood cells, predominantly neutrophils, that have succumbed to bacterial toxins. An abscess is surrounded by an acute inflammatory response composed of a fibrinous exudate, oedema and the cells of acute inflammation. Granulation tissue (macrophages, fibroblasts and new blood vessel proliferation) forms later around the suppurative process and leads to collagen deposition. If it is not drained or resorbed completely, a chronic abscess may result. If it is partly sterilised with antibiotics, an antibioma may form.

Abscesses contain hyperosmolar material that draws in fluid. This increases the pressure and causes pain. If they spread, they usually track along planes of least resistance and point towards the skin. Wound abscesses may discharge spontaneously by tracking to a surface, but may need drainage through a surgical incision. Most abscesses relating to surgical wounds take 7–10 days to form after surgery. As many as 75% of SSIs present after the patient has left hospital and may thus be overlooked by the surgical team.

Abscess cavities need cleaning out after incision and drainage and are traditionally encouraged to heal by secondary intention. When the cavity is left open to drain freely, there is no need for antibiotic therapy as well. Antibiotics should be used if the abscess cavity is closed after drainage, but the cavity should not be closed if there is any risk of retained loculi or foreign material. Thus a perianal abscess can be incised and drained, the walls curretted and the skin closed with good results using appropriate antibiotic therapy, but a pilonidal abscess has a higher recurrence risk after such treatment because a nidus of hair may remain in the subcutaneous tissue adjacent to the abscess. Some small breast abscesses can be managed by simple needle aspiration of the pus and antibiotic therapy.

Summary box 5.7

Abscesses

- Abscesses need drainage
- Modern imaging techniques may allow guided needle aspiration
- Antibiotics are indicated if the abscess cavity is not left open to drain freely
- An open abscess cavity heals by secondary intention

Persistent chronic abscesses may lead to sinus or fistula formation. In a chronic abscess, lymphocytes and plasma cells are seen. There is tissue sequestration and later calcification may occur. Certain organisms are associated with chronicity, and sinus and fistula formation. Common ones are *Mycobacterium* and *Actinomyces*. They should not be forgotten when these complications occur and persist.

Perianastomotic contamination may be the cause of an abscess but, in the abdomen, abscesses are more usually the result of anastomotic leakage. An abscess in a deep cavity such as the pleura or peritoneum may be difficult to diagnose or locate even when there is strong clinical suspicion that it is present (**Figure 5.9**). Plain or contrast radiographs may not be helpful, but ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI) and isotope labelled white cell scans are all useful and may allow guided aspiration without the need for surgical intervention.

CELLULITIS AND LYMPHANGITIS

Cellulitis is a non-suppurative, invasive infection of tissues, which is usually related to the point of injury.There is poor localisation in addition to the cardinal signs of spreading inflammation. Such infections presenting in surgical practice

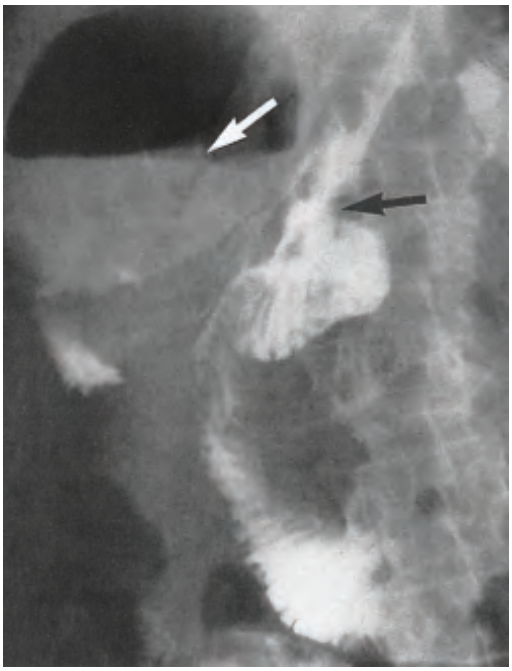

Figure 5.9 Plain radiograph showing a subphrenic abscess with a gas/fluid level (white arrow). Gastrografin is seen leaking from the oesophagojejunal anastomosis (after gastrectomy) towards the abscess (black arrow).

are typically caused by organisms such as β-haemolytic streptococci (**Figure 5.10**), staphylococci (**Figure 5.11**) and *C. perfringens*. Tissue destruction, gangrene and ulceration may follow, which are caused by release of proteases.

Systemic signs (the old-fashioned term is toxaemia) are common, with chills, fever and rigors. These events follow the release of toxins into the circulation, which stimulate a cytokine-mediated systemic inflammatory response even though blood cultures may be negative.

Lymphangitis is part of a similar process and presents as painful red streaks in affected lymphatics draining the source of infection. Lymphangitis is often accompanied by painful lymph node groups in the related drainage area.

Summary box 5.8

Cellulitis and lymphangitis

- Non-suppurative, poorly localised
- Commonly caused by streptococci, staphylococci or clostridia
- Blood cultures are often negative

Specific local wound infections

GAS GANGRENE

Gas gangrene is caused by *C. perfringens*. These gram-positive, anaerobic, spore-bearing bacilli are widely found in nature, particularly in soil and faeces. This infection is particularly relevant to military and trauma surgery. Patients who are immunocompromised, diabetic or have malignant disease are at greater risk, particularly if they have wounds containing

Figure 5.10 Streptococcal cellulitis of the leg following a minor puncture wound.

Figure 5.11 Staphylococcal cellulitis of the face and orbit following severe infection of an epidermoid cyst of the scalp.

necrotic or foreign material, resulting in anaerobic conditions. Military wounds provide an ideal environment as the kinetic energy of high-velocity missiles or shrapnel causes extensive tissue damage. The cavitation which follows passage of a missile through the tissues causes a 'sucking' entry wound, leaving clothing and environmental soiling in the wound in addition to devascularised tissue. Gas gangrene wound infections are associated with severe local wound pain and crepitus (gas in the tissues, which may also be visible on plain radiographs). The wound produces a thin, brown, sweet-smelling exudate, in which Gram staining will reveal bacteria. Oedema and spreading gangrene follow the release of collagenase, hyaluronidase, other proteases and alpha toxin. Early systemic complications with circulatory collapse and organ failure follow if prompt action is not taken.

Summary box 5.9

Gas gangrene

- Caused by *Clostridium perfringens*
- Gas and smell are characteristic
- Immunocompromised patients are most at risk
- Antibiotic prophylaxis is essential when performing amputations to remove dead tissue

Antibiotic prophylaxis should always be considered in patients at risk, especially when amputations are performed for peripheral vascular disease with open necrotic ulceration. Once gas gangrene infection is established, large doses of intravenous penicillin and aggressive debridement of affected tissues are required.

CLOSTRIDIUM TETANI

This is another anaerobic, terminal spore-bearing, gram-positive bacterium, which can cause tetanus following implantation into tissues or a wound (which may have been trivial or unrecognised and forgotten). The spores are widespread in soil and manure, and so the infection is more common in traumatic civilian or military wounds. The signs and symptoms of tetanus are mediated by the release of the exotoxin tetanospasmin, which affects myoneural junctions and the motor neurones of the anterior horn of the spinal cord. A short prodromal period, which has a poor prognosis, leads to spasms in the distribution of the short motor nerves of the face followed by the development of severe generalised motor spasms including opsithotonus, respiratory arrest and death. A longer prodromal period of 4–5 weeks is associated with a milder form of the disease. The entry wound may show a localised small area of cellulitis. Exudate or aspirate may give a sample that can be stained to show the presence of gram-positive rods. Prophylaxis with tetanus toxoid is the best preventative treatment but, in an established infection, minor debridement of the wound may need to be performed and antibiotic treatment with benzylpenicillin provided in addition. Relaxants may also be required, and the patient will require ventilation in severe forms, which are associated with a high mortality. The administration of antitoxin using human immunoglobulin ought to be considered for both at-risk wounds and established infection.

The toxoid is a formalin-attenuated vaccine and should be given in three separate doses to give protection for a 5-year period, after which a single 5-yearly booster confers immunity. It should be given to all patients with open traumatic wounds who are not immunised. At-risk wounds are those when there is late presentation, when there is devitalisation of tissue or when there is wound soiling. For these wounds, a booster of toxoid should be given or, if the patient is not immunised at all, a three-dose course is given together with prophylactic benzylpenicillin, but the use of antitoxin is controversial because of the risk of toxicity and allergy.

SYNERGISTIC SPREADING GANGRENE (SYNONYM: SUBDERMAL GANGRENE, NECROTISING FASCIITIS)

This condition is not caused by clostridia. A mixed pattern of organisms is responsible: coliforms, staphylococci, *Bacteroides* spp., anaerobic streptococci and peptostreptococci have all been implicated, acting in synergy. Often, aerobic bacteria destroy the living tissue, allowing anaerobic bacteria to thrive. Abdominal wall infections are known as Meleney's synergistic gangrene and scrotal infections as Fournier's gangrene (**Figure 5.12**). Patients are almost always immunocompromised, with conditions such as diabetes mellitus. The wound initiating the infection may have been minor, but severely contaminated wounds are more likely to be the cause. Severe wound pain, signs of spreading inflammation with crepitus and smell are all signs of the infection spreading. Untreated, it will lead to widespread local gangrene and systemic multisystem organ failure. The subdermal spread of gangrene is always much more extensive than appears from initial examination. Broad-spectrum antibiotic therapy must be combined with aggressive circulatory support. Locally, there should be wide excision of necrotic tissue and laying open of affected areas. The debridement may need to be extensive, and patients who survive may need large areas of skin grafting.

Systemic infection

Bacteraemia

Bacteraemia is unusual following superficial SSIs, which tend to drain through the wound, but common after deep space SSIs such as follow an intestinal anastomotic breakdown. It is usually transient and can follow procedures undertaken through infected tissues (particularly instrumentation in infected bile or urine). It may also occur through bacterial infection of indwelling intravenous cannulae, which should be replaced regularly in order to avoid colonisation. Bacteraemia is important when a prosthesis has been implanted, as infection of the prosthesis can occur through haematogenous spread. Aerobic gram-negative bacilli are often responsible, but *Staphylococcus aureus* and fungi may be involved, particularly after the use of broad-spectrum antibiotics.

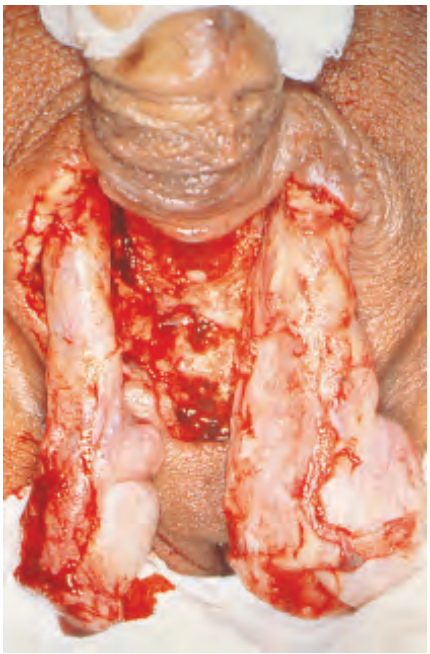

Figure 5.12 A classic presentation of Fournier's gangrene of the scrotum with 'shameful exposure of the testes' following excision of the gangrenous skin.

Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.
Jean Alfred Fournier, 1832–1915, syphilologist, the founder of the Venereal and Dermatological Clinic, Hôpital St. Louis, Paris, France.

Summary box 5.10

Bacteraemia

- Common after anastomotic breakdown
- Dangerous if the patient has a prosthesis, which can become infected
- May be associated with systemic organ failure

Systemic inflammatory response syndrome (SIRS)

SIRS is a systemic manifestation of sepsis (see *Table 5.3*), although the syndrome may also be caused by multiple trauma, burns or pancreatitis without infection. Serious infection, such as secondary peritonitis, may lead to SIRS through the release of lipopolysaccharide endotoxin from the walls of dying gram-negative bacilli (mainly *Escherichia coli*) or other bacteria or fungi. This and other toxins stimulate the release of cytokines from macrophages (see **Figure 5.6**). SIRS should not be confused with bacteraemia although the two may coexist.

Septic manifestations and multiple organ dysfunction syndrome (MODS) in SIRS are mediated by the release of proinflammatory cytokines such as interleukin-1 (IL-1) and tumour necrosis factor alpha (TNFα). These cytokines normally stimulate neutrohil adhesion to endothelial surfaces adjacent to the source of infection and cause them to migrate through the blood vessel wall by chemotaxis, where they can attack the bacterial invasion. A respiratory burst occurs within such activated neutrophils, releasing lysosomal enzymes, oxidants and free radicals which are involved in killing the invading bacteria, but which may also damage adjacent cells. Coagulation, complement and fibrinolytic pathways are also stimulated as part of the normal inflammatory response. This response is usually beneficial to the host and is an important aspect of normal tissue repair and wound healing. In the presence of severe sepsis or bacteraemia, this response may become harmful to the host if it occurs in excess, when it is known as the systemic inflammatory response syndrome or SIRS. There are high circulating levels of cytokines and activated neutrophils which stimulate fever, tachycardia and tachypnoea. The activated neutrophils adhere to vascular endothelium in key organs remote from the source of infection and damage it, leading to increased vascular permeability, which in turn leads to cellular damage within the organs, which become dysfunctional and give rise to the clinical picture of multiple organ dysfunction syndrome or MODS. In its most severe form, MODS may progress into multiple system organ failure (MSOF). Respiratory, cardiac, intestinal, renal and liver failure ensue in combination with circulatory failure and shock. In this state, the body's resistance to infection is reduced and a vicious cycle develops where the more organs that fail, the more likely it becomes that death will follow despite all that a modern intensive care unit can do for organ support.

TABLE 5.3 Definitions of systemic inflammatory response syndrome (SIRS) and sepsis.

SIRS is ***Two of:*** hyperthermia (>38°C) or hypothermia (<36°C) tachycardia (>90/min, no β-blockers) or tachypnoea (>20/min) white cell count >12 × 10^9/litre or <4 × 10^9/litre
Sepsis is SIRS with a documented infection
Severe sepsis or sepsis syndrome is sepsis with evidence of failure of one or more organs: respiratory (acute respiratory distress syndrome), cardiovascular (septic shock follows compromise of cardiac function and fall in peripheral vascular resistance), renal (usually acute tubular necrosis), hepatic, blood coagulation systems or central nervous system

Summary box 5.11

Definitions of infected states

- SSI is an infected wound or deep organ space
- SIRS is the body's systemic response to severe infection
- MODS is the effect that SIRS produces systemically
- MSOF is the end stage of uncontrolled MODS

Viral infections relevant to surgery

Hepatitis

Both hepatitis B and hepatitis C carry risks in surgery as they are blood-borne pathogens that can be transmitted both from the surgeon to the patient and *vice versa*. The usual mode of transmission is blood to blood contact through a needle-stick injury or a cut. Many cases of hepatitis B are asymptomatic and a surgeon may carry the virus without being aware of it. As there is an effective vaccine against hepatitis B, surgeons should know their immune status to hepatitis B and be vaccinated against it. Hepatitis C infection often becomes chronic with the risk of significant liver damage, but is potentially curable with interferon-alpha and ribavirin treatment, so surgeons who are exposed to an infection risk should seek medical advice and antibody measurement. Transmission of hepatitis C from surgeon to patient is extremely rare.

HIV

The type I human immunodeficiency virus (HIV) is one of the viruses of surgical importance because it can be transmitted by body fluids, particularly blood. It is a retrovirus that has become increasingly prevalent through sexual transmission (both homo- and heterosexual), intravenous drug addiction and in infected blood products used to treat haemophiliacs in particular. The risk in surgery is mostly through needle-stick injury during operations.

After exposure, the virus binds to CD4 receptors with a subsequent loss of CD4+ cells, T helper cells and other cells

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the *Bacterium coli commune* in 1886.

involved in cell-mediated immunity, antibody production and delayed hypersensitivity. Macrophages and gut-associated lymphoid tissue (GALT) are also affected. The risk of opportunistic infections (such as *Pneumocystis carinii* pneumonia, tuberculosis and cytomegalovirus) and neoplasms (such as Kaposi's sarcoma and lymphoma) is thereby increased.

In the early weeks after HIV infection, there may be a flu-like illness and, during the phase of seroconversion, patients present the greatest risk of HIV transmission. It is during these early phases that drug treatment, highly active antiretroviral therapy (HAART), is most effective through the ability of these drugs to inhibit reverse transcriptase and protease synthesis, which are the principal mechanisms through which HIV can progress. These drugs suppress the virus but do not clear it completely from the body, and treated patients can still transmit the virus to others. Within 2 years, untreated HIV can progress to acquired immune deficiency syndrome (AIDS) in 25–35% of patients.

Involvement of surgeons with HIV or hepatitis patients (universal precautions)

Patients may present to surgeons for operative treatment if they have a surgical disease and they are known to be infected or 'at risk', or because they need surgical intervention related to their illness for vascular access or a biopsy when they are known to have hepatitis, HIV infection or AIDS. Particular care should be taken when there is a risk of splashing/aerosol formation, particularly with power tools. Universal precautions have been drawn up by the CDC in the United States and largely adopted by the National Health Service (NHS) in the UK (in summary):

- use of a full face mask ideally, or protective spectacles;
- use of fully waterproof, disposable gowns and drapes, particularly during seroconversion;
- boots to be worn, not clogs, to avoid injury from dropped sharps;
- double gloving needed (a larger size on the inside is more comfortable);
- allow only essential personnel in theatre;
- avoid unnecessary movement in theatre;
- respect is required for sharps, with passage in a kidney dish;
- a slow meticulous operative technique is needed with minimised bleeding.

AFTER CONTAMINATION

Needle-stick injuries are commonest on the non-dominant index finger during operative surgery. Hollow needle injury carries the greatest risk of viral transmission. The injured part should be washed under running water and the incident reported. Local policies dictate whether post-exposure antiretroviral treatment should be given. Occupational health advice is required after high-risk exposure, together with the need for hepatitis/HIV testing and the option for continuation in an operative specialty.

PREVENTION OF SURGICAL INFECTION

Preoperative preparation

A short preoperative hospital stay lowers the risk of acquiring MRSA, multiply resistant coagulase-negative staphylococci (MRCNS) and other antibiotic-resistant organisms from the hospital environment. Medical and nursing staff should always wash their hands after any patient contact. Alcoholic hand gels can act as a substitute for hand washing, but do not destroy the spores of *Clostridium difficile*, which may cause pseudomembranous colitis, especially in immunocompromised patients or those whose gut flora is suppressed by antibiotic therapy. Although the need for clean hospitals, emphasised by the media, is logical, the 'clean your hands campaign' is beginning to result in falls in the incidence of HAIs. Staff with open, infected skin lesions should not enter the operating theatres. Ideally, neither should affected patients, especially if they are having a prosthesis implanted. Antiseptic baths (usually chlorhexidine) are popular in Europe, but there is no hard evidence for their value in reducing wound infections. Preoperative skin shaving should be undertaken in the operating theatre immediately before surgery as the SSI rate after clean wound surgery may be doubled if shaving is performed the night before, because minor skin injury enhances superficial bacterial colonisation. Cream depilation is messy and hair clipping is best, with the lowest rate of infection.

Scrubbing and skin preparation

When washing the hands prior to surgery, dilute alcohol-based antiseptic hand soaps such as chlorhexidine or povidone–iodine should be used for hand washing, and the scrub should include the nails.

One application of a more concentrated alcohol-based antiseptic is adequate for skin preparation of the operative site. This leads to a >95% reduction in bacterial count but caution should be taken not to leave a pool of alcohol-based fluid on the skin which could ignite with diathermy and burn the patient.

Theatre technique and discipline also contribute to low infection rates. Numbers of staff in the theatre and movement in and out of theatre should be kept to a minimum. Careful and regular surveillance is needed to ensure the quality of instrument sterilisation, aseptic technique and theatre ventilation. Laminar flow systems direct clean, filtered air over the operating field, with any air potentially contaminated as it passes over the incision then directed away from the patient. Operator skill in gentle manipulation and dissection of tissues is much more difficult to audit, but dead spaces and haematomas should be avoided. There is no evidence that drains, incision drapes or wound guards help to reduce wound infection. There is a high level of evidence that both the perioperative avoidance of hypothermia and the use of supplemental oxygen during recovery significantly reduce the rate of SSIs.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

Prophylactic antibiotics

Prophylactic antibiotics are used when there is a risk of wound contamination with bacteria during surgery. The theoretical degree of contamination, proposed by the National Research Council (USA) over 40 years ago, relates well to infection rates (*Table 5.4*). The value of antibiotic prophylaxis is low in non-prosthetic clean surgery, with most trials showing no clear benefit because infection rates without antibiotics are so low. The exception to this is where a prosthetic implant is used, as the results of infection are so catastrophic that even a small risk of infection is unacceptable.There is undisputed evidence that prophylactic antibiotics are effective in reducing the risk of infection in clean-contaminated and contaminated operations. When wounds are heavily contaminated or when an incision is made into an abscess, a 5-day course of therapeutic antibiotics may be justified on the assumption that the wound is inevitably infected and so treatment is needed rather than prophylaxis.

If antibiotics are given to prevent infection after surgery or instrumentation, they should be used before bacterial growth becomes established (i.e. within the decisive period). Ideally, maximal blood and tissue levels should be present at the time at which the first incision is made and before contamination occurs. Tissue levels of the antibiotic should remain high throughout the operation and antibiotics with a short tissue half life should be avoided. Intravenous administration at induction of anaesthesia is therefore optimal, as unexpected delays in the timing of surgery may occur before then and antibiotic tissue levels may fall off before the surgery starts. In long operations or when there is excessive blood loss, or when unexpected contamination occurs, antibiotics may be repeated at 4-hourly intervals during the surgery, because tissue antibiotic levels often fall faster than serum levels. There is no evidence that further doses of antibiotics after surgery are of any value in prophylaxis against infection and the practice can only encourage the development of antibiotic resistance. The choice of an antibiotic depends on the expected spectrum of organisms likely to be encountered, which will depend on the site and type of surgery and whether or not the patient has any antibiotic allergies. Hospitals in the UK now have standardised antibiotic prophylaxis policies which take account of the above factors and are only deviated from with microbiological advice.

Patients with known valvular disease of the heart (or with any implanted vascular or orthopaedic prosthesis) should have prophylactic antibiotics during dental, urological or open viscus surgery, to prevent bacterial colonisation of the valve or prosthesis during the transient bacteraemia which can occur during such surgery.

TABLE 5.4 SSI rates relating to wound contamination with and without using antibiotic prophylaxis.

Type of surgery	Infection rate with prophylaxis (%)	Infection rate without prophylaxis (%)
Clean (no viscus opened)	1–2	1–2
Clean-contaminated (viscus opened, minimal spillage)	3	6–9
Contaminated (open viscus with spillage or inflammatory disease)	6	13–20
Dirty (pus or perforation, or incision through an abscess)	7	40

Summary box 5.12

Antibiotic prophylaxis

- Not required in clean surgery unless a prosthesis is implanted
- Use antibiotics that are effective against expected pathogens within local hospital guidelines
- Plan for single-shot intravenous administration at induction of anaesthesia
- Repeat only during long operations or if there is excessive blood loss
- Patients with heart valve disease or a prosthesis should be protected from bacteraemia caused by dental work, urethral instrumentation or visceral surgery

Postoperative wound infections

The majority of wound infections arise from endogenous sources within the patient, but exogenous SSI may also occur from bacteria present in the ward or staff and so can be related to poor hospital standards. Strict attention to ward cleanliness, gloving before touching patient wounds and hand washing between all patient contacts are important preventive measures. An outbreak of wound infections on the ward with bacteria having the same antibiotic sensitivity profile implies an exogenous source of infection, which needs to be investigated by swabbing all staff and work surfaces. It may need temporary ward closure and a deep clean to eradicate the infection source.

Now that patients are discharged more quickly after surgery and many procedures are performed as day cases, many SSIs are missed by the surgical team unless they undertake a prolonged and carefully audited follow-up with primary care doctors. Suppurative wound infections take 7–10 days to develop, and even cellulitis around wounds caused by invasive organisms (such as β-haemolytic *Streptococcus*) takes 3–4 days to develop. Major surgical infections with systemic signs **(Figure 5.13)**, evidence of spreading infection, cellulitis or bacteraemia need treatment with appropriate antibiotics. The choice may need to be empirical initially but is best based on culture and sensitivities of isolates harvested at surgery or from culture of wound fluids or wound swabs. Although the identification of organisms in surgical infections is necessary for audit and wound surveillance purposes, it is usually 2–3 days before sensitivities are known **(Figures 5.14 and 5.15)**. It is illogical to withhold antibiotics until results are available but, if clinical response is poor by the time sensitivities are known, then antibiotics can be changed. Such changes are unusual if the empirical choice of antibiotics is sensible; change of antibiotics promotes resistance and risks complications, such as *C. difficile* enteritis.

If an infected wound is under tension, or there is clear evidence of suppuration, sutures or clips need to be removed, with curettage if necessary, to allow pus to drain adequately. In severely contaminated wounds, such as an incision made

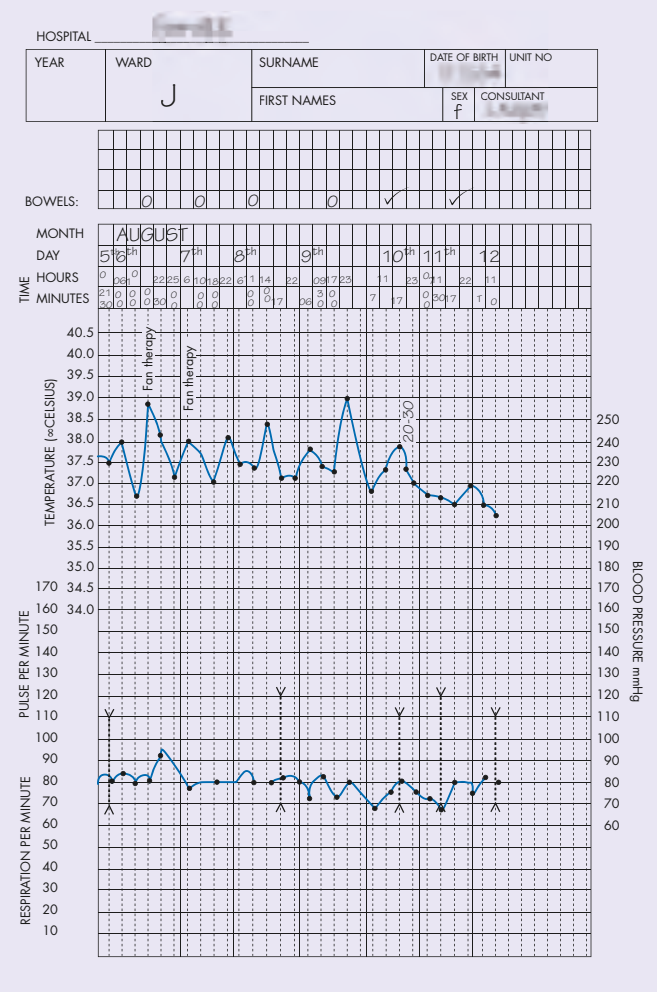

Figure 5.13 Classic swinging pyrexia related to a perianastomotic wound abscess that settled spontaneously on antibiotic therapy.

Figure 5.14 Mixed streptococcal infection of a skin graft with very poor 'take'.

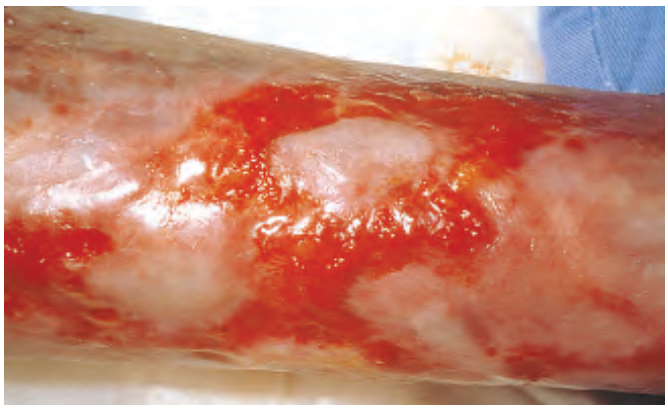

Figure 5.15 After 5–6 days of antibiotics, the infection shown in Figure 5.14 is under control, and the skin grafts are clearly viable.

for drainage of an abscess, it is logical to leave the skin open. Delayed primary or secondary closure can be undertaken when the wound is clean and granulating (**Figures 5.16 and 5.17**). Some heavily infected wounds may be left to heal by secondary intention, with no attempt at closure, particularly where there is a loss of skin cover and healthy granulation tissue develops (**Figure 5.18**). While the end result may be excessive scarring, that can always be revised with plastic surgery under clean surgical conditions at a later stage. Leaving wounds open after a 'dirty' operation, such as laparotomy for faecal peritonitis, is not practised as widely in the UK as in the USA or mainland Europe.

Summary box 5.13

Surgical incisions through infected or contaminated tissues

- When possible, tissue or pus for culture should be taken before antibiotic cover is started
- The choice of antibiotics is empirical until sensitivities are available
- Heavily contaminated wounds are best managed by delayed primary or secondary closure

Figure 5.16 (a, b) Delayed primary closure of fasciotomy wound after 3–5 days.

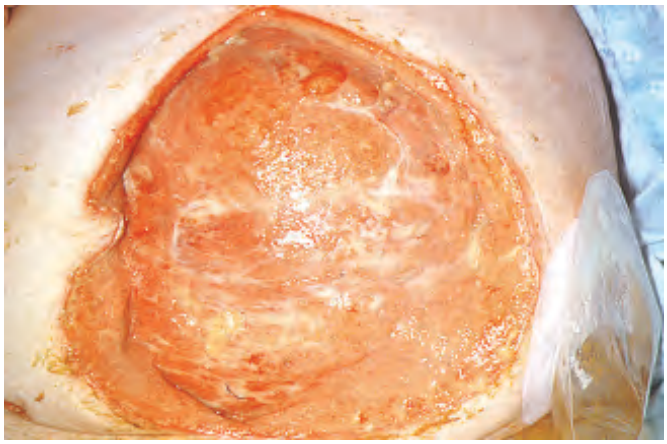

Figure 5.17 Skin layers left open to granulate after laparotomy for faecal peritonitis, ready for skin grafting.

Figure 5.18 Infected animal bite/wound of the upper thigh, treated by open therapy following virulent staphylococcal infection.

When taking pus from infected wounds, specimens should be sent fresh for microbiological culture. Swabs should be placed in transport medium, but the larger the volume of pus sent, the more likely is the accurate identification of the organism involved. Providing the microbiologist with as much information as possible and discussing the results with them gives the best chance of the most appropriate antibiotic treatment. If bacteraemia is suspected, but results are negative, then repeat specimens for blood culture may need to be taken. A rapid report on infective material can be based on an immediate Gram stain.

Topical antiseptics should only be used on heavily contaminated wounds for a short period to clear infection as they inhibit epithelial ingrowth and so impair wound healing.

ANTIMICROBIAL TREATMENT OF SURGICAL INFECTION

Principles

Antimicrobials may be used to prevent or treat established surgical infection.

Summary box 5.14

Principles for the use of antibiotic therapy

- Antibiotics do not replace surgical drainage of infection
- Only spreading infections or signs of systemic infection justify the use of antibiotics
- Whenever possible, the organism and sensitivity should be determined

The use of antibiotics for the treatment of established surgical infection ideally requires recognition and determination of the sensitivities of the causative organisms. Antibiotic therapy should not be held back if it is indicated, the choice being empirical and later modified depending on microbiological findings. Once antibiotics have been administered, it may not be possible to grow bacteria from the wound and so the opportunity to ascertain the most appropriate antibiotic sensitivities is lost if a patient's condition does not improve on empirical antibiotic therapy. Antibiotics alone are rarely sufficient to treat SSIs, which may also need open drainage and debridement.

There are two approaches to antibiotic treatment:

- A **narrow-spectrum antibiotic** may be used to treat a known sensitive infection; for example, MRSA (which may be isolated from pus) is usually sensitive to vancomycin or teicoplanin, but not flucloxacillin.
- **Combinations of broad-spectrum antibiotics** can be used when the organism is not known or when it is suspected that several bacteria, acting in synergy, may be responsible for the infection. For example, during and following emergency surgery requiring the opening of perforated or ischaemic bowel, any of the gut organisms may be responsible for subsequent peritoneal or bacteraemic infection. In this case, a broad spectrum antibiotic such as teicoplenin or meropenem effective against a wide range of aerobic bacteria is combined with metronidazole, effective against anaerobic bacteria. Alternatively, triple therapy is used with amoxacillin, gentamicin and metronidazole. The use of such broad-spectrum antibiotic strategies should be guided by specialist microbiological advice. If clincal response is poor after 3–4 days, there should be a re-evaluation with a review of charts and further investigations requested to exclude the development or persistence of infection such as a collection of pus.

Antibiotics used in treatment and prophylaxis of surgical infection

Antimicrobials may be produced by living organisms (antibiotics) or by synthetic methods. Some are bactericidal, e.g. penicillins and aminoglycosides, and others are bacteriostatic, e.g. tetracycline and erythromycin. In general, penicillins act upon the bacterial cell wall and are most effective against bacteria that are multiplying and synthesising new cell wall materials. The aminoglycosides act at the ribosomal level, preventing or distorting the production of proteins required to maintain the integrity of the enzymes in the bacterial cell. Hospital and Formulary guidelines should be consulted for doses and monitoring of antibiotic therapy.

Penicillin

Benzylpenicillin has proved most effective against gram-positive pathogens, including most streptococci, the clostridia and some of the staphylococci that do not produce β-lactamase. It is still effective against *Actinomyces*, which is a rare cause of chronic wound infection. It may be used specifically to treat spreading streptococcal infections. Penicillin is valuable even if other antibiotics are required as part of multiple therapy for a mixed infection. Some serious infections, e.g. gas gangrene, require high-dose intravenous benzylpenicillin.

Flucloxacillin

Flucloxacillin is resistant to β-lactamases and is therefore of use in treating infections with penicillinase-producing staphylococci which are resistant to benzylpenicillin, but it has poor activity against other pathogens. It has good tissue penetration and therefore is useful in treating soft tissue infections and osteomyelitis.

Ampicillin, amoxicillin and co-amoxiclav

Ampicillin and amoxicillin are β-lactam penicillins and can be taken orally or may be given parenterally. Both are effective against Enterobacteriaceae, *Enterococcus faecalis* and the majority of group D streptococci, but not species of *Klebsiella* or *Pseudomonas*. Clavulanic acid has no antibacterial activity itself, but it does inactivate β-lactamases, so can be used in conjunction with amoxicillin. The combination is known as co-amoxiclav and is useful against β-lactamase producing bacteria that are resistant to amoxicillin on its own. These include resistant strains of *Staphylococcus aureus*, *E. coli*, *Haemophilus influenzae*, *Bacteroides* and *Klebsiella*.

Piperacillin and ticarcillin

These are ureidopenicillins with a broad spectrum of activity against a broad range of gram-positive, gram-negative and anaerobic bacteria. Both are used in combination with β-lactamase inhibitors (tazobactam with piperacillin and clavulanic acid with ticarcillin). They are not active against MRSA but are used in the treatment of septicaemia, hospital-acquired pneumonia and complex urinary tract infections, where they are active against *Pseudomonas* and *Proteus* spp. and have a synergistic effect when used with aminoglycosides such as gentamicin.

Cephalosporins

There are several β-lactamase-susceptible cephalosporins that are of value in surgical practice: cefuroxime, cefotaxime and ceftazidime are widely used. The first two are most effective in intra-abdominal skin and soft-tissue infections, being active against *Staphylococcus aureus* and most Enterobacteriaceae. As a group, the enterococci (*Streptococcus faecalis*) are not sensitive to the cephalosporins. Ceftazidime, although active against the gram-negative organisms and *Staphylococcus aureus*, is also effective against *Pseudomonas aeruginosa*. These cephalosporins may be combined with an aminoglycoside, such as gentamicin, and an imidazole, such as metronidazole, if anaerobic cover is needed.

Aminoglycosides

Gentamicin and tobramycin have similar activity and are effective against gram-negative Enterobacteriaceae. Gentamicin is effective against many strains of *Pseudomonas*, although resistance has been recognised. All aminoglycosides are inactive against anaerobes and streptococci. Serum levels immediately before and 1 hour after intramuscular injection must be taken 48 hours after the start of therapy, and dosage should be modified to satisfy peak and trough levels. Ototoxicity and nephrotoxicity may follow sustained high toxic levels and therefore single, large doses may be safer. Use needs to be discussed with the microbiologist and local policies should be observed.

Vancomycin and teicoplanin

These glycopeptide antibiotics are most active against gram-positive aerobic and anaerobic bacteria and have proved to be effective against MRSA, so are often used as prophylactic antibiotics when there is a high risk of MRSA. They are ototoxic and nephrotoxic, so serum levels should be monitored. They are effective against *C. difficile* in cases of pseudomembranous colitis.

Carbapenems

Meropenem, ertapenem and imipenem are members of the carbapenems. They are stable to β-lactamase, have useful broad-spectrum anaerobic as well as gram-positive activity and are effective for the treatment of resistant organisms, such as ESBL-resistant urinary tract infections or serious mixed-spectrum abdominal infections (peritonitis).

Metronidazole

Metronidazole is the most widely used member of the imidazole group and is active against all anaerobic bacteria. It is particularly safe and may be administered orally, rectally or intravenously. Infections caused by anaerobic cocci and strains of *Bacteroides* and *Clostridia* can be treated, or prevented, by its use. Metronidazole is useful for the prophylaxis and treatment of anaerobic infections after abdominal, colorectal and pelvic surgery and in the treatment of *C. difficile* pseudomembranous colitis.

Ciprofloxacin

Quinolones, such as ciprofloxacin, have a broad spectrum of activity against both gram-positive and gram-negative bacteria but are particularly useful against *Pseudomonas* infections. Many UK hospitals have restricted their use as a preventive measure against the development of *C. difficile* enterocolitis.

Chapter 6

Tropical infections and infestations

Learning objectives

To be able to list:
- The common surgical infections and infestations that occur in the tropics

To appreciate:
- That many patients do not seek medical help until late in the course of the disease because of socioeconomic reasons

To be able to describe:
- The emergency presentations of the various conditions, as patients may not seek treatment until they are very ill

To be able to:
- Diagnose and treat these conditions, particularly as emergencies. The ease of global travel has connected areas where tropical infections are common to areas where they are not. Patients with such an infection who are recently returned from the tropics will mostly present as emergencies

To realise:
- That the ideal management involves a multidisciplinary approach between the surgeon, physician, radiologist, pathologist and microbiologist. In case of doubt, in a difficult situation, there should be no hesitation in seeking help from a specialist centre.

INTRODUCTION

Most surgical conditions in the tropics (regions of the Earth surrounding the equator) are associated with parasitic infestations and infections related to poor hygeinic conditions. With the ease of international travel, diseases that are common in the tropics may present in areas of the world where they are not commonly seen, especially as emergencies.

This chapter deals with the conditions that a surgeon might occasionally see when working in an area where such diseases are uncommon. Typically the patient would be a visitor from a tropical climate or a local resident who has visited the tropics either on holiday or to work. The life cycles of the parasites will not be described. For academic interest readers may refer to the 24th edition of this book should they wish to learn details of the parasitology. The principles of surgical treatment are dealt with in the appropriate sections although, for operative details, referral to a relevant textbook is advised.

AMOEBIASIS

Introduction

Amoebiasis is caused by *Entamoeba histolytica*. The disease is common in the Indian subcontinent, Africa and parts of Central and South America, where almost half the population is infected. The majority remain asymptomatic carriers. The mode of infection is via the faeco-oral route, and the disease occurs as a result of substandard hygiene and sanitation; therefore, the population from the poorer socioeconomic strata are more vulnerable. Amoebic liver abscess, the commonest extraintestinal manifestation, occurs in less than 10% of the infected population and, in endemic areas, is much more common than pyogenic abscess. Patients who are immunocompromised and alcoholics are more susceptible to infection.

Pathogenesis

The organism enters the gut through food or water contaminated with the cyst. In the small bowel, the cysts hatch, and a large number of trophozoites are released and carried to the colon where flask-shaped ulcers form in the submucosa. The trophozoites multiply, ultimately forming cysts, which enter the portal circulation or are passed in the faeces as an infective form that infects other humans as a result of insanitary conditions.

Having entered the portal circulation, the trophozoites are filtered and trapped in the interlobular veins of the liver. They multiply in the portal triads, causing focal infarction of hepatocytes and liquefactive necrosis as a result of proteolytic

enzymes produced by the trophozoites. The areas of necrosis eventually coalesce to form the abscess cavity. The term 'amoebic hepatitis' is used to describe the microscopic picture in the absence of macroscopic abscess, a differentiation only in theory because the medical treatment is the same.

The right lobe is involved in 80% of cases, the left in 10% and the remainder are multiple. One possible explanation for the more common involvement of the right lobe of the liver is that blood from the superior mesenteric vein runs on a straighter course through the portal vein into the larger lobe. The abscesses are most common high in the diaphragmatic surface of the right lobe. This may cause pulmonary symptoms and chest complications. The abscess cavity contains chocolate-coloured, odourless, 'anchovy sauce'-like fluid that is a mixture of necrotic liver tissue and blood. There may be secondary infection of the abscess which causes the pus to smell. While pus in the abscess is sterile unless secondarily infected, trophozoites may be found in the abscess wall in a minority of cases. Untreated abscesses are likely to rupture.

Chronic infection of the large bowel may result in a granulomatous lesion along the large bowel, most commonly seen in the caecum, called an amoeboma.

Summary box 6.1

Amoebiasis – pathology

- *Entamoeba histolytica* is the most common pathogenic amoeba in humans
- The vast majority of carriers are asymptomatic
- Insanitary conditions and poor personal hygiene encourage transmission of the infection
- In the small intestine, the parasite hatches into trophozoites, which invade the submucosa to produce flask-shaped ulcers
- In the portal circulation, the parasite causes liquefactive necrosis in the liver, producing an abscess, the commonest extraintestinal manifestation
- The majority of abscesses occur in the right lobe of the liver
- A mass in the course of the large bowel may indicate an amoeboma

Clinical features

The typical patient with amoebic liver abscess is a young adult male with a history of insidious onset of non-specific symptoms, such as abdominal pain, anorexia, fever, night sweats, malaise, cough and weight loss. These symptoms gradually progress to more specific symptoms of pain in the right upper abdomen and right shoulder tip, hiccoughs and a non-productive cough. A past history of bloody diarrhoea or travel to an endemic area raises the index of suspicion.

Examination reveals a patient who is toxic and anaemic. The patient will have upper abdominal rigidity, tender hepatomegaly, tender and bulging intercostal spaces, overlying skin oedema, a pleural effusion and basal pneumonitis – the last feature is usually a late manifestation. Occasionally, a tinge of jaundice or ascites may be present. Rarely, the patient may present as an emergency due to the effects of rupture of an abscess into the peritoneal, pleural or pericardial cavity.

Amoeboma

This is a chronic granuloma arising in the large bowel, most commonly seen in the caecum. It is prone to occur in longstanding amoebic infection that has been treated intermittently with drugs without completion of a full course, a situation that arises from indiscriminate self-medication, particularly in resource-poor countries. Hence this is more often seen in such countries.

This can easily be mistaken for a carcinoma. An amoeboma should be suspected when a patient from an endemic area with generalised ill health and pyrexia has a mass in the right iliac fossa with a history of blood-stained mucoid diarrhoea. Such a patient is highly unlikely to have a carcinoma because altered bowel habit is not a feature of right-sided colonic carcinoma. While iron deficiency anaemia is a classical elective presentation of a caecal carcinoma, the same is present in an amoeboma because of chronic malnutrition.

Investigations

The haematological and biochemical investigations reflect the presence of a chronic infective process: anaemia, leukocytosis, raised inflammatory markers – erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) – hypoalbuminaemia and deranged liver function tests, particularly elevated alkaline phosphatase.

Serological tests are more specific, with the majority of patients showing antibodies in serum. These can be detected by tests for complement fixation, indirect haemagglutination (IHA), indirect immunofluorescence and enzyme-linked immunosorbent assay (ELISA). These tests are extremely useful in detecting acute infection in non-endemic areas. IHA has a very high sensitivity in acute amoebic liver abscess in non-endemic regions and remains elevated for some time. The persistence of antibodies in a large majority of the population in endemic areas precludes its use as a diagnostic investigation in those locations. In these cases, tests, such as counter-immunoelectrophoresis, are more useful for detecting acute infection.

While flexible sigmoidoscopy is routine in any patient with blood-stained altered bowel habit, an outpatient rigid sigmoidoscopy using a disposable instrument may be a prudent first choice if amoebic infection is suspected in the presence of bloody mucoid diarrhoea. Most amoebic ulcers occur in the rectosigmoid and are therefore within reach of the sigmoidoscope; shallow skip lesions and 'flask-shaped' or 'collar-stud' undermined ulcers may be seen, and can be biopsied or scrapings can be taken along with mucus for immediate microscopic examination. The presence of trophozoites distinguishes the condition from ulcerative colitis.

Imaging techniques

On ultrasound, an abscess cavity in the liver is seen as a hypoechoic or anechoic lesion with ill-defined borders; internal echoes suggest necrotic material or debris (**Figure 6.1**).

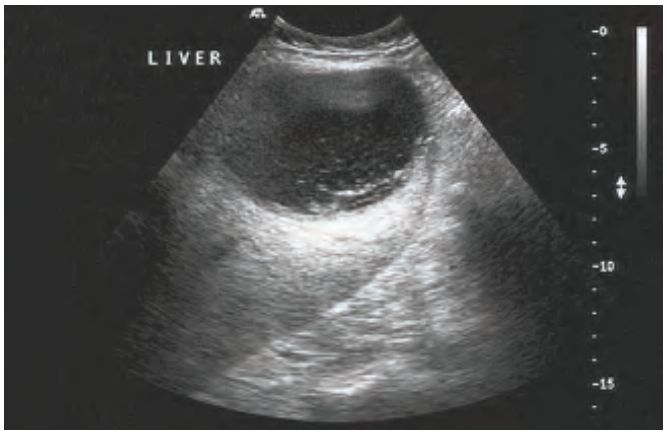

Figure 6.1 Ultrasound of the liver showing a large amoebic liver abscess with necrotic tissue in the right lobe.

The investigation is very accurate and is used for aspiration, both diagnostic and therapeutic. Where there is doubt about the diagnosis, a computed tomography (CT) scan may be helpful (**Figure 6.2**).

Diagnostic aspiration is of limited value except for establishing the typical colour of the aspirate, which is sterile and odourless unless it is secondarily infected.

A CT scan may show a raised right hemidiaphragm, a pleural effusion and evidence of pneumonitis (**Figure 6.3**).

An 'apple-core' deformity on barium enema would arouse suspicion of a carcinoma. A colonoscopy with biopsy is mandatory because the radiological and macroscopic appearance may be indistinguishable from a carcinoma. In doubtful cases, vigorous medical treatment is given, and the patient undergoes colonoscopy again in 3–4 weeks, as these masses are known to regress completely on a full course of drug therapy. If symptoms persist even partially following full medical treatment in a patient who has recently returned from an endemic area, a colonic carcinoma must be excluded forthwith. This is because a dormant colonic carcinoma may become apparent as a result of infestation with amoebic dysentery causing 'traveller's diarrhoea'. However, it must be borne in mind that an amoeboma and a carcinoma can coexist.

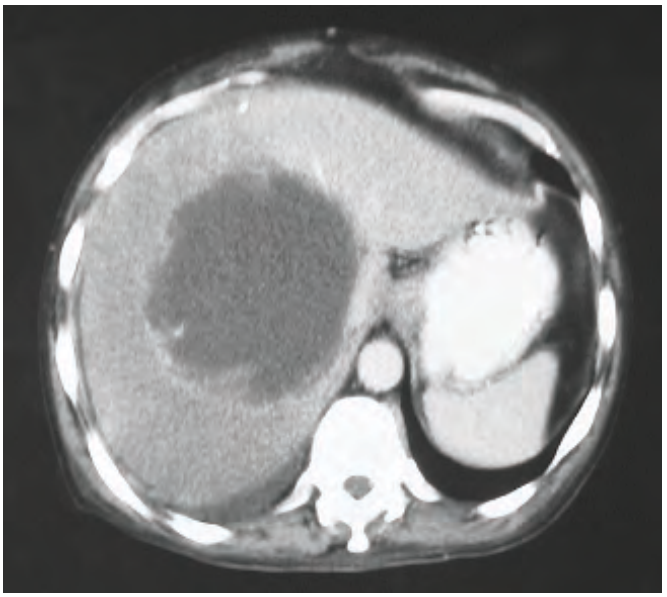

Figure 6.2 Computed tomographic scan showing an amoebic liver abscess in the right lobe.

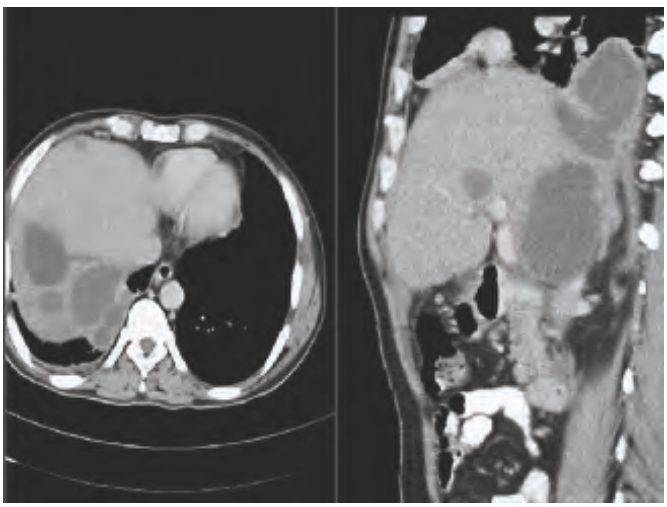

Figure 6.3 Computed tomographic scans showing multiple amoebic liver abscesses with extension into the chest.

Summary box 6.2

Diagnostic pointers for infection with *Entamoeba histolytica*

- Bloody mucoid diarrhoea in a patient from an endemic area or following a recent visit to such a country
- Upper abdominal pain, fever, cough, malaise
- In chronic cases, a mass in the right iliac fossa may be an amoeboma but caecal cancer must be excluded by colonoscopy and biopsy
- Sigmoidoscopy shows typical ulcers – biopsy and scrapes may be diagnostic
- Serological tests are highly sensitive and specific outside endemic areas
- Ultrasound and CT scans are the imaging methods of choice

Treatment

Medical treatment is very effective and should be the first choice in the elective situation, with surgery being reserved for complications. Metronidazole and tinidazole are the effective drugs. After treatment with metronidazole and tinidazole, diloxanide furoate, which is not effective against hepatic infestation, is used for 10 days to destroy any intestinal amoebae.

Aspiration is carried out when imminent rupture of an abscess is expected. Aspiration also helps the penetration of metronidazole, and so reduces the morbidity when carried out with drug treatment in a patient with a large abscess. If there is evidence of secondary infection, appropriate drug treatment is added. The threshold for aspirating an abscess in the left lobe should be lower because of its proximity to the pericardium.

Surgical treatment should be reserved for the complications of rupture into the pleural (usually the right side), peritoneal or pericardial cavities. Resuscitation, drainage and appropriate lavage with vigorous medical treatment are the key principles. In the large bowel, severe haemorrhage and toxic megacolon are rare complications. In these patients, the general principles of a surgical emergency apply, the principles of management being the same as for any toxic megacolon. Resuscitation is followed by resection of bowel with exteriorisation. Then the patient is given vigorous supportive therapy. All such cases are managed in the intensive care unit, as would any patient with toxic megacolon whatever the cause.

An amoeboma that has not regressed after full medical treatment should be managed with colonic resection, particularly if cancer cannot be excluded.

Summary box 6.3

Amoebiasis – treatment

- Medical treatment is very effective
- For large abscesses, repeated aspiration is combined with drug treatment
- Surgical treatment is reserved for complications, such as rupture into the pleural, peritoneal or pericardial cavities
- Acute toxic megacolon and severe haemorrhage are intestinal complications that are treated with intensive supportive therapy followed by resection and exteriorisation: subtotal colectomy with terminal ileostomy and closure of the rectal stump
- When an amoeboma is suspected in a colonic mass, cancer should be excluded by appropriate imaging and biopsy

ROUNDWORM (*ASCARIS LUMBRICOIDES*)

Introduction

Ascaris lumbricoides, commonly called the roundworm, is the commonest intestinal nematode to infect humans and affects a quarter of the world's population. The parasite causes pulmonary symptoms as a larva and intestinal symptoms as an adult worm.

Pathology and life cycle

The eggs can survive in a hostile environment for a long time. The hot and humid conditions in the tropics are ideally suited for the eggs to turn into embryos. The fertilised eggs are present in soil contaminated with infected faeces. Faeco-oral contamination causes human infection.

As the eggs are ingested, the released larvae travel to the liver via the portal system and then through the systemic circulation to reach the lung, the maturation process taking up to 8 weeks. The developed larvae reach the alveoli, are coughed up, swallowed and continue their maturation in the small intestine. Sometimes, the young worms migrate from the tracheobronchial tree into the oesophagus, thus finding their way into the gastrointestinal tract, from where they can migrate to the common bile duct or pancreatic duct. The mature female, once in the small bowel, produces innumerable eggs that are fertilised and thereafter excreted in the stool to perpetuate the life cycle. Eggs in the biliary tract can form a nidus for a stone.

Clinical features

The larval stage in the lungs causes pulmonary symptoms – dry cough, chest pain, dyspnoea and fever – referred to as Loeffler's syndrome. The adult worm can grow up to 45 cm long. Its presence in the small intestine causes malnutrition, failure to thrive, particularly in children, and abdominal pain. Worms that migrate into the common bile duct can produce ascending cholangitis and obstructive jaundice, while features of acute pancreatitis may be caused by a worm in the pancreatic duct.

Small intestinal obstruction can occur, particularly in children, due to a bolus of adult worms incarcerated in the terminal ileum. This is a surgical emergency. Rarely, perforation of the small bowel may occur from ischaemic pressure necrosis from the bolus of worms.

A high index of suspicion is necessary so as not to miss the diagnosis. If a person from a tropical country, or one who has recently returned after spending some time in an endemic area, presents with pulmonary, gastrointestinal, hepatobiliary and pancreatic symptoms, ascariasis should be high on the list of possible diagnoses.

Investigations

As with most parasitic infestations, an increase in the eosinophil count is common. Stool examination may show ova. Sputum or bronchoscopic washings may show Charcot–Leyden crystals or the larvae.

Chest radiograph may show fluffy exudates in Loeffler's syndrome. A barium meal and follow-through may show a bolus of worms in the ileum or lying freely within the small bowel (**Figure 6.4**). Ultrasound may show a worm in the common bile duct (**Figure 6.5**) or pancreatic duct. On magnetic resonance cholangiopancreatography (MRCP), an adult worm may be seen in the common bile duct in a patient presenting with features of obstructive jaundice (**Figure 6.6**). In patients with intestinal obstruction, plain abdominal radiograph may show tubular structures within dilated small bowel, denoting the presence of worms, which would also show up on a contrast CT scan as curvilinear structures.

Wilhelm Loeffler, 1887–1972, Professor of Medicine, Zurich, Switzerland.
Jean Martin Charcot, 1825–1893, Physician, La Salpêtrière, Paris, France.
Ernst von Leyden, 1832–1910, Professor of Medicine, Berlin, Germany.

Figure 6.4 Barium meal and follow-through showing roundworms in the course of the small bowel with barium seen inside the worms in an 18-year-old patient who presented with bouts of colicky abdominal pain and bilious vomiting, which settled with conservative management (courtesy of Dr P Bhattacharaya, Kolkata, India).

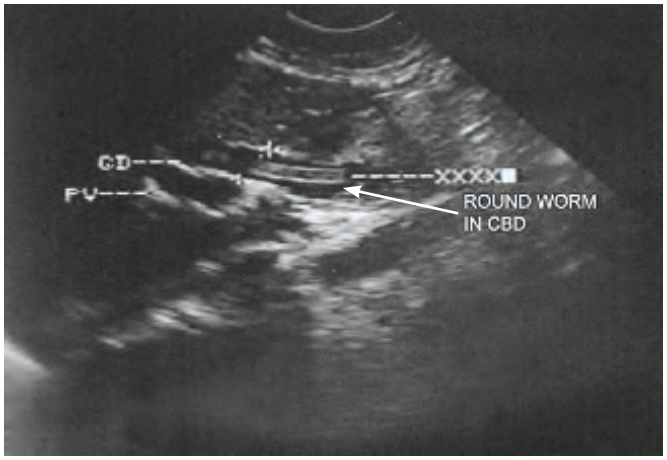

Figure 6.5 Ultrasound scan showing a roundworm in the common bile duct (CBD). The patient presented with obstructive jaundice and had asymptomatic gallstones. On endoscopic retrograde cholangiopancreatography, part of the worm was seen outside the ampulla in the duodenum and was removed through the endoscope. Subsequent laparoscopic cholecystectomy was uneventful.

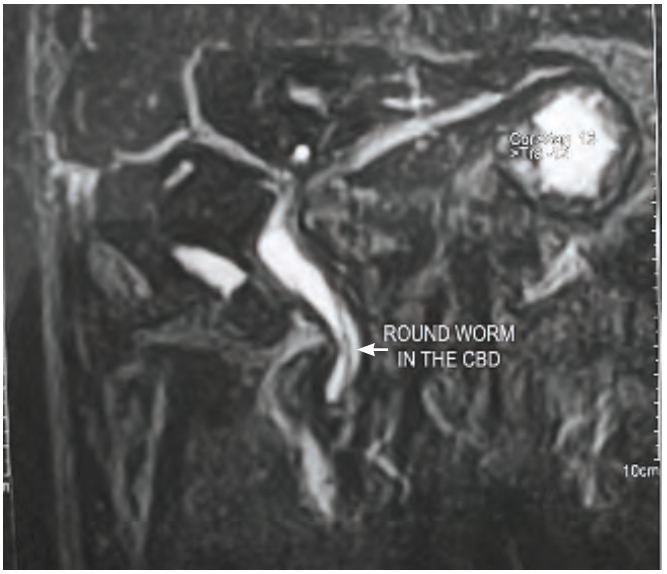

Figure 6.6 Magnetic resonance cholangiopancreatography showing a roundworm in the common bile duct (CBD). The worm could not be removed endoscopically. The patient underwent an open cholecystectomy and exploration of the CBD.

Summary box 6.4

Ascariasis – pathogenesis

- It is the commonest intestinal nematode affecting humans
- Typically found in a humid atmosphere and poor sanitary conditions, hence is seen in the tropics and resource-poor countries
- Larvae cause pulmonary symptoms; adult worms cause gastrointestinal, biliary and pancreatic symptoms
- Distal ileal obstruction is due to a bolus of worms; ascending cholangitis and obstructive jaundice from infestation of the common bile duct
- Acute pancreatitis occurs when a worm is lodged in the pancreatic duct
- Perforation of the small bowel is rare

Treatment

The pulmonary phase of the disease is usually self-limiting and requires symptomatic treatment only. For intestinal disease, patients should ideally be under the care of a physician for treatment with anthelmintic drugs. Certain drugs may cause rapid death of the adult worms and, if there are many worms in the terminal ileum, the treatment may actually precipitate acute intestinal obstruction from a bolus of dead worms. Children who present with features of intermittent or subacute obstruction should be given a trial of conservative management in the form of intravenous fluids, nasogastric suction and hypertonic saline enemas. The last of these helps to disentangle the bolus of worms and also increases intestinal motility.

Surgery is reserved for complications, such as intestinal obstruction that has not resolved on a conservative regime, or when perforation is suspected. At laparotomy, the bolus of worms in the terminal ileum is milked through the ileocaecal valve into the colon for natural passage in the stool.

Postoperatively, hypertonic saline enemas may help in the extrusion of the worms. Strictures, gangrenous areas or perforations need resection and anastomosis. If the bowel wall is healthy, enterotomy and removal of the worms may be performed (Figure 6.7).

Rarely, when perforation occurs due to roundworm, the parasites may be found lying free in the peritoneal cavity. It is safer to bring out the site of perforation as an ileostomy because, in the presence of a large number of worms, the closure of an anastomosis may be at risk of breakdown from the activity of the worms.

When a patient is operated upon as an emergency for a suspected complication of roundworm infestation, the actual diagnosis at operation may turn out to be acute appendicitis, typhoid perforation or a tuberculous stricture, and the presence of roundworms is an incidental finding. Such a patient requires the appropriate surgery depending upon the primary pathology.

Common bile duct or pancreatic duct obstruction from a roundworm can be treated by endoscopic removal, failing which laparoscopic or open exploration of the common bile duct is necessary. Cholecystectomy is also carried out. A full course of antiparasitic treatment must follow any surgical intervention.

Summary box 6.5

Ascariasis – diagnosis and management

- Barium meal and follow-through will show worms scattered in the small bowel
- Ultrasound may show worms in the common bile duct and pancreatic duct
- Plain abdominal radiograph and contrast CT scan will show the worms as tubular or curvilinear structures
- Conservative management with anthelmintics is the first line of treatment even in obstruction
- Surgery is a last resort – various options are available

ASIATIC CHOLANGIOHEPATITIS

Introduction

This disease, also called oriental cholangiohepatitis, is caused by infestation of the hepatobiliary system by *Clonorchis sinensis*. It has a high incidence in the tropical regions of South East Asia, particularly amongst those living in the major sea ports and near river estuaries. The organism, which is a type of liver fluke, resides in snails and fish that act as intermediate hosts. Ingestion of infected fish and snails, when eaten raw or improperly cooked, causes the infection in humans and other fish-eating mammals, which are the definitive hosts.

Pathology

In humans, the parasite matures into the adult worm in the intrahepatic biliary radicles where they may reside for many years. The intrahepatic bile ducts are dilated, with epithelial hyperplasia and periductal fibrosis. These changes may lead to dysplasia, causing cholangiocarcinoma – the most serious and dreaded complication of this parasitic infestation.

The eggs or dead worms may form a nidus for stone formation in the gallbladder or common bile duct, which becomes thickened and much dilated in the late stages. Intrahepatic bile duct stones are also caused by the parasite producing mucin-rich bile. The dilated intrahepatic bile ducts may lead to cholangitis, liver abscess and hepatitis.

Diagnosis

The disease may remain dormant for many years. Clinical features are non-specific and include fever, malaise, anorexia and upper abdominal discomfort. The complete clinical picture can consist of fever with rigors due to ascending cholangitis, obstructive jaundice, biliary colic and pruritus from stones in the common bile duct. Acute pancreatitis may occur because of obstruction of the pancreatic duct by an adult worm. Particularly when presenting in non-endemic areas, it should be noted that if a person from an endemic area complains

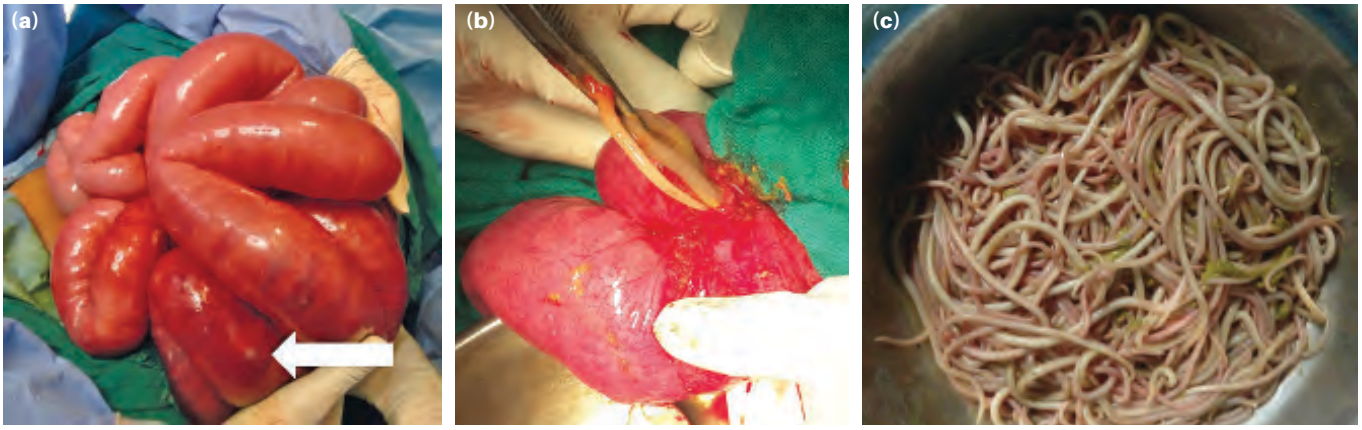

Figure 6.7 **(a)** Roundworms seen through the bowel wall (arrowed). **(b)** Roundworm being removed through enterotomy. **(c)** Removed roundworms.

of symptoms of biliary tract disease, *Clonorchis* infestation should be high in the differential diagnosis.

In advanced cases, liver function tests are abnormal. Confirmation of the condition is by examination of stool or duodenal aspirate, which may show the eggs or adult worms. Ultrasound scan findings may be characteristic, showing uniform dilatation of small peripheral intrahepatic bile ducts with only minimal dilatation of the common hepatic and common bile ducts, although the latter are much more dilated when the obstruction is caused by stones. The thickened duct walls show increased echogenicity and non-shadowing echogenic foci in the bile ducts representing the worms or eggs. Endoscopic retrograde cholangiopancreatography (ERCP) will confirm these findings.

Summary box 6.6

Asiatic cholangiohepatitis – pathogenesis and diagnosis

- Occurs in the Far Eastern tropical zones
- The causative parasite is *Clonorchis sinensis*
- Produces bile duct hyperplasia, intrahepatic duct dilatation and stones
- Increases the risk of cholangiocarcinoma
- May remain dormant for many years
- When active, there are biliary tract symptoms in a generally unwell patient
- Stool examination for eggs or worms is diagnostic
- Ultrasound scan of the hepatobiliary system and ERCP are also diagnostic

Treatment

Praziquantel and albendazole are the drugs of choice. However, the surgeon faces a challenge when there are stones not only in the gallbladder but also in the common bile duct. Cholecystectomy with exploration of the common bile duct is performed when indicated. Repeated washouts are necessary during the exploration, as the common bile duct is dilated and contains stones, biliary debris, sludge and mud. This should be followed by choledochoduodenostomy. As this is a disease with a prolonged and relapsing course, some surgeons prefer to do a choledochojejunostomy to a Roux loop. The Roux loop is brought up to the abdominal wall, referred to as 'an access loop', which allows the interventional radiologist to deal with any future stones.

As a public health measure, people who have emigrated from an endemic area should be offered screening for *Clonorchis* infestation in the form of ultrasound of the hepatobiliary system. This condition can be diagnosed and treated, and even cured, when it is in its subclinical form. Most importantly, the risk of developing the dreadful disease of cholangiocarcinoma is eliminated.

Summary box 6.7

Asiatic cholangiohepatitis – treatment

- Medical treatment can be curative in the early stages
- Surgical treatment is cholecystectomy, exploration of the common bile duct and some form of biliary–enteric bypass
- Prevention – consider offering hepatobiliary ultrasound as a screening procedure to recently arrived migrants from endemic areas

FILARIASIS

Introduction

Filariasis is mainly caused by the parasite *Wuchereria bancrofti* carried by the mosquito. Variants of the parasite called *Brugia malayi* and *Brugia timori* are responsible for causing the disease in about 10% of those infected. The condition affects more than 120 million people worldwide, two-thirds of whom live in India, China and Indonesia. According to the World Health Organization (WHO), after leprosy, filariasis is the most common cause of long-term disability.

Once the host has been bitten by the mosquito, the matured eggs enter the human circulation to hatch and grow into adult worms; the process of maturation takes almost a year. The adult worms mainly colonise the lymphatic system.

Diagnosis

It is mainly males who are affected, because females generally cover a greater part of their bodies with clothing, thus making them less prone to mosquito bites. In the acute presentation, there are episodic attacks of fever with lymphadenitis and lymphangitis.

Occasionally, adult worms may be felt subcutaneously. Chronic manifestations appear after repeated acute attacks over several years. The adult worms cause lymphatic obstruction, resulting in massive lower limb oedema. Obstruction to the cutaneous lymphatics causes skin thickening, not unlike the '*peau d'orange*' appearance in breast cancer, thus exacerbating the limb swelling. Secondary streptococcal infection is common. Recurrent attacks of lymphangitis cause fibrosis of the lymph channels, resulting in a grossly swollen limb with thickened skin, producing the condition of elephantiasis (**Figure 6.8**). Bilateral lower limb filariasis is often associated with scrotal and penile elephantiasis. Early on, there may be a hydrocoele underlying scrotal filariasis (**Figure 6.9**).

Chyluria and chylous ascites may occur. A mild form of the disease can affect the respiratory tract, causing dry cough, and is referred to as tropical pulmonary eosinophilia. The condition of filariasis is clinically very obvious, and thus investigations in the full-blown case are superfluous. Eosinophilia is common, and a nocturnal peripheral blood smear may show

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.
Otto Eduard Heinrich Wucherer, 1820–1873, German physician who practised in Brazil, South America.
Joseph Bancroft, 1836–1894, English physician who worked in Australia.
Peau d'orange is French for 'orange skin'.

Figure 6.8 Left lower limb filariasis – elephantiasis (courtesy of Professor Ahmed Hassan Fahal, FRCS MD MS, Khartoum, Sudan).

the immature forms, or microfilariae. The parasite may also be seen in chylous urine, ascites and hydrocoele fluid.

Treatment

Medical treatment with diethylcarbamazine is very effective in the early stages before the gross deformities of elephantiasis have developed. In the early stages of limb swelling, intermittent pneumatic compression helps, but the treatment has to be repeated over a prolonged period.

A hydrocoele is treated by the usual operation of excision and eversion of the sac with, if necessary, excision of redundant skin. Operations for reducing the size of the limb are hardly ever done these days because the procedures are so rarely successful.

Summary box 6.8

Filariasis

- Caused by *Wuchereria bancrofti*, which is carried by the mosquito
- Lymphatics are mainly affected, resulting in gross limb swelling
- Eosinophilia occurs; immature worms may be seen in a nocturnal peripheral blood smear
- Gross forms of the disease cause a great deal of disability and misery
- Early cases are very amenable to medical treatment
- Intermittent pneumatic compression gives some relief
- The value of various surgical procedures is largely unproven and hence they are rarely performed

Figure 6.9 Filariasis of the scrotum and penis (courtesy of Professor Ahmed Hassan Fahal, FRCS MD MS, Khartoum, Sudan).

HYDATID DISEASE

Introduction and pathology

Hydatid disease is caused by *Ecchinococcus granulosus*, commonly called the dog tapeworm. The disease is globally distributed and, while it is common in the tropics, it is much less common in other countries; for example, in the UK the occasional patient may come from a rural sheep-farming community.

The dog is the definitive host and is the commonest source of infection transmitted to the intermediate hosts – humans, sheep and cattle. In the dog, the adult worm reaches the small intestine, and the eggs are passed in the faeces. These eggs are highly resistant to extremes of temperature and may survive for long periods. In the dog's intestine, the cyst wall is digested, allowing the protoscolices to develop into adult worms. Close contact with an infected dog causes contamination by the oral route, with the ovum thus gaining entry into the human gastrointestinal tract.

The cyst is characterised by three layers, an outer **pericyst** derived from compressed host organ tissues, an intermediate hyaline **ectocyst**, which is non-infective, and an inner **endocyst** that is the germinal membrane and contains viable parasites which can separate forming daughter cysts. A variant of the disease occurs in colder climates caused by *Echinococcus multilocularis*, in which the cyst spreads from the outset by actual invasion rather than expansion.

Classification

In 2003, the WHO Informal Working Group on Echinococcosis (WHO-IWGE) proposed a standardised ultrasound classification based on the status of activity of the cyst. This is universally accepted, particularly because it helps to decide on the appropriate management. Three groups have been recognised:

- Group 1: Active group – cysts larger than 2 cm and often fertile.

- Group 2: Transition group – cysts starting to degenerate and entering a transitional stage because of host resistance or treatment, but may contain viable protoscolices.
- Group 3: Inactive group – degenerated, partially or totally calcified cysts; unlikely to contain viable protoscolices.

Clinical features

As the parasite can colonise virtually every organ in the body, the condition can be protean in its presentation. When a sheep farmer, who is otherwise healthy, complains of a gradually enlarging painful mass in the right upper quadrant with the physical findings of a liver swelling, a hydatid liver cyst should be considered. The liver is the organ most often affected. The lung is the next most common. The parasite can affect any organ (**Figures 6.10 and 6.11**) or several organs in the same patient (**Figure 6.12**).

The disease may be asymptomatic and discovered coincidentally at postmortem or when an ultrasound or CT scan is done for some other condition. Symptomatic disease presents with a swelling causing pressure effects. Thus, a hepatic lesion causes dull pain from stretching of the liver capsule, and a pulmonary lesion, if large enough, causes dyspnoea. Daughter cysts may communicate with the biliary tree, causing obstructive jaundice and all the usual clinical features associated with it in addition to symptoms attributable to a parasitic infestation (**Figure 6.13**). Features of raised intracranial pressure

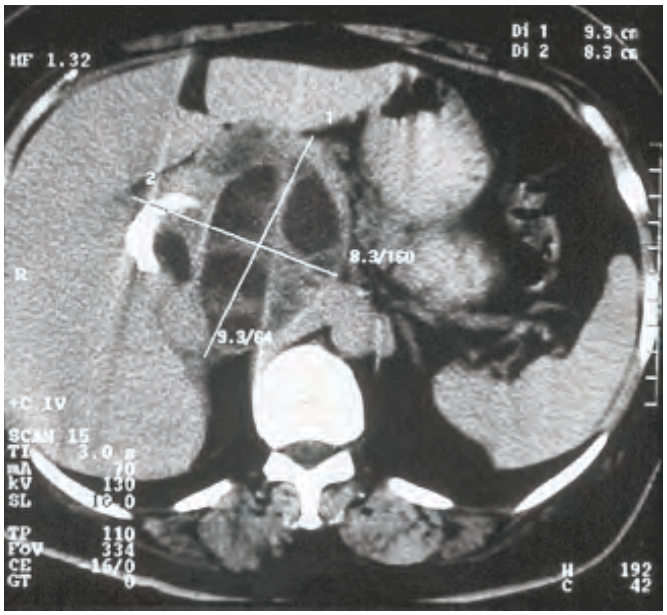

Figure 6.10 Computed tomographic scan showing a hydatid cyst of the pancreas. A differential diagnosis of hydatid cyst or a tumour was considered. At exploration, the patient was found to have a hydatid cyst, which was excised followed by 30 months of treatment with albendazole, and remains free of disease.

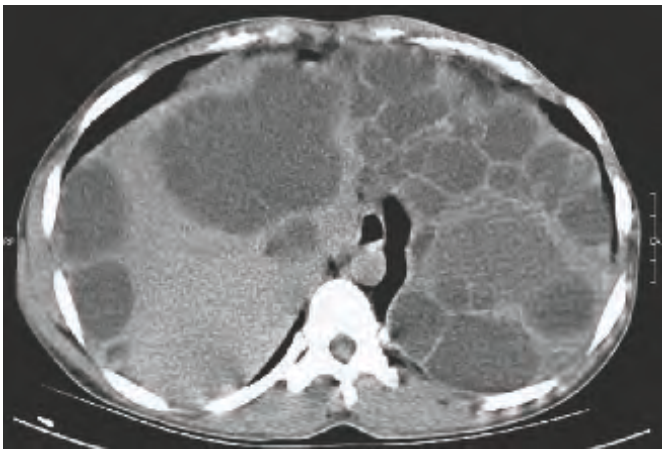
Figure 6.12 Computed tomographic scan showing disseminated hydatid cysts of the abdomen. The patient was started on albendazole but was lost to follow-up (courtesy of Dr P Bhattacharaya, Kolkata, India).

Figures 6.11 Anteroposterior **(a)** and lateral **(b)** views of computed tomographic scans showing a large hydatid cyst of the right adrenal gland. The patient presented with a mass in the right loin and underwent an adrenalectomy (courtesy of Dr P Bhattacharaya, Kolkata, India).



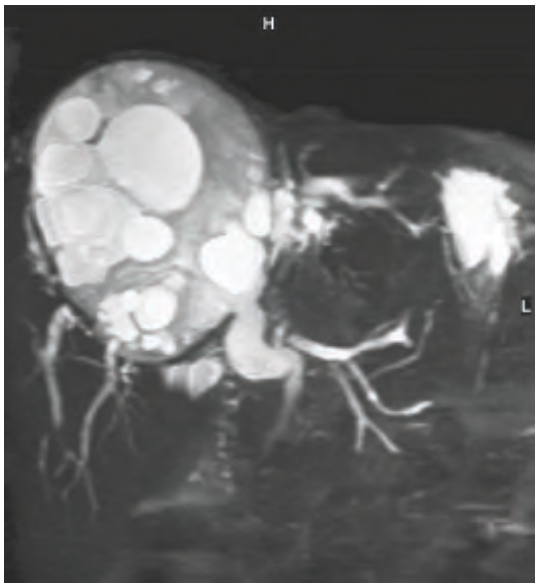


Figure 6.13 Magnetic resonance cholangiopancreatography showing a large hepatic hydatid cyst with daughter cysts communicating with the common bile duct, causing obstruction and dilatation of the entire biliary tree (courtesy of Dr B Agarwal, New Delhi, India).

or unexplained headaches in a patient from a sheep-rearing community should raise the suspicion of a cerebral hydatid cyst.

The patient may present as an emergency with severe abdominal pain following minor trauma, when the CT scan may be diagnostic (**Figure 6.14**). Rarely, a patient may present as an emergency with features of anaphylactic shock without any obvious cause. Such a patient may subsequently cough up white material that contains scolices that have travelled into the tracheobronchial tree from rupture of a hepatic hydatid on the diaphragmatic surface of the liver.

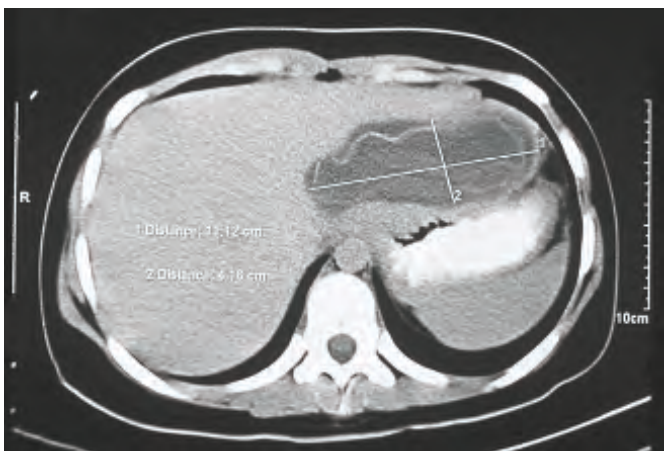

Figure 6.14 Computed tomographic (CT) scan of the upper abdomen showing a hypodense lesion of the left lobe of the liver; the periphery of the lesion shows a double edge. This is the lamellar membrane of the hydatid cyst that separated after trivial injury. The patient was a 14-year-old girl who developed a rash and pain in the upper abdomen after dancing. The rash settled down after a course of antihistamines. The CT scan was performed 2 weeks later for persisting upper abdominal pain.

Diagnosis

There should be a high index of suspicion. Investigations show a raised eosinophil count; serological tests, such as ELISA and immunoelectrophoresis, point towards the diagnosis. Ultrasound and CT scan are the investigations of choice. The CT scan shows a smooth space-occupying lesion with several septa. Ultrasound of the biliary tract may show abnormality in the gallbladder and bile ducts, when hydatid infestation of the biliary system should be suspected. Ultimately, the diagnosis is made by a combination of good history and clinical examination supplemented by serology and imaging.

Summary box 6.9

Hydatid disease – diagnosis

- In the UK, the usual sufferer is a sheep farmer
- While any organ may be involved, the liver is by far the most commonly affected
- Elective clinical presentation is usually in the form of a painful lump arising from the liver
- Anaphylactic shock due to rupture of the hydatid cyst is the emergency presentation
- CT scan is the best imaging technique – the diagnostic feature is a space-occupying lesion with a smooth outline with septa

Treatment

Here, the treatment of hepatic hydatid is outlined because the liver is most commonly affected, but the same general principles apply whichever organ is involved.

These patients should be treated in a tertiary unit where good teamwork between an expert hepatobiliary surgeon, an experienced physician and an interventional radiologist is available. Surgical treatment by minimal access therapy is best summarised by the mnemonic PAIR (puncture, aspiration, injection and reaspiration). This is done after adequate drug treatment with albendazole, although praziquantel has also been used, both of these drugs being available only on a 'named patient' basis.

Whether the patient is treated only medically or in combination with surgery will depend upon the clinical group (which gives an idea as to the activity of the disease), the number of cysts and their anatomical position. Radical total or partial pericystectomy with omentoplasty or hepatic segmentectomy (especially if the lesion is in a peripheral part of the liver) are some of the surgical options. During the operation, scolicidal agents are used, such as hypertonic saline (15–20%), ethanol (75–95%) or 1% povidone iodine (although some use a 10% solution). This may cause sclerosing cholangitis if biliary radicles are in communication with the cyst wall. A laparoscopic approach to these procedures is being tried (see below).

Obviously, cysts in other organs need to be treated in accordance with the actual anatomical site, along with the general principles described. An asymptomatic cyst which is inactive (group 3) may be left alone.

Summary box 6.10

Hydatid cyst of the liver – treatment

- Ideally managed in a tertiary unit by a multidisciplinary team of hepatobiliary surgeon, physician and interventional radiologist
- Leave asymptomatic and inactive cysts alone – monitor size by ultrasound
- Active cysts should first be treated by a full course of albendazole
- Several procedures are available – PAIR, pericystectomy with omentoplasty and hepatic segmentectomy; appropriate management is customised according to the particular patient and organ involved
- Increasingly, a laparoscopic approach is being tried

Laparoscopic management

Currently, surgeons trained in minimal access surgery perform hydatid surgery using minimal access. Laparoscopic marsupialisation of the cyst (de-roofing), consisting of removal of the cyst containing the endocyst along with daughter cysts, is the most common procedure. In the initial steps, the cyst is aspirated, taking care not to spill any contents, using povidone iodine or hypertonic saline as a scolicidal agent. Any communication with the biliary tree is oversewn and pedicled omentum is sutured to the margins of the cyst.

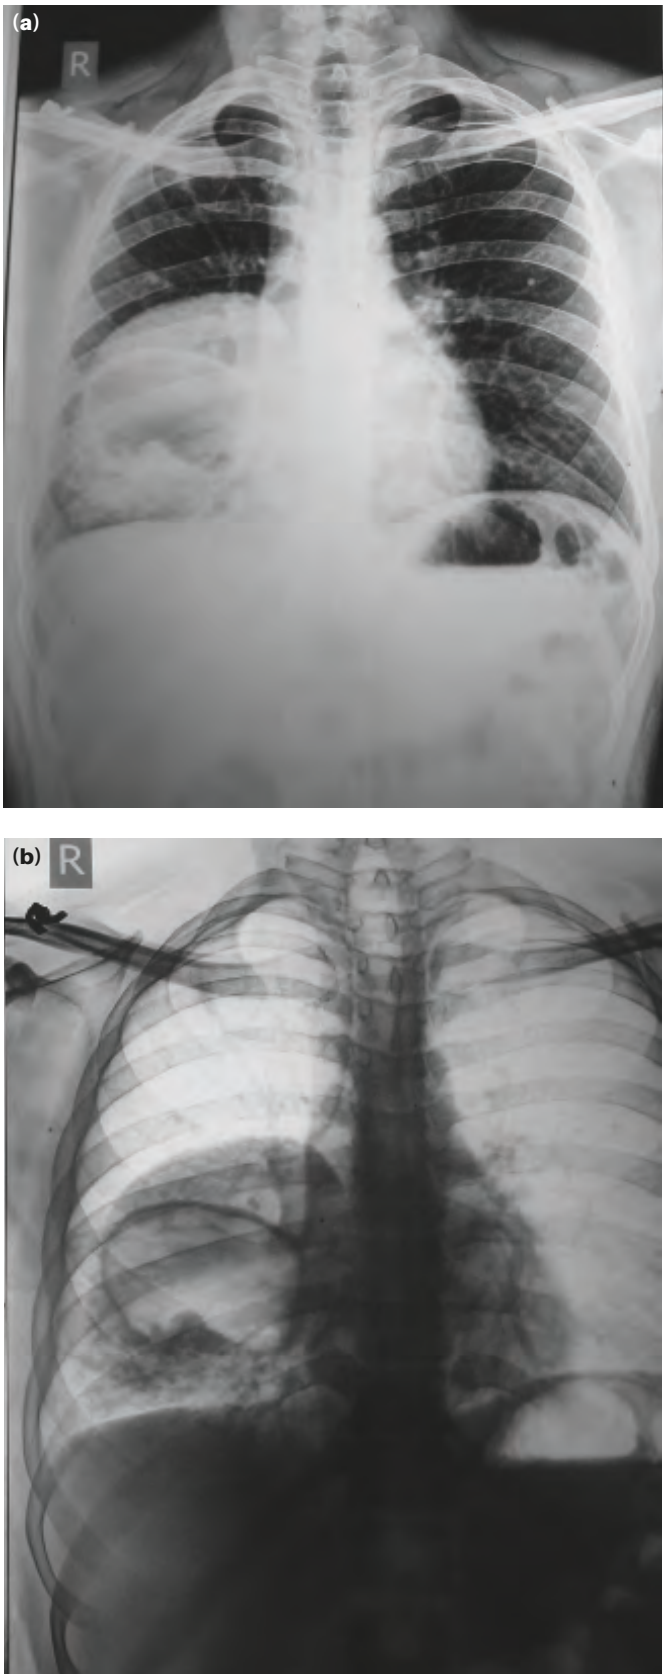
If the cyst is small, superficial and in the left lobe, cystopericystectomy is performed at centres experienced enough to do more advanced surgery, removing the entire cyst intact.

Pulmonary hydatid disease

The lung is the second commonest organ affected after the liver. The size of the cyst can vary from very small to a considerable size. The right lung and lower lobes are slightly more often involved. The cyst is usually single, although multiple cysts do occur and concomitant hydatid cysts in other organs, such as the liver, are not unknown. The condition may be silent and found incidentally. Symptomatic patients present with cough, expectoration, fever, chest pain and sometimes haemoptysis. Silent cysts may present as an emergency due to rupture or an allergic reaction.

Uncomplicated cysts present as rounded or oval lesions on chest radiography. Erosion of the bronchioles results in air being introduced between the pericyst and the laminated membrane and gives a fine radiololucent crescent, the 'meniscus or crescent sign' (**Figure 6.15**). This is often regarded as a sign of impending rupture. When the cyst ruptures, the crumpled collapsed endocyst floats in the residual fluid, giving rise to the 'water-lily' sign on CT scan (**Figure 6.16**). Rupture into the pleural cavity results in pleural effusion. CT scan defines the pathology in greater detail.

The mainstay of treatment of pulmonary hydatid is surgery. Medical treatment is less successful and considered when surgery is not possible because of poor general condition or diffuse disease affecting both lungs, or recurrent or ruptured cysts. The principle of surgery is to preserve as much viable lung tissue as possible. The exact procedure can vary: cystotomy, capittonage, pericystectomy, segmentectomy or occasionally pneumonectomy.



Figures 6.15 Chest radiographs: **(a)** showing a smooth rounded cystic lesion in the right lower lobe; **(b)** showing a 'meniscus or crescent' sign (courtesy of Professor Saibal Gupta, MS, FRCS, Professor of Cardiovascular Surgery, Kolkata, India and Dr Rupak Bhattacharya, Kolkata, India).

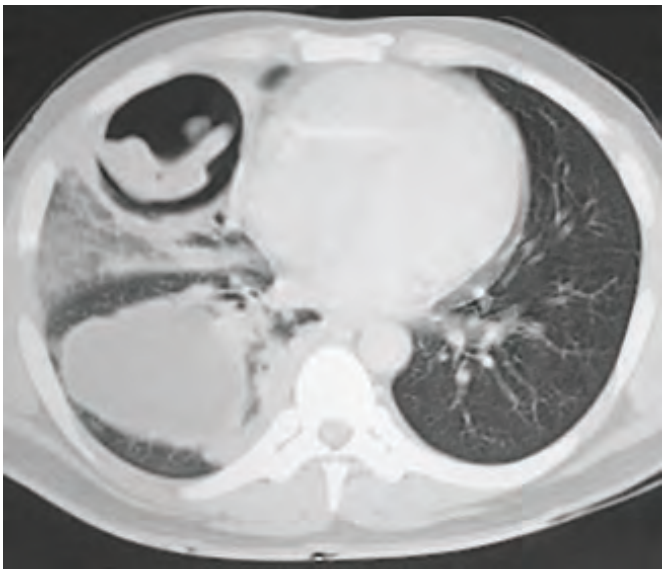


Figure 6.16 Computed tomographic scan showing the 'water-lily' sign. A young mountaineer, while on a high altitude trip, complained of sudden shortness of breath, cough and copious expectoration consisting of clear fluid and flaky material. At first thought to be due to pulmonary oedema, it turned out to be ruptured hydatid cyst, successfully treated by surgery (courtesy of Professor Saibal Gupta, MS, FRCS, Professor of Cardiovascular Surgery, Kolkata, India and Dr Rupak Bhattacharya, Kolkata, India).

Summary box 6.11

Pulmonary hydatid disease

- The second most common organ involved
- Size of the cyst has a wide variation
- May present as an incidental finding
- Clinical presentation may be elective or as an emergency due to rupture
- Plain radiograph shows 'meniscus or crescent' sign; CT shows 'water-lily' sign
- Ideal treatment is surgical – various choices are available

LEPROSY

Introduction

Leprosy, also called Hansen's disease, is a chronic infectious disease caused by an acid-fast bacillus, *Mycobacterium leprae*, that is widely prevalent in the tropics. Globally, India, Brazil, Nepal, Mozambique, Angola and Myanmar account for 91% of all cases; India alone accounts for 78% of the world's disease. Patients suffer not only from the primary effects of the disease but also from social discrimination, sadly compounded by use of the word 'leper' for one afflicted with this disease.

Close contact over a long duration (several years) is required for disease transmission. Ignorance of this fact on the part of the general public results in ostracism and social stigma. History records that in the distant past sufferers were made to wear cow bells so that other people could avoid them. The use of the term 'leper', still used metaphorically to denote an outcast, does not help to break down the social barriers that continue to exist against the sufferer.

Pathology

The bacillus inhabits the colder parts of the body – hence it is found in the nasal mucosa and skin in the region of the ears, thus involving the facial nerve as it exits from the stylomastoid foramen. The disease is transmitted from the nasal secretions of a patient, the infection being contracted in childhood or early adolescence. After an incubation period of several years, the disease presents with skin, upper respiratory or neurological manifestations. The bacillus is acid fast but weakly so when compared with *Mycobacterium tuberculosis*.

The disease is broadly classified into two groups – lepromatous and tuberculoid. In lepromatous leprosy, there is widespread dissemination of abundant bacilli in the tissues, with macrophages and few lymphocytes. This is a reflection of the poor immune response, resulting in depleted host resistance from the patient. In tuberculoid leprosy, on the other hand, the patient shows a strong immune response with scant bacilli in the tissues, epithelioid granulomas, numerous lymphocytes and giant cells. The tissue damage is inversely proportional to the host's immune response. There are various grades of the disease between the two main spectra.

Summary box 6.12

Mycobacterium leprae – pathology

- Leprosy is a chronic curable infection caused by *Mycobacterium leprae*
- It occurs mainly in tropical regions and resource-poor countries
- The majority of cases are located in the Indian subcontinent
- Transmission is through nasal secretions, the bacillus inhabiting the colder parts of the body
- It is attributed to poor hygiene and insanitary conditions
- The incubation period is several years
- The initial infection occurs in childhood
- Lepromatous leprosy denotes a poor host immune reaction
- Tuberculoid leprosy occurs when host resistance is stronger than the virulence of the organism

Clinical features and diagnosis

The disease is slowly progressive and affects the skin, upper respiratory tract and peripheral nerves. In tuberculoid leprosy, the damage to tissues occurs early and is localised to one part of the body, with limited deformity of that organ. Neural involvement is characterised by thickening of the nerves, which are tender. There may be asymmetrical well-defined

Owing to the stigma attached to the word 'leper', RG Cochrane suggested that the best name for **leprosy** is 'Hansen's disease'.
Gerhard Henrik Armauer Hansen, 1841–1912, physician in charge of a leper hospital near Bergen, Norway.
Robert Greenhill Cochrane, 1899–1985, medical missionary who became an international authority on leprosy; he devoted his time to leprosy patients in South East Asia, particularly India.

Figure 6.17 Lateral view of the face showing collapse of the nasal bridge due to destruction of nasal cartilage by leprosy.

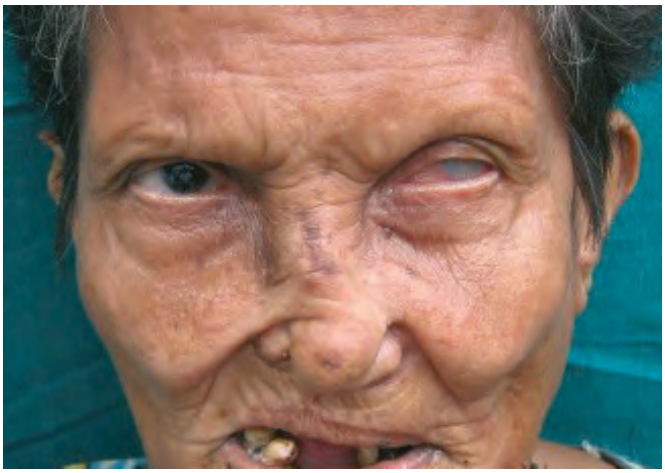

Figure 6.18 Frontal view of the face showing eye changes in leprosy – paralysis of orbicularis oculi and loss of eyebrows.

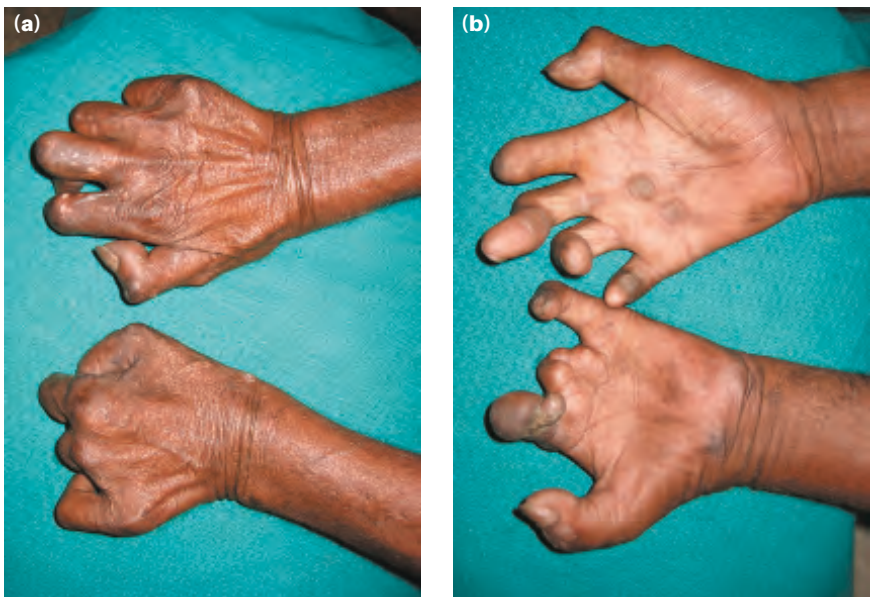
anaesthetic hypopigmented or erythematous macules with elevated edges and a dry and rough surface – lesions called leprids. In lepromatous leprosy, the disease is symmetrical and extensive. Cutaneous involvement occurs in the form of several pale macules that form plaques and nodules called lepromas. The deformities produced are divided into primary, which are caused by leprosy or its reactions, and secondary, resulting from effects such as anaesthesia of the hands and feet.

Nodular lesions on the face in the acute phase of the lepromatous variety are known as 'leonine facies' (looking like a lion). Later, there is wrinkling of the skin, giving an aged appearance to a young individual. There is loss of the eyebrows and destruction of the lateral cartilages and septum of the nose with collapse of the nasal bridge and lifting of the tip of the nose (**Figure 6.17**). There may be paralysis of the branches of the facial nerve in the bony canal or of the zygomatic branch. Blindness may be attributed to exposure keratitis or iridocyclitis. Paralysis of the orbicularis oculi causes incomplete closure of the eye, epiphora and conjunctivitis (**Figure 6.18**). The hands are typically clawed (**Figure 6.19**) because of involvement of the ulnar nerve at the elbow and the median nerve at the wrist. Anaesthesia of the hands makes these patients vulnerable to frequent burns and injuries. Similarly, clawing of the toes (**Figure 6.20**) occurs as a result of involvement of the posterior tibial nerve. When the lateral popliteal nerve is affected, it leads to foot drop, and the nerve can be felt to be thickened behind the upper end of the fibula. Anaesthesia of the feet predisposes to trophic ulceration (**Figure 6.21**), chronic infection, contraction and autoamputation. Involvement of the testes causes atrophy,



Figures 6.19 (a, b) Typical bilateral claw hand from leprosy due to involvement of the ulnar and median nerves.

Figure 6.20 Claw toes from involvement of the posterior tibial nerve by leprosy; also note autoamputation of toes of the right foot.

Figure 6.21 Bilateral trophic ulceration of the feet due to anaesthesia of the soles resulting from leprosy; also note claw toes on the left foot.

which in turn results in gynaecomastia (**Figure 6.22**). Confirmation of the diagnosis is obtained by a skin smear or skin biopsy, which shows the classical histological and microbiological features.

Summary box 6.13

Leprosy – diagnosis

- Typical clinical features and awareness of the disease should help to make a diagnosis
- The face has an aged look, with collapse of the nasal bridge and ocular changes
- Thickened peripheral nerves, patches of anaesthetic skin, claw hands, foot drop and trophic ulcers are characteristic
- Microbiological examination of the acid-fast bacillus and typical histology on skin biopsy are confirmatory

Treatment

A herbal derivative from the seeds of *Hydrocarpus wightiana* called chalmoogra oil was the mainstay of treatment, with some success, until the advent of dapsone (diamino-diphenyl sulphone). Dapsone, one of the principal drugs, was a derivative of prontosil red (Domagk). This is used according to the WHO guidelines along with rifampicin and clofazimine. During treatment, the patient may develop acute manifestations. These are controlled with steroids. Multiple drug therapy for 12 months is the key to treatment. A team approach between an infectious diseases specialist, plastic surgeon, ophthalmologist, and hand or orthopaedic surgeon is important.

Figure 6.22 Typical leonine facies and gynaecomastia in leprosy.

Surgical treatment is indicated in advanced stages of the disease for functional disability of limbs, cosmetic disfigurement of the face and visual problems. These entail major reconstructive surgery, the domain of the plastic surgeon.

Surgery for deformities in the hand is aimed at returning the ability to achieve a grasp and a pinch grip. Tendon transfers are used to recreate the function of the lumbricals which have been lost due to damage to the ulnar nerve. In the foot, damage to the common peroneal nerve leads to a foot drop due to paralysis of tibialis anterior. If a foot-drop splint is not adequate then once again a tendon transfer (tibialis posterior into the dorsum of the foot) will improve function. Ulcers resulting from an insensate foot should be completely debrided followed by protection with a plaster cast.

Gerhard Domagk, 1895–1964, German physician, Lecturer in Pathologic Anatomy, University of Munster, Germany, discovered prontosil in 1935, for which he was awarded the Nobel Prize for Physiology or Medicine in 1939.

Paul Wilson Brand CBE, FRCS, 1914–2003, was born to missionary parents in Southern India, and qualified in London in 1943. He himself was a dedicated missionary who was 'An extraordinary gifted orthopaedic surgeon who straightened crooked hands and unravelled the riddle of leprosy.' As a pioneer in tendon transfer techniques, he established and practised initially in New Life Center, Vellore, South India and Schieffelin Leprosy Research Centre, Karigiri, South India. Initially he trained as a carpenter and builder and maintained that his training as a carpenter helped him in his expertise in tendon transplantation. When he was awarded the CBE, his wife, Margaret, came to know about it when she found a letter from Her Majesty's Government informing him of the award, while emptying the pockets of his trousers before they were put into the wash. He later moved to Louisiana State University, Baton Rouge, LA, where he continued his work, and finally to Seattle as Emeritus Professor of Orthopaedics in the University of Washington, Seattle, USA.

Margaret Brand, alongside her husband, Paul Brand, also contributed immensely to the health of leprosy patients by concentrating on research to prevent blindness in leprosy. She became known as 'the woman who first helped lepers to see'.

Frank Tovey OBE, b.1927, another English surgeon at about the same time (1951–1967), also performed extensive tendon transfers, facial and other reconstructive surgery on leprosy patients in Southern India in the State of Mysore. In this he was helped by his wife, Winifred, who organised the physiotherapy and rehabilitation of the patients and established village diagnostic and treatment centres).

The general surgeon may be called upon to treat a patient when the deformity is so advanced that amputation is required or an abscess needs drainage as an emergency.

All surgical procedures obviously need to be done under antileprosy drug treatment. This is best achieved by a team approach. Educating patients about the dreadful sequelae of the disease so that they seek medical help early is important. It is also necessary to educate the general public that patients suffering from the disease should not be made social outcasts.

Summary box 6.14

Leprosy – treatment

- Multiple drug therapy for a year
- Team approach
- Surgical reconstruction requires the expertise of a hand surgeon, orthopaedic surgeon and plastic surgeon
- Education of the patient and general public should be the keystone in prevention

MYCETOMA

(This section has been contributed by: Professor Ahmed Hassan Fahal MBBS, FRCS, FRCSI, FRCSG, MD, MS, FRCP (London), Professor of Surgery, University of Khartoum, Khartoum, Sudan)

Introduction

Mycetoma is a chronic, specific, granulomatous, progressive, destructive inflammatory disease, which involves the skin, subcutaneous tissues and deeper structures. The causative organism may be true fungi, when the condition is called eumycetoma; when caused by bacteria it is called actinomycetoma. The pathognomonic feature is the triad of painless subcutaneous mass, multiple sinuses and seropurulent discharge. It causes tissue destruction, deformity, disability, and death in extreme cases.

Epidemiology and pathogenesis

The condition predominently occurs in the 'mycetoma belt' that lies between the latitudes 15° south and 30° north, comprising the countries of Sudan, Somalia, Senegal, India, Yemen, Mexico, Venezuela, Columbia, Argentina and a few others. The route of infection is inoculation of the organism that is resident in the soil through a traumatised area. Although in the vast majority there is no history of trauma, the portal of entry is always an area of minor unrecognised trauma in a bare-footed individual walking in a terrain full of thorns. Hence the foot is the commonest site affected. Mycetoma is not contagious.

Once the granuloma forms it increases in size, and the overlying skin becomes stretched, smooth, shiny and attached to the lesion. Areas of hypo- or hyperpigmentation sometimes develop. Eventually it invades the deeper structures. This is usually gradual and delayed in eumycetoma. In actinomycetoma, invasion to deeper tissues occurs earlier and is more extensive. The tendons and nerves are spared until late in the disease. This may explain the rarity of neurological and trophic changes even in patients with long-standing disease. Trophic changes are rare because the blood supply is adequate.

Summary box 6.15

Mycetoma – pathogenesis

- Mostly occurs in the 'mycetoma belt'
- There are two types – eumycetoma and actinomycetoma
- Caused by fungi or bacteria entering through a site of trauma which may not be apparent; hence the foot is most commonly affected
- Produces a chronic, specific, granulomatous, progressive, destructive inflammatory lesion
- Results in tissue destruction, deformity, disability and sometimes death

Clinical presentation

As mycetoma is painless, presentation is late in the majority. It presents as a slowly progressive, painless, subcutaneous swelling commonly at the site of presumed trauma. The swelling is variable in its physical characteristics: firm and rounded, soft and lobulated, rarely cystic, and is often mobile. Multiple secondary nodules may evolve; they may suppurate and drain through multiple sinus tracts. The sinuses may close transiently after discharge during the active phase of the disease. Fresh adjacent sinuses may open while some of the old ones may heal completely. They coalesce and form abscesses, the discharge being serous, serosanguineous or purulent. During the active phase of the disease the sinuses discharge grains, the colour of which can be black, yellow, white or red depending upon the organism. Pain supervenes when there is secondary bacterial infection.

The common sites affected are those that come into contact with soil during daily activities: the foot in 70% (**Figure 6.23**) and the hand in 12% (**Figure 6.24**). In endemic areas the knee (**Figure 6.25**), arm, leg, head and neck (**Figure 6.26**), thigh and perineum (**Figure 6.27**) can

Figure 6.23 Mycetoma of the foot.

Figure 6.24 Mycetoma of the hand.

Figure 6.25 Mycetoma of the knee.

Figure 6.26 Actinomycetoma of the head and neck.

Fibure 6.27 Extensive sattelite inguinal actinomycetoma from a primary foot lesion involving the anterior abdominal wall and perineum.

be involved. Rare sites are the chest, abdominal wall, facial bones, mandible, testes, paranasal sinuses and eye.

In some patients there may be areas of local hyperhidrosis over the lesion. This may be due to sympathetic overactivity or increased local temperature due to raised arterial blood flow caused by the chronic inflammation. In the majority of patients, the regional lymph nodes are small and shotty. Lymphadenopathy is common. This may be due to secondary bacterial infection, lymphatic spread of mycetoma or a local immune response to the disease.

The condition remains localised; constitutional disturbances are a sign of secondary bacterial infection. Cachexia and anaemia from malnutrition and sepsis may be seen in late cases. It can be fatal, especially in cases of cranial mycetoma.

Spread

Local spread occurs predominantly along tissue planes. The organism multiplies to form colonies which spread along the fascial planes to skin and underlying structures. Lymphatic spread, more common in actinomycetoma, occurs to the regional lymph nodes, and increases with repeated inadequate surgical excision procedures. During the active phase of the disease, these lymphatic satellites may suppurate and discharge; lymphadenopathy may also be due to secondary bacterial infection. Spread via the blood stream can occur.

The apparent clinical features of mycetoma are not always a reliable indicator of the extent and spread of the disease. Some small lesions with few sinuses may have many deep connecting tracts, through which the disease can spread quite extensively. Therefore surgery in mycetoma under local anaesthesia is contraindicated.

Differential diagnosis

Mycetoma should be distinguished from Kaposi's sarcoma, malignant melanoma, fibroma and foreign body (thorn) granuloma. A radiograph that demonstrates the presence of bone destruction in the absence of sinuses is suggestive of tuberculosis. The radiological features of advanced mycetoma are similar to those of primary osteogenic sarcoma. Primary osseous mycetoma is to be differentiated from chronic osteomyelitis, osteoclastoma, bone cysts and syphilitic osteitis. In endemic areas the dictum should be 'any subcutaneous swelling must be considered a mycetoma until proven otherwise'.

Diagnosis

Several imaging techniques are available to confirm the diagnosis: plain radiography, ultrasound, CT and magnetic resonance imaging (MRI).

Plain radiograph

In the early stages, soft tissue shadows (often multiple) with calcification and obliteration of the fascial planes may be seen. As the disease progresses, the cortex may be compressed from the outside by the granuloma, leading to bone scalloping. Periosteal reaction with new bone spicules may create a sun-ray appearance and Codman's triangle, not unlike an osteogenic sarcoma (**Figure 6.28**). Late in the disease, there may be multiple punched-out cavities throughout the bone.

Figure 6.28 Plain x-ray of the knee showing multiple large cavities involving the lower femur, upper tibia and fibula, with well-defined margins and periosteal reaction typical of eumycetoma.

Ultrasound

This can differentiate between eumycetoma and actinomycetoma as well as between mycetoma and other conditions. In eumycetoma, the grains produce numerous sharp bright hyper-reflective echoes. There are multiple thick-walled cavities with absent acoustic enhancement. In actinomycetoma, the findings are similar but the grains are less distinct. The size and extent of the lesion can be accurately determined ultrasonically, a finding useful in planning surgical treatment.

MRI

This helps to assess bone destruction, periosteal reaction, and particularly soft tissue involvement (**Figure 6.29**). MRI usually shows multiple 2–5 mm lesions of high signal intensity, which indicates the granuloma, interspersed within a low-intensity matrix denoting the fibrous tissue. The 'dot-in-circle sign', which indicates the presence of grains, is highly characteristic.

CT scan

CT findings in mycetoma are not specific but are helpful to detect early bone involvement.

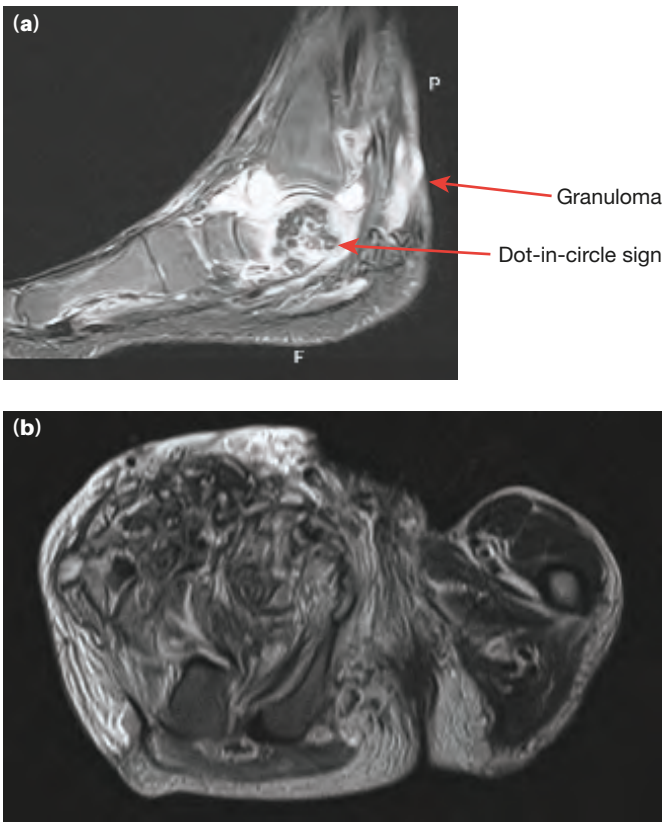


Figure 6.29 **(a)** Magnetic resonance imaging (MRI) of the foot showing multiple lesions of high signal intensity, which indicates granuloma, interspersed within a low-intensity matrix, which is the fibrous tissue and the 'dot-in-circle sign', which indicates the presence of grains. **(b)** MRI showing massive upper thigh and lower abdominal actinomycetoma.

Moritz Kaposi, 1837–1902, Hungarian born, Professor of Dermatology, University of Vienna, Austria, was born to a Jewish family; originally his surname was Kohn. When he converted to Catholicism in 1871, he changed his surname to Kaposi. He described the sarcoma in 1872. The viral cause was discovered in 1994.
Ernest Codman, 1869–1940, American surgeon. Codman's triangle can be seen in osteosarcoma, Ewing's sarcoma and subperosteal abscess and haematoma.

Histopathological diagnosis

Deep biopsy is obtained under general or regional anaesthesia, although the chance of local spread is high. The biopsy should be adequate, contain grains and should be fixed immediately in 10% formal saline.

Three types of host tissue reaction occur against the organism.

- **Type I:** the grains are usually surrounded by a layer of polymorphonuclear leukocytes. The innermost neutrophils are closely attached to the surface of the grain, sometimes invading the grain and causing its fragmentation. The hyphae and cement substance disappear and only remnants of brown pigmented cement are left behind. Outside the zone of neutrophils there is granulation tissue containing macrophages, lymphocytes, plasma cells and few neutrophils. The mononuclear cells increase in number towards the periphery of the lesion. The outermost zone of the lesion consists of fibrous tissue.
- **Type II:** the neutrophils largely disappear and are replaced by macrophages and multinucleated giant cells which engulf grain material. This consists largely of pigmented cement substance although hyphae are sometimes identified.
- **Type III:** this is characterised by the formation of a well organised epithelioid granuloma with Langhan's type giant cells. The centre of the granuloma will sometimes contain remnants of fungal material.

Fine needle aspiration cytology (FNAC)

Fine needle aspiration cytology (FNAC) can yield an accurate diagnosis and helps in distinguishing between eumycetoma and actinomycetoma. The technique is simple, rapid and sensitive.

Culture

A variety of microorganisms are capable of producing mycetoma that can be identified by their textural description, morphology and biological activities in pure culture. Deep surgical biopsy is always needed to obtain the grains which are the source of culture. The grains extracted through the sinuses are usually contaminated and not viable and hence should be avoided. Several media may be used to isolate and grow these organisms.

In the absence of the classical triad of mycetoma, the demonstration of significant antibody titres against the causative organism may be of diagnostic value and aid follow up. The common serodiagnostic tests are immunoelectrophoresis and ELISA.

Summary box 6.16

Mycetoma – diagnosis

- Usually presents late as it is painless
- Triad of painless subcutaneous mass, multiple sinuses and seropurulent discharge
- Clinical picture may be deceptive as there may be deep-seated extension
- May spread to lymph nodes
- Can be confused with Kaposi's sarcoma
- Radiologically can be mistaken for osteosarcoma
- MRI shows typical 'dot-in-circle' sign
- Open biopsy and FNAC are confirmatory

Management

Ideally this should be a combined effort between the physician and the surgeon. In actinomycetoma, combined drug therapy with amikacin sulphate and co-trimoxazole in the form of cycles is the treatment of choice. Amoxicillin–clavulanic acid, rifampacin, sulphonamides, gentamicin and kanamycin are used as a second line of treatment. Long-term drug treatment can have serious side effects.

In eumycetoma, ketoconazole, intraconazole and voriconazole are the drugs of choice. They may need to be used for up to a year. Use of these drugs should be closely monitored for side effects. While not curative, these drugs help to localise the disease by forming thickly encapsulated lesions which are then amenable to surgical excision. Medical treatment for both types of mycetoma must continue until the patient is cured and also in the postoperative period.

Surgical treatment

Surgery is indicated for small localised lesions, resistance to medical treatment or for a better response after medical treatment in patients with massive disease. Excision may need to be much more extensive than suggested at first on clinical appearance because the disease may extend to deeper planes which are not clinically apparent. The surgical options are wide local and debulking excisions and amputations. Amputation, used as a life-saving procedure, is indicated in advanced mycetoma (**Figure 6.30**) refractory to medical treatment with severe secondary bacterial infection.The amputation rate is 10–25%.

Postoperative medical treatment should continue for an adequate period to prevent recurrence. The recurrence rate varies from 25 to 50%. This can be local or distant, to regional lymph nodes. Recurrence is usually due to inadequate surgical excision, use of local anaesthesia, lack of surgical experience, non-compliance with drugs for financial reasons and lack of health education.

Theodor Langhans, 1839–1915, Professor of Pathological Anatomy, University of Berne, Switzerland.

Figure 6.30 Hip disarticulation for a massive thigh eumycetoma.

Summary box 6.17

Mycetoma – management

- Ideally combined management by physician and surgeon
- Medical treatment with appropriate long-term antibiotics
- In large lesions medical treatment to reduce the size followed by excision
- Beware of serious drug side effects
- Surgery in the form of wide excision and amputation as a life-saving procedure
- High recurrence rate

POLIOMYELITIS

Introduction

Poliomyelitis is an enteroviral infection that sadly still affects children in certain parts of the world – this is in spite of effective vaccination having been universally available for several decades. The virus enters the body by inhalation or ingestion. Clinically, the disease manifests itself in a wide spectrum of symptoms – from a few days of mild fever and headache to the extreme variety consisting of extensive paralysis of the bulbar form that may not be compatible with life because of involvement of the respiratory and pharyngeal muscles.

Diagnosis

The disease targets the anterior horn cells, causing lower motor neurone paralysis. Muscles of the lower limb are affected twice as frequently as those of the upper limb (**Figures 6.31 and 6.32**). Fortunately, only 1–2% of sufferers develop paralytic symptoms but, when they do occur, the disability causes much misery (**Figure 6.33**). When a patient develops fever with muscle weakness, Guillain–Barré syndrome needs to be

Figure 6.31 Polio affecting predominantly the upper limb muscles with wasting of the intercostal muscles.

Figure 6.32 **(a, b)** A 12-year-old patient with polio showing marked wasting of the left upper arm muscles with flexion contractures of the left knee and hip; there is equinus deformity of the foot (courtesy of Dr SM Lakhotia, MS and Dr PK Jain, MD, DA, Kolkata, India).

Georges Guillain, 1876–1961, Professor of Neurology, The Faculty of Medicine, Paris, France.
Jean Alexandre Barré, 1880–1967, Professor of Neurology, Strasbourg, France.
Guillain and Barré described the condition in a joint paper in 1916 whilst serving as Medical Officers in the French Army during the First World War.

Figure 6.33 A young patient with polio showing paralysis of the lower limb and paraspinal muscles causing marked scoliosis and a deformed pelvis.

excluded. The latter has sensory symptoms and signs. Cerebrospinal fluid (CSF) analysis should help to differentiate the two conditions.

Management

Surgical management is directed mainly towards the rehabilitation of the patient who has residual paralysis, the operations being tailored to the particular individual's disability. Children especially may show improvement in their muscle function for up to 2 years after the onset of the illness. Thereafter, many patients learn to manage their disability by incorporating various manoeuvres ('trick movements') into their daily life. The surgeon must be cautious in considering such a patient for any form of surgery.

Surgical treatment in the chronic form of the disease is the domain of a highly specialised orthopaedic surgeon who needs to work closely with the physiotherapist both in assessing and in rehabilitating the patient. Operations are only considered after a very careful and detailed assessment of the patient's needs. A multidisciplinary team, consisting of the orthopaedic surgeon, neurologist, physiotherapist, orthotist and the family, should decide upon the need for and advisability of any surgical procedure.

A description of the operations for the various disabilities is beyond the scope of this book. The reader should therefore seek surgical details in a specialist textbook. In 2012, WHO declared India a polio-free country.

Summary box 6.18

Poliomyelitis

- A viral illness that is preventable
- Presents with protean manifestations of fever, headache and muscular paralysis without sensory loss, more frequently affecting the lower limbs
- Treatment is mainly medical and supportive in the early stages
- Surgery should only be undertaken after very careful assessment as most patients learn to live with their disabilities
- Surgery is considered for the various types of paralysis in the form of tendon transfers and arthrodesis, which is the domain of a specialist orthopaedic surgeon

TROPICAL CHRONIC PANCREATITIS

Introduction

Tropical chronic pancreatitis is a disease affecting the younger generation from poor socioeconomic strata in resource-poor countries, seen mostly in southern India. The aetiology remains obscure, with malnutrition, dietary, familial and genetic factors being possible causes. Alcohol ingestion does not play a part in the aetiology.

Aetiology and pathology

Cassava (tapioca) is a root vegetable that is readily available and inexpensive and is therefore consumed as a staple diet by people from a poor background. It contains derivatives of cyanide that are detoxified in the liver by sulphur-containing amino acids. The less well-off among the population lack such amino acids in the diet. This results in cyanogen toxicity, causing the disease. Several members of the same family have been known to suffer from this condition; this strengthens the theory that cassava toxicity is an important cause because family members eat the same food.

Macroscopically, the pancreas is firm and nodular with extensive periductal fibrosis, with intraductal calcium carbonate stones of different sizes and shapes that may show branches and resemble a staghorn. The ducts are dilated. Microscopically, intralobular, interlobular and periductal fibrosis is the predominant feature, with plasma cell and lymphocyte infiltration. There is a high incidence of pancreatic cancer in these patients.

Summary box 6.19

Pathology of tropical chronic pancreatitis

- Almost exclusively occurs in resource-poor countries and is due to malnutrition; alcohol is not a cause
- Cassava ingestion is regarded as an aetiological factor because of its high content of cyanide compounds
- Dilatation of pancreatic ducts with large intraductal stones
- Fibrosis of the pancreas as a whole
- A high incidence of pancreatic cancer in those affected by the disease

Diagnosis

The patient, usually male, is almost always below the age of 40 years and from a poor socioeconomic background. The clinical presentation is abdominal pain, thirst, polyuria and features of gross pancreatic insufficiency causing steatorrhoea and malnutrition. The patient looks ill and emaciated.

Initial routine blood and urine tests confirm that the patient has type 1 diabetes mellitus. This is known as fibrocalculous pancreatic diabetes, a label that is aptly descriptive of the typical pathological changes. Serum amylase is usually normal; in an acute exacerbation, it may be elevated. A plain abdominal radiograph shows typical pancreatic calcification in the form of discrete stones in the duct (**Figure 6.34**). Ultrasound and CT scanning of the pancreas confirm the diagnosis. An ERCP, as an investigation, should only be done when the procedure is also being considered as a therapeutic manoeuvre for removal of ductal stones in the pancreatic head by papillotomy.

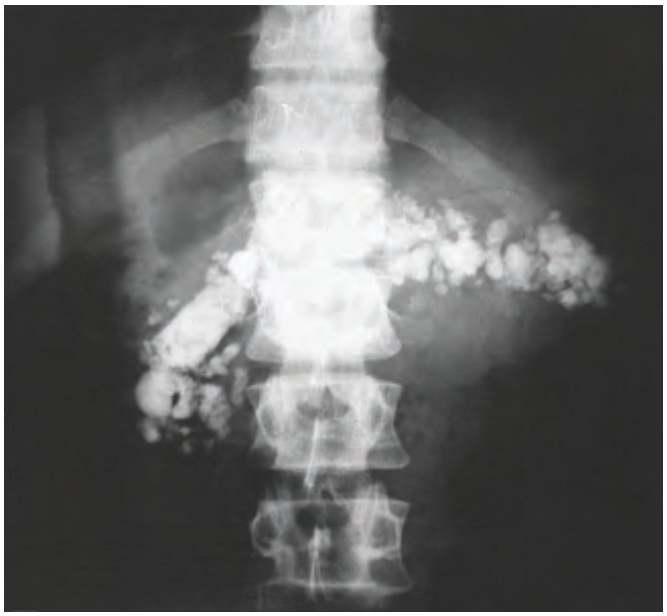

Figure 6.34 Plain radiograph of the abdomen showing large stones along the main pancreatic duct typical of tropical chronic pancreatitis (courtesy of Dr V Mohan, Chennai, India).

Summary box 6.20

Diagnosis of tropical chronic pancreatitis

- The usual sufferer is a type 1 diabetic under 40 years of age
- Serum amylase may be elevated in an acute exacerbation
- Plain radiograph shows stones along the pancreatic duct
- Ultrasound and CT scan of the pancreas confirm the diagnosis
- ERCP should be used as an investigation only when combined with a therapeutic procedure

Treatment

The treatment is mainly medical, with exocrine support using pancreatic enzymes, treatment of diabetes with insulin and the management of malnutrition. Treatment of pain should be along the lines of the usual analgesic ladder: non-opioids, followed by weak and then strong opioids and, finally, referral to a pain clinic.

Surgical treatment is necessary for intractable pain, particularly when there are stones in a dilated duct. Removal of the stones, with a side-to-side pancreaticojejunostomy to a Roux loop, is the procedure of choice. As most patients are young, pancreatic resection is only very rarely considered, and only as a last resort, when all available methods of pain relief have been exhausted.

Summary box 6.21

Treatment of tropical chronic pancreatitis

- Mainly medical – pain relief, insulin for diabetes and pancreatic supplements for malnutrition
- Surgery is reserved for intractable pain when all other methods have been exhausted
- Operations are side-to-side pancreaticojejunostomy; resection in extreme cases

TUBERCULOSIS

Although tuberculosis can affect all systems in the body, in the tropical world the surgeon is most often faced with tuberculosis affecting the cervical lymph nodes and the small intestine. Therefore, in this chapter tuberculous cervical lymphadenitis and tuberculosis of the small bowel will be described.

TUBERCULOUS CERVICAL LYMPHADENITIS

Introduction

This is common in the Indian subcontinent. A young person who has recently arrived from an endemic area, presenting with cervical lymphadenopathy, should be diagnosed as having tuberculous lymphadenitis unless otherwise proven. With acquired immune deficiency syndrome (AIDS) being globally prevalent, this is not as rare in the West in the indigenous population as it used to be.

Diagnosis

Any of the cervical group of lymph nodes (jugulodigastric, submandibular, supraclavicular, posterior triangle) can be involved. The patient has the usual general manifestations of tuberculosis: evening pyrexia, cough (maybe from pulmonary tuberculosis) and malaise; if the sufferer is a child, failure to thrive is a significant finding. Locally there will be regional lymphadenopathy where the lymph nodes may be matted; in late stages a cold abscess may form – a painless, fluctuant, mass which is not warm; significantly there are no signs of inflammation (**Figure 6.35**), hence it is called a 'cold abscess'. This is a clinical manifestation of underlying caseation.

Left untreated, the cold abscess, initially deep to the deep fascia, bursts through into the space just beneath the

Figure 6.35 Cervical tuberculous: cold abscess about to burst.

superficial fascia. This produces a bilocular mass with cross fluctuation. This is called a 'collar-stud' abscess. Eventually this may burst through the skin, discharging pus and forming a tuberculous sinus (**Figure 6.36**). The latter typically has watery discharge with undermined edges.

Figure 6.36 Cervical tuberculous sinus with typical overhanging edges (courtesy of Professor Ahmed Hassan Fahal, FRCS MD MS, Khartoum, Sudan).

Summary box 6.22

Tuberculous cervical lymphadenitis

- This is a common condition at any age
- A matted lymph nodal mass is the typical clinical feature
- In later stages the mass may be cystic, denoting an abscess
- The abscess denotes underlying caseation and does not show any features of inflammation – hence called a cold abscess
- Ultimately the abscess may burst, forming a sinus
- Diagnosis is clinched by culture of pus and biopsy of the lymph node
- Involvement of other systems must be excluded
- Treatment is mainly medical

Investigations

Raised ESR and CRP, low haemoglobin and a positive Mantoux test are usual, although the last is not significant in a patient from an endemic area. The Mantoux test (tuberculin skin test), although in use for over a hundred years, has now been superseded by interferon-gamma (IFN-γ) release assays. This is an *in vitro* blood test of cellular immune response. Antigens unique to *Mycobacterium tuberculosis* are used to stimulate and measure T cell release of IFN-γ. This helps to earmark patients who have latent or subclinical tuberculosis and thus will benefit from treatment.

Sputum for culture and sensitivity (the result may take several weeks) and staining by the Ziehl–Neelsen method for acid-fast bacilli (the result is obtained much earlier) should be carried out.

Specific investigations would include aspiration of the pus from a cold abscess for culture and sensitivity. If the mass is still in the early stages of adenitis, excision biopsy should be done. Here, part of the lymph nodes should be sent fresh and unfixed to the laboratory, who should be warned of the arrival of the specimen so that the tissue can be appropriately processed immediately.

Treatment

This must be combined management between the physician and the surgeon. Tuberculous infection at other sites must be excluded and suitably managed. Medical treatment is the mainstay. The reader is asked to look up details of medical treatment in an appropriate source.

TUBERCULOSIS OF SMALL INTESTINE

Introduction

Infection by *Mycobacterium tuberculosis* is common in the tropics. In these days of international travel and increased migration, tuberculosis in general and intestinal tuberculosis in particular are no longer clinical curiosities in non-endemic countries. Any patient, particularly one who has recently

A **collar-stud abscess** is so-called because it resembles a collar stud (which has two parts) used in shirts with detachable collars, now largely out of fashion.
Charles Mantoux, 1877–1947, physician, Le Cannet, Alpes Maritimes, France, described the intradermal tuberculin skin test in 1908.
Franz Heinrich Paul Ziehl, 1859–1926, neurologist, Lubeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1894, pathologist, Prosector, the Stadt-Krankenhaus, Dresden, Germany.

arrived from an endemic area and who has features of generalised ill health and altered bowel habit, should arouse suspicion for intestinal tuberculosis. The increased prevalence of human immunodeficiency virus (HIV) infection worldwide has also made tuberculosis more common.

Pathology

There are two types: ulcerative and hyperplastic. In both types, there may be marked mesenteric lymphadenopathy.

- **Ulcerative type:** When a patient with pulmonary tuberculosis swallows infected sputum, the organism colonises the lymphatics of the terminal ileum, causing transverse ulcers with typical undermined edges. The serosa is usually studded with tubercles. Histology shows caseating granuloma with giant cells (**Figure 6.37**). This pathological entity, referred to as the ulcerative type, denotes a severe form of the disease in which the virulence of the organism overwhelms host resistance.
- **Hyperplastic type:** This occurs when host resistance has the upper hand over the virulence of the organism. It is caused by drinking infected unpasteurised milk. There is a marked inflammatory reaction causing hyperplasia and thickening of the terminal ileum because of its abundance of lymphoid follicles, thus resulting in narrowing of the lumen and obstruction. Macroscopically, this type may be confused with Crohn's disease. The small intestine shows areas of stricture and fibrosis, most pronounced at the terminal ileum (**Figure 6.38**). As a result, there is shortening of the bowel with the caecum being pulled up into a subhepatic position.

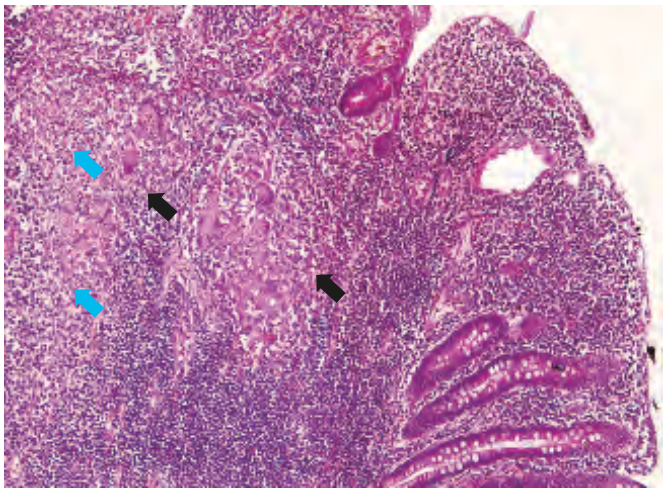

Figure 6.37 Histology of ileocaecal tuberculosis showing epithelioid cell granuloma (black arrows) with caseation (blue arrows) (courtesy of Dr AK Mandal, New Delhi, India).

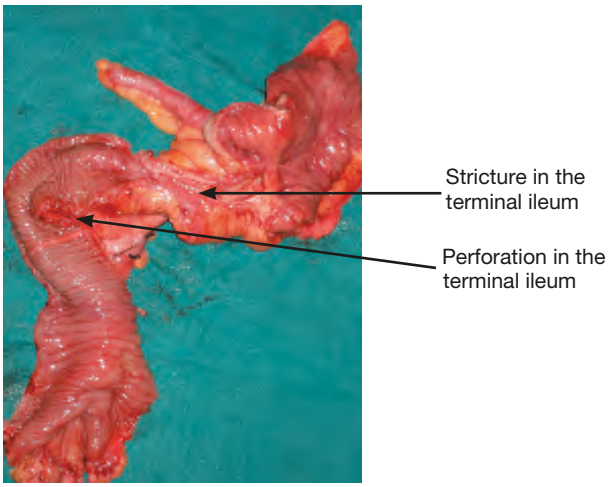

Figure 6.38 Emergency limited ileocolic resection: specimen showing a tuberculous stricture in the terminal ileum and perforation of a transverse ulcer just proximal to the stricture.

Summary box 6.23

Tuberculosis – pathology

- Increasingly being seen in non-endemic areas, mostly among immigrants from endemic areas
- Two types are recognised – ulcerative and hyperplastic
- The ulcerative type occurs when the virulence of the organism is greater than the host defence
- The opposite occurs in the hyperplastic type
- Small bowel strictures are common in the hyperplastic type, mainly affecting the ileocaecal area and presenting with obstructive symptoms
- In the ulcerative type, the bowel serosa is studded with tubercles
- Localised areas of ascites occur in the form of cocoons
- The lungs and other organs, particularly of the genitourinary system, may also be involved simultaneously

Clinical features

Patients present electively with weight loss, chronic cough, malaise, evening rise in temperature with sweating, vague abdominal pain with distension and alternating constipation and diarrhoea. As an emergency, they present with features of distal small bowel obstruction from strictures of the small bowel, particularly the terminal ileum. Rarely, a patient may present with features of peritonitis from perforation of a tuberculous ulcer in the small bowel (**Figure 6.38**).

Examination shows a chronically ill patient with a 'doughy' feel to the abdomen from areas of localised ascites. In the hyperplastic type, a mass may be felt in the right iliac fossa. In addition, some patients may present with

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932 along with Leon Ginzburg and Gordon Oppenhiemer.

fistula-in-ano, which is typically multiple with undermined edges and watery discharge.

As this is a disease mainly seen in certain resource-poor countries, patients may present late as an emergency from intestinal obstruction. Abdominal pain and distension, constipation and bilious and faeculent vomiting are typical of such a patient, who is usually *in extremis*.

There may be involvement of other systems, such as the genitourinary tract, when the patient complains of frequency of micturition. Clinical examination does not show any abnormality. The genitourinary tract should then be investigated.

Summary box 6.24

Tuberculosis – clinical features

- Intestinal tuberculosis should be suspected in any patient from an endemic area who presents with weight loss, malaise, evening fever, cough, alternating constipation and diarrhoea and intermittent abdominal pain with distension
- The abdomen has a doughy feel; a mass may be found in the right iliac fossa
- The emergency patient presents with features of distal small bowel obstruction – abdominal pain, distension, bilious and faeculent vomiting
- Peritonitis from a perforated tuberculous ulcer in the small bowel can be another emergency presentation

Investigations

General investigations are the same as those for suspected tuberculosis anywhere in the body. They have been detailed in the previous section.

A barium meal and follow-through (or small bowel enema) shows strictures of the small bowel, particularly the ileum, typically with a high subhepatic caecum with the narrow ileum entering the caecum directly from below upwards in a straight line rather than at an angle (**Figures 6.39 and 6.40a**). Laparoscopy reveals the typical picture of tubercles on the bowel serosa, multiple strictures, a high caecum, enlarged lymph nodes, areas of caseation and ascites. Culture of the ascitic fluid may be helpful. A chest radiograph is essential (**Figure 6.40b**).

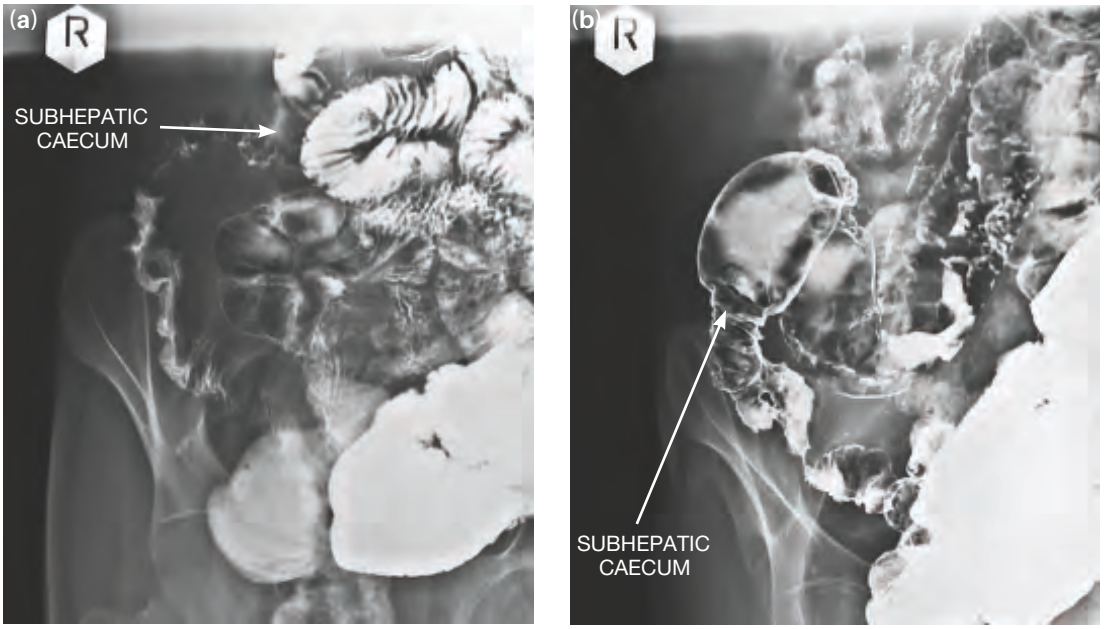
If the patient complains of urinary symptoms, urine is sent for microscopy and culture; the finding of sterile pyuria should alert the clinician to the possibility of tuberculosis of the urinary tract, when the appropriate investigations should be done. A flexible cystoscopy would be very useful in the presence of sterile pyuria. A contracted bladder ('thimble' bladder) with ureteric orifices that are in-drawn ('golf-hole' ureter) may be seen; these changes are due to fibrosis.

In the patient presenting as an abdominal emergency, urea and electrolytes show evidence of gross dehydration. A plain abdominal radiograph shows typical small bowel obstruction – valvulae conniventes of dilated jejunum and featureless ileum with evidence of fluid between the loops.

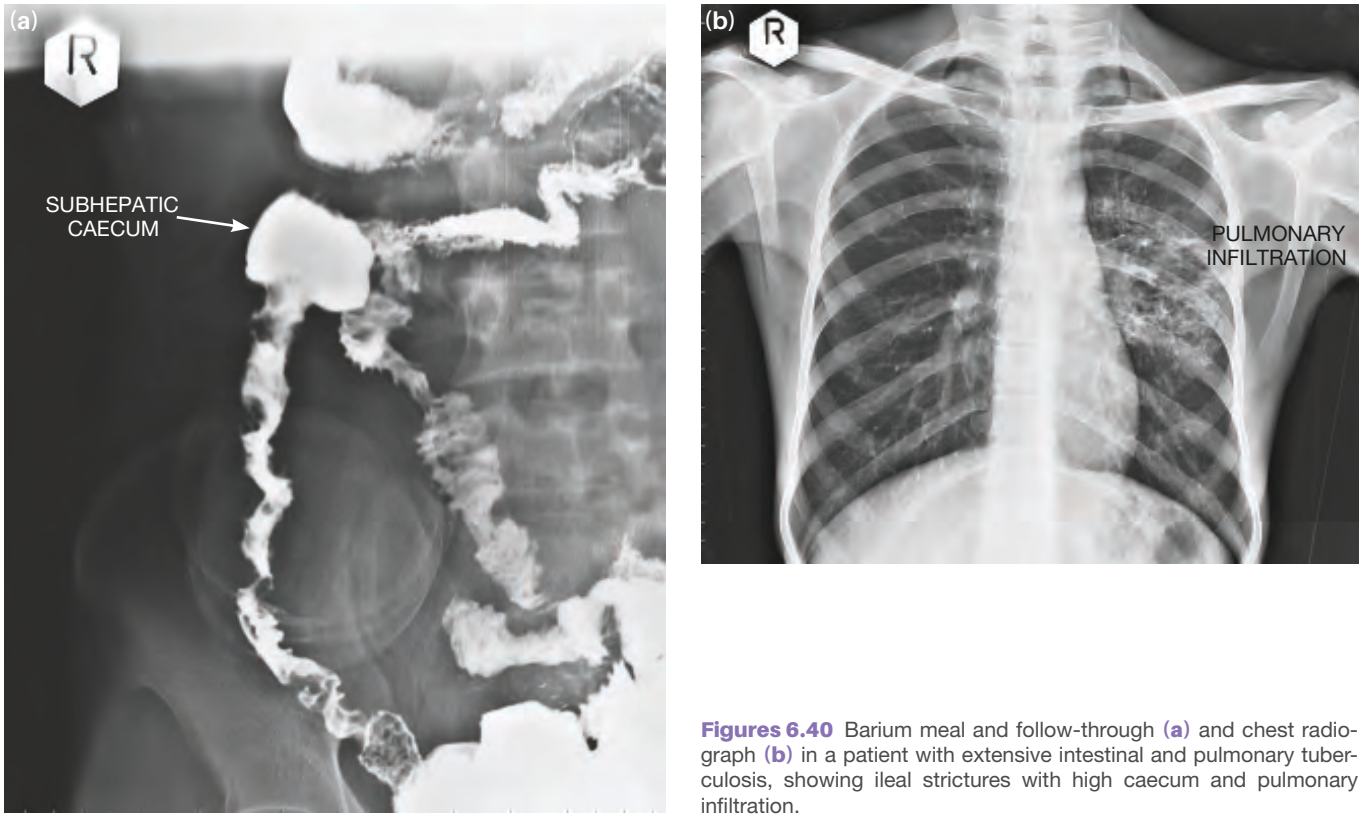
Summary box 6.25

Intestinal tuberculosis – investigations

- Raised inflammatory markers, anaemia and positive sputum culture
- Interferon-γ release assays for subclinical infection
- Ultrasound of the abdomen may show localised areas of ascites
- Chest radiograph shows pulmonary infiltration
- Barium meal and follow-through shows multiple small bowel strictures particularly in the ileum, with a subhepatic caecum
- If symptoms warrant, the genitourinary tract is also investigated



Figures 6.39 (a, b) Series of a barium meal and follow-through showing strictures in the ileum, with the caecum pulled up into a subhepatic position.



Figures 6.40 Barium meal and follow-through **(a)** and chest radiograph **(b)** in a patient with extensive intestinal and pulmonary tuberculosis, showing ileal strictures with high caecum and pulmonary infiltration.

Treatment

On completion of medical treatment, the patient's small bowel is reimaged to look for significant strictures. If the patient has features of subacute intermittent obstruction, bowel resection, in the form of limited ileocolic resection with anastomosis between the terminal ileum and ascending colon, strictureplasty or right hemicolectomy, is performed as deemed appropriate. The surgical principles and options in the elective patient are very similar to those for Crohn's disease, where resections should be kept as conservative as possible.

The emergency patient presents a great challenge. Such a patient is usually from a poor socioeconomic background, hence the late presentation of acute, distal, small bowel obstruction. The patient is extremely ill from dehydration, malnutrition, anaemia and probably active pulmonary tuberculosis. Vigorous resuscitation should precede the operation. At laparotomy, the minimum life-saving procedure is carried out, such as a side-to-side ileotransverse anastomosis for a terminal ileal stricture. If the general condition of the patient permits, a one-stage resection and anastomosis may be performed.

Thereafter, the patient should ideally be under the combined care of the physician and surgeon for a full course of antituberculous chemotherapy and improvement in nutritional status, which may take up to 3–6 months. The patient who had a simple bypass procedure is reassessed and, when the disease is no longer active (as evidenced by return to normal inflammatory markers, weight gain, negative sputum culture), an elective right hemicolectomy is done to remove the blind loop. This may be supplemented with strictureplasty for short strictures at intervals.

Perforation is treated by thorough resuscitation followed by resection of the affected segment. Anastomosis is performed, provided it is regarded as safe to do so, when peritoneal contamination is minimal and widespread disease is not encountered; otherwise, as a first stage, resection and exteriorisation is done followed by restoration of bowel continuity as a second stage later on after a full course of antituberculous chemotherapy and improvement in nutritional status.

Summary box 6.26

Tuberculosis – treatment

- Patients should ideally be under the combined care of a physician and surgeon
- Vigorous supportive and full drug treatment are mandatory in all cases
- Symptomatic strictures are treated by the appropriate resection, e.g. local ileocolic resection or strictureplasty as an elective procedure once the disease is completely under control
- Acute intestinal obstruction from distal ileal stricture is treated by thorough resuscitation followed by side-to-side ileotransverse bypass
- Once the patient has recovered with medical treatment, then the second-stage definitive procedure of right hemicolectomy is done to remove the blind loop
- One-stage resection and anastomosis can be considered if the patient's general condition permits
- Perforation is treated by appropriate local resection and anastomosis or exteriorisation if the condition of the patient is very poor; this is later followed by restoration of bowel continuity after the patient has fully recovered with antituberculous chemotherapy

TYPHOID

Introduction

Typhoid fever is caused by *Salmonella typhi*, also called the typhoid bacillus, a gram-negative organism. Like most infections occurring in the tropics, the organism gains entry into the human gastrointestinal tract as a result of poor hygiene and inadequate sanitation. It is a disease normally managed by physicians, but the surgeon may be called upon to treat the patient with typhoid fever because of perforation of a typhoid ulcer.

Pathology

Following ingestion of contaminated food or water, the organism colonises the Peyer's patches in the terminal ileum, causing hyperplasia of the lymphoid follicles followed by necrosis and ulceration. The microscopic picture shows erythrophagocytosis with histiocytic proliferation (**Figure 6.41**). If the patient is left untreated or inadequately treated, the ulcers may lead to perforation and bleeding. The bowel may perforate at several sites including the large bowel.

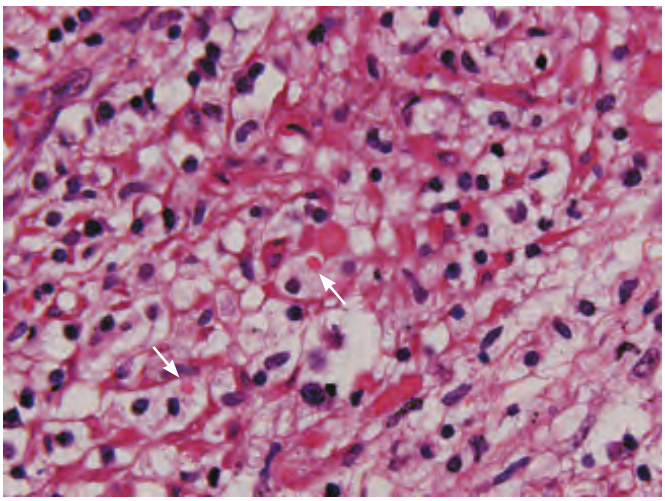


Figure 6.41 Histology of enteric perforation of the small intestine showing erythrophagocytosis (arrows) with predominantly histiocytic proliferation (courtesy of Dr AK Mandal, New Delhi, India).

Diagnosis

A typical patient is from an endemic area or has recently visited such a country and suffers from a high temperature for 2–3 weeks. The patient may be toxic with abdominal distension from paralytic ileus and may have melaena due to haemorrhage from a typhoid ulcer; this can lead to hypovolaemia.

Blood and stool cultures confirm the nature of the infection and exclude malaria. Although obsolete in some parts of the world, the Widal test is still done in the Indian subcontinent. The test looks for the presence of agglutinins to O and H antigens of *Salmonella typhi* and *paratyphi* in the patient's serum. In endemic areas, laboratory facilities may sometimes be limited. Certain other tests have been developed that identify sensitive and specific markers for typhoid fever. Practical and cheap kits are available for their rapid detection that need no special expertise and equipment. These are Multi-Test Dip-S-Ticks to detect immunoglobulin G (IgG), Tubex to detect immunoglobulin M (IgM) and TyphiDot to detect IgG and IgM. These tests are particularly valuable when blood cultures are negative (due to prehospital treatment or self-medication with antibiotics) or facilities for such an investigation are not available.

In the second or third week of the illness, if there is severe generalised abdominal pain, this indicates a perforated typhoid ulcer unless otherwise proven. The patient, who is already very ill, deteriorates further with classical features of peritonitis. An erect chest radiograph or a lateral decubitus film (in the very ill, as they usually are) will show free gas in the peritoneal cavity. In fact, any patient being treated for typhoid fever who shows a sudden deterioration accompanied by abdominal signs should be considered to have a typhoid perforation until proven otherwise.

Summary box 6.27

Diagnosis of bowel perforation secondary to typhoid

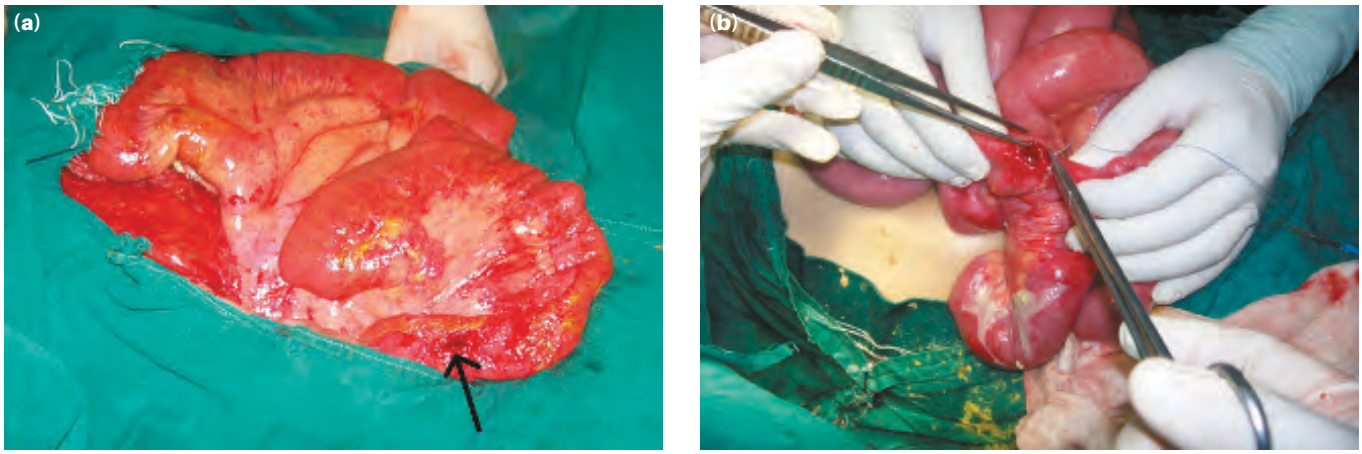
- The patient presents in, or has recently visited, an endemic area
- The patient has persistent high temperature and is very toxic
- Positive blood or stool cultures for *Salmonella typhi* and the patient is already on treatment for typhoid
- After the second week, signs of peritonitis usually denote perforation, which is confirmed by the presence of free gas seen on radiograph

Treatment

Vigorous resuscitation with intravenous fluids and antibiotics in an intensive care unit gives the best chance of stabilising the patient's condition. Metronidazole, cephalosporins and gentamicin are used in combination. Chloramphenicol, despite its potential side effect of aplastic anaemia, is still used occasionally in resource-poor countries. Laparotomy is then carried out.

Several surgical options are available, and the most appropriate operative procedure should be chosen judiciously depending upon the general condition of the patient, the site of perforation, the number of perforations and the degree of peritoneal soiling. The alternatives are closure of the perforation (**Figure 6.42**) after freshening the edges, wedge resection of the ulcer area and closure, resection of bowel with or without anastomosis (exteriorisation), closure of the perforation and side-to-side ileotransverse anastomosis, ileostomy or colostomy where the perforated bowel is exteriorised after refashioning the edges.

Daniel Elmer Salmon, 1850–1914, veterinary pathologist, Chief of the Bureau of Animal Industry, Washington, DC, USA.
Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.
Georges Fernand Isidore Widal, 1862–1929, Professor of Internal Pathology, and later of Clinical Medicine, The Faculty of Medicine, Paris, France.



Figures 6.42 (a, b) Typhoid perforation of the terminal ileum.

After closing an ileal perforation, the surgeon should look for other sites of perforation or necrotic patches in the small or large bowel that might imminently perforate, and deal with them appropriately. Thorough peritoneal lavage is essential. The linea alba is closed, leaving the rest of the abdominal wound open for delayed closure, as wound infection is almost inevitable and dehiscence not uncommon. In the presence of rampant infection, laparostomy may be a good alternative.

When a typhoid perforation occurs within the first week of illness, the prognosis is better than if it occurs after the second or third week because, in the early stages, the patient is less nutritionally compromised and the body's defences are more robust. Furthermore, the shorter the interval between diagnosis and operation, the better the prognosis.

Summary box 6.28

Treatment of bowel perforation from typhoid

- Manage in intensive care
- Resuscitate and give intravenous antibiotics
- Laparotomy – choice of various procedures
- Commonest site of perforation is the terminal ileum
- Having found a perforation, always look for others
- In the very ill patient, consider some form of exteriorisation
- Close the peritoneum and leave the wound open for secondary closure

Chapter 7

Basic surgical skills and anastomoses

Learning objectives

To understand:
- The principles of patient positioning and operating theatre safety
- The principles of skin and abdominal incisions
- The principles of laparoscopic trocar insertion
- The principles of wound closure

To know the principles in performing:
- Bowel anastomoses
- Vascular anastomoses

To be aware of:
- The principles of drain usage
- The principles of diathermy and advanced energy devices

INTRODUCTION

Successful outcomes in surgery depend on knowledge, skills and judgement. While this chapter concentrates on technical skill, it is important for the modern surgeon to remember that non-technical skills, such as communication, empathy and teamwork, are but a few of the skills required. We used to think of technical skill starting with 'knife to skin'; it is also important to realise that a successful outcome for a patient is dependent on a surgeon who takes responsibility to make sure that the patient reaches that point, with all factors, such as positioning and equipment, considered first. Teamwork includes adherence to modern 'human factors' principles, such as team brief and debrief, and the use of safety checklists.

PATIENT POSITIONING AND SAFETY ON THE OPERATING TABLE

The safety of the patient in the operating theatre is paramount at all times, and is a key responsibility of the surgeon, regardless of grade, experience or seniority. For all cases it is the surgeon's responsibility to make sure the patient is placed on the table to maximise exposure for the procedure itself and to ensure risks of injury are avoided. These are categorised below.

Transfer to and from the operating table

The transfer of the anaesthetised patient is a critical moment where there are significant risks of falls, injuries and, rarely, death, not to mention injury to operating theatre personnel. Staff should all receive regular training in manual handling. Patients at additional risk include the obese, elderly and emaciated. These groups require additional care and specialised equipment.

Positioning on the table

Safe and effective positioning of the anaesthetised patient also requires good training, appropriate equipment and attention to detail. The surgeon should take personal responsibility to maintain safety and to make sure exposure is adequate for the procedure. This includes placement of the passive diathermy electrode ('pad') to minimise the risk of electrosurgical burns and to account for metallic prostheses and pacemakers. The surgeon should also make sure that ancillary equipment, such as energy generators, suction, laparoscopic stack systems and the scrub assistants, is appropriately located around the surgeon and the patient on the operating table. The operating lights should also be placed in an optimal starting position. All these actions need to be undertaken before the surgical team scrubs, including any final checks before the patient is prepped and draped.

Pressure areas

Patients at risk from pressure sores include those with diabetes, immunodeficiency, obesity or malnutrition, and those undergoing prolonged procedures. The areas of the body prone to injury are the heels, sacrum and other bony prominences. These areas should receive particular attention during positioning with additional measures taken in the at-risk groups.

Nerve injury

There are certain areas of the body where an anaesthetised patient can be exposed to neuropraxia (nerve injury) which in some cases can be permanent and disabling. These are the brachial plexus, ulnar nerve and common peroneal nerve. The surgeon should lead the theatre team in ensuring these areas are protected, particularly in high-risk groups and for long procedures.

Compartment syndrome

Acute postoperative compartment syndrome refers, in the context of surgery, to the consequences of increased pressure in a muscle compartment, usually in the lower limb, that can result in permanent disability or amputation. This occurs as a result of underperfusion, usually during prolonged surgery, often with elevation of the leg. Postoperatively, the pressure in the affected compartment rises to the point beyond which irreversible ischaemic damage to muscles and nerves occurs. It manifests with pain, reduced power, swelling, numbness and tingling. Early recognition is essential and prompt surgical fasciotomy is required to avoid the disastrous and permanently disabling sequelae.

Considerations for laparoscopic surgery

Laparoscopic surgery requires some different considerations to open surgery to ensure patient safety and to maximise the ergonomic performance of the procedure. Often, steep angles of tilt to the side, or Trendelenberg (head down) and reverse-Trendelenberg (head up) positions are required to move the abdominal viscera, such as small bowel, away from the operative field. There is significant danger that the patient can slide, or in some cases, fall off the operating table and be injured. It is the surgeon's responsibility to ensure the patient is safely and securely placed on the operating table with appropriate restraints if indicated. So-called 'side boards' or arm restraints are best avoided in laparoscopic surgery as they can interfere with the laparoscopic instruments. Any restraints must be placed in such a way as to avoid or minimise the risk of nerve injury, e.g. the brachial plexus with shoulder supports. Devices such as suction bean bags and antislip mats can be used to help secure placement of the patient. Occasionally, laparoscopic surgery is performed in a lateral position to expose the target organ, e.g. kidney or spleen, with the aid of gravity. Experience and training are required to maintain safety and security for such procedures.

SKIN INCISIONS

Skin incisions should be made with a scalpel, with the blade being pressed firmly down at right angles to the skin and then drawn gently across the skin in the desired direction to create a clean incision, the site and extent of which should have been clearly planned by the surgeon. It is important not to incise the skin obliquely because such a shearing mechanism can lead to necrosis of the undercut edge. The incision is facilitated by tension being applied across the line of the incision by the fingers of the non-dominant hand, but the surgeon must ensure that at no time is the scalpel blade directed at their own fingers as any slip may result in a self-inflicted injury. Blades for skin incisions usually have a curved cutting margin, while those used for an arteriotomy or drain-site insertion have a sharp tip (**Figure 7.1**). Scalpels should at all times be passed in a kidney dish rather than by a direct hand-to-hand process because the latter can lead to injury. Diathermy, laser, harmonic scalpels and combination devices can be used instead of blades when opening deeper tissues, as they can reduce blood loss and save operating time, and may reduce postoperative pain.

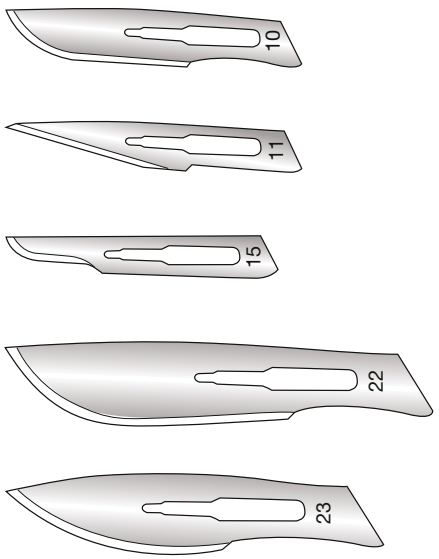

Figure 7.1 Scalpel blade sizes and shapes. The 22-blade is often used for abdominal incisions, the 11-blade for arteriotomy and the 15-blade for minor surgical procedures.

When planning a skin incision, four factors should be considered:

1. **Skin tension lines** (Langer's lines). These lines represent the orientation of the dermal collagen fibres and any incision placed parallel to these lines results in a better scar (**Figure 7.2**).
2. **Anatomical structure**. Incisions should avoid bony prominences and crossing skin creases if possible, and take into consideration underlying structures, such as nerves and vessels.
3. **Cosmetic factors**. Any incision should be made bearing in mind the ultimate cosmetic result, especially in exposed parts of the body, as an incision is the only part of the operation the patient sees.
4. **Adequate access for the procedure**. The incision must be functionally effective for the procedure in hand because any compromise purely on cosmetic grounds may render the operation ineffective or even dangerous.

Occasionally, it may be necessary to excise a skin lesion with a circular incision in an area where the direction of

Karl Ritter Von Langer, 1847–1888, Austrian anatomist.

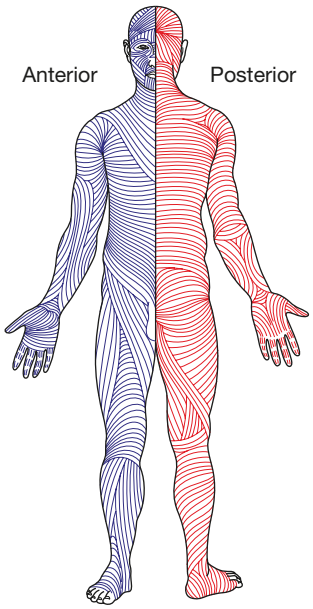

Figure 7.2 Langer's lines. These depict the orientation of the dermal collagen fibres. Reproduced with permission from Thomas WEG, Senninger N (eds). *Short stay surgery*. Berlin: Springer-Verlag, 2008.

Langer's lines is not apparent. However, once the circular incision has been made, it can often be observed that the circular incision is converted to an ellipse, thus indicating the lines of tension. This circular incision should then be formally converted into an elliptical incision, remembering the rule of thumb that 'an elliptical incision must be at least three times as long as it is wide' for the wound to heal without tension. Occasionally, 'dog ears' remain in the corner of elliptical incisions in spite of adequate care having been taken during formation and primary closure of an elliptical wound. In these situations, it is advisable to pick up the 'dog ear' with a skin hook and excise it as shown in **Figure 7.3**. This allows for a satisfactory cosmetic outcome.

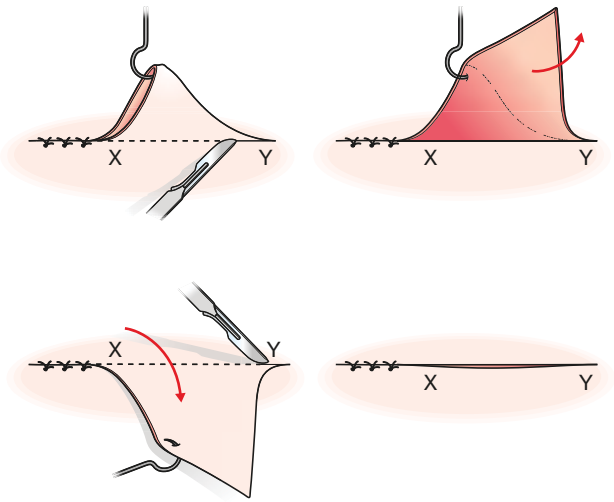

Figure 7.3 Dealing with a 'dog ear' at the corner of an elliptical incision. Reproduced with permission from Thomas WEG, Senninger N (eds). *Short stay surgery*. Berlin: Springer-Verlag, 2008.

Abdominal incisions

As for skin incisions, all abdominal incisions should be planned in advance of surgery and take into consideration access to the relevant organs, surface landmarks, pain control and cosmetic outcome, e.g. transverse incisions tend to be associated with fewer respiratory complications and a better cosmetic outcome. In the past, traditional vertical midline or paramedian incisions were used for the majority of abdominal procedures, but there is a current trend to utilise transverse incisions wherever possible because these minimise post-operative complications. The incision should be carried deeper through the subcutaneous tissues and then, depending on the site of the incision **(Figure 7.4)**, the muscle layers should be divided or split, and the peritoneum displayed. This should be picked up between two clips and gently incised to ensure there is no damage to the underlying organs. This is particularly important in the emergency situation when there may be dilatation of the bowel. Every incision should be made with closure in mind, and the layers appropriately delineated. Mass closure of the abdominal wall is usually advocated, using large bites and short steps in the closure technique and either non-absorbable (e.g. nylon or polypropylene) or very slowly absorbable suture material (e.g. polydioxanone suture (PDS)). It has been estimated that, for abdominal wall closure, the length of the suture material should be at least four times the length of the wound to be closed to minimise the risk of abdominal dehiscence or later incisional hernia.

Laparoscopic surgery

Similar attention to detail applies to laparoscopic surgery, where access is of equal importance to open surgery. Correct port site placement and closure are crucial to the success of the operative procedure. Laparoscopic surgery is covered in more detail in Chapter 8.

Summary box 7.1

The benefits of laparoscopic surgery

- Less postoperative pain
- Better cosmesis
- Earlier return of normal physiological function
- Shorter hospital stay
- Earlier resumption of normal activities

Summary box 7.2

The principles of safe laparoscopic surgery

- The umbilicus is preferred for primary trocar insertion
- An open or semi-open technique is prefered by most surgeons
- Open insertion away from the umbilicus is safer if there is a midline scar
- Secondary trocars should be inserted and removed under direct vision
- All trocars should be placed perpendicular to the abdominal wall
- All trocar sites above 5 mm in length should undergo closure of the fascial layer

The basic principles of port (trocar) site placement in laparoscopic surgery are:

1 The umbilicus is a convenient and safe point of insertion of the first (primary) trocar because the skin here is fused to the peritoneum. Care must be taken to avoid bowel regardless of the technique employed. Great care and good technique must be employed to avoid injury to the major vessels (aorta, vena cava and iliac vessels), particularly in thin female patients, who are at greater risk. Elsewhere, the midline is safe for further (secondary) trocars, though care must be taken below the umbilicus to avoid the bladder.
2 An 'open' or 'semi-open' technique is practised by many general surgeons to minimise, if not eradicate, the possibility of injury to an underlying viscus during insertion of the primary trocar.
3 Scars should be avoided as bowel is more likely to be adherent to the undersurface; for midline scars, the primary trocar should be inserted away from the midline with an open cutdown or an optical trocar.
4 All secondary trocars should be inserted under direct vision to avoid damage to bowel, bladder and blood vessels. A 'two-handed' technique should be used to avoid sudden trocar movements that may inadvertently puncture a viscus.
5 Trocars should always be inserted perpendicular to the abdominal wall. Oblique insertion results in increased pressure or torque while instruments are being used, which fatigues the surgeon and causes increased trauma to the patient's abdominal wall. This is of particular relevance in obese patients.
6 A hand's breadth (the patient's hand) either side of the midline is the rectus sheath which contains the epigastric vessels. By placing non-midline trocars lateral to the rectus sheath, usually in the mid-clavicular line, the epigastric vessels can be avoided.
7 Where possible, smaller diameter trocars should be used as they are associated with less postoperative pain, a lower incidence of port-site incisional hernia and better cosmesis. All port sites above 5 mm in diameter should undergo suture closure of the fascial layers to reduce the possibility of port-site hernia in the acute postoperative setting and incisional hernia longer term.
8 All secondary trocars should be removed under direct vision to observe for port site bleeding.
9 Bladed trocars should be avoided near blood vessels to reduce the risk of bleeding.

Technique for laparoscopic primary trocar insertion

There are a number of different techniques described for primary trocar insertion. In most cases the umbilicus is the preferred site because the skin is fused to the peritoneum, even in obese patients. The presence of a scar at the umbilicus is a relative contraindication as bowel may be adherent resulting in injury which can be overlooked and result in postoperative peritonitis. The author uses a semi-open technique for a 10–12 mm trocar and this is described here:

1 The umbilical cicatrix is everted with a tissue grasping forceps such as a Littlewood's. It is important to grasp the cicatrix directly as this is closest to the adherent peritoneum. Counter-traction is maintained throughout the subsequent steps until the primary trocar is inserted **(Figure 7.5)**.
2 The umbilical stalk is palpated inferior to the everted cicatrix while maintaining cephalad (towards the head) traction.
3 A curved 10–12 mm transverse incision is made inferior to the cicatrix **(Figure 7.6)**.
4 The umbilical stalk is exposed with sharp and blunt dissection to reveal the decussation (crossing) of fibres just above its junction with the linea alba **(Figure 7.7)**.
5 A 5 mm vertical incision is made through the decussation with an 11-blade, taking care only to incise the fascia at this point and not to enter the peritoneum **(Figure 7.8)**.
6 A blunt haemostat is then pushed through the preperitoneal fat and peritoneum; the surgeon will feel a 'pop' as the instrument enters the peritoneal cavity **(Figure 7.9)**.
7 A blunt-tipped 10 or 12 mm trocar is pushed through the same point of insertion as the haemostat and in the same direction **(Figure 7.10)**.
8 The laparoscopic camera is used to confirm successful placement in the peritoneal cavity before insufflation with CO_2 gas.
9 CO_2 gas insufflation is commenced at low flow (1–4 litres per minute) and increased to a maximum pressure of 15 mmHg and with a maximum flow rate of 20 litres per minute.
10 For patients with scars from previous abdominal surgery, the safest technique is a full open approach at Palmer's

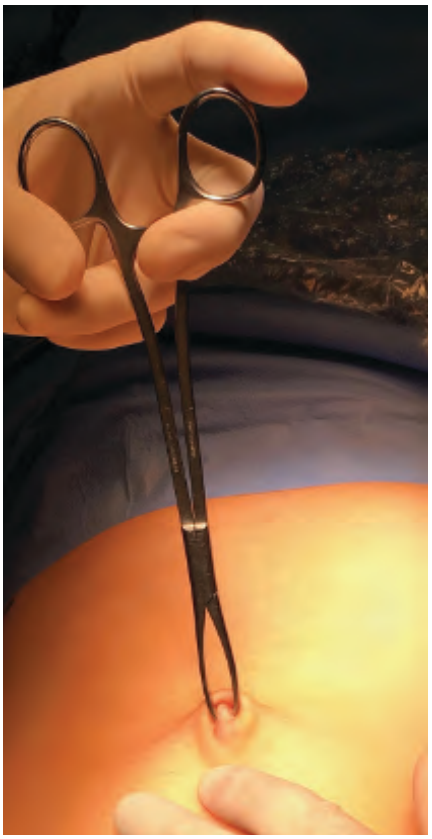

Figure 7.5 The umbilical cicatrix is grasped with a tissue-grasping forceps (e.g. Littlewood's) and everted.

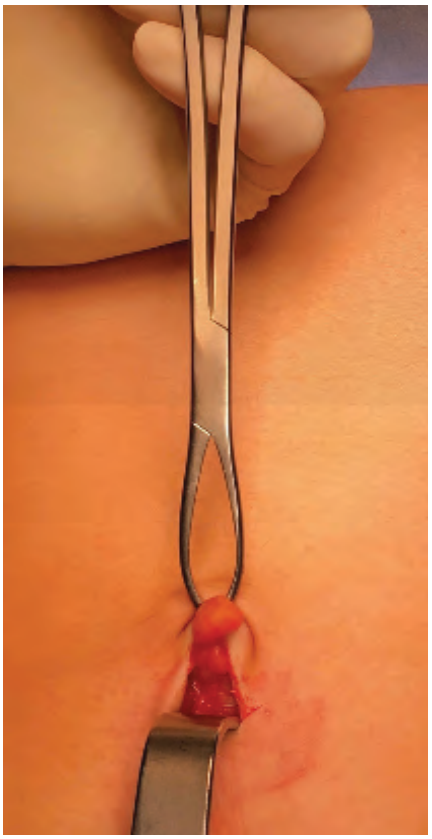

Figure 7.7 The skin is retracted to reveal the junction of the stalk and the linea alba.

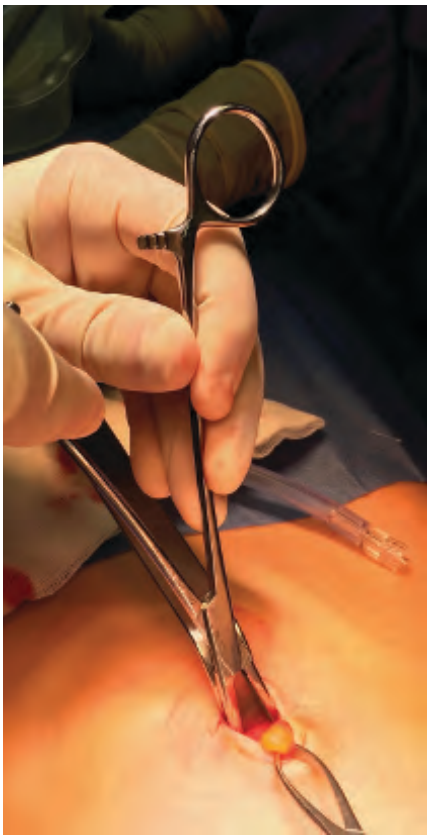

Figure 7.9 A blunt, long haemostat is used to enter the peritoneum and enlarge the incision in the umbilical stalk.

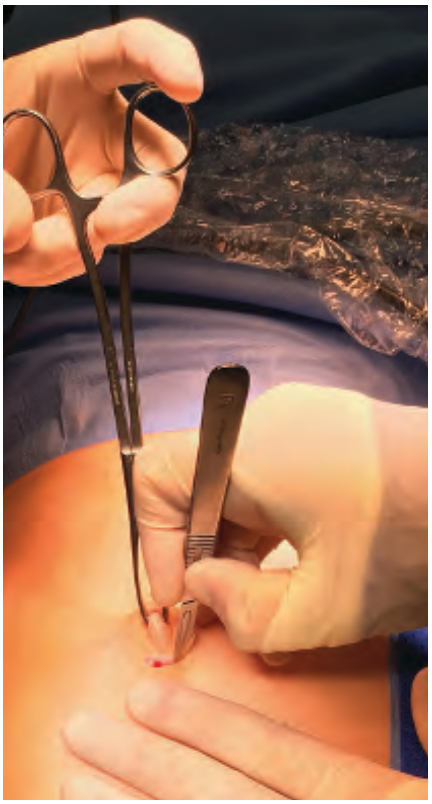

Figure 7.6 A curved subumblilical incision is made.

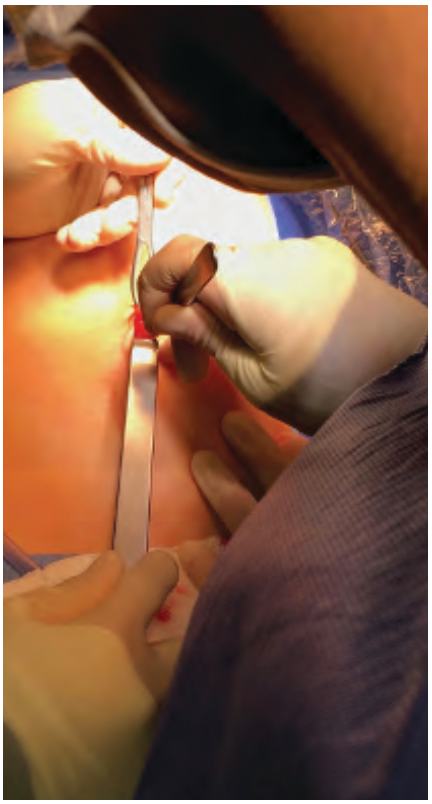

Figure 7.8 A small vertical incision is made in the junction using an 11 bladed scalpel.

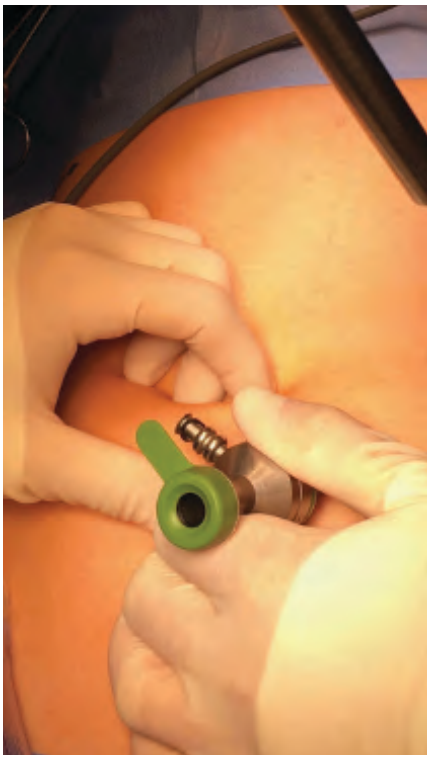

Figure 7.10 A blunt primary trocar and cannula are inserted and their position is confirmed with the laparoscopic camera before insufflation.

point, 3 cm below the left subcostal margin in the mid-clavicular line. Adequate lighting and good assistance with retraction are essential.

11 In obese patients with scars from previous surgery an optical blunt trocar can be used to enter the peritoneal cavity under vision.

WOUND CLOSURE

The suturing of any incision or wound needs to take into consideration the site and tissues involved, and the technique for closure should be chosen accordingly. There is no ideal wound closure technique that would be appropriate for all situations, and the ideal suture has yet to be produced, although many of the desired characteristics are listed in *Summary box 7.3*. Therefore, the correct choice of suture technique and suture material is vital, but will never compensate for inadequate operative technique, and, for any wound to heal well, there must be a good blood supply and no tension on the closure. Clean uninfected wounds with a good blood supply heal by primary intention and therefore closure simply requires accurate apposition of the wound edges. However, if a wound is left open, it heals by secondary intention through the formation of granulation tissue, which is tissue composed of capillaries, fibroblasts and inflammatory cells. Wound contraction and epithelialisation assist in ultimate healing, but the process may take several weeks or months. Delayed primary closure, or tertiary intention, is utilised when there is a high probability of the wound being infected. The wound is left open for a few days and, provided any infective process has resolved, the wound is closed to heal by primary intention. Skin grafting is another form of tertiary intention healing.

Summary box 7.3

Suture material: desired characteristsics

- Easy to handle
- Predictable behaviour in tissues
- Predictable tensile strength
- Sterile
- Glides through tissues easily
- Secure knotting ability
- Inexpensive
- Minimal tissue reaction
- Non-capillary
- Non-allergenic
- Non-carcinogenic
- Non-electrolytic
- Non-shrinkage

Summary box 7.4

Types of wound healing

- Primary intention
  - Clean wound
- Secondary intention
  - Healthy granulation tissue
  - Overexuberant granulation tissue
  - Infected sloughy wound
  - Black eschar
- Tertiary intention
  - Delayed closure
  - Skin grafting

When choosing suture materials, there are certain specific requirements depending on the tissues to be sutured; for example, vascular anastomoses require smooth, non-absorbable, non-elastic material, while biliary anastomoses require an absorbable material that will not promote tissue reaction or stone formation. When using absorbable material, the time for which wound support is required and maintained will vary according to the tissues in which it is inserted. Furthermore, certain tissues require wound support for longer than others, for example muscular aponeuroses compared with subcutaneous tissues. It is therefore crucial for the surgeon to select the suture material and suture technique that will most effectively achieve the desired objective for each wound closure or anastomosis.

Suture materials

History

> Sutures are best made of soft thread, not too hard twisted that it may sit easier on the tissue, nor are too few nor too many of either of them to be put in.
>
> Aurelius Cornelius Celsus, 25BC–AD50

Multiple examples of early surgery abound, with East African tribes ligating blood vessels with tendon strips, and closing wounds with acacia thorns pushed through the wound with strips of vegetable matter wound round these in a figure of eight. A South American method of wound closure involved using large black ants to bite the wound together with their pincers or jaws acting like skin clips, and then the ant's body was twisted off leaving the head in place keeping the wound apposed. By 1000BC, Indian surgeons were using horsehair, cotton and leather sutures while, in Roman times, linen and silk and metal clips, called fibulae, were commonly used to close gladiatorial wounds. By the end of the nineteenth century, developments in the textile industry led to major advances, and both silk and catgut became popular as suture materials. Lister believed that catgut soaked in chromic acid

Aurelius Cornelius Celsus, Roman physician, 25BC–AD50.
Joseph Lister (Lord Lister), Professor of Surgery in Glasgow, Edinburgh and King's College Hospital, London and Vice President of Royal College of Surgeons of England, 1827–1912.
Alexis Carrel, 1873–1944, surgeon from Lyons in France, worked at the Rockefeller Institute for Medical Research in New York, NY, USA. He received the Nobel Prize for Physiology or Medicine in 1912 'in recognition for his works on vascular suture and the transplantation of blood vessels and organs'.
Gladiators were so called because they fought with a Roman sword called a '*gladius*'.

(a form of tanning) prevented early dissolution in body fluids and tissues, while Moynihan felt that chromic catgut was ideal as it could be sterilised, was non-irritant to tissues, kept its strength until its work was done and then disappeared. However, catgut is no longer in use as it causes an inflammatory cellular reaction with release of proteases and may also carry the risk of prion transmission if of bovine origin.

Suture characteristics

There are five characteristics of any suture material that need to be considered:

1 **Physical structure**. Suture material may be monofilament or multifilament. Monofilament suture material is smooth and tends to slide through tissues easily without any sawing action, but is more difficult to knot effectively. Such material can be easily damaged by gripping it with needle holder or forceps and this can lead to fracture of the suture material. Multifilament or braided sutures are much easier to knot, but have a surface area of several thousand times that of monofilament sutures and thus have a capillary action and interstices where bacteria may lodge and be responsible for persistent infection or sinuses. In order to overcome some of these problems, certain materials are produced as a braided suture, which is coated with silicone in order to make it smooth.

2 **Strength**. The strength of a suture material depends upon its constituent material, its thickness and how it is handled in the tissues. Suture material thickness is classified according to its diameter in tenths of a millimetre (*Table 7.1*), although the figure assigned is also dependent upon the nature of the material, e.g. absorbable material and non-absorbable material, such as polypropylene, may differ in their designations. The tensile strength of a suture can be expressed as the force required to break it when pulling the two ends apart, but is only a useful approximation as to its strength in the tissues, because what matters is the material's *in vivo* strength. Absorbable sutures show a decay of this strength with the passage of time and although a material may last in the tissues for the stated period in the manufacturer's product profile, its tensile strength cannot be relied on *in vivo* for this entire period. Materials, such as catgut (no longer in use in the UK), have a tensile strength that lasts only about a week, while PDS will remain strong in the tissues for several weeks. However, even non-absorbable sutures do not necessarily maintain their strength indefinitely, and may degrade with time. Those non-absorbable materials of synthetic origin, such as polypropylene, probably retain their tensile strength indefinitely and do not change in mass in the tissues, although it is still possible for them to fracture. Non-absorbable materials of biological origin, such as silk, will definitely fragment with time and lose their strength, and such materials should never be used in vascular anastomoses for fear of late fistula formation.

3 **Tensile behaviour**. Suture materials behave differently depending upon their deformability and flexibility. Some may be 'elastic', where the material will return to its original length once any tension is released, while others may be 'plastic', in which case this phenomenon does not occur. Sutures may be deformable, in that a circular cross-section may be converted to an oval shape, or they may be more rigid and have the somewhat irritating capacity to kink and coil. Many synthetic materials demonstrate 'memory', so that they keep curling up in the shape they adopted within the packaging. A sharp but gentle pull on the suture material helps to diminish this memory, but the more memory a suture material has, the lower is the knot security. Therefore, knotting technique also plays a significant role in any suture line's tensile strength and it is important to recognise that sutures lose 50% of their strength at the knot.

4 **Absorbability**. Suture materials may be non-absorbable (*Table 7.2*) or absorbable (*Table 7.3*) and this property must be taken into consideration when choosing suture materials for specific wound closures or anastomoses. Sutures for use in the biliary or urinary tract need to be absorbable in order to minimise the risk of stone production. However, a vascular anastomosis requires a non-absorbable material and it is wise to avoid braided material because platelet adherence may predispose to distal embolisation. Non-absorbable materials tend to be preferred where persistent strength is required and, as an artificial graft or prosthesis never heals fully or integrates into a host artery, persistent monofilament suture materials, such as polypropylene, are almost universally used.

5 **Biological behaviour**. The biological behaviour of suture material within the tissues depends upon the constituent raw material. Biological or natural sutures, such as catgut, are proteolysed, but this involves a process that is not entirely predictable and can cause local irritation, and such materials are therefore seldom used. Synthetic polymers are hydrolysed and their disappearance in the tissues is more predictable. However, the presence of pus, urine or faeces influences the final result and renders the outcome more unpredictable. There is also some evidence that, in

TABLE 7.1 Size of suture material.

Metric (EurPh)	Range of diameter (mm)	USP ('old')
1	0.100–0.149	5–0
1.5	0.150–0.199	4–0
2	0.200–0.249	3–0
3	0.300–0.349	2–0
3.5	0.350–0.399	0
4	0.400–0.499	1
5	0.500–0.599	2

Berkley George Andrew Moynihan (Lord Moynihan of Leeds), 1865–1936, Professor of Clinical Surgery, University of Leeds, Leeds, UK. Moynihan felt that English surgeons knew little about the work of their colleagues both at home and abroad. Therefore, in 1909, he established a small travelling club which in 1929 became the Moynihan Chirurgical Club. It still exists today. He took a leading part in founding the British Journal of Surgery in 1913 and became the first chairman of the editorial committee until his death.

the gut, cancer cells may accumulate at sites where sutures persist, possibly giving rise to local recurrence. For this reason, synthetic materials that have a greater predictability and elicit minimal tissue reaction may have an important non-carcinogenic property.

Barbed sutures

Recently, novel suture materials have helped surgeons to reduce or eradicate the need for knot tying in some situations, such as laparoscopic surgery. These sutures have unidirectional or bidirectional barbs that secure the suture in the tissues.

Suture techniques

There are four frequently used suture techniques.

1 **Interrupted sutures**. Interrupted sutures require the needle to be inserted at right angles to the incision and then to pass through both aspects of the suture line and exit again at right angles (**Figure 7.11**). It is important for the needle to be rotated through the tissues rather than to be dragged through, to avoid unnecessarily enlarging the needle hole. As a guide, the distance from the entry point of the needle to the edge of the wound should be approximately the same as the depth of the tissue being sutured, and each successive suture should be placed at twice this distance apart (**Figure 7.12**). Each suture should reach into the depths of the wound and be placed at right angles to the axis of the wound. In linear wounds, it is sometimes easier to insert the middle suture first and then to complete the closure by successively inserting sutures, halving the remaining deficits in the wound length.

2 **Continuous sutures**. For a continuous suture, the first suture is inserted in an identical manner to an interrupted suture, but the rest of the sutures are inserted in a continuous manner until the far end of the wound is reached (**Figure 7.13**). Each throw of the continuous suture should be inserted at right angles to the wound, and this will mean that the externally observed suture material will usually lie diagonal to the axis of the wound. It is important to have an assistant who will follow the suture, keeping it at the same tension in order to avoid either purse stringing the wound by too much tension, or leaving the suture material too slack. There is more danger of producing too much tension by using too little suture length than there is of leaving the suture line too lax. Postoperative oedema will often take up any slack in the suture material. At the far end of the wound, this suture line should be secured either by using an Aberdeen knot or by tying the free end to the loop of the last suture to be inserted.

3 **Mattress sutures**. Mattress sutures may be either vertical or horizontal and tend to be used to produce either eversion or inversion of a wound edge (**Figure 7.14**). The initial suture is inserted as for an interrupted suture, but then the needle moves either horizontally or vertically, and traverses both edges of the wound once again. Such sutures are very useful in producing accurate approximation of wound edges, especially when the edges to be anastomosed are irregular in depth or disposition.

TABLE 7.2 Non-absorbable suture materials.

Suture	Types	Raw material	Tensile strength	Absorption rate	Tissue reaction	Contraindications	Frequent uses	How supplied
Silk	Braided or twisted multifilament. Dyed or undyed. Coated (with wax or silicone) or uncoated	Natural protein Raw silk from silkworm	Loses 20% when wet; 80–100% lost by 6 months. Because of tissue reactions and unpredictability, silk is increasingly not recommended	Fibrous encapsulation in body at 2–3 weeks Absorbed slowly over 1–2 years	Moderate to high Not recommended Consider suitable absorbable or non-absorbable	Not for use with vascular prostheses or in tissues requiring prolonged approximation under stress Risk of infection and tissue reaction makes silk unsuitable for routine skin closure	Ligation and suturing when long-term tissue support is necessary For securing drains externally	10/0–2 with needles, 4/0–1 without needles
Linen	Twisted	Long staple flax fibres	Stronger when wet Loses 50% at 6 months; 30% remains at 2 years	Non-absorbable Remains encapsulated in body tissues	Moderate	Not advised for use with vascular prostheses	Ligation and suturing in gastrointestinal surgery. No longer in common use in most centres	3/0–1 with needles, 3/0–1 without needles
Surgical steel	Monofilament or multifilament	An alloy of iron, nickel and chromium	Infinite (>1 year)	Non-absorbable Remains encapsulated in body tissues	Minimal	Should not be used in conjunction with prosthesis of different metal	Closure of sternotomy wounds Previously found favour for tendon and hernia repairs	Monofilament: 5/0–5 with needles; multifilament: 5/0–3/0 with needles
Nylon	Monofilament or braided multifilament Dyed or undyed	Polyamide polymer	Loses 15–20% per year	Degrades at approximately 15–20% per year	Low	None	General surgical use, e.g. skin closure, abdominal wall mass closure, hernia repair, plastic surgery, neurosurgery, microsurgery, ophthalmic surgery	Monofilament: 11/0–2 with needles (including loops in some sizes), 4/0–2 without needles; multifilament: 6/0–2 with needles, 3/0–1 without needles
Polyester	Monofilament or braided multifilament Dyed or undyed Coated (polybutylate or silicone) or uncoated	Polyester (polyethylene terephthalate)	Infinite (>1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Cardiovascular, ophthalmic, plastic and general surgery	Monofilament: (ophthalmic) 11/10; 10/0 with needles; multifilament: 5/0–1 with needles
Polybutester	Monofilament. Dyed or undyed	Polybutylene terephthalate and polytetramethylene ether glycol	Infinite (>1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Exhibits a degree of elasticity. Particularly favoured for use in plastic surgery	7/0–1 with needles
Polypropylene	Monofilament. Dyed or undyed	Polymer of propylene	Infinite (>1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Cardiovascular surgery, plastic surgery, ophthalmic surgery, general surgical subcuticular skin closure	10/0–1 with needles

TABLE 7.3 Absorbable suture materials.

Suture	Types	Raw material	Tensile strength retention *in vivo*	Absorption rate	Tissue reaction	Contraindications	Frequent uses	How supplied
Catgut	Plain	Collagen derived from healthy sheep or cattle	Lost within 7–10 days Marked patient variability Unpredictable and not recommended	Phagocytosis and enzymatic degradation within 7–10 days	High	Not for use in tissues that heal slowly and require prolonged support Synthetic absorbables are superior	Ligate superficial vessels, suture subcutaneous tissues Stomas and other tissues that heal rapidly	6/0–1 with needles; 4/0–3 without needles
Catgut	Chromic	Collagen derived from healthy sheep or cattle Tanned with chromium salts to improve handling and to resist degradation in tissue	Lost within 21–28 days Marked patient variability Unpredictable and not recommended	Phagocytosis and enzymatic degradation within 90 days	Moderate	As for plain catgut Synthetic absorbables superior	As for plain catgut	6/0–3 with needles; 5/0–3 without needles
Polyglactin	Braided multifilament	Copolymer of lactide and glycolide in a ratio of 90:10, coated with polyglactin and calcium stearate	Approximately 60% remains at 2 weeks Approximately 30% remains at 3 weeks	Hydrolysis minimal until 5–6 weeks. Complete absorption 60–90 days	Mild	Not advised for use in tissues that require prolonged approximation under stress	General surgical use where absorbable sutures required, e.g. gut anastomoses, vascular ligatures. Has become the 'workhorse' suture for many applications in most general surgical practices, including undyed for subcuticular wound closures. Ophthalmic surgery	8/0–2 with needles; 5/0–2 without needles
Polyglyconate	Monofilament Dyed or undyed	Copolymer of glycolic acid and trimethylene carbonate	Approximately 70% remains at 2 weeks Approximately 55% remains at 3 weeks	Hydrolysis minimal until 8–9 weeks. Complete absorption by 180 days	Mild	Not advised for use in tissues that require prolonged approximation under stress	Popular in some centres as an alternative to Vicryl and PDS	7/0–2 with needles
Polyglycolic acid	Braided multifilament Dyed or undyed Coated or uncoated	Polymer of polyglycolic acid. Available with coating of inert, absorbable surfactant poloxamer 188 to enhance surface smoothness; 87% excreted in urine within 3 days	Approximately 40% remains at 1 week Approximately 20% remains at 3 weeks	Hydrolysis minimal at 2 weeks, significant at 4 weeks. Complete absorption 60–90 days	Minimal	Not advised for use in tissues that require prolonged approximation under stress	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	9/0–2 with needles; 9/0–2 without needles
Polydioxanone (PDS)	Monofilament Dyed or undyed	Polyester polymer	Approximately 70% remains at 2 weeks Approximately 50% remains at 4 weeks Approximately 14% remains at 8 weeks	Hydrolysis minimal at 90 days. Complete absorption at 180 days	Mild	Not for use in association with heart valves or synthetic grafts, or in situations in which prolonged tissue approximation under stress is required	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	Polydioxanone suture (PDS) 10/0–2 with needles
Polyglycaprone	Monofilament	Copolymer of glycolite and caprolactone	21 days maximum	90–120 days	Mild	No use for extended support	Subcuticular in skin, ligation, gastrointestinal and muscle surgery	8/0–2 with needles

4 **Subcuticular suture**. This technique is used in skin where a cosmetic appearance is important and where the skin edges may be approximated easily (**Figure 7.15**). The suture material used may be either absorbable or non-absorbable. For non-absorbable sutures, the ends may be secured by means of a collar and bead, or tied loosely over the wound. When absorbable sutures are used, the ends may be secured using a buried knot. Small bites of the subcuticular tissues are taken on alternate sites of the wound and then gently pulled together, thus approximating the wound edges without the risk of the cross-hatched markings of interrupted sutures.

Needles

In the past, needles had eyes in them and suture material had to be loaded into them, which was not only time consuming, but it meant that the needle holes in tissues were considerably larger than the suture material being used. Currently, needles are eyeless or 'atraumatic', with the suture material embedded within the shank of the needle. The needle has three main parts:

1 shank;
2 body;
3 point.

The needle should be grasped by the needle holder approximately one-third to one-half of the way back from the rear of the needle, avoiding both the shank and the point. The closer the needle holder is to the tip of the needle, the greater the accuracy of suture placement and the less the degree of rotation of the surgeon's hand required in suturing. The needle should never be grasped nearer than one-third of the way back from the rear of the needle.

The body of the needle is either round, triangular or flattened. Round-bodied needles gradually taper to a point, while triangular needles have cutting edges along all three sides. The actual point of the needle can be round with a tapered end, conventional cutting which has the cutting edge facing the inside of the needle's curvature, or reverse cutting in which the cutting edge is on the outside (**Figure 7.16**). Round-bodied needles are designed to separate tissue fibres rather than cut through them and are commonly used in intestinal and cardiovascular surgery. Cutting needles are used where tough or dense tissue needs to be sutured, such as skin and fascia. Blunt-ended needles are now being advocated in certain situations, such as closure of the abdominal wall, in order to diminish the risk of needle-stick injuries in this era of blood-borne infectious diseases. The choice of needle shape tends to be dictated by the accessibility of the tissue to be sutured, and the more confined the operative space, the more curved the needle. Hand-held straight needles may be used on skin, although today it is advocated that needle holders should be used in all cases to reduce the risk of needle-stick injuries. Half circle needles are commonly utilised in the gastrointestinal tract, while J-shaped needles, quarter circle needles and compound curvature needles are used in special situations, such as the vagina, eye and oral cavity, respectively. The size of the needle tends to correspond with the gauge of the suture material, although it is possible to get similar sutures with differing needle sizes.

Knotting techniques

Knot tying is one of the most fundamental techniques in surgery and yet is often performed poorly. The principles behind a secure knot are poorly understood by many surgeons and sadly a poorly constructed knot may jeopardise an otherwise successful surgical procedure. The general principles behind knot tying include:

- The knot must be tied firmly, but without strangulating the tissues.
- The knot must be unable to slip or unravel.
- The knot must be as small as possible to minimise the amount of foreign material.
- The knot must be tightened without exerting any tension or pressure on the tissues being ligated, i.e. the knot should be bedded down carefully, only exerting pressure against counter-pressure from the index finger or thumb.
- During tying, the suture material must not be 'sawed' as this weakens the thread.
- The suture material must be laid square during tying, otherwise tension applied during tightening may cause breakage or fracture of the thread.
- When tying an instrument knot, the thread should only be grasped at the free end, as gripping the thread with artery forceps or needle holders can damage the material and again result in breakage or fracture.

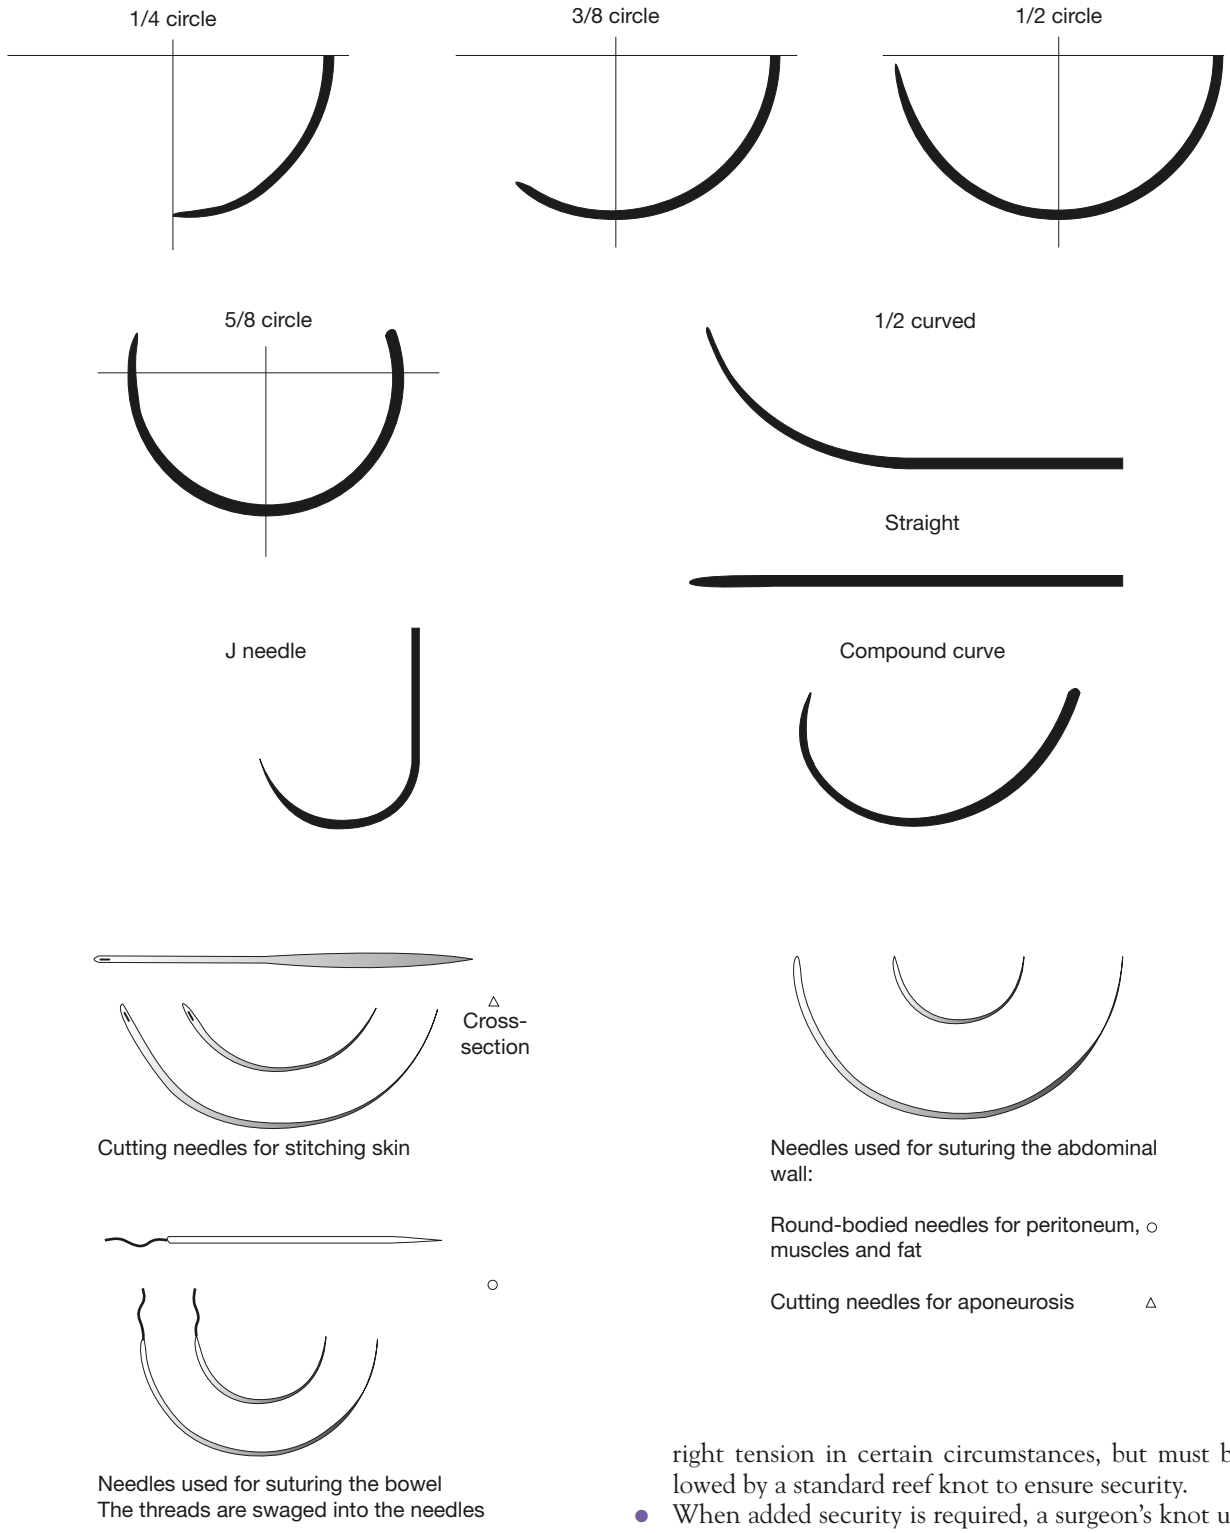

Figure 7.16 Types of needle.

- The standard surgical knot is the reef knot (**Figure 7.17**), with a third throw for security, although with monofilament sutures, such as used for vascular surgery, six to eight throws are required for security.
- A granny knot involves two throws of the same type of throw and is a slip knot. It may be useful in achieving the right tension in certain circumstances, but must be followed by a standard reef knot to ensure security.
- When added security is required, a surgeon's knot using a two throw technique is advisable to prevent slippage.
- When using a continuous suture technique, an Aberdeen knot may be used for the final knot. The free end of the suture is partially pulled through the final loop several times before being pulled through a final time completely prior to cutting.
- When the suture is cut after knotting, the ends should be left about 1–2 mm long to prevent unraveling. This is particularly important when using monofilament material.

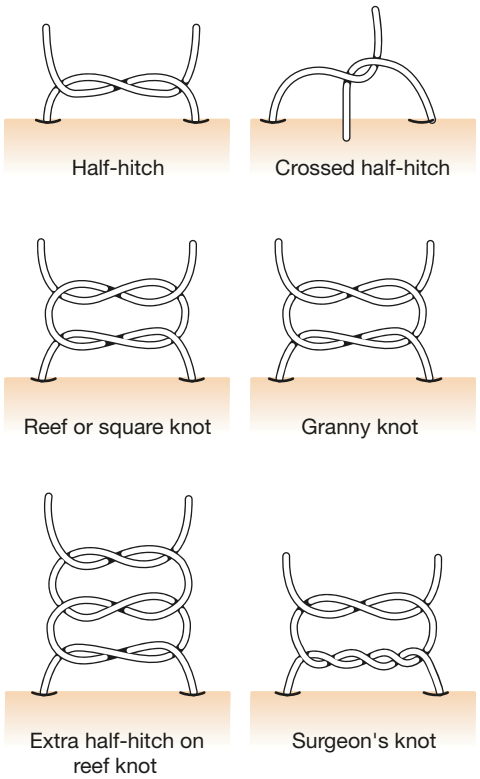

Figure 7.17 Standard knotting formations.

Alternatives to sutures

Many alternatives to standard suture techniques now exist and are in common usage.

Skin adhesive strips

For the skin, self-adhesive tapes or steristrips may be used where there is no tension and not too much moisture, such as after a wide excision of a breast lump. They may also be used to minimise 'spreading' of a scar. Other adhesive polyurethane films, such as Opsite, Tegaderm or Bioclusive, may provide a similar benefit, while such transparent dressings also allow wound inspection and may protect against cross-infection.

Tissue glue

Tissue glue is also available, based upon a solution of *n*-butyl-2-cyanoacrylate monomer. When it is applied to a wound, it polymerises to form a firm adhesive bond, but the wound does need to be clean, dry, with near perfect haemostasis and under no tension. Some specific uses have been described, such as closing a laceration on the forehead of a fractious child in Accident and Emergency, thus dispensing with local anaesthetic and sutures. Although it is relatively expensive, it is quick to use, does not delay wound healing and is associated with an allegedly low infection rate. Other tissue glues involve fibrin and work on the principles of converting fibrinogen to fibrin by thrombin with crosslinking by factor XIII, and the addition of aprotinin to slow the breaking up of the fibrin network by plasmin. This process has good adhesive properties and has been used for haemostasis in the liver and spleen, for dural tears, in ear, nose and throat (ENT) and ophthalmic surgery, to attach skin grafts and also to prevent haemoserous collections under flaps. Fibrin glues have also been used to control gastrointestinal haemorrhage endoscopically, but do not work when the bleeding is brisk.

Laparoscopic wound closure

Laparoscopic wounds are generally 3–12 mm in length. As with all incisions they should be parallel to Langer's lines where possible. Skin closure can be carried out with sutures, using curved or straight needles, or glue, and can be further secured with adhesive strips.

Staples

Mechanical stapling devices were first used successfully by Hümer Hültl in Hungary in 1908 to close the stomach after resection. Today, there is a wide range of mechanical devices with linear, side-to-side and end-to-end stapling devices that can be used both in the open surgery setting and laparoscopically. Most of these devices are disposable and relatively expensive, but their cost is offset by the saving of operative time and the potential increase in the range of surgery possible (see below).

STAPLING DEVICES

In the gastrointestinal tract, stapling devices tend to apply two rows of staples, offset in relation to each other, to produce a sound anastomosis (**Figure 7.18**). Many of them also simultaneously divide the bowel or tissue that has been stapled while other devices merely insert the staples and the bowel has to be divided separately. For all stapling devices, it is crucial for the surgeon to understand the principles behind the device and to know intimately the mechanism and function of the instrument.

- **End-to-end anastomoses**. Circular stapling devices allow tubes to be joined together, and such instruments are in common use in the oesophagus and low rectum. The detached stapling head/anvil is introduced into one end of the bowel, usually being secured within it by means of a purse-string suture. The body of the device is then inserted into the other end of the bowel, either via the rectum for a low rectal anastomosis, or via an enterotomy for an oesophago-jejunostomy, and the shaft is either extended through a small opening in the bowel wall or secured by a further purse-string suture. The head/anvil is reattached to the shaft and the two ends approximated. Once the device is fully closed, as indicated by the green indicator in the window, the device is fired, and, after unwinding, the stapler is gently withdrawn. It is important to assess the integrity of the anastomosis by examining the 'doughnuts' of tissue excised for completeness. It is essential that no extraneous tissue is allowed to become interposed between the two bowel walls on closing the stapler.

Hümer Hültl, surgeon, St Stephen's Hospital, Budapest, Hungary, described his gastric stapler in 1908.

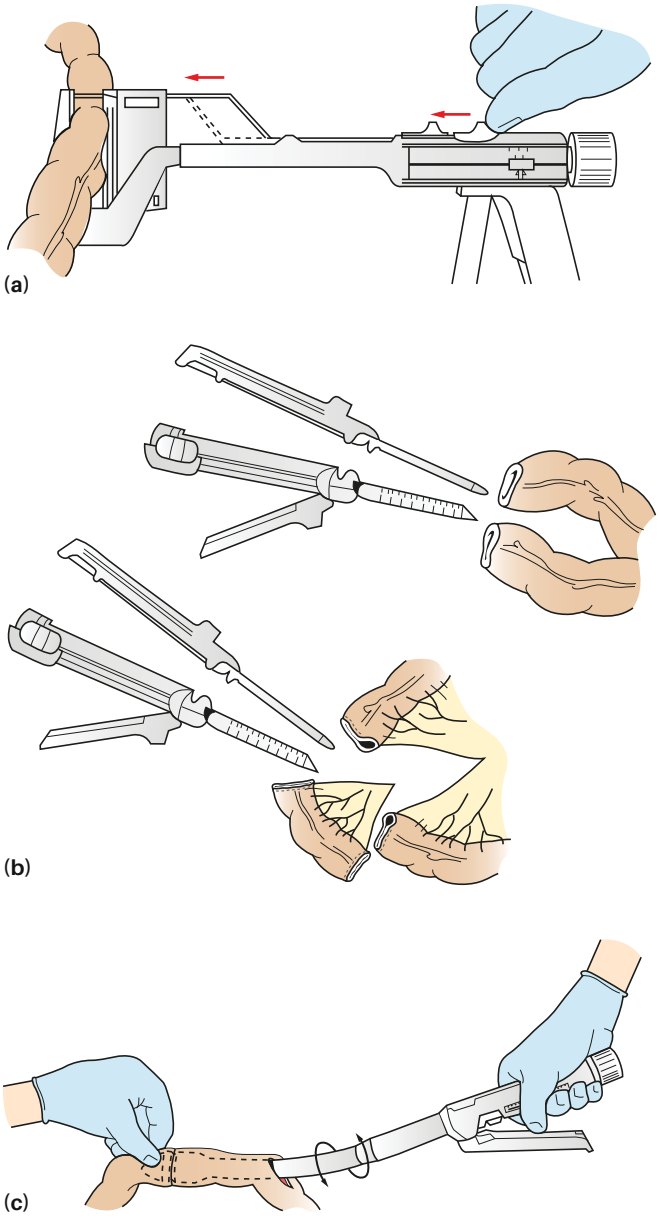

Figure 7.18 (a-c) Standard stapling devices.

- **Transverse anastomoses**. These instruments, which come in different sizes, simply provide two rows of staples for a single transverse anastomosis. They are useful for closing bowel ends, and the larger sizes have been used to create gastric tubes and gastric partitioning. One technical point of importance is that the bowel should be divided before the instrument is reopened after firing, as the instrument is designed with a ridge along which to pass a scalpel to ensure that the cuff of bowel that remains adjacent to the staple line is of the correct length. Down in the pelvis it may be helpful to use such a device with a moveable head (roticulator).
- **Intraluminal anastomoses**. These instruments have two limbs which can be detached. Each limb is introduced into a loop of bowel, the limbs reassembled and the device closed. On firing, two rows of staples are inserted either side of the divided bowel, the division occurring by means of a built-in blade that is activated at the same time as the insertion of staples. Such an instrument may be used in fashioning a gastro-jejunostomy or jejuno-jejunostomy and is used in ileal pouch formation.
- **Other devices**. Other devices are produced that will staple/ligate and divide blood vessels. Skin closure may also be undertaken using hand-held stapling devices rather than individually picking up staples/clips and inserting them as described above.

LAPAROSCOPIC STAPLING DEVICES

Since the early 1990s, increasingly complex surgical procedures have been performed laparoscopically. This revolution in practice has gone hand-in-hand with rapid evolutions in technology to allow existing open instruments and devices to be used laparoscopically, including surgical staplers. Many of the intestinal stapling devices are now adapted to be inserted down trocars during laparoscopic surgery, and although they look very different, the principles of function are identical to their open surgical equivalent. Linear cutting staplers allow bowel and blood vessels to be sealed and divided. Linear and circular staplers also allow intracorporeal anastomoses to be performed. As with open staplers, the surgeon must be trained in their safe use and aware of the principles, including different staple sizes.

THE PRINCIPLES OF ANASTOMOSES

Bowel anastomoses

The word anastomosis comes from the Greek '*ana*', without, and '*stoma*', a mouth, reflecting the join of a tubular viscus (bowel) or vessel (usually arteries) after a resection or bypass procedure. Prior to the nineteenth century, intestinal surgery was limited to exteriorisation by means of a stoma, or closure of simple lacerations. Lembert then described his seromuscular suture technique for bowel anastomosis in 1826, while Senn advocated a two-layer technique for closure. Kocher's method utilised a two-layer anastomosis, first a continuous all-layer suture using catgut, then an inverting continuous (or interrupted) seromuscular layer suture using silk, which became the mainstay of bowel anastomoses for many years (**Figure 7.19**). However, Halsted favoured a one-layer extramucosal closure, and this was subsequently advocated by Matheson as

Antoine Lembert, 1802–1851, surgeon, Hôtel Dieu, Paris, France.

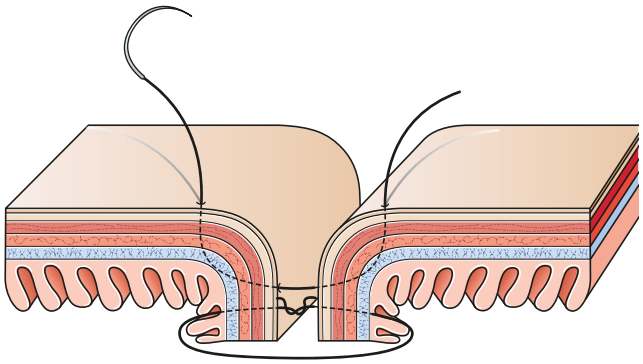

Figure 7.19 Standard two-layer bowel anastomosis. Reproduced with permission from Kocher T, Harder F, Thomas WEG (eds). *Anastomosis techniques in the gastrointestinal tract*, 1st edn. Wollerau: Covidien, 2007.

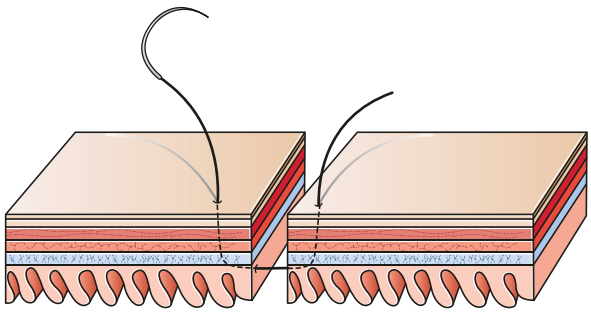

Figure 7.20 Extramucosal technique taking care to include the submucosa. Reproduced with permission from Kocher T, Harder F, Thomas WEG (eds). *Anastomosis techniques in the gastrointestinal tract*, 1st edn. Wollerau: Covidien, 2007.

it was felt to cause the least tissue necrosis or luminal narrowing (**Figure 7.20**). This technique has now become widely accepted, although it is essential that this is not confused with a seromuscular suture technique. The extramucosal suture must include the submucosa because this has a high collagen content and is the most stable suture layer in all sections of the gastrointestinal tract. There are several prospective randomised trials comparing two-layer and single-layer anastomoses demonstrating that there is probably little to choose between these techniques, provided basic essentials as highlighted in *Summary box 7.5* are observed. However, catgut and silk have been replaced by synthetic, usually absorbable, polymers. In the past, great emphasis was placed on good bowel preparation prior to any anastomosis. The rationale was that, with good bowel preparation and an empty bowel, there was less likelihood of faecal contamination and therefore it was probably not necessary to apply bowel clamps (even of the soft occlusion type). However, this tradition is now being challenged, and there is evidence to suggest that conventional bowel preparation provides little benefit, and indeed at times may prove detrimental to the outcome. In spite of this, many surgeons still use some form of bowel preparation, especially for colorectal surgery. Furthermore, if there is any risk of intestinal spillage during anastomosis, when bowel is unprepared or obstructed for example, atraumatic intestinal clamps should be used across the lumen of the bowel. Clamps should not impinge on the mesentery or the vasculature of the bowel for fear of damage to the vessels resulting in ischaemic changes. Ideally, the bowel edges should be pink and bleeding prior to anastomosis. The gold standard for a good blood supply for any anastomosis is the presence of arterial bleeding from the marginal vessel immediately adjacent to the cut end of the bowel and the absence of venous congestion. Excessive bleeding from the bowel wall may need oversewing if natural haemostasis is inadequate.

Summary box 7.5

Intestinal anastomoses

- Ensure good blood supply to both bowel ends before and after formation of anastomosis
- Ensure the anastomosis is under no tension
- Avoid risk to mesenteric vessels by clamps or sutures
- Use atraumatic bowel clamps to minimise contamination
- Interrupted and continuous single-layer suture techniques are adequate and safe
- Stapling devices are an alternative when speed is required or access is a major factor

For all intestinal anastomoses, the bowel ends must be brought together without tension. Stay sutures, which avoid the need for tissue forceps, are invaluable for displaying the bowel ends and help with the accurate alignment of the bowel and the placement of the sutures. If the anastomosis is being undertaken on mobile bowel, the anterior wall layer of sutures can be inserted, either in a continuous or interrupted manner, and then the bowel rotated and the posterior wall sutured in an identical manner to the anterior wall. As the mesenteric edge of the bowel is the most difficult, especially when a fatty mesentery is present, this angle should be dealt with first, with the final sutures being inserted at the antimesenteric border which is far more accessible and visible. The apposition of bowel edges should be as accurate as possible and the suture bites should be approximately 3–5 mm deep and 3–5 mm apart, depending on the thickness of the bowel wall. The suture materials should be of 2/0–3/0 size and made of an absorbable polymer, which can be braided (e.g. polyglactin) or monofilament (e.g. polydioxanone), mounted on an atraumatic round-bodied needle. Braided, coated sutures are the easiest to handle and knot.

It is crucial that only bowel of similar diameter is brought together to form an end-to-end anastomosis. In cases of major size discrepancy, a side-to-side or end-to-side anastomosis may be safer. In cases where the size discrepancy is not marked, a Cheatle split (making a cut into the antimesenteric border) may help to enlarge the lumen of distal, collapsed bowel and allow an end-to-end anastomosis to be fashioned. After all anastomoses, the mesentery should always be closed to avoid the later risk of an internal hernia through a persistent mesenteric defect. Care must be taken during closure of this defect to prevent damage to any mesenteric vessels running in

Sir George Lenthal Cheatle, 1865–1951, surgeon, King's College Hospital, London, UK.

the edge of the mesentery. In certain situations, as indicated above, stapling devices are used to fashion the anastomosis, but as they are expensive, many surgeons reserve them for specific indications, such as oesophageal, rectal and gastric pouch procedures. Several studies have shown them not to be cost effective in routine small bowel surgery, although many surgeons still use them for ease of use and to save time.

Vascular anastomoses

Vascular anastomoses require an extremely accurate closure as they must be immediately watertight at the end of the operation when the vascular clamps are removed. In many cases, some form of prosthetic material or graft may be used which will never be integrated into the body tissues and so the integrity of the suture line needs to be permanent. For this reason, polypropylene is one of the best sutures because it is not biodegradable. It is used in its monofilament form, mounted on an atraumatic, curved, round-bodied needle. Knot security is important, and as polypropylene is monofilament and the anastomosis often depends on one final knot, several throws (between six and eight) of a well-laid reef knot are required. The suture line must be regular and watertight with a smooth intimal surface to minimise the risk of thrombosis and embolus, as well as to avoid any leakage. Suture size depends on vessel calibre: 2/0 is suitable for the aorta, 4/0 for the femoral artery and 6/0 for the popliteal to distal arteries. Microvascular anastomoses are made using a loupe and an interrupted suture down to 10/0 size. All vessel walls must be treated with great care, avoiding causing any damage to the intima. If any significant manipulation is necessary, atraumatic forceps (such as DeBakey's) are utilised. Vascular clamps should be applied with great care, particularly for calcified vessels, and in some cases encircling rubber loops or intraluminal balloon catheters may be less traumatic for control.

Vessels should always be sewn with the needle moving from within to without on the downstream edge of the vessel to avoid creating an intimal flap and to fix any atherosclerotic plaque. The tip of the needle should be inserted at right angles to the surface of the intima and the curve of the needle followed to prevent vessel trauma. The assistant should 'follow' by keeping the suture taut and, once the closure is complete, the distal clamp is released first, before the final watertight knot is made. This allows backflow to clear any clot or air from the anastomosis. The proximal clamp can then be released, a process which minimises the risk of distal embolus. Suture bites should be placed an equal distance apart, with the bite size dependent on the vessel diameter. Care needs to be taken to avoid damaging the suture, which should not be gripped by any surgical instrument. All haemostats that are used to hold any suture material should be shod with soft rubber to prevent suture material damage. A transverse arteriotomy is less likely to stenose following closure than a longitudinal arteriotomy, but may not give adequate access, and a longitudinal arteriotomy is easier to make.

A vein patch can be used if there is any danger of stenosis or doubt about the size of the lumen (**Figure 7.21**). The suture line can be started at the apex of the arteriotomy with a double-ended suture, and then carried down each side with the final knot being placed at the midpoint of the vein patch graft, and not at the far end. The suture should go from outside to inside on the graft and from inside to outside on the artery, again to minimise the risk of intimal flap formation. When prosthetic materials or grafts are used, similar non-absorbable monofilament sutures are used with the same in–out technique to ensure eversion of the graft edge and a smooth intimal surface. Again the needle should go from outside to inside on the graft and from inside to outside on the artery. Double-ended sutures make the procedures easier.

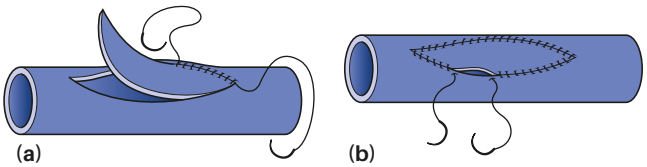

Figure 7.21 (a, b) Arteriotomy being closed by vein patch. The technique involves a double armed suture, ensuring that the final knot is half way along one side of the arteriotomy. Summary box 7.6

Vascular anastomosis

- Non-absorbable monofilament suture material should be used, e.g. polypropylene
- A smooth intimal suture line is essential
- Knots require multiple throws in order to ensure security
- The suture must pass from within outwards on the downflow aspect of the anastomosis

Laparoscopic anastomosis

The same principles apply to laparoscopic anastomosis as to open anastomosis: good blood supply, the avoidance of tension and gentle tissue handling. Both sutured and stapled anastomoses can be performed using laparoscopic needle holders and staplers adapted to laparoscopic surgery. If the ends of the bowel have been adequately mobilised, and there is a specimen extraction site (e.g. right hemicolectomy), an extracorporeal anastomosis can be performed using open surgical techniques. If one or both ends of the bowel to be anastomosed cannot be exteriorised, an intracorporeal anastomosis can be performed. In intra-abdominal surgery, enterotomies are performed in the proximal and distal ends to be anastomosed and a linear stapler is used to join the two ends. The resulting common enterotomy is then closed with a running suture.

DRAINS

Drains are inserted to allow fluid or air that might collect at an operation site or in a wound to drain freely to the surface. The fluid to be drained may include blood, serum, pus, urine,

Michael Ellis DeBakey, b.1908, Professor of Surgery, Baylor University, Houston, TX, USA.

faeces, bile or lymph. Drains may also allow wound irrigation in certain specific circumstances. The adequate drainage of fluid collections prevents the development of cavities or spaces that may delay wound healing. Their use can be regarded as prophylactic in elective surgery and therapeutic in emergency surgery. Three basic principles apply in the use of drains:

1 Open drains that utilise the principle of gravity
2 Semi-open drains that work on the principle of the capillary effect
3 Closed drain systems that utilise suction.

They may be placed through the wound or through a separate incision, although it has been clearly shown that placing them through the wound leads to an increased risk of wound infection. With regard to the indications for drainage, drains were in common use ever since Lawson Tait suggested, in 1887, 'when in doubt drain!' However, this edict has come under strong criticism recently and the value and use of drains has been the subject of close scrutiny; their use remains controversial.

Protagonists suggest that the use of drains may:

- remove any intraperitoneal or wound collection of ascites, serum, bile, chyle, pancreatic or intestinal secretion;
- act as a signal for any postoperative haemorrhage or anastomotic leakage;
- provide a track for later drainage.

However, the antagonists claim that the presence of a drain may:

- increase intra-abdominal and wound infections;
- increase anastomotic insufficiency;
- increase abdominal pain;
- increase hospital stay;
- decrease pulmonary function.

In reality, the use of drains currently tends to depend on a surgeon's individual preference. There are randomised controlled trials suggesting that their use in gastric, duodenal, small bowel, appendix and biliary surgery is unnecessary and may cause more problems than benefits, and this is now reflected in current practice. There are also randomised controlled trials to suggest that they are also not required in colorectal, liver and pancreatic surgery, and yet in today's practice the majority of surgeons will still utilise drains in these forms of surgery. The only area of alimentary tract surgery where drains are still routinely advocated is for oesophageal surgery, although even here the evidence is low, with the level of evidence being only 5 and the level of recommendation being 'D' (i.e. based on expert opinion).

Specialist uses of drains

There are certain clinical situations where specialist forms of drainage are required.

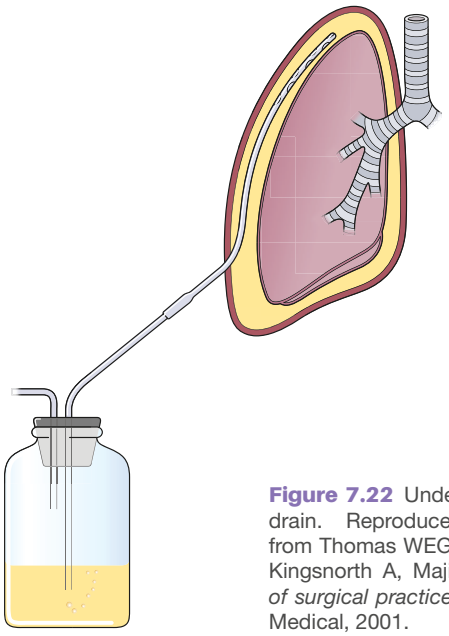

Figure 7.22 Underwater sealed chest drain. Reproduced with permission from Thomas WEG. Basic principles. In: Kingsnorth A, Majid A (eds). *Principles of surgical practice*. London: Greenwich Medical, 2001.

Chest drains

These are indicated for a pneumothorax, pleural effusion, haemothorax or to prevent the collection of fluid or air after thoracotomy. Once the drain has been inserted, it should be connected to an underwater sealed drain **(Figure 7.22)**. This system allows air to leave the pleural cavity, but it cannot be drawn back in by the negative pressure that is created in the intrathoracic cavity. During the respiratory process, it should be checked that the meniscus of the fluid is swinging, to ensure that the tube is not blocked. Suction can be applied to the venting tube at the bottle whenever there is significant drainage of fluid or air expected. Between 10 and 20 mm of mercury is adequate to obtain a gentle flow of bubbles from the chest cavity.

T-tube drains

After exploration of the common bile duct, a T-tube **(Figure 7.23)** may be inserted into the duct which allows bile to drain while the sphincter of Oddi is in spasm postoperatively. Once the sphincter relaxes, bile drains normally down the bile duct and into the duodenum. To assist choleresis, it is often advisable to convert the lumen of the limb of the T into a gutter, which also facilitates removal.

Image guided drainage

For many intra-abdominal collections or abscesses, drains may be inserted under ultrasound or computed tomography (CT) control. In order for such drains to remain in site, the end is often fashioned with a pigtail to discourage inadvertent removal. These techniques have been in increasing use as a less invasive method to manage both primary and secondary

(after surgery) collections of fluid. In the context of sepsis they are often used with intravenous or oral antimicrobial therapy.

Removal of drains

A drain should be removed as soon as it is no longer required because, if left in, it can itself predispose to fluid collection as a result of tissue reaction. Indeed there is evidence that by 7 days only 20% of drains are still functioning. It should be stressed how important it is to define the objective of each individual drain and to ensure that once that objective has been met, the drain is removed. If a drain is used at all, the following principles may apply.

- Drains put in to cover perioperative bleeding may usually be removed after 24 hours, e.g. thyroidectomy.
- Drains put in to drain serous collections usually can be removed after 5 days, e.g. mastectomy.
- Drains put in because of infection should be left until the infection is subsiding or the drainage is minimal.
- Drains put in to cover colorectal anastomoses should be removed at about 5–7 days. However, it should be stressed that in no way does a drain prevent any intestinal leakage, but merely may assist any such leakage to drain externally rather than to produce life-threatening peritonitis.
- Common bile duct T-tubes should remain in for 10 days. However, once the T-tube cholangiogram has shown that there is free flow of bile into the duodenum and that there are no retained stones, some surgeons like to clamp the T-tube prior to removal. The 10-day period is required to minimise the risk of biliary peritonitis after removal. T-tubes are traditionally and intentionally made of latex to stimulate fibrosis, which results in the formation of a tract to allow the drainage of bile if required. It is important to use an alternative to latex if the patient is allergic, bearing in mind the decreased potential for fibrosis of silicone-based T-tubes. The increase in less invasive means of intervention for bile duct pathology has resulted in fewer T-tubes being used.
- Any suction drain should have the suction taken off prior to removal of the drain. Even in the absence of suction, a blocked drain may be difficult to remove owing to the creation of a relative vacuum as it is pulled out. This can be released by twisting the drain on removal or flushing with a small volume of sterile saline under aseptic conditions.
- During removal of a chest drain, the patient should be asked to breathe in and hold their breath, thus doing a Valsalva manoeuvre. In this way, no air is sucked into the pleural cavity as the tube is removed. Once the drain is out, a previously inserted purse-string suture should be tied.

Laparoscopic surgery is often accompanied by 'Enhanced Recovery after Surgery' pathways. These pathways comprise a package of pre-, peri- and postoperative care whose objectives are to reduce complications and hospital stay. Such pathways often discourage the use of drains. However the laparoscopic surgeon should always be prepared to use drains where indicated.

THE PRINCIPLES OF DIATHERMY: ELECTROSURGERY

Development of the first commercial electrosurgical device is credited to William T Bovie, who developed the first electrosurgical device while employed at Harvard University. The first use of an electrosurgical generator in an operating room occurred in 1926 at Peter Bent Brigham Hospital in Boston, Massachusetts. The operation – removal of a mass from a patient's head – was performed by Harvey Cushing.

For many years, short wave diathermy has proved a most valuable and versatile aid to surgical technique. Its most common use is in securing haemostasis by means of coagulation, but by varying the strength or wave form of the current produced, it can also result in a cutting effect. Both these effects have been used in open surgery, as well as in laparoscopic surgery or down intraluminal endoscopes, as in transurethral resection of the prostate. However, although diathermy is a valuable surgical tool, many accidents have occurred due to surgeons being unaware of, or not fully understanding, the principles of its use. Most accidents are avoidable if the diathermy or electrocautery is used with care. It is therefore vital for a surgeon to have a sound understanding of the principles and practice of diathermy, and how to avoid complications.

Antonio Maria Valsalva, 1666–1723, Italian physician and anatomist.

Principle of diathermy

When an electrical current passes through a conductor, some of its energy appears as heat. The heat produced depends on:

- the intensity of the current;
- the wave form of the current;
- the electrical property of the tissues through which the current passes;
- the relative sizes of the two electrodes.

There are two basic types of diathermy system in use, monopolar diathermy and bipolar diathermy (Figure 7.24). In monopolar diathermy, which is the most commonly used form, an alternating current is produced by a suitable generator and passed to the patient via an active electrode which has a very small surface area. The current then passes through the tissues and returns via a very large surface plate (the passive electrode) back to the earth pole of the generator. As the surface area of contact of the active electrode is small in comparison to the passive electrode, the concentrated powerful current produces heat at the operative site. However, the large surface area electrode of the patient plate spreads the returning current over a wide surface area, so it is less concentrated and produces little heat. In bipolar diathermy, the two active electrodes are usually represented by the limbs of a pair of diathermy forceps. Both forceps ends are therefore active and current flows between them, and only the tissue held between the limbs of the forceps heats up. This form of diathermy is used when it is essential that the surrounding tissues should be free from either the risk of being burned or having current passed through them.

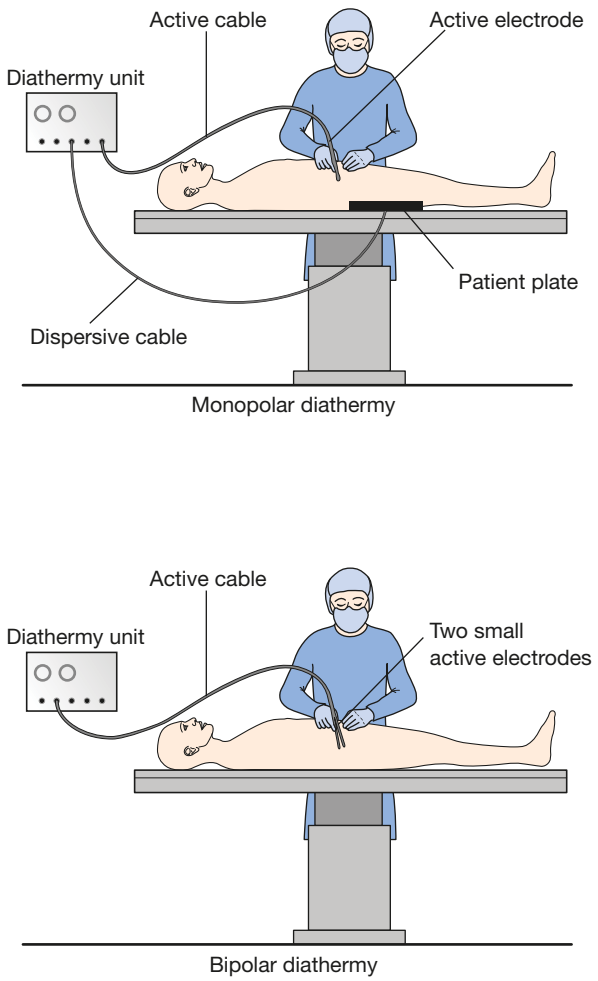

Figure 7.24 The principles of diathermy. **(a)** Monopolar diathermy. **(b)** Bipolar diathermy. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

Effects of diathermy

Diathermy can be used for three purposes:

1 Coagulation: the sealing of blood vessels.
2 Fulguration: the destructive coagulation of tissues with charring.
3 Cutting: used to divide tissues during bloodless surgery.

In **coagulation**, a heating effect leads to cell death by dehydration and protein denaturation. Bleeding is therefore stopped by a combination of the distortion of the walls of the blood vessel, coagulation of the plasma proteins, dried and shrunken dead tissue and stimulation of the clotting mechanism. In an ideal situation, intracellular temperatures should not reach boiling during coagulation, because if this occurs an unwanted cutting effect may be experienced. Cutting occurs when sufficient heat is applied to the tissue to cause cell water to explode into steam. The cut current is a continuous wave form and monopolar diathermy is most effective when the active electrode is held a very short distance from the tissues. This allows an electrical discharge to arc across the gap, creating a series of sparks which produce the high temperatures needed for cutting. In fulguration, the diathermy machine is set to coagulation and a higher effective voltage is used to make larger sparks jump an air gap, thus fulgurating the tissues. This can continue until carbonisation or charring occurs. The voltage and power output can be varied by adjusting the duration of bursts of current, as well the intensity, to give a combination of both cutting and coagulation. This is known as blended current and provides both forms of diathermy activity.

Complications of diathermy

Electrocution

Today, diathermy machines are manufactured to very high safety standards which minimise the risk of any part of the machine becoming live with mains current. However, as with any such instrument, there must be regular and expert servicing.

Explosion

Sparks from the diathermy equipment can ignite any volatile or inflammable gas or fluid within the theatre. Alcohol-based skin preparations can catch fire if they are allowed to pool on or around the patient. Furthermore, diathermy should not be used in the presence of explosive gases, including those which may occur naturally in the

colon, especially after certain forms of bowel preparation, such as mannitol, which has now been banned for this use for this very reason.

Burns

These are the most common type of diathermy accidents in both open and endoscopic surgery. They occur when the current flows in some way other than that which the surgeon intended and are far more common in monopolar than bipolar diathermy. Burns may occur as a result of:

- Faulty application of the indifferent electrode with inadequate contact area.
- The patient being earthed by touching any metal object, e.g. the Mayo table, the bar of an anaesthetic screen, an exposed metal arm rest or a leg touching the metal stirrups used in maintaining the lithotomy position.
- Faulty insulation of the diathermy leads, either due to cracked insulation or instruments, such as towel clips, pinching the cable.
- Inadvertent activity, such as the accidental activation of the foot pedal, or accidental contact of the active electrode with other metal instruments, such as retractors, instruments or towel clips.

Channelling

Heat is produced wherever the current intensity is greatest. Normally, this would be at the tip of the active electrode, but if current passes up a narrow channel or pedicle to the active electrode, enough heat may be generated within this channel or pedicle to coagulate the tissues. This can prove disastrous, for example:

- coagulation of the penis in a child undergoing circumcision;
- coagulation of the spermatic cord when the electrode is applied to the testis.

In such situations, diathermy should not be used or, if it is necessary, bipolar diathermy should be employed.

Pacemakers

Diathermy currents can interfere with the working of a pacemaker, with obvious potential danger to the patient's health. Modern pacemakers are designed to be inhibited by high frequency interference, so the patient may receive no pacing stimulation at all while the diathermy is in use. Certain demand pacemakers may revert to the fixed rate of pacing and therefore it is important for the anaesthetist to have a magnet to deactivate the device during surgery.

Laparoscopic surgery

Diathermy burns are a particular hazard of laparoscopic surgery owing to relative lack of visibility of the instrumentation and the actual structure of the instruments used. Such burns may occur by:

- Diathermy of the wrong structure because of lack of clarity of vision or misidentification.
- Faulty insulation of any of the laparoscopic instruments or equipment.
- Intraperitoneal contact of the diathermy with another metal instrument while activating the pedal.
- Inadvertent activation of the pedal while the diathermy tip is out of vision of the camera.
- Retained heat in the diathermy tip touching susceptible structures, such as bowel.
- Capacitance coupling (**Figure 7.25**). This is a phenomenon in which a capacitor is created by having an insulator sandwiched between two metal electrodes. This can be created in situations where there is a metal laparoscopic port and the diathermy hook is passed through it. The insulation of the diathermy hook acts as the sandwiched insulator and, by means of electromagnetic induction, the diathermy current flowing through the hook can induce a current in the metal port, which can potentially damage intraperitoneal structures. In most cases, this current is dissipated from the metal port through the abdominal wall, but if a plastic cuff is used this dissipation of current does not occur and the danger of capacitance coupling is significantly increased. Therefore, metal ports should never be used with a plastic cuff. The danger of capacitance coupling can be prevented by using entirely plastic ports. Reusable instruments are subject to damage and 'wear and tear' through use, cleaning and sterilisation, which can lead to direct coupling that can activate an otherwise passive instrument. Therefore, it is important for the operator, assistants and scrub team to inspect such instruments for damage that may compromise safety.

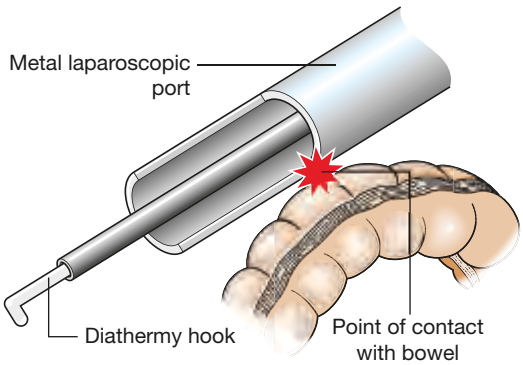

Figure 7.25 Capacitance coupling during laparoscopic surgery. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

PRINCIPLES OF ADVANCED ENERGY DEVICES

Advanced laparoscopic procedures have become widely adopted over the last 25 years. Such 'image based surgery' has driven a parallel explosion in novel technologies which facilitate the performance of such procedures. This is particularly the case for energy devices. Monopolar diathermy still plays a vital and effective role in laparoscopic surgery but has limitations in terms of sealing larger blood vessels and is accompanied by the risks outlined above. Therefore, surgeons have

increasingly used advanced energy devices to facilitate dissection and to seal and divide blood vessels up to 7 mm diameter.

There are three main types of advanced energy device: bipolar electrosurgery, harmonic scalpel and combination devices. In all cases the surgeon needs to be aware of the characteristics of these devices and their capacity to cause thermal injury in order to use them safely.

Bipolar electrosurgery devices

Advanced bipolar tissue fusion technology is a vessel sealing system that is used in both open and laparoscopic surgery. It actually fuses the vessel walls to create a permanent seal and is in wide use in a range of surgical specialties, including gynaecology, colorectal, urology and general surgery. It uses a combination of pressure and energy to create vessel fusion which can withstand up to three times the normal systolic pressure. New technology, such as the Ligasure system™ (Medtronic), involves advanced bipolar technology that uses the body's own collagen and elastin to both seal and divide, allowing surgeons to reduce instrument handling when dissecting, ligating and grasping – a valuable asset particularly during laparoscopic surgery. The feedback sensing technology incorporated in the instrument is designed to manage the energy delivery in a precise manner and results in an automatic discontinuation of energy once the seal is complete, thus removing any concern that the surgeon has to use guesswork as to when the seal is complete. The newer instruments actively monitor tissue impedance and provide a real-time adjustment of the energy being delivered. Using this technology, Ligasure can seal vessels of up to 7 mm diameter, with an average seal time of 2–4 seconds, as well as pedicles, tissue bundles and lymphatics, with a consistent controlled and predictable effect on tissue, including less desiccation. Therefore, the new Ligasure Advance™ (Medtronic) can dissect, seal and divide and was designed to be the only tool that a surgeon would need.

Harmonic scalpel devices

The harmonic scalpel is an instrument that uses ultrasound technology to cut tissues while simultaneously sealing them. It utilises a hand-held ultrasound transducer and scalpel which is controlled by a hand switch or foot pedal. During use, the scalpel vibrates in the 20 000–50 000 Hz range and cuts through tissues, effecting haemostasis by sealing vessels and tissues by means of protein denaturation caused by vibration rather than heat (in a similar manner to whisking an egg white). It provides cutting precision, even through thickened scar tissue, and visibility is enhanced because less smoke is created by this system during use when compared with routine electrosurgery. However, the harmonic scalpel does take longer to cut and coagulate tissues than diathermy, and while diathermy can be used to coagulate a bleeding vessel at any time, the harmonic scalpel can only coagulate as it cuts. It is claimed that patients experience less swelling, bleeding and bruising after the use of the harmonic scalpel than when a conventional scalpel is used, and blood vessels are sealed with a much lower temperature than conventional diathermy and so there is less thermal damage to adjacent tissue, with less charring and desiccation. Furthermore, it is suggested that the use of the harmonic scalpel reduces operative time and recovery is thus enhanced. Currently, the harmonic scalpel is in common use during laparoscopic procedures, as well as in open surgery, such as thyroidectomy, and several plastic surgery operations, e.g. cosmetic breast surgery. There are several such devices on the market, which vary in form and function. Surgeons need to be aware of, and trained in the use of such devices to prevent, complications such as thermal injury of vital structures near to where the energy is activated. There are several manufacturers of harmonic scalpels and the latest versions can seal and divide arteries and veins up to 7 mm in diameter.

Combination energy devices

In the last 5 years, technology has evolved with respect to both harmonic and bipolar advanced energy devices. One product, the Thunderbeat S™ (Olympus), has combined both modalities in a single device. By simultaneously using ultrasonic vibration and bipolar diathermy, this device is able to seal and divide arteries and veins up to 7 mm in diameter. There is also a 'seal only' mode activated by a separate button, which activates bipolar diathermy only.

Chapter 8

Principles of laparoscopic and robotic surgery

Learning objectives

To understand:

- The principles of laparoscopic and robotic surgery
- The advantages and disadvantages of such surgery
- The safety issues and indications for laparoscopic and robotic surgery
- The principles of postoperative care

DEFINITION

Minimal access surgery is a product of modern technology and surgical innovation that aims to accomplish surgical therapeutic goals with minimal somatic and psychological trauma. This type of surgery has reduced wound access trauma, as well as being less disfiguring than conventional techniques. It can offer cost-effectiveness to both health services and employers by shortening operating times, shortening hospital stays, improving operative precision compared to open surgery in some (but not all) cases and allowing faster recuperation.

EXTENT OF MINIMAL ACCESS SURGERY

The first introduction of an experimental laparoscopic procedure was by Georg Kelling of Dresden in 1901 (he termed it 'celioscopy' and used a Nitze-cystoscope). This was followed by Hans Christian Jacobaeus' successful application in humans in Sweden. Despite the work of these pioneers, it took another 70 years before Patrick Steptoe applied this approach to patients in the United Kingdom in 1980, and Phillipe Mouret's first video-laparoscopic cholecystectomy was performed in Lyon, France in 1987. However, since its mainstream adoption in the mid-1990s, minimal access surgery has crossed all traditional boundaries of specialties and disciplines. Shared, borrowed and overlapping technologies and information are encouraging a multidisciplinary approach that serves the whole patient, rather than a specific organ system.

The core principles of minimal access surgery (independent of procedure or device) can be summarized by the acronym **I-VITROS**:

- **I**nsufflate/create space – to allow surgery to take place in the minimal access setting
- **V**isualise – the tissues, anatomical landmarks and the environment for the surgery to take place
- **I**dentify – the specific structures for surgery
- **T**riangulate – surgical tools (such as port placement) to optimise the efficiency of their action, and ergonomics by minimising overlap and clashing of instruments
- **R**etract – and manipulate local tissues to improve access and gain entry into the correct tissue planes
- **O**perate – incise, suture, anastomose, fuse
- **S**eal/haemostasis.

Broadly speaking, minimal access techniques can be categorised as follows:

Laparoscopy

A rigid endoscope (laparoscope) is introduced through a port into the peritoneal cavity. This is insufflated with carbon dioxide to produce a pneumoperitoneum. Further ports are inserted to enable instrument access and their use for dissection (**Figure 8.1**). It is generally accepted that laparoscopic cholecystectomy has revolutionised the surgical management of cholelithiasis and has become the mainstay of management of uncomplicated gallstone disease. With improved instrumentation, advanced procedures, such as laparoscopic colectomies for malignancy, previously regarded as controversial, have also become fully accepted. There continues to be substantive evidence demonstrating the short-term benefits of laparoscopic surgery over open surgery with regard to postoperative pain, length of stay and earlier return to normal activities; however, the equivalence of the benefits in long-term outcomes, such as oncological quality and cancer-related survival, has not been established.

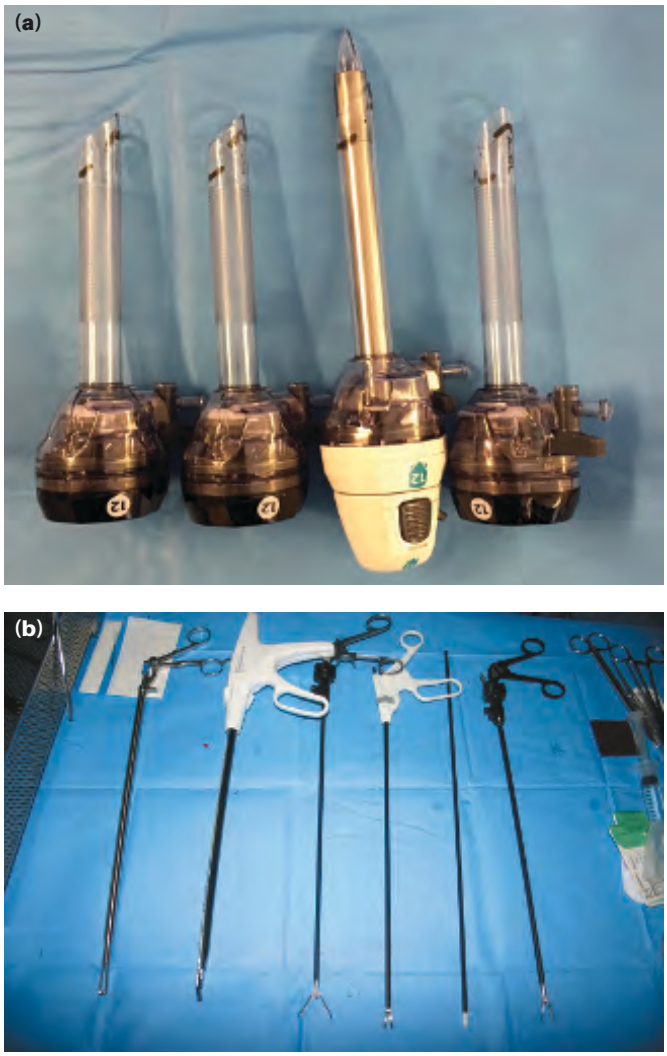

Figure 8.1 **(a)** Common laparoscopic trocars. **(b)** Common laparoscopic instruments (photo courtesy of Daniel Leff).

Thoracoscopy

A rigid endoscope is introduced through an incision in the chest to gain access to the thoracic contents. Usually there is no requirement for gas insufflation, as the operating space is held open by the rigidity of the thoracic cavity. In specific cases, such as mediastinal tumour resection and diaphragmatic surgery, gas insufflation at low pressure (5–8 mmHg) may be applied.

Endoluminal endoscopy

Flexible or rigid endoscopes are introduced into hollow organs or systems, such as the urinary tract, upper or lower gastrointestinal tract, and respiratory and vascular systems.

Perivisceral endoscopy

Body planes can be accessed even in the absence of a natural cavity. Examples are mediastinoscopy, retroperitoneoscopy and retroperitoneal approaches to the kidney, aorta and lumbar sympathetic chain. Extraperitoneal approaches to the retroperitoneal organs, as well as hernia repair, are now becoming increasingly commonplace, further decreasing morbidity associated with visceral peritoneal manipulation. Other, more recent, examples include subfascial ligation of incompetent perforating veins in varicose vein surgery.

Arthroscopy and intra-articular joint surgery

Orthopaedic surgeons have applied arthroscopic access to the knee for some time and are applying this modality to other joints, including the shoulder, wrist, elbow and hip.

Combined approach

The diseased organ is visualised and treated by an assortment of endoluminal and extraluminal endoscopes and other imaging devices. Examples include the combined laparoendoscopic approach for the management of biliary lithiasis, colonic polyp excision and several urological procedures, such as pyeloplasty and donor nephrectomy. In some cases the application of this combined approach offers the ability to execute operations via a single incision, thereby better adhering to the minimally invasive approach. The evidence for improved outcomes using these combined approaches remains limited for the majority of procedures.

SURGICAL TRAUMA IN OPEN, MINIMALLY INVASIVE AND ROBOTIC SURGERY

Most of the trauma of an open procedure is inflicted because the surgeon must have a wound that is large enough to give adequate exposure for safe dissection at a target site. The wound is often the cause of morbidity, including infection, dehiscence, bleeding, herniation and nerve entrapment. Wound pain prolongs recovery time and, by reducing mobility, contributes to an increased incidence of pulmonary atelectasis, chest infection, paralytic ileus and deep venous thrombosis.

Mechanical and human retractors cause additional trauma. Body wall retractors can inflict localised damage that may be as painful as the wound itself. In contrast, during laparoscopy, the retraction is provided by the low-pressure pneumoperitoneum, giving a diffuse force applied gently and evenly over the whole body wall, causing minimal trauma.

Exposure of any body cavity to the atmosphere also causes morbidity through cooling and fluid loss by evaporation. There is also evidence that the incidence of postsurgical adhesions has been reduced by the use of the minimally invasive (laparoscopic, thoracoscopic) and robotic approaches, which has been suggested to result from less damage to delicate serosal coverings. In the manual handling of intestinal loops, the surgeon and assistant disturb the peristaltic activity of the gut and provoke adynamic ileus.

Minimal access surgery has many advantages, such as a reduction in the trauma of access and exposure and an improvement in visualisation. While minimal access methods have been an established modality in some elective surgical procedures, they are now also being increasingly applied with success in emergency surgical procedures (including perforated viscus repair, such as omental patch repair of the stomach, and washout of localised perforation of diverticular disease).

Summary box 8.1

Advantages of minimal access surgery

- Decrease in wound size
- Reduction in wound infection, dehiscence, bleeding, herniation and nerve entrapment
- Decrease in wound pain
- Improved mobility
- Decreased wound trauma
- Decreased heat loss
- Improved visualisation

LIMITATIONS OF MINIMAL ACCESS SURGERY

Despite its many advantages, minimal access surgery has its limitations. To perform minimal access surgery with safety, the surgeon must operate remote from the surgical field, using an imaging system that provides a two-dimensional (2D) representation of the operative site. The endoscope offers a whole new anatomical landscape, which the surgeon must learn to navigate without the usual 'open approach' clues that make it easy to judge depth. The instruments are longer and sometimes more complex to use than those commonly used in open surgery. This results in the novice being faced with significant problems of hand–eye coordination. Here there is a well-described learning curve for novice surgeons and experienced 'open' surgeons when adopting the minimally invasive approach.

Some of the procedures performed by these new approaches are more technically demanding and are slower to perform, and they often have a more difficult learning curve as tactile feedback to the surgeon is lost. Indeed, on occasion, a minimally invasive operation is so technically demanding that both patient and surgeon are better served by conversion to an open procedure. Unfortunately, there seems to be a sense of shame associated with conversion, which is quite unjustified. It is vital for surgeons and patients to appreciate that the decision to close or to convert to an open operation is not a complication but, instead, usually implies sound surgical judgement in favour of patient safety.

Another problem occurs when there is intraoperative arterial bleeding. Haemostasis may be very difficult to achieve endoscopically because blood obscures the field of vision and there is a significant reduction of the image quality due to light absorption.

Another disadvantage of laparoscopic surgery is the loss of tactile feedback in the context of some procedures (although many procedures have been successfully performed without 'traditional sense' of tactile feedback). This is an area of ongoing research in haptics and biofeedback systems. Early work suggested that laparoscopic ultrasonography might be a substitute for the need to 'feel' in intraoperative decision-making. The rapid progress in advanced laparoscopic techniques, including biliary tract exploration and surgery for malignancies, has provided a strong impetus for the development of laparoscopic ultrasound. Now more developed, this technique already has advantages that far outweigh its disadvantages.

In more advanced techniques, large pieces of resected tissue, such as the lung or colon, may have to be extracted from the body cavity. Occasionally, the extirpated tissue may be removed through a nearby natural orifice, such as the rectum or the mouth. At other times, a novel route may be employed. For instance, a benign colonic specimen may be extracted through an incision in the vault of the vagina. Several innovative tube systems have been shown to facilitate this extraction. Although tissue 'morcellators, mincers and liquidisers' can be used in some circumstances, they have the disadvantage of reducing the amount of information available to the pathologist. Previous reports of tumour implantation in the locations of port sites raised important questions about the future of the laparoscopic treatment of malignancy, but large-scale trials have shown this claim to be false. Although emerging evidence from large-scale international prospective trials implicates surgical skill as an important aetiological factor, it is important to consider the biological implications of minimally invasive strategies on the tumours. The use of carbon dioxide and helium as insufflants causes locoregional hypoxia and may also change pH. The resultant modulation of the behaviour of spilled tumour cells is increasingly being studied, although the risks of recurrence at port sites seem to be minimised by appropriate tissue handling, separating any tumours by bagging, and washing and protecting the site.

Hand-assisted laparoscopic surgery is a well-developed technique. It involves the intra-abdominal placement of a hand or forearm through a minilaparotomy incision, while pneumoperitoneum is maintained. In this way, the surgeon's hand can be used as in an open procedure. It can be used to palpate organs or tumours, reflect organs atraumatically, retract structures, identify vessels, dissect bluntly along a tissue plane and provide finger pressure to bleeding points, while proximal control is achieved. This approach has been suggested to offer technical and economic efficiency when compared with a totally laparoscopic approach, in some instances, reducing both the number of laparoscopic ports and the number of instruments required. Some advocates of the technique claim that it is also easier to learn and perform than totally laparoscopic approaches, and that there may be increased patient safety.

There has been a continued improvement in dissection techniques in laparoscopic/thoracoscopic surgery beyond that of standard electrosurgery/diathermy and laser technology to improve dissection precision and haemostatic efficacy. Ultrasonic dissection, tissue fusion devices and tissue removal continue to be adopted across specialties and practitioners. This has taken place as a consequence of continuous and incremental technical improvements in devices, increased

familiarity with their use and some improvements in cost of access. The adaptation of the technology to minimally invasive surgery grew out of the search for alternative, possibly safer, methods of dissection. Some current units combine the functions of three or four separate instruments, reducing the need for instrument exchanges during a procedure. This flexibility, combined with the ability to provide a clean, smoke-free field, has the potential to improve safety and shorten operating times.

Although dramatic cost savings are possible with laparoscopic cholecystectomy when compared with open cholecystectomy, the position was less clear-cut with other procedures initially. There is another factor that may complicate the computation of the cost–benefit ratio. A significant rise in the rate of cholecystectomy followed the introduction of the laparoscopic approach because the threshold for referring patients for surgery became lower. The increase in the number of procedures performed has led to an overall increase in the cost of treating symptomatic gallstones.

Three-dimensional (3D) imaging systems have been available for some time, but remain expensive and currently are not commonplace, partially because many surgeons feel that 3D technology has not yet offered the ability to perform procedures with significant technical enhancement or to improve safety or outcomes across a range of operations. Stereoscopic imaging for laparoscopy and thoracoscopy is still progressing. Future improvements in these systems carry the potential to enhance manipulative ability in critical procedures, such as knot tying and dissection of closely overlapping tissues. There are, however, some drawbacks, such as reduced display brightness and interference with normal vision because of the need to wear specially designed glasses for some systems. It is likely that brighter projection displays will be developed, at increased cost. However, the need to wear glasses will not be easily overcome.

Looking further to the future, it is evident that the continuing reductions in the costs of elaborate image-processing techniques will result in a wide range of transformed presentations becoming available. It should ultimately be possible for a surgeon to call up any view of the operative region that is accessible to a camera and present it stereoscopically in any size or orientation, superimposed on past images taken in other modalities. Such augmented reality systems have been available for several years but continue to improve. It is for the medical community to decide which of these many potential imaginative techniques will contribute most to effective surgical procedures.

Summary box 8.2

Limitations of minimal access surgery

- Reliance on remote vision and operating
- Loss of tactile feedback
- Dependence on hand–eye coordination
- Difficulty with haemostasis
- Reliance on new techniques
- Extraction of large specimens

ROBOTIC SURGERY

A robot is a mechanical device that performs automated physical tasks according to direct human supervision, a predefined program or a set of general guidelines, using artificial intelligence techniques. In terms of surgery, robots have been used to assist surgeons during procedures. This has been primarily in the form of automated camera systems and telemanipulator systems, thus resulting in the creation of a human–machine interface.

Even though laparoscopic surgery has progressed greatly over the last two decades, owing to its widespread use and dissemination in that time, there are, as discussed above, limitations. To those already mentioned may be added reduced degrees of freedom of movement and ergonomically difficult positions for the surgeon. Such problems undoubtedly affect surgical precision. This has led to interest in robotic surgical systems, which currently exist as two main categories:

- **Teleoperated systems:** a human surgeon performs an operation via a robot and its robotic instruments through a televisual computerised platform, either via onsite connections or remotely through the internet or other digital channels – hence the publicity of 'operating on a patient from another country' (such 'remote' operations are currently rarely performed but their existence is established).
- **Image-guided systems:** A surgical robot completes a preprogrammed surgical task which is guided by preoperative imaging and real-time anatomical constraints and cues through the application of inbuilt navigation systems.

In the current era the concept of the master–slave system prevails (where the surgeon is the master, i.e. the operator, and the robot is the slave). The two are linked by underlying hardware and software components within an advanced computer construction. Such devices have been available for the past 30 years and have become more available during the past two decades. They still remain a relative rarity owing to a multitude of factors including cost, applicability and benefits for a particular operation/pathology, training requirements and the support that is necessary, beyond just that of the individual surgeon but rather at whole institution level.

Since their first clinical use in 1985, with the PUMA 560 being used for a brain biopsy, surgical robots have been considered to offer many benefits, which have arisen as a result of new technology in lenses, cameras and computer software. Just as laparoscopic surgery benefited from advances in light technology, allowing the targeted transmission of light down tubing, robotic surgery benefited from computer integration of mechanical (surgical) arms that paved the way for computer-integrated surgery (CIS). The advantages of robotic surgery are two-fold: first for the patient (as for laparoscopic surgery, see *Summary box 8.1*) and second for the surgeon. The advantages for the surgeon include better visualisation (higher magnification) with stereoscopic views; elimination of hand tremor allowing greater precision; improved manoeuvring as a result of the 'robotic wrist', which in some systems allows up to seven degrees of freedom; and the fact that large external movements of the surgical hands can be scaled down and transformed to limited internal movements of the

'robotic hands', extending the surgical ability to perform complex technical tasks in a limited space. Also, the surgeon is able to work in an ergonomic environment with less stress and to achieve higher levels of concentration. The computer may also be able to compensate for the beating movement of the heart, making it unnecessary to stop the heart during cardiothoracic surgery. There may also be less need for assistance once surgery is under way.

Many surgical specialties have embraced the progression of robot-assisted techniques, including general surgery, cardiothoracic surgery, urology, orthopaedics, ear, nose and throat (ENT) surgery, gynaecology and paediatric surgery. Specialties that use microsurgical techniques also benefit from this technology. Current robotic systems were designed to offer multifunctionality including multi-anatomy and speciality capability in both operating theatre and remote environments. In the current era, however, these devices seem most often applied in pelvic surgery (typically urology, colorectal and gynaecology) within inhouse operating areas.

One major operative barrier to adoption remains the prohibitive costs for many healthcare environments. As a result the current robotic surgical market is dominated by the master–slave da Vinci system (Intuitive Surgical, MenloPark, CA, USA) (Figure 8.2), although there are several other commercially available robots and a market open to a small number of new entrants, but also a history of unsuccessful (financially

Figure 8.2 **(a)** The DaVinci Xi system. **(b)** The surgical console. **(c)** The robotic arms draped for a robotic coronary artery bypass grafting procedure. **(d)** Robotic distal coronary anastomosis.

or functionally) or withdrawn/ removed devices. This is partly because of the high cost of design and development of new robot technologies and surgical instruments compatible with them, which all require design, translation and intellectual property costs. In addition to the remote master–slave platform design, direct robot systems exist and include:

- tremor suppression robots;
- active guidance systems;
- articulated mechatronic devices;
- force control systems;
- haptic feedback devices.

Each of these systems offers different advantages to the operating surgeon, ranging from reducing the need for assistants and providing better ergonomic operating positions to providing experienced guidance from surgeons not physically present in the operating theatre.

Robotic surgery – the first 30 years

The largest systematic overview of all robot surgical procedures from inception and covering the field's first 30 years revealed only 99 prospective or randomised studies reporting clinical outcomes from over 28 000 peer-reviewed research articles that mentioned the term 'robotic surgery'. The 99 studies revealed data from approximately 14 500 patients in trials undergoing robotic surgical procedures versus open and minimally invasive operations. The overall pooled results, regardless of specialty, revealed a decrease in blood loss and blood transfusion rate with robotic surgery when compared with both open surgery and minimally invasive surgery. Specifically, when compared with open surgery, robotic procedures demonstrated that there was a reduction in length of hospital stay and overall complication rate. However, robotic procedures did suffer from significantly longer operative times and their cost-effectiveness varied depending on operative site, technique, patient and healthcare setting. While this reveals an overall perspective from the first 30 years of robotics surgery, there remains an incumbent need to offer clearer clinical evidence regarding the most apposite operative method and technology for each individual patient.

PREOPERATIVE EVALUATION

Preparation of the patient

Although the patient may be in hospital for a shorter period, careful preoperative management is essential to minimise morbidity.

History

Patients must be fit for general anaesthesia and open operation if necessary. Potential coagulation disorders (e.g. associated with cirrhosis) are particularly dangerous in laparoscopic surgery. As adhesions may cause problems, previous abdominal operations or peritonitis should be documented.

Summary box 8.3

Preparation for laparoscopic or robotic surgery

- Overall fitness: cardiac arrhythmia, emphysema, medications, allergies
- Previous surgery: scars, adhesions
- Body habitus: obesity, skeletal deformity
- Normal coagulation
- Thromboprophylaxis
- Informed consent

Examination

Routine preoperative physical examination is required as for any major operation. Although, in general, laparoscopic/ thoracoscopic surgery allows quicker recovery, it may involve longer operating times and the establishment of the pneumoperitoneum may provoke cardiac arrhythmias. Severe chronic obstructive airways disease and ischaemic heart disease may be contraindications to the laparoscopic approach. Particular attention should be paid to the presence or absence of jaundice, abdominal scars, palpable masses or tenderness. Moderate obesity does not increase operative difficulty significantly, but massive obesity may make pneumoperitoneum difficult and standard instrumentation may be too short. Access may prove difficult in very thin patients, especially those with severe kyphosis.

Premedication

Premedication is the responsibility of the anaesthetist, with whom coexisting medical problems should be discussed.

Prophylaxis against thromboembolism

Venous stasis induced by the reverse Trendelenburg position during laparoscopic surgery may be a particular risk factor for deep vein thrombosis, as is a lengthy operation and the obesity of many patients. Subcutaneous low molecular weight heparin and antithromboembolic stockings should be used routinely, in addition to pneumatic leggings during the operation. Patients already taking warfarin for other reasons should have this stopped temporarily or converted to intravenous heparin, depending on the underlying condition, as it is not safe to perform laparoscopic surgery in the presence of a significant coagulation deficit.

Urinary catheters and nasogastric tubes

In the early days of laparoscopic surgery, routine bladder catheterisation and nasogastric intubation were advised. Most surgeons now omit these, but it remains essential to check that the patient is fasted and has recently emptied their bladder, particularly before the blind insertion of a Verres needle. However, currently, most general surgeons prefer the direct cut-down technique into the abdomen for the introduction of the first port for the establishment of the pneumoperitoneum (Hasson technique and modified Hasson approaches). More

Harrith Hasson, Professor of Gynaecology, Chicago, IL, USA.

recently, direct optical entry has been used, especially in the setting of bariatric surgery.

Informed consent

The basis of many complaints and much litigation in surgery, especially laparoscopic surgery, relates to the issue of informed consent. It is essential that the patient understands the nature of the procedure, the risks involved and, when appropriate, the alternatives that are available. A locally prepared explanatory booklet concerning the laparoscopic procedure to be undertaken is extremely useful.

In an elective case, a full discussion of the proposed operation should take place in the outpatient department with a surgeon of appropriate seniority, preferably the operating surgeon, before the decision is made to operate. On admission, it is the responsibility of the operating surgeon and anaesthetist to ensure that the patient has been fully counselled, although the actual witnessing of the consent form may have been delegated. The patient should understand what laparoscopic surgery involves and that there is a risk of conversion to open operation. If known, this risk should be quantified, for example the increased risk with acute cholecystitis or in the presence of extensive upper abdominal adhesions. The conversion rate will also vary with the experience and practice of the surgeon. Common complications should be mentioned, such as shoulder tip pain and minor surgical emphysema, as well as rare but serious complications, including injury to the bile ducts and visceral injury from trocar insertion or diathermy.

Preparation is very similar to that for open surgery and aims to ensure that:

- The patient is fit for the procedure.
- The patient is fully informed and has consented.
- Operative difficulty is predicted when possible.
- Appropriate theatre time and facilities are available (especially important for robotic cases).

THEATRE SET UP AND TOOLS

Operating theatre design, construction and layout are key to its smooth running on a daily basis. Originally, the video and diathermy equipment and other key tools used in laparoscopic surgery were moved around on stacks, taking up valuable floor space and cluttering up the theatre environment, which was not always ergonomic for the operating team. New theatres are designed with moveable booms that come down from the ceiling; these are easy to place and do not have long leads or wires trailing behind them (**Figure 8.3**). The equipment consists of at least two high-resolution liquid crystal display (LCD) monitors (and, more recently, high definition (HD) monitors for even clearer images), the laparoscopic kit for maintaining pneumoperitoneum and the audiovisual kit. The advent of DVD and other digital recording equipment has also led to these being incorporated into the rigs so that cases can be recorded with ease. This is further facilitated by cameras being inserted into the light handles of the main overhead lights so that open surgery can also be recorded without distracting the surgeons.

Figure 8.3 Modern laparoscopic theatre set up.

Image quality is vital to the success of laparoscopic surgery. New camera and lens technology allows the use of smaller cameras. Many centres now use 5-mm laparoscopes routinely. Automatic focusing and charge-coupled devices (CCDs) are used to detect different levels of brightness and adjust for the best image possible. Flat panel monitors with HD images are used to give the surgeon the best views possible and 3D technology is now being used for visualisation more routinely in some centres. The usability of the kit has also improved; touch screen panels and even voice-activated systems are now available on the market.

As minimally invasive and robotic procedures have become routine in some institutions, the dedicated theatre team for such procedures has also evolved. Surgeons and anaesthetists, as well as scrub and circulating nurses, have become familiar with working with the equipment and each other. The efficient working of the team is crucial to high-quality surgery and quick yet safe turnover. Laparoscopic tools have also changed. Disposable equipment is more readily available, which does unfortunately increase the cost of the surgery. However, easy to use, ergonomically designed and reliable surgical tools are essential for laparoscopic and robotic surgery. Simple designs for new laparoscopic ports are now being studied, with the aim of reducing the incidence of port-site hernias; see-through (optical) ports that allow the surgeon to cut down through the abdomen while observing the layers through the cameras, and new light sources within the abdomen may be simple ideas that affect surgical technique in the near future.

GENERAL INTRAOPERATIVE PRINCIPLES

Laparoscopic and thoracoscopic principles have specific principles that require careful clinical consideration. As such, they are not purely a less invasive equivalent of an open operation. For example, laparoscopic cholecystectomy is now the 'gold standard' for operative treatment of symptomatic gallstone disease. The main negative aspect of the technique is the increased incidence of bile duct injury compared with open cholecystectomy. Better understanding of the mechanisms of injury, coupled with proper training, will avoid most of these errors. The following sections highlight the important

technical steps that should be taken during any form of laparoscopic surgery to avoid complications.

Creating a pneumoperitoneum

There are two methods for creation of a pneumoperitoneum: open and closed.

The closed method involves blind puncture using a Verres needle. Although this method is fast and relatively safe, there is a small but significant potential for intestinal or vascular injury on introduction of the needle or first trocar.

The routine use of the open technique for creating a pneumoperitoneum avoids the morbidity related to a blind puncture. To achieve this, a 1 cm vertical or transverse incision is made at the level of the umbilicus. The umbilicus carries importance as it is a reliable anatomical landmark deriving from the embryological coalescence of the rectus sheath and peritoneum and is devoid of other myofascial planes that could complicate subsequent entry into the peritoneum. Two small retractors are used to dissect bluntly the subcutaneous fat and expose the midline fascia. Two sutures are inserted each side of the midline incision (into the rectus sheath confluence), followed by the creation of a 1 cm opening in the fascia. Free penetration into the abdominal cavity is confirmed by the gentle introduction of a finger. Finally, a Hasson trocar (or other blunt-tip trocar) is inserted and anchored with the fascial sutures (**Figure 8.4**). This is considered the Hasson or 'modified Hasson' approach. The term 'modified' is used here to denote the same principle as the original Hasson with the midline exposure and access, except that the exact technique has been changed to suit an individual surgeon, such as the adoption of a particular angle of retraction of the umbilicus before an incision into the midline is made to get access to the peritoneum.

Rarely, a third, or combination, approach may be employed. Here an open technique is followed with a smaller than usual midline incision. Once access to the peritoneum is visualised, a Verres needle is inserted under direct vision, and then insufflation is carried out. This small open approach then allows the introduction of a laparoscopic port with a view to reducing trauma of the pneumoperitoneum. Such an approach may have benefits for complex cases, such as those for 're-do' procedures, where the risk of umbilical adhesions during pneumoperitoneum may be high.

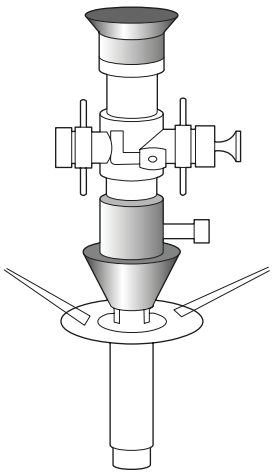

Figure 8.4 Open technique with Hasson port. Apply safe principles of closed technique.

The open technique may initially appear time consuming and even cumbersome; however, with practice, it is quick, efficient and safe overall. Optical entry to the abdomen under direct vision using optical ports (especially in bariatric surgery) is gaining favour with many laparoscopic surgeons. This allows quick and safe entry to the peritoneal cavity using bladeless see-through trocars that allow the different layers to be dissected through using the laparoscope within an optical port to be inserted into the abdomen.

Preoperative problems

Previous abdominal surgery

Previous abdominal surgery is no longer a contraindication to laparoscopic surgery, but preoperative evaluation is necessary to assess the type and location of surgical scars. As mentioned earlier, the open technique for insertion of the first trocar is safer. Before trocar insertion, the introduction of a fingertip helps to ascertain penetration into the peritoneal cavity and also allows adhesions to be gently removed from the entry site. After the tip of the cannula has been introduced, a laparoscope is used as a blunt dissector to tease adhesions gently away and form a tunnel towards the quadrant where the operation is to take place. This step is accomplished by a careful pushing and twisting motion under direct vision. With experience, the surgeon learns to differentiate visually between thick adhesions that may contain bowel and should be avoided and thin adhesions that would lead to a window into a free area of the peritoneal cavity.

Obesity

Laparoscopic and robotic surgery has proved to be safe and effective in the obese population. In fact, some procedures are less difficult than their open counterparts for the morbidly obese patient, e.g. in bariatric surgery. Technical difficulties occur, however, in obtaining pneumoperitoneum, reaching the operative region adequately and achieving adequate exposure in the presence of an obese colon. Increased thickness of the subcutaneous fat makes insufflation of the abdominal cavity more difficult. With the closed technique, a larger Verres needle is often required for morbidly obese patients. Pulling the skin up for fixation of the soft tissues is better accomplished with towel clamps. Only moderate force should be used, to avoid separating the skin farther from the fascia. The needle should be passed at nearly a right angle to the skin and preferably above the umbilicus, where the peritoneum is more firmly fixed to the midline. The open technique of inserting a Hasson trocar is easier and safer for obese patients, but technically demanding in morbidly obese patients, where optical entry is now more commonplace. The main difficulty is reaching the fascia. A larger skin incision (1–3 cm), starting at the umbilicus and extending superiorly, may facilitate this. To reach the operative area adequately, the location of some of the ports has to be modified and, in some instances, larger and

longer instruments are necessary. When the length of the laparoscope appears to be insufficient to reach the operative area adequately, the initial midline port should be placed nearer to the operative field. Recently, the use of optical port entry for laparoscopic bariatric surgery has revolutionised port entry for morbid obesity cases.

Operative problems

Intraoperative perforation of a viscus

Perforation of any viscus, such as bowel, solid organs and blood vessels (including the aorta), is a potential hazard of using the laparoscopic approach and these complications may be minimised with surgical experience, education, preparation and patient selection. One example, in a common laparoscopic procedure such as cholecystectomy, includes perforation of the gallbladder. This is more common with the laparoscopic technique than with the open technique (see also Chapter 67). Some authors have reported an incidence of up to up to 30%, but it does not appear to be a factor in increasing the early postoperative morbidity. However, it is well known that bile is not a sterile fluid and bacteria can be present in the absence of cholecystitis. Unless the perforation is small, closure with endoloops or endoclips should be attempted to avoid contamination prior to extraction, which should be with the use of an endobag. Bilious leakage should be suctioned and washed out. If there is stone spillage, every attempt must be made to collect and extract the stones, and if there is a possibility of stones being retained in the peritoneum, then an ultrasound should be arranged 6 weeks postoperatively to assess a collection around a stone and the patient should be informed of this outcome postoperatively.

Antibiotics to manage known sepsis or septicaemia in a patient undergoing surgery

Operating on a patient with established septicaemia or sepsis is not typically recommended unless the operation will contribute to removing or minimising infectious origins. Where necessary pre-, peri- and postoperative antibiotics should be administered, in accordance with local microbiological advice.

Antibiotics to prevent infections and sepsis

A single dose of antibiotics should be administered within 1 hour of skin incision; in contaminated, semi-contaminated or complex procedures, additional doses should be administered, based on local microbiological advice.

Bleeding

In some of the larger series, bleeding has been the most common cause of conversion to an open procedure. Bleeding plays a more important role in laparoscopic surgery because of factors inherent to the technique. These include a limited field that can easily be obscured by relatively small amounts of blood, magnification that makes small arterial bleeding appear to be a significant haemorrhage and light absorption that obscures the visual field.

HOW TO AVOID BLEEDING

As in any surgical procedure, the best way to handle intraoperative bleeding is to prevent it from happening. This can usually be accomplished by identifying patients at high risk of bleeding, having a clear understanding of the laparoscopic anatomy and employing careful surgical technique.

Risk factors that predispose to increased bleeding include:

- cirrhosis;
- inflammatory conditions (acute cholecystitis, diverticulitis);
- patients on clopidogrel and or dipyridamole;
- coagulation defects: these are contraindications to a laparoscopic procedure.

BLEEDING FROM A MAJOR VESSEL

Damage to a large vessel requires immediate assessment of the magnitude and type of bleeding. When the bleeding vessel is identified, a fine-tip grasper can be used to grasp it and apply either electrocautery or a clip, depending on its size. When the vessel is not identified early and a pool of blood forms, compression should be applied immediately with a blunt instrument, a cotton swab (ENT or mastoid swab) or with the adjacent organ. Good suction and irrigation are of utmost importance. Once the area has been cleaned, pressure should be released gradually to identify the site of bleeding. Insertion of an extra port may be required to achieve adequate exposure and at the same time to enable the concomitant use of a suction device and an insulated grasper. Although most bleeding vessels can be controlled laparoscopically, judgement should be used in deciding when not to prolong bleeding, but to convert to an open procedure at an early stage. Surgicel® (absorbable fibrillar oxidized cellulose polymer) or other clot-promoting strips, tissue glues or other haemostatic agent may also be used laparoscopically to aid haemostasis. If at any stage bleeding is difficult to stem laparoscopically, there should be no delay in converting to an open procedure in the interests of patient safety.

BLEEDING FROM ORGANS ENCOUNTERED DURING SURGERY

Intraoperative bleeding from organs can usually be prevented by performing the dissection in the correct plane. As previously mentioned, the common laparoscopic example of a cholecystectomy requires understanding the management of bleeding from the gallbladder bed. When a bleeding site appears during detachment of the gallbladder, the dissection should be carried a little farther to expose the bleeding point adequately. Once this step has been performed, direct application of electrocautery usually controls the bleeding. If bleeding persists, indirect application of electrocautery is useful because it avoids detachment of the formed crust. This procedure is accomplished by applying pressure to the bleeding point with a blunt, insulated grasper and then applying electrocoagulation by touching this grasper with a second insulated grasper that is connected to the electrocautery device. One must be careful to keep all conducting surfaces of the graspers within the visual field while applying the electrocautery current.

BLEEDING FROM A TROCAR SITE

Bleeding from the trocar sites is usually controlled by applying upwards and lateral pressure with the trocar itself. Considerable bleeding may occur if the falciform ligament is impaled with the substernal trocar or if one of the epigastric vessels is injured. If significant continuous bleeding from the falciform ligament occurs, haemostasis is achieved by percutaneously inserting a large, straight needle at one side of the ligament. A monofilament suture attached to the needle is passed into the abdominal cavity and the needle is exited at the other side of the ligament using a grasper (**Figure 8.5**). The loop is suspended and compression is achieved. Maintaining compression throughout the procedure usually suffices. After the procedure has been completed, the loop is removed under direct laparoscopic visualisation to ensure complete haemostasis. When significant continuous bleeding from the abdominal wall occurs, haemostasis can be accomplished either by pressure or by suturing the bleeding site. Pressure can be applied using a Foley balloon catheter. The catheter is introduced into the abdominal cavity through the bleeding trocar site wound, the balloon is inflated and traction is placed on the catheter, which is bolstered in place to keep it under tension. The catheter is left *in situ* for 24 hours and then removed. Although this method is successful in achieving haemostasis, the authors favour direct suturing of the bleeding vessel. This manoeuvre is accomplished by extending the skin incision by 3 mm at both ends of the bleeding trocar site wound. Two figure-of-eight sutures are placed in the path of the vessel at both ends of the wound. Devices such as the EndoClose may also be used to apply transabdominal sutures under direct laparoscopic view to close port sites that bleed.

EVACUATION OF BLOOD CLOTS

The best way of dealing with blood clots is to avoid them. As mentioned, careful dissection and identification of the cystic artery and its branches, as well as identifying and carrying out dissection of the gallbladder in the correct plane, help to prevent bleeding from the cystic vessels and the hepatic bed. Nevertheless, clot formation takes place when unsuspected bleeding occurs or when inflammation is severe and a clear plane is not present between the gallbladder and the hepatic bed. The routine use of 5000–7000 units of heparin per litre of irrigation fluid helps to avoid the formation of clots. When extra bleeding is foreseen, a small pool of irrigation fluid can be kept in the operative field to prevent clot formation. After clots have formed, a large bore suction device should be used for their retrieval. Care should be taken to avoid suctioning in proximity to placed clips.

Principles of electrosurgery during laparoscopic surgery

Electrosurgical injuries during laparoscopy are potentially serious. The vast majority occur following the use of monopolar diathermy. The overall incidence is between one and two cases per 1000 operations. Electrical injuries are usually unrecognised at the time that they occur, with patients commonly presenting 3–7 days after injury with complaints of fever and abdominal pain. As these injuries usually present late, the reasons for their occurrence are largely speculative. The main theories are: (1) inadvertent touching or grasping of tissue during current application; (2) direct coupling between a portion of bowel and a metal instrument that is touching the activated probe (**Figure 8.6**); (3) insulation breaks in the electrodes; (4) direct sparking to bowel from the diathermy probe; and (5) current passage to the bowel from recently coagulated, electrically isolated tissue. Bipolar diathermy is safer and should be used in preference to monopolar diathermy, especially in anatomically crowded areas. If monopolar diathermy is to be used, important safety measures include attainment of a perfect visual image, avoiding excessive current application and meticulous attention to insulation. Alternative methods of performing dissection, such as the use of ultrasonic devices, may improve safety.

POSTOPERATIVE CARE

The postoperative care of patients after laparoscopic surgery is generally straightforward, with a low incidence of pain or other problems. The most common routine postoperative symptoms are a dull upper abdominal pain, nausea and pain

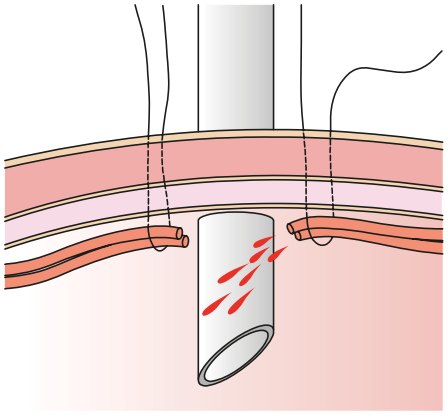

Figure 8.5 Management of bleeding from a surgical trocar site.

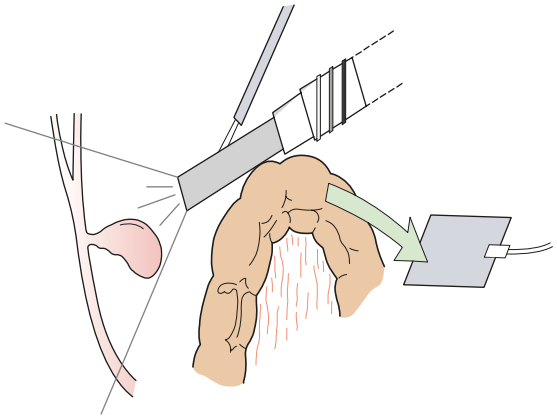

Figure 8.6 Direct coupling between bowel and laparoscope, which is touching the activated probe.

Frederic Eugene Basil Foley, 1891–1966, urologist, Ankher Hospital, St Paul, MN, USA.

around the shoulders (referred from the diaphragm). There has been some suggestion that the instillation of local anaesthetic to the operating site and into the suprahepatic space, or even leaving 1 litre of normal saline in the peritoneum, serves to decrease postoperative pain. It is a good general rule that if the patient develops a fever or tachycardia, or complains of severe pain at the operation site, something is wrong and close observation is necessary. In this case, routine investigation should include a full blood count, C reactive protein (CRP) measurement, liver function tests, an amylase test and, probably, an ultrasound scan of the upper abdomen to detect fluid collections. If bile duct leakage is suspected, endoscopic retrograde cholangiopancreatography (ERCP) may be needed. If in doubt, relaparoscopy or laparotomy should be performed earlier rather than later. Death following technical errors in laparoscopic cholecystectomy has often been associated with a long delay in deciding to re-explore the abdomen.

In the absence of problems, patients should be fit for discharge within 24 hours. They should be given instructions to telephone the unit or their general practitioner and to return to the hospital if they are not making satisfactory progress.

Nausea

About half of patients experience some degree of nausea after laparoscopic surgery and, rarely, this may be severe. It usually responds to an antiemetic, such as ondansetron, and settles within 12–24 hours. It is made worse by opiate analgesics and these should be avoided.

Shoulder tip pain

The patient should be warned about this preoperatively and told that the pain is referred from the diaphragm and not due to a local problem in the shoulders. It can be at its worst 24 hours after the operation. It usually settles within 2–3 days and is relieved by simple analgesics, such as paracetamol.

Abdominal pain

Pain in one or other of the port site wounds is not uncommon and is worse if there is haematoma formation. It usually settles very rapidly. Increasing pain after 2–3 days may be a sign of infection and, with concomitant signs, antibiotic therapy is occasionally required. Occasionally, herniation through a port may account for localised pain and this can sometimes be due to a Richter's hernia, such that the patient exhibits no sign of intestinal obstruction. Successful laparoscopic surgery should not cause a patient increasing or undue pain. If there are any clinical concerns postoperatively due to worsening pain, tachycardia and or pyrexia, senior review with a view to imaging, or increasingly commonly relaparoscopy, should be considered.

Analgesia

A 100-mg diclofenac suppository may be given at the time of the operation (if this medication is not contraindicated). It is important that the patient provides separate consent for this if the suppository is to be administered peroperatively. Suppositories may be administered a further two or three times postoperatively for relief of more severe pain. Otherwise, 500–1000 mg of paracetamol 4-hourly usually suffices (orally or, if more pain, intravenously). Opiate analgesics cause nausea and should be avoided unless the pain is very severe. In this case, suspect a postoperative complication (as above). The majority of patients require between one and four doses of 1 g of paracetamol postoperatively. Severe pain after routine laparoscopic cases should warn the clinician that there may be an iatrogenic or surgical cause of this pain that may need further investigation with blood tests, imaging and even relaparoscopy

Orogastric tube

An orogastric tube may be placed during the operation if the stomach is distended and obscuring the view. It is not necessary in all cases. It should be removed as soon as the operation is over and before the patient regains consciousness. This is more routinely used in bariatrics and oesophagogastric surgery, where a larger (32F or 34F) tube is used.

Oral fluids

There is no significant ileus after laparoscopic surgery, except in resectional procedures, such as colectomy or small bowel resection. Patients can start taking oral fluids as soon as they are conscious; they usually do so 4–6 hours after the end of the operation.

Oral feeding

Provided that the patient has an appetite, a light meal can be taken 4–6 hours after the operation. Some patients remain slightly nauseated at this stage, but almost all eat a normal breakfast on the morning after the operation.

Patients will require advice about what they can eat at home. They should be told that they can eat a normal diet but should avoid excess. It seems sensible to avoid high-fat meals for the first week, although there is no clear evidence that this is necessary.

Urinary catheter

This depends on the operation. If a urinary catheter has been placed in the bladder during an operation with likely short stay, it should be removed before the patient regains consciousness if the procedure has proceeded well. The patient should be warned of the possibility and symptoms of postoperative cystitis and told to ask advice in the unlikely event of this occurring.

Drains

The use of postoperative drains in laparoscopy patients depends on the operation performed. Drains are used to assess postoperative blood loss if this is a clinical concern or to assess the nature of intraperitoneal fluids, depending on procedure

and postoperative monitoring needs. Some surgeons drain the abdomen at the end of laparoscopic cholecystectomy, although this is controversial. If a drain is placed to vent the remaining gas and peritoneal fluid, it should be removed within 1 hour of the operation. If it has been placed because of excessive hepatic bleeding or bile leakage it should be removed when that problem has resolved, usually after 12–24 hours. Continued blood loss from a drain is an indication for re-exploration of the abdomen.

Summary box 8.4

Surgical principles

- Meticulous care in the creation of a pneumoperitoneum
- Controlled dissection of adhesions
- Adequate exposure of operative field
- Avoidance and control of bleeding
- Avoidance of organ injury
- Avoidance of diathermy damage
- Vigilance in the postoperative period

DISCHARGE FROM HOSPITAL

Patient discharge is based on clinical indicators and their fitness for recuperating in a non-hospital environment. One of the core drivers for the application of minimally invasive surgery is an earlier recovery and therefore discharge from hospital. For the common laparoscopic procedure of cholecystectomy, most surgeons discharge a significant proportion of their laparoscopic cholecystectomy patients on the day of surgery, but some are kept in overnight and discharged the following morning. Patients should not be discharged until they are seen to be comfortable, have passed urine and are eating and drinking satisfactorily. They should be told that if they develop abdominal pain or other severe symptoms they should return to the hospital or to their general practitioner. Even for more major cases, including procedures such as laparoscopic anterior resection, some units have demonstrated a safe and feasible protocol for a 23-hour stay.

Skin sutures

If non-absorbable sutures or skin staples have been used, they can be removed from the port sites after 7 days.

Mobility and convalescence

Patients can get out of bed to go to the toilet as soon as they have recovered from the anaesthetic and they should be encouraged to do so. Such movements are remarkably pain free when compared with the mobility achieved after an open operation. Similarly, patients can cough actively and clear bronchial secretions, and this helps to diminish the incidence of chest infections. Many patients are able to walk out of hospital on the evening of their operation and almost all are fully mobile by the following morning. Thereafter, the postoperative recovery is variable. Some patients prefer to take things quietly for the first 2–3 days, interspersing increasing exercise with rest. After the third day, patients will have undertaken increasing amounts of activity. The average return to work is about 10 days.

THE PRINCIPLES OF COMMON LAPAROSCOPIC PROCEDURES

The principles of common laparoscopic procedures are described in the appropriate chapters:

- laparoscopic cholecystectomy (Chapter 67);
- laparoscopic inguinal hernia repair (Chapter 60);
- laparoscopic antireflux surgery (Chapter 63);
- laparoscopic appendicectomy (Chapter 72);
- laparoscopic bariatric surgery (Chapter 64);
- laparoscopic colectomy/anterior resection (Chapters 70 and 73);
- laparoscopic upper gastrointestinal (GI) surgery (Chapters 62, 63 and 69)

Other elective minimally invasive (laparoscopic, thoracoscopic) or robotic procedures that are now widely utilised in certain specialist centres include:

- colectomy;
- gastrectomy;
- splenectomy;
- nephrectomy;
- adrenalectomy;
- prostatectomy (typically robotic);
- thyroid and parathyroid surgery;
- aortic aneurysm surgery;
- single-vessel coronary artery bypass surgery;
- video-assisted thorascopic surgery (VATS);
- laparoscopic hernia surgery (inguinal, femoral, paraumbilical, incisional).

Laparoscopy has also been used in certain emergency situations (in stable patients) in the hands of experienced laparoscopic surgeons. These include laparoscopic appendicectomy (typically the most common minimally invasive emergency procedure), repair of a perforated duodenal ulcer, laparoscopic cholecystectomy in severe cholecystitis (so-called 'hot' cholecystectomies), and treatment of intestinal obstruction secondary to adhesions, strangulated hernia repairs and, also, the laparoscopic evaluation of stable trauma patients.

Procedures that have been carried out using robotically assisted minimally invasive surgery include all of those listed above. Currently, robotic surgery still has certain disadvantages:

- increased cost;
- increased set up of the system and operating time;
- socioeconomic implications;
- significant risk of conversion to conventional techniques;
- prolonged learning curve;
- multiple repositioning of the arms can cause trauma;
- haemostasis;
- collision of the robotic arms in extreme positions.

Until these are overcome, by continued development of the technology and the drive of surgeons to progress in the field, robotically assisted surgery will not be commonplace. However, the potential for such systems is immense and continued research and clinical trials will pave the way for future generations of surgeons and patients alike.

FURTHER DEVELOPMENTS THAT HAVE MADE MINIMALLY INVASIVE SURGERY EVEN LESS INVASIVE

Single incision laparoscopic surgery

Laparoscopy has reduced the trauma from surgery, compared with open techniques, and is now used routinely for benign and oncological surgery in many centres. However, there is continued work on how to reduce the trauma and scarring from the incisions used in laparoscopic surgery because multiple port sites are needed for most procedures. Natural orifice transluminal endoscopic surgery (NOTES) (see below) addresses this but, at present, the safety of the transgastric route is not sufficient for the routine use of this approach to surgery. Advanced laparoscopists have therefore turned to focussing on the single incision for open entry via the umbilicus as an alternative. Single incision laparoscopic surgery (SILS) is a technique adopted by some surgeons to insert all the instrumentation via a single incision, through a multiple channel port via the umbilicus, to carry out the procedure. The benefit is that only one incision, through a natural scar (the umbilicus), is made, therefore these procedures are virtually 'scarless'. Second, the use of fewer port sites around the abdomen gives the potential for less pain, less risk of port site bleeding and reduced incidence of port site hernia. This technique has many other synonyms, including laparoendoscopic single site surgery (LESS) and single port access (SPA) surgery among many others, although SILS has gained the most recognition. It does require specially manufactured multichannel ports and often roticulating instruments. There has been an explosion of activity in SILS procedures in the last few years and, in some units, laparoscopic cholecystectomies and hernias are routinely started as SILS cases. The clinical benefit and cost-effectiveness of this technique, which has a difficult and steep learning curve and specific instrument requirements, remain under review, although it has been adopted as a routine approach for some procedures in some units. Early evidence understandably demonstrated better cosmetic outcomes and less pain in the immediate postoperative period; however, this needs to be further corroborated with higher levels of evidence with longer-term follow-up results. Specifically, because the SILS approach was not designed for improving clinical outcomes when compared with standard minimally invasive approaches, any improvements in pain and cosmesis between SILS and standard minimally invasive approaches require further elucidation.

Natural orifice translumenal endoscopic surgery (NOTES)

This technique, whereby surgeons enter the peritoneal cavity via endoscopic puncture of a hollow viscus, has been much publicised in recent years. The NOTES approach has been utilised in nearly every body system and operative speciality addressing the pelvis, abdomen and thorax. Worldwide adoption rates compared to standard open and minimally invasive approaches remain very low. Transvaginal NOTES cholecystectomies have been performed in humans successfully, although hybrid procedures (joint laparoscopy and NOTES) are still employed regularly for safety reasons. The closure of the visceral puncture site is the issue that has prevented widespread uptake of this technique, as transgastric and transcolonic closure of peritoneal entry sites in a routinely safe way remains unperfected for general use. Also, the equipment needed has significant cost and training needs (including surgeons and a large variety of ancillary team members that range from scrub nurses to anaesthetists) and requires a large number of practitioners in the team at present. Nevertheless, it has much promise to be a technique for truly scarless surgery in the future and much research continues in this field, which is less widely adopted at present than SILS.

THE FUTURE

Although there is no doubt that minimal access surgery has changed the practice of surgeons, it has not changed the nature of disease. The basic principles of good surgery still apply, including appropriate case selection, excellent exposure, adequate retraction and a high level of technical expertise. If a procedure makes no sense with conventional access, it will make no sense with a laparoscopic approach. Laparoscopic and robotic surgery training is key to allow the specialty to progress. The pioneers of yesterday have to teach the surgeons of tomorrow not only the technical and dextrous skills required, but also the decision-making and innovative skills necessary for the field to continue to evolve. Training is often perceived as difficult, as trainers have less control over the trainees at the time of surgery and caseloads may be smaller, especially in centres where laparoscopic and robotic procedures are not common. However, trainees now rightly expect exposure to these procedures, and training systems should be adaptable for international exposure so that these techniques can be disseminated worldwide. The predominant video and digital component of these new techniques opens the door for simulation approaches for training in these modalities, which has demonstrated benefits in reducing learning curves and in turn is aimed at improving patient outcomes. The ultimate goal for this educational approach is to develop expert surgeons through the 'totally safe' and 'risk free' environment of simulation before they actually have to operate on patients. The current status for laparoscopic trainees reflects their decreased experience in open approaches so that they feel less comfortable converting cases such as laparoscopic cholecystectomies to open cases. It is important that the 'straight to minimally invasive' trainees continue to have

training in open skills so that they can apply both approaches where necessary.

Improvements in instrumentation, the continued progress of robotic surgery and the development of structured training programmes are key to the future of minimal access surgery. The use of robots in surgery has increased dramatically in the last decade. Indeed, robots are now available not only for assisting in surgery, but also for aiding in the perioperative management of surgical patients. The remote presence systems (In Touch Health, Santa Barbara, CA, USA) allow clinicians to assess patients in real time and interact with them while they are not on site or even on a different continent. Applying established devices in different contexts also offers the introduction of innovation; for example, the LABEL procedure (Laser Assisted Bile duct Exploration by Laparoendoscopy for choledocholithiasis) was developed when the concept of laser stone management in urology was applied to laparoscopic biliary tree surgery. Continued advances in related technologies, such as computer science, will allow the incorporation of augmented reality systems alongside robotic systems to enhance surgical precision in image-guided surgery. Endoluminal robotic surgery remains in its infancy, but systems are being developed that will enable navigation within the colon to allow surgery on lesions in spaces that are accessible from the outside without an exterior incision being made. The advent of nanotechnology should also bring about much change in surgery. Miniaturisation may be possible, potentially allowing surgery at a cellular level to be carried out.

At present, work has already started on single-port laparoscopy (see above under Single incision laparoscopic surgery), in which a single port may act as a camera and have unfolding instruments that open up once they are inside the peritoneum to perform the surgery, therefore reducing the number of port sites needed. Extensive research is also being carried out in the field of NOTES. Minimising the potential contamination of the peritoneum and the ability to carry out a safe closure of the peritoneal entry site are the main technical challenges of this type of minimally invasive and essentially 'scarless' or 'incisionless' surgery. It is certain that there is much that is new in minimal access surgery. Only time will tell how much of what is new is truly better.

Specifically, the future evolution of robotic systems includes full integration with next generation technologies such as advanced augmented reality, autobionics, neuromorphic visual processing and real-time diagnostics and theranostics, exemplified by the i-Knife (real-time tissue metabolic profiling and tissue-level diagnosis, developed by Zoltan Takats at Imperial College London). Large master–slave constructions with multiple arms are likely to give way to flexible access bio-inspired (FAB) systems. These will probably offer full robotic arm articulation in much more portable devices with low energy needs. They would be totally modular with integrated imaging and would have platforms to offer multipurpose usage to increase utilisation and cost efficiency. These systems would also result in a smaller physical footprint, with cheaper devices offering more utility, precision and dexterity on platforms that allow both master–slave and direct functionality.

One major obstacle in minimally invasive technology includes the 'Achilles heel' of cost efficiency and device financing in an increasingly rationed global healthcare environment; this is an issue which will require surgical liaison with hospital management and national policy providers. Surgeons need to continue to have a dialogue, discussing their experiences and ideas regarding all the minimally invasive approaches. None of these techniques needs to exist in isolation. The future can offer hybridisation of these approaches, including a vast array of possibilities such as Robotic-SILS, Robotic-NOTES or even endoscopic NOTES-augmented SILS (endoscopes passed through a SILS port). Such cross-fertilisation can offer new innovation and techniques; thus, harvesting the advantages of newer procedures and discarding the individual weaknesses of others can ultimately improve patient outcomes and results.

> The cleaner and gentler the act of operation, the less the patient suffers, the smoother and quicker his convalescence, the more exquisite his healed wound.
>
> Berkeley George Andrew Moynihan (1920)

Chapter 9

Principles of paediatric surgery

Learning objectives

At the end of this chapter, you will be able to:

- Describe clinically important differences between adults and children
- Explain the principles of trauma management in children
- Safely prescribe perioperative fluids in children
- Avoid the pitfalls that often delay the diagnosis of common emergency conditions
- Outline some congenital malformations managed by neonatal surgeons that may present later to general surgeons
- Recognise common safeguarding issues in children and know how to proceed if abuse is suspected

INTRODUCTION

Premature and term neonates differ in their anatomy, physiology, neurology, psychology, pathology and pharmacology, just as infants differ from school-age children and adolescents from adults. These differences underpin the principles of paediatric surgery. As you progress through this chapter and consider children of different ages (*Table 9.1*) you should make your own list of differences and their clinical implications; a few examples appear in *Table 9.2* and in **Figure 9.1** to get you started.

Paediatric surgeons study developmental biology and teratology but because some anomalies first present to adult services (e.g. duplications, malrotation) this knowledge can help adult surgeons. Adult services also need to cater for the transitional needs of those graduating to adulthood, sometimes after complex paediatric surgical care. Most children escape the comorbidities of degenerative diseases but no longer are they free from lifestyle problems. Paediatric bariatric surgery is now developing in a multidisciplinary context with psychologists, dieticians and gastroenterologists.

We start with three important areas: thermoregulation, airway and fluid management, and then outline trauma, some common problems in older children, a collection of neonatal surgical conditions, oncology and conclude with safeguarding.

TABLE 9.1 Common terms.

Preterm	<37 completed weeks of gestation
Full term	Between 37 and 42 completed weeks of gestation
Neonate	Newborn baby up to 28 days after the estimated date of delivery (EDD)
Infant	Up to 1 year of age
Child	All ages up to 16 years (minimum school leaving age), divided into preschool child (usually <5 years), child and adolescent (puberty up to 16 years).
Young person	A popular term referring to anyone under 18 years

TABLE 9.2 Some example differences between adults and children.

Facts	Infants and small children have a wide abdomen, a broad costal margin and a shallow pelvis
	The edge of the liver comes below the costal margin and the bladder is largely intra-abdominal
	The ribs are more horizontal and are flexible
	The umbilicus is relatively low lying
Implications	Transverse supraumbilical incisions give greater access than vertical midline ones for open surgery
	Trauma (including surgical access) can easily damage the liver or bladder
	The geometry of the ribs means that ventilation requires greater diaphragmatic movement. Their flexibility means that rib fractures are rare and often a sign of abuse
	A stoma in the lower abdomen of a neonate must be carefully sited for its bag not to interfere with the umbilicus

MAINTAINING TEMPERATURE

In comparison with older children, infants have less subcutaneous fat, immature vasomotor control, greater heat loss from

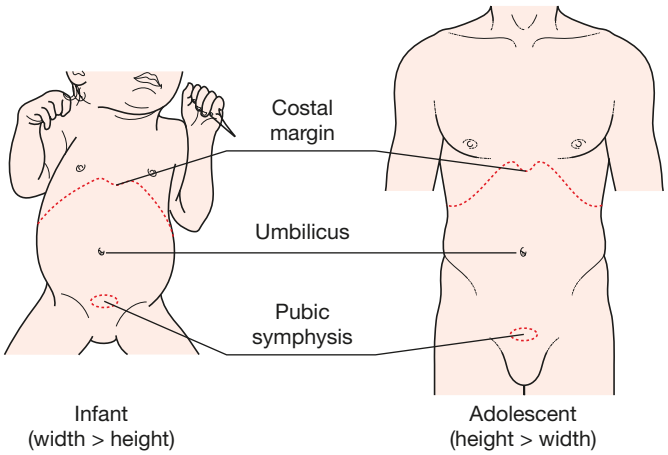

Figure 9.1 Topographical differences in the abdomen.

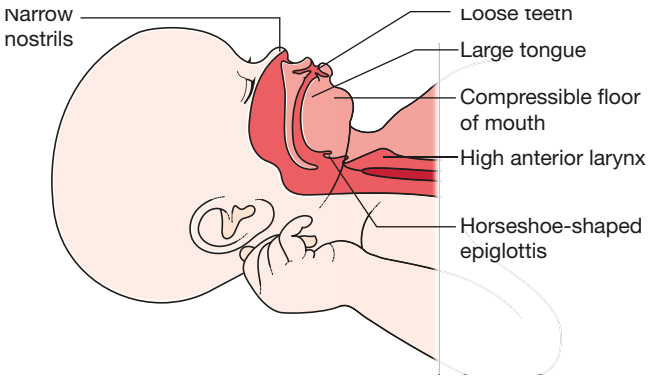

Figure 9.2 Summary of upper airway anatomy in an infant.

pulmonary evaporation and their surface area to weight ratio is higher. Consider these when managing sick children in the Emergency Department, anaesthetic room or theatre. These environments must be warm and the infant's head (20% of surface area, cf. 9% in an adult) should be insulated. Infusions are warmed and respiratory gases both warmed and humidified. Core temperature is monitored and safe direct warming is needed for lengthy operations.

AIRWAY

Anatomical differences in the airway have clinical implications (see **Figure 9.2**). The infant's large head and short neck predispose to flexion. The large tongue can obstruct the airway when the infant is unconscious and impede the airway and laryngoscopy. The epiglottis projects posteriorly and the larynx is high; a straight-bladed laryngoscope is favoured in those under 1 year of age. Uncuffed tubes are preferred as the cricoid ring is the narrowest region (cf. the larynx in an adult) and this is covered in loose epithelium that is easily irritated; damage can result in subglottic stenosis.

PERIOPERATIVE FLUIDS IN CHILDREN

Before prescribing fluids (or drugs), it is important to know the child's weight, their vital signs and their fluid and electrolyte requirements and consider these in relation to normal values and ranges (see *Table 9.3*). Dehydration is difficult to assess: moderate dehydration (5% loss of total body water) may manifest in poor urine output, dry mouth, and sunken eyes and fontanelle; severe dehydration (>10%) in decreased skin turgor, drowsiness, tachycardia and poor capillary refill (>2 seconds) and signs of hypovolaemia.

Children develop hyponatraemic encephalopathy at higher sodium levels than adults because they have a higher brain:skull ratio. A few children have had symptomatic hyponatraemic encephalopathy attributable to poor prescription and monitoring of fluids; some have died and others have permanent neurological disability. Problems have arisen when: (1) hypotonic maintenance fluids (e.g. 0.18% saline) have been inappropriately given to resuscitate or replace loses, or (2) maintenance fluids have been given in excess (3–5 times requirements).

UK National Guidelines are that maintenance fluid administration should contain sodium levels of 131–154 mmol/L.

TABLE 9.3 Basic paediatric data.

(a) Weight

Age	Weight (kg)
Term neonate	3.5
1 year	10
5 years	20
10 years	30

(b) Vital signs

Age (years)	Heart rate (bpm)	Systolic blood pressure (mmHg)	Respiratory rate (b/min)
<1	110–160	70–90	30–40
2–5	90–140	80–100	25–30
5–12	80–120	90–110	20–25

(c) Maintenance fluid requirements

Weight	Daily fluid requirement (mL/kg/day)	mL/kg/hour
Neonate	120–150	5
First 10 kg	100	4
Second 10 kg	50	2
Each subsequent kg	20	1

(d) Maintenance electrolyte requirements

Weight	Sodium (mmol/kg/day)	Potassium (mmol/kg/day)	Energy (kcal/kg/day)
<10 kg	2–4	1.5–2.5	110
>10 kg	1–2	0.5–1.0	40–75

Approximate guide: weight (kg) = 2 × (age in years +4), or use a Broselow tape which estimates the weight from the height.
Systolic blood pressure = 80 + (age in years × 2) mmHg.
Circulating blood volume = 80 mL/kg (90 mL/kg in infants).

Learning objectives for this section are to:

- Know the four reasons for giving intravenous (IV) fluids.
- Be able to calculate fluid rates for children of different weights (see *Table 9.3*).
- Understand the risks of low-sodium containing fluids.
- Understand how the body's response to stress and illness affects fluid balance.
- Know how to recognise and manage hyponatraemia (<135 mmol/L).

Tonicity and osmolarity

The term 'isotonic' is now considered in relation to the tonicity of the electrolyte components of fluids. Thus, isosmolar fluids, such as 0.18% saline with 4% glucose, and hyperosmolar fluids, such as 0.45% saline with 5% glucose, are now considered hypotonic because the glucose is ignored.

Prescribing intravenous fluids.

The four reasons for prescribing fluids are detailed in *Summary box 9.1*. The body's response to stress is to hold on to water, which can promote hyponatraemia. The stresses that drive the non-osmotic retention of water include trauma, head injury, chest infections and the postoperative state. Restricting maintenance fluids to 70% can be appropriate for 24 hours after major surgery. In sick patients, raising the maintenance rate is best guided by the trend in daily electrolyte levels. Urine output often decreases after major surgery without morbidity but a common response can be to increase maintenance fluids inappropriately, leading to hyponatraemia. A postoperative bolus of fluid is appropriate if there is hypovolaemia, hypotension or poor peripheral perfusion but giving it simply because urine output is low can be inappropriate.

Hyponatraemia in the surgical patient is usually a consequence of too much free water and not of insufficient sodium. If mild and asymptomatic (e.g. 135 mmol/L) then fluid restriction is appropriate. If symptomatic with headache, lethargy or seizures and the Na concentration is <125 mmol/L a rapid infusion of 3% hypertonic saline (1 mL/kg over 15 minutes) is needed and paediatric intensive care unit (PICU) admission is required.

Summary box 9.1

Fluids in children

Fluids are given intravenously for four reasons:

- Circulatory support in resuscitating vascular collapse
  - 0.9% saline, blood, 4.5% albumin colloid: Given as a bolus of 10 or 20 mL/kg over periods up to 20 minutes with close monitoring of the response. Can be repeated up to 40 mL/kg then seek urgent help
- Replacement of previous fluid and electrolyte deficits
  - 0.9% saline + 0.15% KCl, Hartmann's solution: Given over a longer period (up to 48 hours) with clinical and biochemical review
- Replacement of ongoing losses
  - 0.9% saline + 0.15% KCl, Hartmann's solution: Or a fluid tailored to the losses e.g. 4.5% albumin if protein loss is great. Replace losses mL for mL
- Maintenance outside neonatal period
  - Plasmalyte 148, Hartmann's ± glucose, 0.9% saline + 0.15% KCl ± glucose: Hypotonic 0.18% saline should not be used outside the neonatal period
- Maintenance in the neonate
  - In **term** neonates in the first 48 hours of life 10% glucose at 60 mL/kg/day
  - Sodium 0.18% and potassium 0.15% are added on day 2
  - From day 3 around 4–5 mL/kg/hour or 100–120 mL/kg/day
  - Preterm babies or those <2 kg may require 180 mL/kg/day of fluid
  - Consider impaired gluconeogenesis: monitor and keep glucose above 2.6 mmol/L

HISTORY AND EXAMINATION

Time, patience and a genuine interest help establish a good rapport with the child and their parents or carers. An opportunistic rather than a systematic approach to the history and examination may be needed but appropriate areas must be covered. Do not forget to explore perinatal problems and the family and social background. Children should be told what to expect from an examination, investigation or surgical procedure in terms that they can understand. Fear, anxiety and pain can be reduced by involving the parents and by looking after the child in an appropriate environment. For elective surgery a preadmission service and anaesthetic review should be considered, with general health concerns being redirected to a paediatrician. Consent for surgery in the young child is obtained from someone with parental responsibility.

OPERATIVE SURGERY

A well-prepared patient who has not been excessively fasted, with appropriate consent, is anaesthetised in a child-friendly anaesthetic room. Surgery benefits from meticulous and gentle technique, strict haemostasis, fine suture materials and magnification. Basic principles apply: maintaining well-vascularised tissues, avoiding tension, minimising tissue necrosis and contamination. The intestine can be anastomosed with single-layer interrupted or continuous extramucosal sutures. Abdominal wounds are closed with absorbable sutures using a layered or a mass closure. Wound dehiscence is rare and usually the result of poor technique. Clean skin incisions are best closed with absorbable subcuticular sutures. Endoscopic minimally invasive approaches can be used at all ages with instruments and insufflation pressures tailored to the size of the child. Postoperatively, children recover swiftly. Analgesia must be adequate and appropriate, recognising the potential for respiratory depression with opioids. Appropriately trained staff monitor the airway, vital signs, oxygen saturation, fluid balance, temperature, pain control and glucose levels during recovery.

Summary box 9.2

Fasting instructions

- Two hours for clear fluids
- Four hours for breast milk
- Six hours for solids

Summary box 9.3

Surgical technique in children

- Gentle tissue handling
- Abdominal incisions can be closed with absorbable sutures
- Bowel can be anastomosed with interrupted or continuous single-layer extramucosal sutures
- Skin can be closed with absorbable subcuticular sutures or glue

Stomas are necessary in some children. A gastrostomy may be required for nutritional support, particularly in the neurologically disabled child (often with a fundoplication). Temporary intestinal stomas are used in the management of anorectal malformations, necrotising enterocolitis and Hirschsprung's disease. Infants with a proximal stoma and high losses frequently require salt or bicarbonate supplements to avoid deficits, which can cause poor weight gain and acidosis. Ileostomies and colostomies are usually spouted but mucous fistulas may be flush.

The long-term outcomes of paediatric surgical conditions should be considered. For example, ileal resection in the neonate may later be complicated by vitamin B12 deficiency, malabsorption of fat-soluble vitamins, gallstones, renal oxalate stones and perianastomotic ulceration. Long-term concerns with other treated anomalies include the impact on continence, fertility, sexual activity, psychosocial adaptation and the potential risk of late malignancy (e.g. undescended testis, choledochal cyst, duplication cysts, oesophageal atresia).

PAEDIATRIC TRAUMA

Trauma remains a leading cause of avoidable death in children and adolescents worldwide. Surgeons should attend the Advanced Trauma Life Support (ATLS) programme which covers trauma in children. Some of the important differences for children follow:

- Avoid overextension of the neck which can obstruct the airway.
- Use a Broselow tape if the weight is not known.
- Blood pressure is often normal until >25% of the circulating blood volume is lost.
- Cardiorespiratory arrest is usually due to hypoxia and not vascular disease.
- Non-operative management is often possible for splenic and liver injuries.

Resuscitation

For fluids see *Summary box 9.1*. High-flow oxygen is required if there is cardiorespiratory compromise, and endotracheal intubation and ventilation are required if oxygenation is inadequate, to control a flail chest or in children with a serious head injury (Glasgow Coma Scale score ≤8). Seriously injured children require two large peripheral intravenous cannulae. The following veins can be used: long saphenous at the ankle, femoral, external jugular and, in babies, scalp veins. Central venous access should only be attempted by an expert. Intraosseous infusion, however, is straightforward and particularly useful in children (**Figure 9.3**).

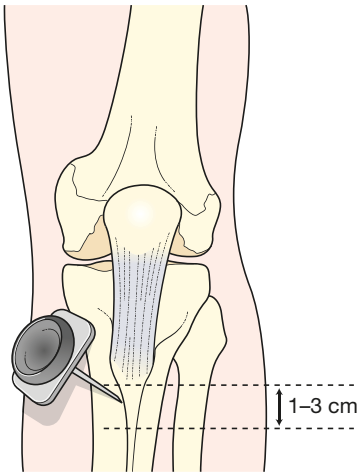

Figure 9.3 The intraosseous needle is inserted into the medullary cavity of the proximal tibia about 1–3 cm below the tibial tuberosity.

A major spinal cord injury can be present in a child without radiographic abnormalities. After major trauma, a cervical spine injury should be assumed and the neck immobilised until cross sectional imaging 'clears' the spine. Other considerations include intravenous analgesia and, in the unconscious or ventilated child or those with major abdominal injuries, a nasogastric tube (orogastric if there is suspicion of a basal frontal skull fracture) and a urethral catheter (if no evidence of a urethral injury).

Secondary survey and emergency management

Chest trauma

Children have elastic ribs that rarely fracture but deformation causes lung contusions. A major thoracic injury may exist despite a normal chest radiograph. The airway is secured, oxygen is given and hypovolaemia is corrected. A tension pneumothorax should be suspected clinically before the chest x-ray (CXR) is requested and immediate needle thoracocentesis (second intercostal space, mid-clavicular line) performed. A chest drain is then placed (fifth intercostal space, mid-axillary

The **Glasgow Coma Scale** was introduced in 1977 by William Bryan Jennet, Professor of Neurosurgery, and Graham Michael Teasdale, a neurosurgeon at the University Department of Neurosurgery at the Institute of Neurological Sciences, The Southern General Hospital, Glasgow, UK. Professor Teasdale was later knighted and became President of the Royal College of Physicians and Surgeons of Glasgow.

line). Massive haemothorax needs a chest drain. Cardiac tamponade may follow blunt or penetrating injury and requires emergency subxyphoid needle pericardiocentesis. The role of emergency department thoracotomy (EDT) in major chest trauma in children remains controversial. Diaphragmatic rupture after blunt abdominal trauma is detected by chest radiography or computed tomography (CT) scan; surgical repair is undertaken once the patient is stable (**Figure 9.4**).

Abdomen

Blunt trauma is more common than penetrating trauma. The liver and spleen are more vulnerable in children, being less well protected by the rib cage. The abdomen is inspected for patterned bruising from seatbelts (**Figure 9.5**) or tyres. Compression will have been against the rigid skeleton. Intra-abdominal or intrathoracic bleeding should be considered promptly in the shocked child if external bleeding has not been profuse. Plasma amylase levels may be normal despite pancreatic injury (**Figure 9.6**).

Imaging

Focused assessment with sonography for trauma (FAST) looks for fluid in the perihepatic and hepatorenal space, the perisplenic area, the pelvis and the pericardium. It has a role in children but it does not detect solid organ injuries or replace CT. In the haemodynamically stable child a CT scan with IV contrast is required (**Figure 9.7**).

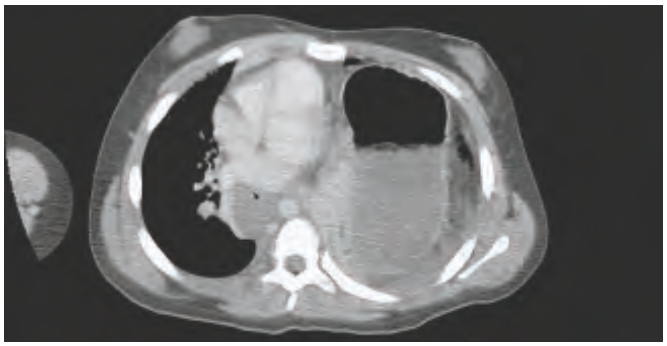

Figure 9.4 Traumatic diaphragmatic rupture.

Figure 9.5 Bruises from a lap belt.

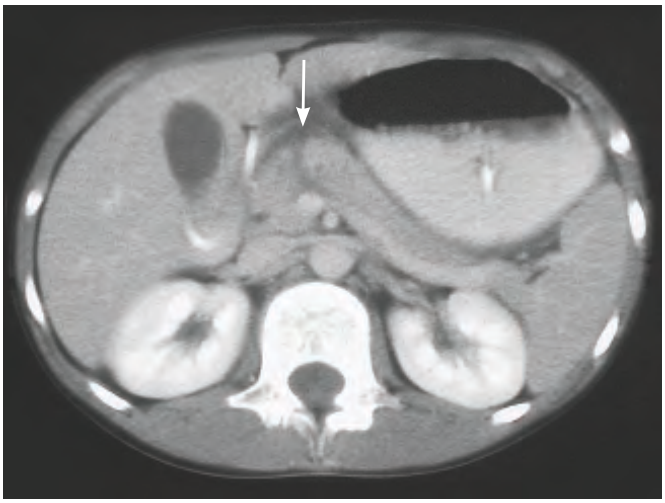

Figure 9.6 Abdominal computed tomographic scan showing a transection through the neck of the pancreas (arrow) from a bicycle handlebar injury.

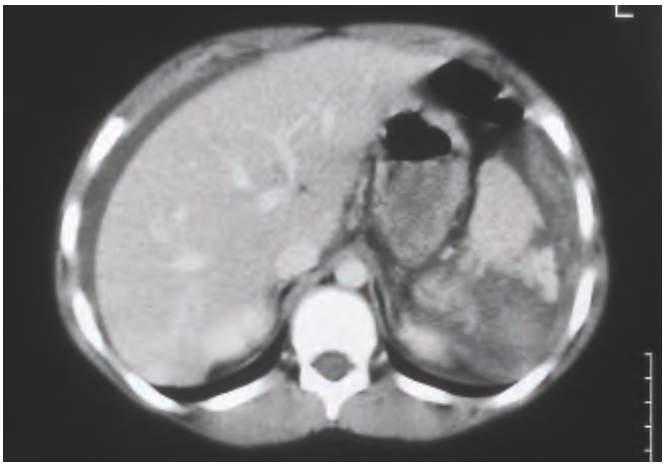

Figure 9.7 Abdominal computed tomographic scan after intravenous contrast in an 11-year-old boy showing a ruptured spleen (successfully managed non-operatively).

Bowel perforation or deep penetrating trauma requires a laparoscopy or laparotomy. Isolated blunt splenic and/or liver injuries identified on a CT scan can be safely and effectively managed non-operatively in the majority of children, so avoiding surgery and the long-term risks of splenectomy (infection from encapsulated bacteria *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*).

Summary box 9.4

Successful non-operative management of isolated blunt liver or spleen trauma

- Haemodynamic stability after resuscitation with no more than 60 mL/kg of fluid
- A good-quality CT scan
- No evidence of hollow visceral injury
- Close monitoring and the immediate availability of surgical expertise and facilities

Ongoing intra-abdominal bleeding requires a laparotomy, though angiography and arterial embolisation can be useful in some. Bile leaks are uncommon and can usually be managed by an interventional radiological technique. Uncomplicated unoperated cases of liver/spleen trauma can be discharged after 5–7 days but activity is restricted for 3–6 weeks and contact sports avoided for 2–3 months. Blunt renal trauma can be managed conservatively but an acutely non-functioning kidney following abdominal trauma may need urgent exploration with a view to revascularisation.

Patterns of injury

- **Lap belts**: the small intestine or lumbar spine.
- **Bicycle handlebars**: pancreatic, duodenal, mesenteric or liver trauma (**Figure 9.7**).
- **Straddle injuries**: the urethra and pelvis.
- **Run-over injuries**: severe crushing of the chest and/or abdomen.

Summary box 9.5

Paediatric trauma

- Use Advanced Trauma Life Support (ATLS) principles
- Overextension of the neck will compromise the airway
- Cervical spine injury can be present without radiographic signs
- Intraosseous vascular access is helpful in small children
- Lung contusion can occur without rib fractures
- Patterned skin bruising suggests underlying organ injury
- In a stable child, abdominal injuries are best assessed by CT
- Isolated liver or splenic injury can usually be managed non-operatively

COMMON PAEDIATRIC SURGICAL CONDITIONS

Inguinoscrotal disorders

Most genital abnormalities in boys are developmental anomalies. The testis develops from the urogenital ridge on the posterior abdominal wall. Gonadal induction leading to a testis is regulated by genes on the Y chromosome. During abdominal descent the testis migrates towards the internal ring, guided by mesenchymal tissue (gubernaculum). Descent into the scrotum is mediated by testosterone from the fetal testis. A tongue of peritoneum precedes the migrating testis through the inguinal canal and becomes the processus vaginalis. The processus normally becomes obliterated after birth, and failure leads to the development of an inguinal hernia or hydrocoele (**Figure 9.8**).

Inguinal hernias

Inguinal hernias in children are almost always indirect and due to a patent processus vaginalis. Inguinal hernias are common

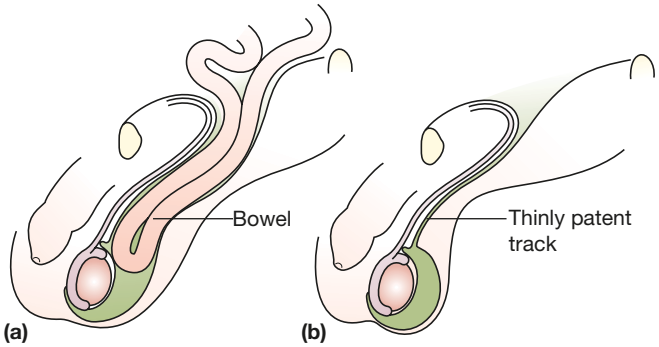

Figure 9.8 **(a)** Inguinal hernia and **(b)** hydrocoele in children are the result of incomplete obliteration of the processus vaginalis.

in boys (1:50), especially if premature, and are more common on the right-hand side (2:1) with 15% being bilateral. Rarely, bilateral inguinal hernias in a phenotypic girl may be the presentation of androgen insensitivity syndrome (testicular feminisation) and the sac may then contain a testis.

An inguinal hernia typically causes an intermittent swelling in the groin or scrotum on crying or straining (**Figure 9.9**). Unless an inguinal swelling is observed, diagnosis relies on the history and the presence of palpable thickening of the spermatic cord (or the round ligament in girls). Some inguinal hernias present as a firm, tender, irreducible lump in the groin or scrotum because of incarceration at the external ring. The infant may be irritable and may vomit. Most incarcerated hernias in children can be successfully reduced by sustained gentle compression ('taxis') aided by cautious analgesia. Repair can be delayed for 24 hours to let the oedema settle. If truly irreducible, emergency surgery is required because of the risk of vascular compromise to the bowel, ovary or testis.

Inguinal herniotomy is performed via an inguinal skin crease incision, opening Scarpa's fascia and then the external oblique. The cremaster is cut and, through an initially small opening, the sac is grasped and gently delivered. The vas and vessels are separated from the sac which is then divided and proximally ligated. Outside the neonatal period inguinal herniotomy is a day-case procedure. A laparoscopic approach is feasible but has a higher recurrence rate.

Summary box 9.6

Inguinal hernias

- More common in premature boys (right > left)
- 15% bilateral
- Indirect with a patent processus vaginalis
- Groin lump that appears on straining or crying
- Incarcerated inguinal hernias can usually be reduced with gentle pressure
- In infants they can transilluminate like a hydrocoele, making the test redundant when the distinction is difficult
- If reduction is impossible emergency surgery is needed
- In infants: repaired promptly to prevent the risk of strangulation
- The hernial sac is isolated, ligated and divided

Hydrocoeles

A patent processus vaginalis may allow peritoneal fluid (but no intestine) to track down to form a hydrocoele. Hydrocoeles are unilateral or bilateral, asymptomatic, non-tender scrotal swellings. Hydrocoeles may be tense or lax but typically transilluminate (**Figure 9.9**). The majority resolve spontaneously as the processus continues to obliterate but ligation and division is recommended in boys over 3 years of age. Rarely, a baby can have a tense painful hydrocoele warranting early repair. A hydrocoele can occasionally extend back up into the canal or abdomen (abdomino-scrotal hydrocoele).

Figure 9.9 A left inguinal swelling. Clinical examination is needed to confidently distinguish a hydrocoele from an inguinal hernia.

Undescended testes are palpable or impalpable

At birth, 4% of full-term boys have unilateral or bilateral undescended testes, but after 3 months of age the incidence is <1% and it changes little thereafter. The incidence is higher in preterm infants, attributed to the testis descending through the canal in the third trimester. A normal testis reaches the base of the scrotum with a good length of cord above it. Testes cannot be palpated in the inguinal canal but can be milked from there into the superficial pouch (**palpable undescended testis**) or in to the scrotum with a good length of cord (normal). A **retractile testis** can be manipulated into the base of the scrotum without tension but is pulled up by the cremaster muscle. With time, retractile testes reside permanently in the scrotum; however, follow-up is advisable because, rarely, the testis ascends back into the inguinal canal. The **ascending testis** needs an orchidopexy. An **ectopic** testis lies outside its normal line of descent, often in the perineum.

A palpable undescended testis ideally requires a day-case orchidopexy between 6 and 12 months of age. The testis is mobilised through an inguinal incision, preserving the vas deferens and testicular vessels. The associated patent processus vaginalis is ligated and divided at the internal ring and the testis is placed in a subdartos scrotal pouch.

Impalpable undescended testes are either absent or located in the abdomen or inguinal canal. There is no benefit from imaging and these are best managed with a laparoscopy (**Figure 9.10**) and usually a staged approach.

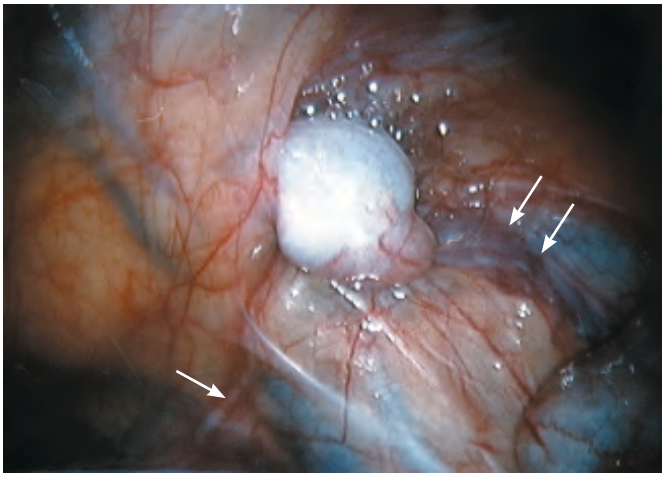

Figure 9.10 Laparoscopic view of a right-sided intra-abdominal testis visible at the internal ring. Vas (single arrow) and testicular vessels (double arrow).

The benefits of orchidopexy include:

- **Fertility.** To optimise spermatogenesis the testis needs to be in the scrotum below core temperature at a young age. Orchidopexy around 6–12 months of age is currently recommended. Fertility after orchidopexy for a unilateral undescended testis is near normal. Men with a history of bilateral intra-abdominal testes are often infertile.
- **Malignancy.** Undescended testes are histologically abnormal and at an increased risk of malignancy. The greatest risk is in patients with bilateral intra-abdominal testes. Early orchidopexy for a unilateral undescended testis may reduce the risk but this is not proven.
- **Cosmetic and psychological.** In an older boy a prosthetic testis can be inserted to replace an absent one.

Summary box 9.7

The undescended testis

- A retractile testis reaches the base of the scrotum but retracts
- An undescended testis may be palpable or impalpable
- An ectopic testis lies outside the normal line of descent
- Palpable undescended testes undergo a single stage orchidopexy
- Impalpable undescended testes undergo a single stage orchidopexy
- Orchidopexy before 1 year of age improves fertility and may reduce the risk of malignancy

The acute scrotum

Testicular torsion is most common in adolescents, but may occur at any age and is usually inside the tunica vaginalis. Perinatal torsion differs and is usually extravaginal. The pain

is not always scrotal and may be felt in the groin or lower abdomen. Scrotal oedema and erythema can be absent. Sometimes there is a history of previous transient episodes. Torsion of the testis must be relieved within 6–8 hours of the onset of symptoms for there to be a good chance of testicular salvage. At operation, viability of the testis is assessed after derotation. If salvageable, three-point fixation of both testes with non-absorbable sutures is performed. Expert assessment of testicular blood flow by colour Doppler ultrasound may help in the differential diagnosis but the scrotum must be explored urgently if torsion cannot be excluded.

Torsion of a testicular or epididymal appendage characteristically affects boys just before puberty (Figure 9.11), possibly because of enlargement of the hydatid in response to gonadotrophins. A hydatid of Morgagni is an embryological remnant found on the upper pole of the testis or epididymis. The pain often increases over a day or two. Occasionally, the torted hydatid can be felt or seen (blue dot sign). Excision of the appendage leads to rapid resolution of symptoms. Viral or bacterial **epididymo-orchitis** may cause an acute scrotum in infants and toddlers but this diagnosis is often only made after scrotal exploration. Other conditions can rarely cause acute scrotal symptoms, and signs include idiopathic scrotal oedema (typically painless, erythematous scrotal swelling in a young boy extending off the scrotum into the groin and towards the anus), an incarcerated inguinal hernia, vasculitis or a scrotal haematoma.

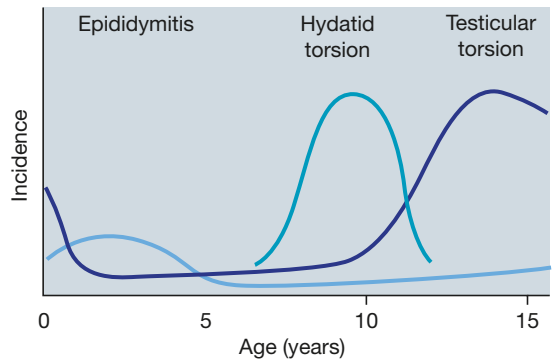

Figure 9.11 Acute scrotal pathology at different ages.

Summary box 9.8

Diagnosis and treatment of the acute scrotum

- Torsion of the testis must be assumed until proven otherwise
- Testicular torsion can present with acute inguinal or abdominal pain
- Urgent surgical exploration is crucial if testicular torsion cannot be excluded
- If torsion is confirmed an orchidopexy should be performed on both sides
- Torsion of a testicular appendage usually occurs just before puberty
- An incarcerated inguinal hernia must be considered in the differential diagnosis

The penis

Hypospadias

In hypospadias, seen in 1:300 boys, the urethra opens proximally and ventrally. Most commonly, the opening is just proximal to the glans but it can open on the penile shaft or onto the perineum. It is attributed to failure of complete urethral tubularisation in the fetus. The foreskin is deficient ventrally (Figure 9.12) and there is a variable degree of chordee (a ventral curvature of the penis most apparent on erection). Glanular hypospadias needs correction for cosmetic reasons but more proximal anomalies interfere with micturition and erection. In a newborn with severe hypospadias and bilateral undescended testes disorders of sexual development (DSDs) should be considered. A distal hypospadias is usually repaired before 2 years of age in one or two stages. Proximal varieties require complex staged procedures. Surgery aims to achieve a terminal urethral meatus so that the boy can stand to micturate with a normal stream, a straight erection and a penis that looks normal. Ritual circumcision is contraindicated in infants with hypospadias because the foreskin is often required for the reconstruction.

The foreskin and circumcision

At birth, the foreskin is adherent to the glans penis. These adhesions separate spontaneously with time, allowing the foreskin to become retractile. At 1 year of age, about 50% of boys have a non-retractile foreskin. By 4 years this has declined to 10% and by 16 years to just 1%. Ballooning of the normal non-retractile foreskin on micturition brings many young boys to doctors, and explanation and reassurance are required – but no operation. Gentle retraction of the foreskin

Figure 9.12 Hypospadias: note the hooded foreskin and the ventral meatus.

Giovanni Batista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy for 59 years, regarded as the founder of morbid anatomy.

at bath times helps to maintain hygiene but forcible retraction should never be attempted. The presence of preputial adhesions, when the foreskin remains partially adherent to the glans, is normal and resolves spontaneously. Smegma pearls accumulating under the foreskin are commonly mistaken for tumours – reassurance is needed.

Circumcision has been an important tradition in Jewish, Muslim and other cultures. Proponents observe that circumcision reduces the incidence of urinary tract infection in infant boys; however, circumcision is not without risk of significant morbidity. The medical indications for circumcision are:

- **Phimosis.** This term is often wrongly applied to describe a normal, non-retractile foreskin. True phimosis is seen as a whitish scarring of the foreskin and is rare before 5 years of age (**Figure 9.13**). It is caused by the localised skin disease balanitis xerotica obliterans (BXO), which also affects the glans penis and can cause urethral meatal stenosis.
- **Recurrent balanoposthitis.** A single episode of inflammation of the foreskin, sometimes with a purulent discharge, is not uncommon and usually resolves spontaneously; antibiotics are sometimes needed. Recurrent attacks are unusual but may be an indication for circumcision.
- **Recurrent urinary tract infection.** Circumcision is occasionally justified in boys with an abnormal upper urinary tract anomaly and recurrent urinary infection. It may also help boys with spina bifida who need to perform clean intermittent urethral catheterisation.

An emerging but controversial indication for circumcision is in the prevention of sexually acquired human immunodeficiency virus (HIV) infection in communities where this is common; large clinical trials have shown that circumcision reduces the risk of HIV transmission.

Circumcision for medical reasons is best performed under general anaesthesia. A long-acting local anaesthetic regional block can be given to reduce postoperative pain. Circumcision is not a trivial operation; bleeding and infection are well-recognised complications and more serious hazards, such as injury to the glans, may occur if the procedure is not carried out well.

Figure 9.13 True phimosis from balanitis xerotica obliterans.

Summary box 9.9

Circumcision

- Medical indications are BXO and recurrent balanoposthitis, paraphimosis, scarring from trauma
- Circumcision is not indicated for an otherwise healthy non-retractile foreskin
- Complications include bleeding, poor cosmesis (too much or too little skin removed), and trauma to the glans or urethra

Midline hernias

In the embryo, the umbilical ring is a relatively large defect in the ventral abdominal wall transmitting several structures that connect the fetus to the placenta (**Figure 9.14**). An umbilical hernia is common and caused by incomplete closure of the umbilical ring; incarceration is very rare. Most umbilical hernias resolve by 4 years of age. Supraumbilical hernias occur through defects in the linea alba just above the umbilical ring and do not close but are still repaired at around 4 years of age. Epigastric hernias are defects higher still that allow a small amount of preperitoneal fat to prolapse. They are repaired if symptomatic.

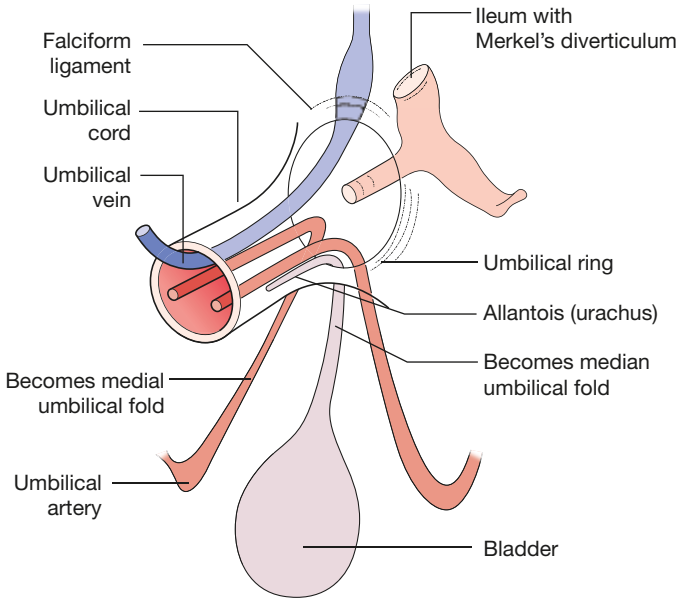

Figure 9.14 Structures at the umbilicus.

Infantile hypertrophic pyloric stenosis (IHPS)

Infantile hypertrophic pyloric stenosis (IHPS) presents with **non**-bilious projectile vomiting between 2 and 8 weeks of

age and is only rarely seen after 13 weeks. It is easily distinguished from many other serious causes of vomiting, such as infections, because the baby is particularly hungry. IHPS is a progressive condition and a detailed history helps distinguish it from the more common gastroesophageal reflux (GOR) which is commonly seen in infancy. In the UK it affects 1:300 infants, with a male:female ratio of 4:1. However, if a girl has IHPS her offspring have a high chance of developing it, suggesting a genetic predisposition.

The non-bilious nature is stressed here to contrast the condition with the **bilious vomiting** of the potentially life-threatening malrotation and volvulus seen occasionally in neonates.

IHPS can be diagnosed clinically. During a test feed there is visible gastric peristalsis passing from left to right across the upper abdomen and in a relaxed baby the pyloric 'tumour' is palpable as an 'olive' in the right upper quadrant. The diagnosis can be confirmed by an ultrasound, which shows the thickened pyloric muscle. IHPS is readily treated by surgery but the infant must be adequately rehydrated and the hypochloraemic hypokalaemic alkalosis corrected; this may take 48 hours if the chloride is 85 mmol/L or lower. In most babies, the dehydration and alkalosis can be corrected by giving 150–180 mL/kg/day of 0.9% saline with 0.15% KCl in 5% glucose. Oral feeding is discontinued and the stomach emptied with an 8–10 Fr nasogastric tube; ongoing gastric losses should be replaced intravenously.

Ramstedt's pyloromyotomy is performed by a laparoscopic or open supraumbilical incision. A serosal incision is made and the 'tumour' spread (**Figure 9.15**). The end result should be an intact bulging submucosa from duodenal fornix to gastric antrum. Perforation of the duodenal fornix is uncommon and not serious provided that it is recognised and repaired immediately.

Postoperatively, intravenous fluids are continued until oral feeding is re-established within 24 hours. Occasionally the baby has small vomits on the first few feeds but this resolves after 72 hours. If it persists then an incomplete myotomy or GOR should be considered. Surgical complications include duodenal perforation, haemorrhage, wound infection and wound dehiscence – all are uncommon and avoidable. Pyloromyotomy has no significant long-term sequelae.

Summary box 9.10

Infantile hypertrophic pyloric stenosis

- Most commonly affects boys aged 2–8 weeks
- Projectile vomiting after feeds
- Test feed or ultrasound to confirm the diagnosis
- Gastric peristalsis can be seen and an 'olive' felt
- Hypochloraemic metabolic alkalosis must be corrected before surgery
- Pyloromyotomy splits the hypertrophied muscle leaving the mucosa intact

Figure 9.15 Pyloromyotomy for infantile hypertrophic pyloric stenosis.

Other common or serious causes of vomiting in infancy are shown in *Table 9.4*.

Gastro-oesophageal reflux (GOR) is common and tends to resolve spontaneously with maturity. Persistent symptoms respond to thickened feeds and antireflux medication. Complications, such as failure to thrive or respiratory problems, demand further investigation and in some cases laparoscopic fundoplication.

TABLE 9.4 Vomiting in infancy.

Bile-stained	Neonate	Intestinal malrotation with volvulus
		Duodenal atresia/stenosis (Down syndrome, antenatal diagnosis)
		Jejunal/ileal atresia (often isolated anomalies)
		Hirschsprung's disease
		Anorectal malformations
		Meconium ileus (cystic fibrosis)
		Necrotising enterocolitis (an acquired condition in the premature)
		Incarcerated inguinal hernia
	Older infant	Intestinal malrotation with volvulus
		Intussusception (often non-bilious initially)
		Incarcerated inguinal hernia
Non-bilious	Infantile hypertrophic pyloric stenosis	
	Gastro-oesophageal reflux	
	Feeding difficulties (technique/volume)	
	Non-specific marker of illness, e.g. infection (urinary tract infection, meningitis, gastroenteritis, respiratory, metabolic disorder, raised intracranial pressure, congenital adrenal hyperplasia)	

Wilhelm Conrad Ramstedt, 1867–1963, surgeon, The Rafaelklinik, Münster, Germany, performed his first pyloromyotomy in 1911.

Intussusception

Most intussusceptions (Figure 9.16) in children occur from 2 months to 2 years of age. They are life-threatening. Intussusception typically causes a strangulating bowel obstruction, which can progress to gangrene and perforation. Intussusception is classified according to the site of the intussusceptum and intussuscipiens. In children, more than 80% are ileocolic, beginning several centimetres proximal to the ileocaecal valve with their apex found in the ascending or transverse colon.

In the majority, the cause is hyperplasia of Peyer's patches (lymphoid tissue), which may be secondary to a viral infection. In 10% of children, there is a pathological lead point, such as a Meckel's diverticulum, enteric duplication cyst or even a small bowel lymphoma. Such cases are more likely in children over the age of 2 years and in those with recurrent intussusception.

Classically, a previously healthy infant presents with colicky pain and vomiting (milk then bile). Between episodes, the child initially appears well. Later, they may pass a 'redcurrant jelly' stool. Clinical signs include dehydration, abdominal distension and a palpable sausage-shaped mass in the right upper quadrant. Rectal examination may reveal blood or rarely the apex of the intussusceptum.

Summary box 9.11

Presentation of intussusception

- Bilious vomiting in an infant is a sign of intestinal obstruction until proved otherwise
- Intussusception classically presents with colicky pain and vomiting
- Intussusception should be considered in any infant with bloody stools
- Age range is between 2 and 24 months of age

A plain radiograph is rarely requested but if done it commonly shows signs of small bowel obstruction and a soft-tissue opacity. Diagnosis is confirmed on an abdominal ultrasound.

Figure 9.16 Ileocolic intussusception causing small bowel obstruction.

After resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction is attempted using an air enema (Figure 9.17). Successful reduction is recognised if air flows into the small bowel, together with later resolution of symptoms and signs. An air enema is contraindicated if there is peritonitis, perforation or shock. More than 70% of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic reduction is a recognised hazard but is rare. Recurrent intussusception occurs in up to 5% of patients after non-operative reduction.

Operative reduction can be performed open or laparoscopically. The intussusception is milked distally by gentle

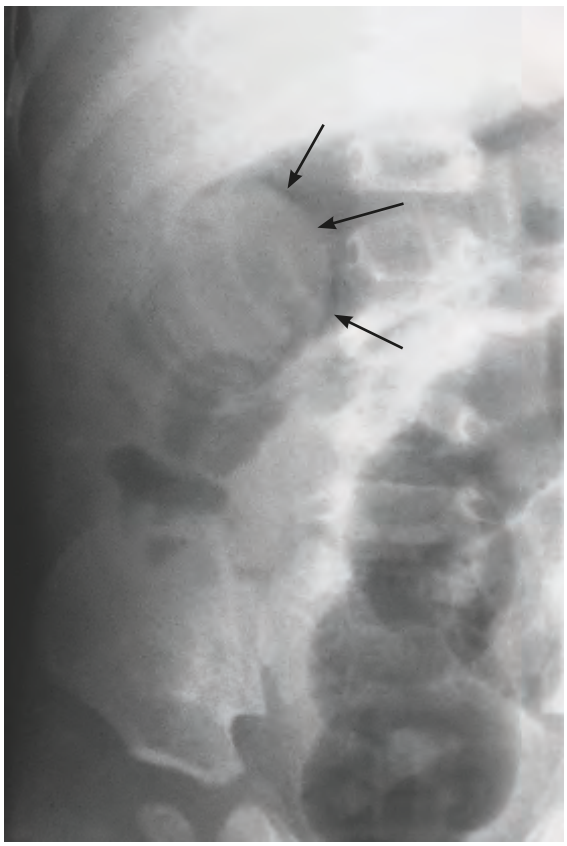

Figure 9.17 Air enema reduction of an intussusception (the arrows mark the soft tissue shadow of the intussusceptum).

Summary box 9.12

Management of intussusception

- Bowel infarction will result without treatment
- Most are ileocolic
- Diagnosis can be confirmed by ultrasound scan
- Fluid and electrolyte resuscitation is essential
- Most intussusceptions can be reduced non-operatively using an air enema
- If there are signs of peritonitis or perforation then an emergency operation is needed

compression from its apex at an open procedure. Both the intussusceptum and the intussuscipiens are inspected for areas of non-viability. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Acute abdominal pain in children over 3 years of age

Between one-third and one-half of children admitted to hospital with acute abdominal pain have non-specific abdominal pain (NSAP). The term mesenteric adenitis is unhelpful and should be dropped. Another one-third have acute appendicitis. Relatively benign conditions, such as constipation and urinary tract infections, account for most of the remainder. A small proportion of children have more serious pathology.

History and examination

Time and patience are required to evaluate the child with acute abdominal pain accurately. The child may be frightened and the parents worried. Young children find it difficult accurately to describe or localise abdominal pain but can often give a good history. The abdomen, genitalia, chest, throat and neck are examined. The abdomen may need reassessment after analgesia and a number of reviews. A gentle abdominal examination of the sleeping toddler, before removing their clothes, may reveal tenderness, guarding or a mass. Rectal examination is only performed if a pelvic appendicitis is suspected and by the surgeon whose decisions will be altered by the findings. **Active observation** acknowledges that a definitive diagnosis is not always possible when the patient is first seen. The surgeon reassesses the child after a few hours while rehydrating with IV fluids or allowing clear fluids and simple analgesics. This approach reduces the need for investigations and can reduce the negative appendicectomy rate to as low as 4%. Ultrasound and CT scans have a role in selected children.

Summary box 9.13

Work-up of children with acute abdominal pain

- A careful history and examination and active observation are paramount
- Routine tests include full blood count (FBC), C-reactive protein (CRP), urine analysis, microscopy and culture
- Abdominal ultrasound scan (not mandated initially but may be useful)
- Other tests may be helpful after a period of observation: abdominal ultrasound scan (can diagnose pelvic and urinary tract pathology)
- Occasionally helpful tests: a plain supine abdominal radiograph (particularly in the preschool child with pain and vomiting), ultrasound or CT scan in complex cases
- Selective specific investigations: blood culture, stool culture, plasma amylase, diagnostic laparoscopy

Acute non-specific abdominal pain (NSAP)

The clinical features of NSAP are similar to those of acute appendicitis but the pain is poorly localised, not aggravated by movement and rarely accompanied by guarding. The site and severity of maximum tenderness often vary during the course of repeated examinations. Symptoms are typically self-limiting within 48 hours. The aetiology of NSAP in children is obscure but viral infections and transient intussusception account for some cases. Viral infections can cause reactive lymphadenopathy, fever and diffuse abdominal pain. In some children, recurrent acute abdominal pain can be organic or sometimes an expression of underlying psychosocial problems or abuse.

Acute appendicitis and its pitfalls

Classically there is anorexia and a few vomits with central abdominal pain which settles in the right iliac fossa. In early acute appendicitis there is a fever of 37.3–38.4°C and localised tenderness. Finding persistent guarding in the right iliac fossa on repeated examination is the key to making the diagnosis and distinguishing it from NSAP, which usually resolves over 24–48 hours. NSAP does not have persistent guarding. Acute appendicitis was principally always a clinical diagnosis but more recently early ultrasound is proving useful. Investigations may help but cannot replace regular expert clinical review. The pitfalls include wrongly making the diagnosis of gastroenteritis when there are loose stools or attributing pain on micturition and pyuria to a urinary tract infection (UTI). Both of these can occur when there is pelvic appendicitis or a pelvic collection. Referred pain from a right lower lobe pneumonia should be considered and it is important to remember that if antibiotics have been given the signs may be reduced and presentation can be delayed. The diagnosis can be difficult in those under 5 years of age. Many under-fives present with a perforated appendix, not because the diagnosis is made late but rather because the omentum is less well developed and inflammation is not well contained. The treatment starts with resuscitation with intravenous fluids, analgesia and broad-spectrum antibiotics. Appendicectomy can be performed laparoscopically or through a muscle-splitting right iliac fossa incision. An appendix mass in a child who is not obstructed may respond to non-operative management with antibiotics, and an interval appendicectomy can be considered 6 weeks later.

Summary box 9.14

Acute appendicitis

- Anorexia, vomiting, low-grade fever
- Tenderness and guarding in the right iliac fossa
- Exclude referred pain from right lower lobe pneumonia
- Surgery is the treatment of choice after resuscitation and antibiotics

Other causes of acute abdominal pain in children

- **Intestinal obstruction.** Consider intussusception, inguinal hernia, adhesions and Meckel's diverticulum.
- **Constipation.** Often over-diagnosed as a cause of acute abdominal pain, particularly as the plain x-ray of a dehydrated ill child frequently shows faecal loading.

- **Urinary tract disorders.** UTI is an uncommon cause of acute abdominal pain. Urinary symptoms, fever and vomiting tend to predominate. Urinalysis, microscopy and culture are useful but a sterile pyuria may accompany acute appendicitis. Children with pelviureteric junction obstruction can present with acute or recurrent abdominal pain and no urinary symptoms.
- **Gastroenteritis.** May cause colicky abdominal pain. Onset of pain before the diarrhoea and the presence of lower abdominal tenderness should raise the suspicion of appendicitis.
- **Tropical diseases.** Ascariasis, typhoid and amoebiasis can cause acute abdominal pain.

There are numerous rarer causes of acute abdominal pain in children including Henoch–Schönlein purpura, sickle cell disease, primary peritonitis, acute pancreatitis, biliary colic, testicular torsion, gynaecological pathology (e.g. ovarian cysts and tumours, pelvic inflammatory disease, haematometrocolpos) and urinary stone disease.

Summary box 9.15

Rare causes of acute abdominal pain in children

- Obstruction from intussusception, adhesions, Meckel's diverticulum or an inguinal hernia
- Constipation
- Urinary tract disorders
- Gastroenteritis
- Ascariasis
- Typhoid

Urinary tract infection

UTIs in children may be due to a urinary tract abnormality which may carry a risk of developing renal scarring from ascending infection. Infection and obstruction are particularly hazardous. Older children complain of dysuria and frequency, whereas infants present with vomiting, fever and poor feeding. Urine specimens from children are easily contaminated during collection and results must be interpreted with care. A proven infection is investigated by an ultrasound scan. Micturating cystography and radioisotope renography are helpful in excluding vesicoureteric reflux and renal scarring. Treatment aims to relieve symptoms, correct causes and preventing renal scarring. Vesicoureteric reflux may resolve spontaneously, some may need antibiotic prophylaxis or in a very small number of cases an endoscopic treatment or a re-implantation of the ureter.

Children with **neuropathic bladders** (e.g. spina bifida) are at risk of secondary upper renal tract complications. Management of these children must take into account their dexterity and motivation. An adequate capacity, low-pressure bladder can frequently be managed by clean intermittent catheterisation but a high-pressure bladder is hazardous and other strategies, such as bladder augmentation, may be necessary. Some of these children empty their bladder via a non-refluxing catheterisable channel fashioned from the appendix, the bowel or a redundant ureter interposed between the abdominal wall and bladder (Mitrofanoff).

Anorectal problems

CONSTIPATION

The passage of hard or infrequent stools is common in children in the West. Severe constipation may be secondary to an anal fissure, Hirschsprung's disease, an anorectal malformation or a neuropathic bowel. A detailed history and examination of the abdomen, anus and spine will identify most causes. Rectal examination and plain abdominal radiography may be helpful in severe cases. In the absence of specific underlying pathology, the child is best managed jointly with a paediatrician, using a combination of diet, extra fluids, reward systems and laxatives.

RECTAL PROLAPSE

Mucosal rectal prolapse can occur in toddlers and is exacerbated by straining or squatting on a potty. It is typically intermittent and frequently self-limiting. Rarely, it may be secondary to cystic fibrosis or spinal dysraphism. The differential diagnosis includes a prolapsing rectal polyp. Underlying factors, such as constipation, should be treated. Recurrent symptomatic prolapse usually responds to injection sclerotherapy. Strapping the buttocks is ineffective.

RECTAL BLEEDING

Unlike in adults, malignancy is an exceptionally rare cause of rectal bleeding. In newborns, the life-threatening causes are malrotation and necrotising enterocolitis, and in older infants and children, intussusception. The quantities of blood loss are small but the conditions are serious. Other causes include anal fissures, juvenile polyps **(Figure 9.18)** and certain gastroenteritides (e.g. *Campylobacter* infection).

The 4-year-old patient who presents with a haemoglobin (Hb) of 40 g/L will most likely have bled profusely from an ulcer adjacent to a Meckel's diverticulum containing ectopic gastric mucosa **(Figure 9.19)**. A technetium scan may confirm the presence of ectopic gastric mucosa **(Figure 9.20)**.

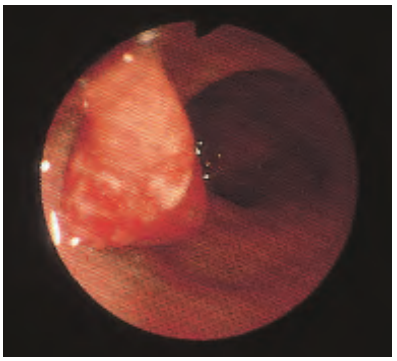

Figure 9.18 Colonic juvenile polyp: these are typically pedunculated.

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, published his description of this form of purpura in 1837.
Paul Mitrofanoff, b.1934, Professor of Paediatric Surgery, Rouen, France.

Figure 9.19 Meckel's diverticulum containing ectopic gastric mucosa.

Figure 9.20 A positive Meckel's scan.

A Meckel's diverticulum may also be complicated by an obstructing band between the diverticulum and the umbilicus, diverticulitis, intussusception, intestinal volvulus or perforation.

Swallowed or inhaled foreign bodies

Coins are the most frequently swallowed foreign bodies in children. Once beyond the cardia, they are usually passed in a few days. A plain radiograph of the abdomen, chest and neck should establish the site of radio-opaque objects. Oesophageal objects can be removed endoscopically under general anaesthesia. Button batteries must be removed within hours because if they remain in the oesophagus they can perforate into the trachea or aorta. Batteries in the stomach are either removed urgently or followed very closely with repeat x-rays over a couple of days. The need to remove sharp objects depends on their size, the age of the child and their position in the gut. Ingested magnets can cause entero-enteric fistulae when they fix to one another in adjacent loops of bowel. Battery ingestion in older children and young people may be a manifestation of self-harm.

Inhaled foreign bodies cause sudden-onset coughing and stridor. If there is worsening dyspnoea or signs of hypoxia then the infant should be given back blows in a head-down position. Abdominal thrusts (Heimlich manoeuvre) can be used in older children. A foreign body is suggested by: a unilateral wheeze, decreased transmitted breath sounds and a hyperinflated lung from air trapping on an expiratory CXR (**Figure 9.21**). A rigid bronchoscopy with a ventilating bronchoscope and appropriate optical forceps is needed to assess and remove objects.

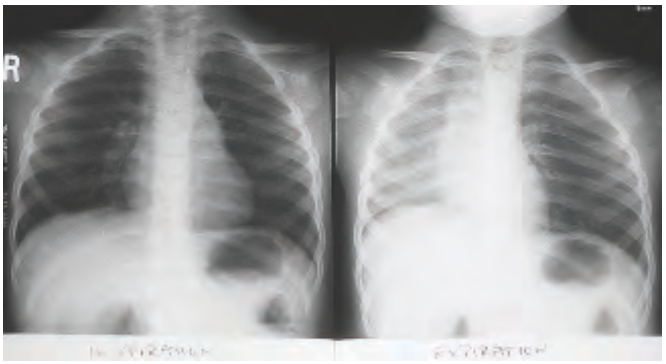

Figure 9.21 An inspiratory (left) and expiratory (right) chest radiograph demonstrating left-sided pulmonary air trapping after inhalation of a radiolucent foreign body.

Summary box 9.16

Swallowed and inhaled objects

- Most swallowed objects pass spontaneously
- Batteries need watching – they must pass quickly if their contents are not to leak
- Objects jammed in the airway or oesophagus need removing promptly

CONGENITAL MALFORMATIONS

Around 2% of babies are born with one or more major structural anomalies caused by genetic defects or teratogenic insults. Some are diagnosed antenatally and surgeons are involved in antenatal counselling. Termination of pregnancy or planned delivery in a specialist centre are options for severe malformations. Prenatal diagnosis may include checking the karyotype (e.g. Down syndrome: trisomy 21) or testing for genetic disorders, such as cystic fibrosis.

The incidence of congenital malformations is variable (*Table 9.5*). Some examples relevant to the general surgeon are briefly outlined in the following sections.

Henry J Heimlich, b.1920, thoracic surgeon, Xavier University, Cincinnati, OH, USA.
John Langdon Haydon Down (sometimes given as Langdon-Down), 1838–1896, physician, The London Hospital, London, UK, published '*Observations on an ethnic classification of idiots*' in 1866.

TABLE 9.5 Incidence of selected malformations.

Abnormality	Incidence
Thoracic	
Congenital diaphragmatic hernia	1:3000
Oesophageal atresia/tracheo-oesophageal fistula	1:3500
Cardiac	
Congenital heart disease	1:150
Gastrointestinal	
Gastroschisis	1:7500
Hirschsprung's disease	1:5000
Anorectal malformations	1:4–5000
Hepatobiliary	
Biliary atresia	1:17 000
Choledochal cyst	1:50 000
Urogenital	
Hypospadias	1:300
Pelviureteric junction dysfunction	1:1000

Oesophageal atresia

A blind proximal pouch with a distal tracheo-oesophageal fistula is the most common type (**Figure 9.22**). Affected infants present soon after birth with drooling and cyanotic episodes on attempting to feed. There may have been polyhydramnios due to failure to swallow amniotic fluid. The diagnosis is confirmed when a nasogastric tube goes no further than the upper oesophageal pouch on the CXR and abdominal gas signifies the tracheo-oesophageal fistula (**Figure 9.22**). Associated anomalies are common and include cardiac, renal and skeletal defects. Repair is usually via a right-sided extrapleural thoracotomy within a day or two of birth – thoracoscopic repair is challenging but feasible, although the magnified view is excellent . The fistula is divided and the tracheal side closed. The oesophageal ends are anastomosed. The blood supply is poor and the anastomosis is under tension.

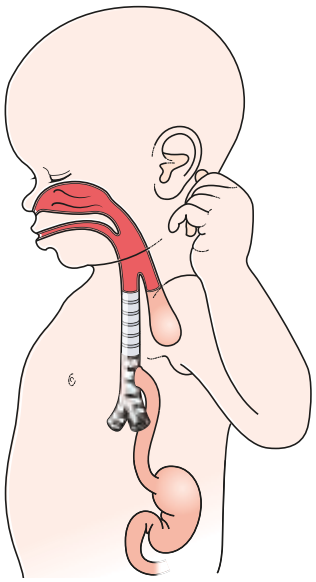

Figure 9.22 Oesophageal atresia with a distal tracheo-oesophageal fistula.

Postoperative complications include anastomotic leak, stricture, recurrent fistula formation and gastro-oesophageal reflux. Infants with pure oesophageal atresia and no tracheo-oesophageal fistula are usually best managed by a temporary gastrostomy and delayed primary repair or an oesophageal replacement. Except for very-low-birth weight babies and those with major congenital heart disease, most infants with repaired oesophageal atresia have a good prognosis.

Congenital diaphragmatic hernia (CDH)

Typically, there is a left-sided posterolateral diaphragmatic defect allowing herniation of abdominal viscera into the chest (**Figure 9.23**). Many are detected antenatally and the prognosis relates to the severity of the associated pulmonary hypoplasia. Despite intensive respiratory support or extracorporeal membrane oxygenation (ECMO), up to 30% of babies with a CDH die from respiratory failure. If the baby can be stabilised, the diaphragmatic defect is repaired. Small diaphragmatic hernias may present with respiratory or gastrointestinal symptoms in later childhood.

Figure 9.23 Left-sided congenital diaphragmatic hernia.

Intestinal atresias

Duodenal atresia may take the form of a membrane or the proximal and distal duodenum may be completely separated. Prenatal ultrasound finds a 'double bubble' in the fetal abdomen with polyhydramnios. There is an association with Down syndrome. Postnatally, there is bilious vomiting if the atresia is distal to the ampulla. A plain abdominal x-ray also shows the double-bubble (**Figure 9.24**). Repair is by open duodeno-duodenostomy (**Figure 9.25**). Occasionally, there is a duodenal membrane with a modest central perforation, which may delay symptoms until later childhood.

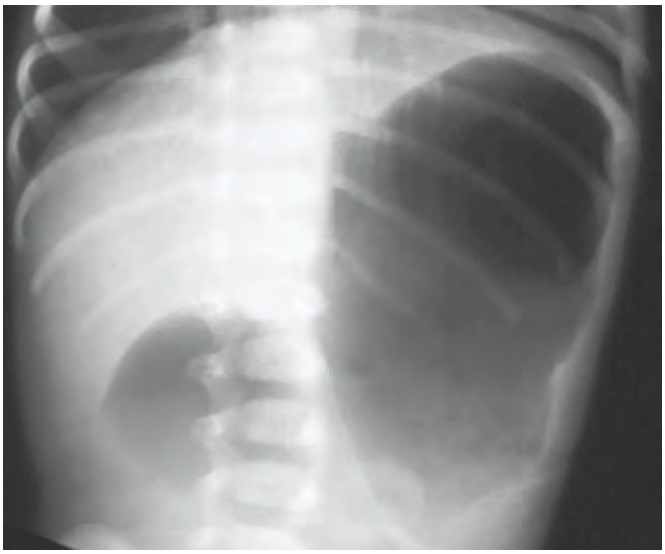

Figure 9.24 Neonatal abdominal x-ray showing the 'double bubble' of duodenal atresia.

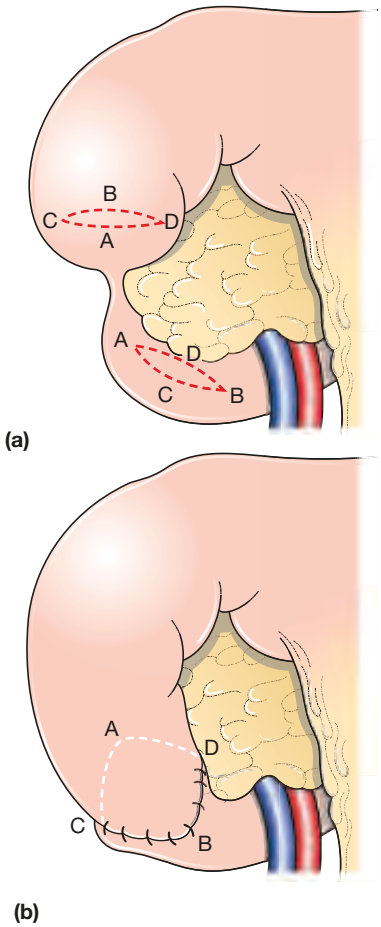

Figure 9.25 (a, b) Duodenal atresia and the incisions used to repair it: a diamond anastomosis is shown.

Jejunal/ileal atresias vary from an obstructing membrane through to widely separated blind-ended bowel ends associated with a mesenteric defect. Small bowel atresias may be single or multiple and are probably secondary to a prenatal vascular or mechanical insult causing sterile infarction of a segment of gut. They present with intestinal obstruction soon after birth. The proximal bowel is often extremely dilated and needs to be tapered prior to anastomosis to the distal bowel (Figure 9.26).

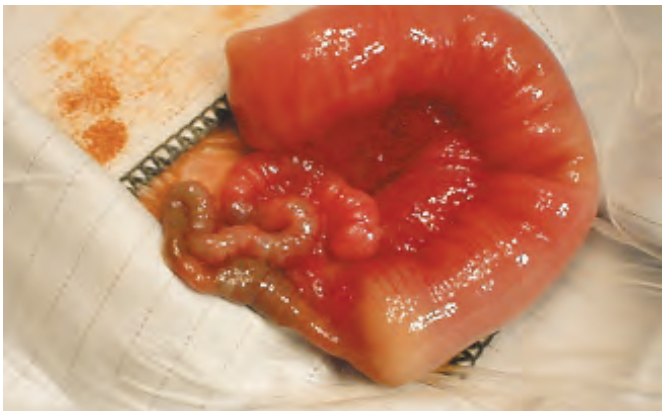

Figure 9.26 Small bowel atresia.

Meconium ileus is a cause of intestinal obstruction from inspissated meconium in the terminal ileum in neonates, most of whom have cystic fibrosis. Meconium is a mixture of epithelial cells, mucin and bile. Babies with uncomplicated meconium ileus (no associated atresia, volvulus or perforation) can sometimes be managed with hyperosmolar contrast enemas to clear the meconium.

Meconium peritonitis is consequent upon a fetal intestinal perforation. The baby is born with a firm, distended, discoloured abdomen and signs of obstruction. An abdominal x-ray shows dilated intestinal loops and areas of calcification. Occasionally, the perforation has resolved spontaneously before birth but most neonates with meconium peritonitis will need surgery. The peritonitic insult is chemical and not bacterial, although in late pregnancy meconium does contain bacteria.

Intestinal malrotation. By the 12th week of gestation, the midgut has returned to the fetal abdomen from the extraembryonic coelom and has begun rotating counterclockwise around the superior mesenteric artery axis. In classical intestinal malrotation, this process fails; the duodenojejunal flexure lies to the right of the midline and the caecum is central, creating a narrow base for the small bowel mesentery, which predisposes to midgut volvulus (Figure 9.27). Malrotation with volvulus is life-threatening and typically presents with bilious vomiting. Bile-stained vomiting in the infant is a sign of intestinal obstruction until proved otherwise.

As the gut strangulates, the baby may pass bloodstained stools and becomes progressively sicker. An upper gastrointestinal contrast study confirms the malrotation (Figure 9.27). Resuscitation and urgent surgery are needed to untwist the volvulus, widen the base of the small bowel mesentery, straighten the duodenum and position the bowel in a non-rotated position with the small bowel on the right and the colon on the left (Ladd's procedure). The appendix is usually removed to avoid leaving it in an abnormal site within the abdomen.

William Edward Ladd, 1880–1967, Professor of Child Surgery, The University of Harvard, Boston, MA, USA.

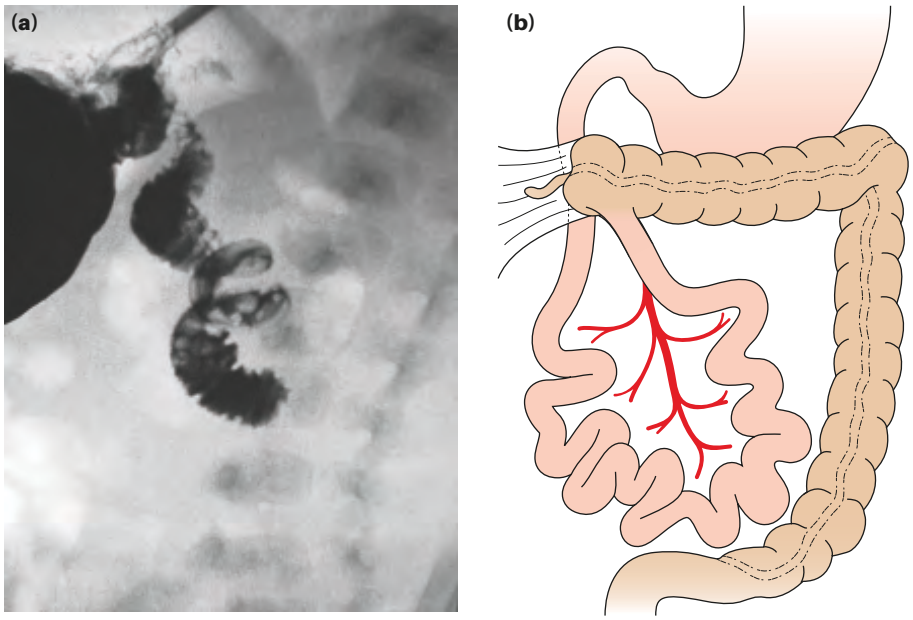

Figure 9.27 **(a)** Contrast showing malrotation with a volvulus. **(b)** The narrow origin of the small bowel mesentery predisposes to midgut volvulus.

Abdominal wall defects

Gastroschisis is now the commonest anomaly in babies born to mothers under 20 years of age. The fetal gut prolapses through a defect to the right of the umbilicus. At birth, the bowel is non-rotated, foreshortened and covered by a fibrinous peel (Figure 9.28). After reduction of the bowel, which may need to be staged using a silo, the defect is closed. A silo is a manufactured or hand-sewn plastic or silastic bag attached to the abdominal wall and, containing the herniated viscera, it is gently reduced every 12–24 hours. Gastroschisis has a good prognosis although gut dysmotility delays recovery. Some infants have an intestinal atresia, and some boys have undescended testes but other anomalies are rare.

Exomphalos is a distinctly different anomaly in which the intestines and sometimes the liver are covered with a membranous amniotic sac from which the umbilical cord arises (Figure 9.29). It may be associated with chromosomal or cardiac anomalies.

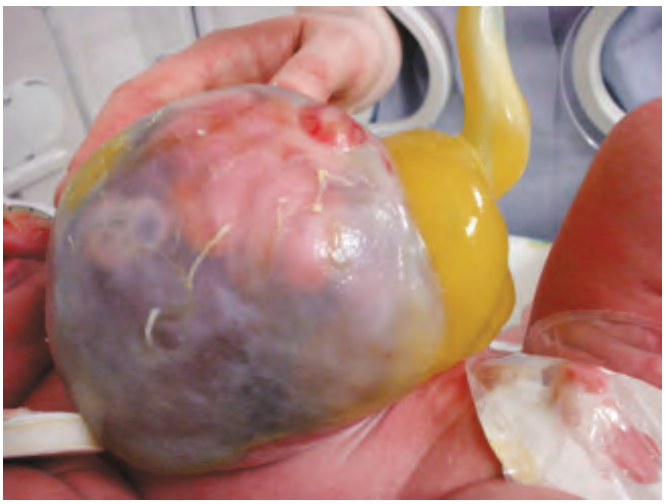

Figure 9.29 Exomphalos major.

Figure 9.28 A newborn infant with gastroschisis.

Biliary atresia

In biliary atresia the extrahepatic bile ducts are occluded, causing obstructive jaundice (conjugated hyper-bilirubinaemia) and progressive liver fibrosis in early infancy. It should be considered if jaundice persists after 2 weeks of age. Fat malabsorption can lead to a coagulopathy correctable with vitamin K. An abdominal ultrasound scan may show a small or absent gallbladder and no visible bile ducts, and a biliary radionuclide scan may show no excretion. A liver biopsy shows proliferation of small bile ducts. It is treated by a Kasai porto-enterostomy in which the occluded extrahepatic bile ducts are excised and a jejunal Roux loop anastomosed to the

Morio Kasai, 1922–2008, formerly Professor of Surgery, The University of Tokyo, Tokyo, Japan.

hepatic hilum. Effective drainage is more likely with surgery before 8 weeks of age and may obviate the subsequent need for liver transplantation.

Alimentary tract duplications

Alimentary tract duplications are rare and are usually single, variable in size and spherical or tubular. Most are located on the mesenteric border of the intestine. Typically, they are lined by alimentary tract mucosa and share a common smooth muscle wall and blood supply with the adjacent bowel, with which they may communicate. Duplications can contain heterotopic gastric mucosa and be associated with spinal anomalies. Most duplications present in infancy or early childhood with intestinal obstruction, haemorrhage, intussusception or perforation (**Figure 9.30**). Rarely, they present in adults and sometimes with a malignancy, which has been reported more often with rectal duplication cysts. Complete excision is the treatment of choice.

Figure 9.30 A duplicated colon; note the two appendices.

Hirschsprung's disease

Hirschsprung's disease is characterised by the congenital absence of intramural ganglion cells (aganglionosis) and the presence of hypertrophic nerves in the distal large bowel. The absence of ganglion cells is due to a failure of migration of vagal neural crest cells into the developing gut. The affected gut is in spasm, causing a functional bowel obstruction. The aganglionosis is restricted to the rectum and sigmoid colon in 75% of patients (short segment), involves the proximal colon in 15% (long segment) and affects the entire colon and a portion of terminal ileum in 10% (total colonic aganglionosis). A transition zone exists between the dilated, proximal, normally innervated bowel and the narrow, distal aganglionic segment.

Hirschsprung's disease may be familial or associated with Down syndrome or other genetic disorders. Gene mutations have been identified on chromosome 10 (involving the *RET* proto-oncogene) and on chromosome 13 in some patients. Hirschsprung's disease typically presents in the neonatal period with delayed passage of meconium, abdominal distension and bilious vomiting but it may not be diagnosed until later in childhood or even adult life, when it manifests as severe chronic constipation. Enterocolitis is a potentially fatal complication.

The diagnosis requires an adequate rectal biopsy and an experienced pathologist. A contrast enema may show the narrow aganglionic segment, a cone and the dilated proximal bowel (**Figure 9.31**). Surgery aims to remove the aganglionic segment and 'pull-through' ganglionic bowel to the anus (e.g. Swenson, Duhamel, Soave and transanal procedures), and can be done in a single stage or in stages after first establishing a proximal stoma in normally innervated bowel. Most patients achieve good bowel control but a significant minority experience residual constipation and/or faecal incontinence or further enterocolitis.

Figure 9.31 Barium enema in an infant, showing a 'transition zone' in the proximal sigmoid colon between the dilated proximal normally innervated bowel and the contracted aganglionic rectum.

Anorectal malformations

The anus is either imperforate or replaced by a fistula which does not pass through the muscle complex and opens away from the specialised skin which represents the true anal site. The sacrum and genitourinary tract are often abnormal. In boys, there may be a rectoperineal fistula but the most common anomaly is an imperforate anus with a rectobulbar urethral fistula (**Figure 9.32**). In girls, the commonest anomalies are a

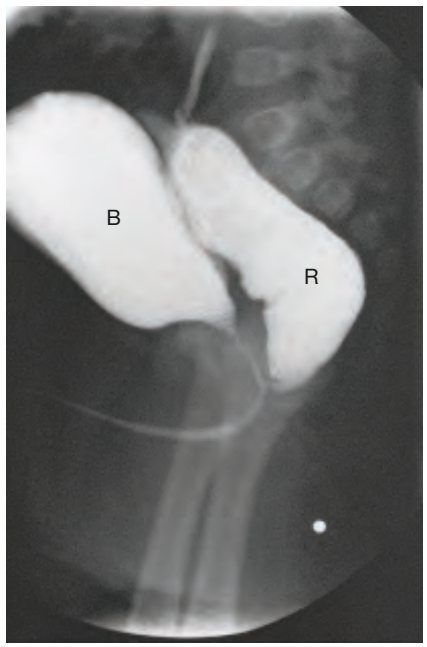

Figure 9.32 **(a)** An imperforate anus in a neonate associated with **(b)** a rectourethral fistula, visible on a contrast study performed via a sigmoid colostomy. The bladder is filled with contrast via the fistula and the radio-opaque dot has been placed on the infant's perineum over the normal site of the anus. B, bladder; R, rectum.

fistula opening in the posterior vestibule behind the vagina or on the perineum. Cloacal malformations, in which the rectum and genitourinary tract share a common outflow channel, are also seen in girls. Where there is a fistula, meconium can be passed and the diagnosis can be delayed for months because the perineum has not been inspected carefully. Most low malformations are treated by an anoplasty soon after birth. Higher, more complex defects need a temporary colostomy, detailed investigation and then reconstructive surgery. Functional outcome is related to the type of malformation and the integrity of the sacrum and pelvic muscles (low defects are associated with constipation, higher defects with faecal incontinence). For children with residual intractable faecal incontinence, antegrade colonic enemas administered via a catheterisable appendicostomy (**Figure 9.33**) (the Malone procedure) enable the child to achieve social continence.

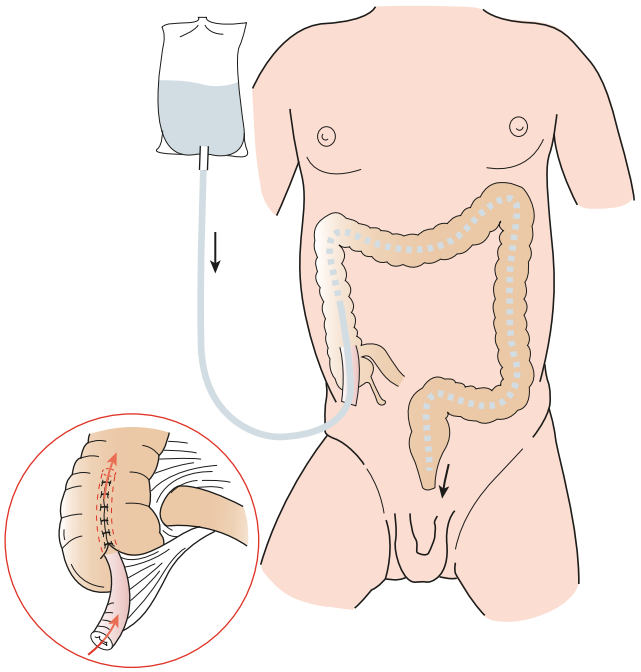

Figure 9.33 Appendicostomy for the delivery of antegrade colonic enemas.

Summary box 9.17

Congenital causes of intestinal obstruction

- Intestinal atresia: may be multiple
- Cystic fibrosis: can present with intestinal obstruction from inspissated meconium
- Intestinal malrotation: predisposes to potentially lethal midgut volvulus
- Alimentary tract duplications: may present with obstruction, haemorrhage or intussusception
- Hirschsprung's disease: typically presents with delay in passing meconium after birth
- Anorectal malformations

Urinary tract malformations

Many of these malformations are now detected by prenatal ultrasound scan. Others present in childhood with urinary infection, obstruction or an abdominal mass. Urinary tract disorders in children are investigated by urine microscopy and culture, ultrasound scan, assessment of renal function and a combination of radioisotope renography (uptake and excretion), contrast radiology and endoscopy.

In many infants, prenatally diagnosed mild to moderate hydronephrosis resolves spontaneously. Those with more significant pelviureteric junction obstruction may be asymptomatic or present in later childhood with urinary tract infection or loin pain. Pyeloplasty is indicated for symptoms or impaired renal function. In boys, partial membranous obstruction in the posterior urethra (valves) can cause a severe prenatal obstructive uropathy. This condition demands urgent investigation and treatment soon after birth to preserve bladder

Patrick Malone, paediatric urologist, Southampton, UK.

and kidney function. Renal failure develops in about one-third of affected boys despite early endoscopic ablation of the obstructing valves. Other congenital urinary tract malformations include ureteric abnormalities (e.g. duplex, ureterocoele, vesicoureteric reflux), multicystic dysplastic kidney and bladder exstrophy.

NECROTISING ENTEROCOLITIS

This is an acquired inflammatory condition of the neonatal gut, mostly affecting premature infants. Immaturity, formula feeds (breast milk is protective), bacterial infection and impaired gut blood flow are implicated in the pathogenesis. The neonate becomes septic, with abdominal distension, bloody stools and bilious aspirates. Patchy or extensive pneumatosis intestinalis progresses to necrosis and perforation (**Figure 9.34**). It commonly affects the terminal ileum and colon. Small intestinal loss can be sufficient to cause severe intestinal failure. Milder cases respond to antibiotics, gut rest and parenteral nutrition but severe cases need an urgent laparotomy. The mortality remains over 30%.

Figure 9.34 Operative appearance of neonatal necrotising enterocolitis.

PAEDIATRIC SURGICAL ONCOLOGY

Neoplasms, though less common in children than in adults, are, with trauma, a leading cause of death in those over 1 year of age. In the West, leukaemia, central nervous system (CNS) tumours, lymphomas, neuroblastomas and nephroblastomas account for most paediatric malignancies. Neuroblastoma and nephroblastoma are among the more common solid abdominal tumours. The prognoses for these cancers have improved after treatments have been refined following numerous multicentre trials.

Neuroblastoma is a malignancy of neuroblasts in the adrenal medulla or sympathetic ganglia and typically presents as an abdominal or paravertebral mass. These cells metastasise to lymph nodes, bone and the liver and raise urinary catecholamine levels. Small localised tumours are excised. Patients with more advanced tumours have surgery after chemotherapy. Survival relates to tumour biology and stage (>90% for small localised tumours, <50% for advanced tumours).

Wilms' tumour (nephroblastoma) is a malignant renal tumour derived from embryonal cells; it typically affects children from 1 to 4 years of age. A mutation in the Wilms' tumour suppressor gene (*WT1*) is responsible for some cases. Wilms' tumours usually present with an abdominal mass. The tumour can extend into the renal vein and vena cava and it metastasises to lymph nodes and lungs. Treatment is with chemotherapy and surgery. Survival depends on tumour spread, completeness of excision and the histological appearance but exceeds 70% even with advanced tumours.

SAFEGUARDING

All staff must be able to recognise abuse and neglect and know the law and their local child safeguarding contacts. In the UK three children die each week from neglect or abuse and half of these deaths are at the hands of the parents. One in a hundred emergency department attendances results from abuse. Consider abuse if any of the following are present: bruises away from bony prominences (face, back, abdomen, arms, buttocks, ears and hands); bruises in clusters or in the pattern of an implement; multiple injuries at different stages of healing; different types of injury (e.g. soft tissue, burns or scalds, cuts and bruises); rib fractures; bite marks (adult bites are difficult to distinguish from child bites, but adult bites are associated with fatal abuse); significant delay between the injury and seeking medical advice; an inconsistent or vague history; or inappropriate parental behaviour.

SERVICE DELIVERY AND SUMMARY

General Paediatric Surgeons working in District General Hospitals in the UK manage the common elective and acute problems of childhood that have been briefly outlined in this chapter for those older than 1 or 2 years. Specialist Paediatric Surgeons and Paediatric Urologists work mainly in regional units, providing a similar service up to age 16, but they also manage infants and neonates with a wide range of conditions. The principles of the speciality arise from the differences that are consequent upon age and development.

Chapter 10

Principles of oncology

Learning objectives

To understand:

- The biological nature of cancer
- That treatment is only one component in the overall management of cancer
- The principles of cancer prevention and early detection
- The principles underlying non-surgical treatments for cancer

To appreciate:

- The principles of cancer aetiology and the major known causative factors
- The likely shape of future developments in cancer management
- The multidisciplinary management of cancer
- The distinction between palliative care and end-of-life care
- The principles of palliative care

WHAT IS CANCER?

History

The name cancer from the Greek word for a crab (καρκινος), and refers to the claw-like blood vessels extending over the surface of an advanced breast cancer.

The study of cancer has always been a part of clinical medicine: theories have moved from divine intervention, through the humours, and are now firmly based on the cellular origin of cancer. Rudolf Virchow is credited with being first to demonstrate that cancer is a disease of cells and that the disease progresses as a result of abnormal proliferation, encapsulated by his famous dictum '*omnes cellula e cellula*' (every cell from a cell). In 1914, Theodor Boveri pointed out the importance of chromosomal abnormalities in cancer cells and, in the 1940s, Oswald Avery demonstrated that DNA was the genetic material within the chromosomes. In 1953, Watson and Crick described the structure of DNA and this key discovery paved the way for the study of the molecular biology of cancer. We can now investigate, and sometimes even understand, the biochemical mechanisms whereby cancer cells are formed and which mediate their abnormal behaviour.

The psychopath within

Cancer cells are psychopaths. They have no respect for the rights of other cells. They violate the democratic principles of normal cellular organisation. Their proliferation is uncontrolled; their ability to spread is unbounded. Their inexorable, relentless, progress destroys first the tissue and then the person.

In order to behave in such an unprincipled fashion, to become truly malignant, cells have to acquire a number of characteristics. No one characteristic is sufficient and not all characteristics are necessary. These features, based on articles by Hanahan and Weinberg, are summarised in *Summary box 10.1*.

Rudolf Ludwig Carl Virchow, 1821–1902, Professor of Pathology, Berlin, Germany.
Theodor Heinrich Boveri, 1862–1913, Professor of Zoology and Comparative Anatomy, Wurzburg, Germany.
Oswald Theodore Avery, 1877–1955, bacteriologist, Rockefeller Institute, New York, NY, USA.
James Dewey Watson, b.1928, American biologist who worked at Cambridge, UK, and later became Director of the Cold Spring Harbor Laboratory, New York, NY, USA.
Francis Harry Compton Crick, 1916–2004, British molecular biologist who worked at the Cavendish Laboratory, Cambridge, UK and later at the Salk Institute, San Diego, CA, USA. Watson and Crick shared the 1962 Nobel Prize for Physiology or Medicine with Maurice Hugh Frederick Wilkins, 1916–2004, of King's College, London.
Douglas Hanahan, b.1951, American biologist and director of the Swiss Institute for Experimental Cancer Research (ISREC), Lausanne, Switzerland.
Robert A Weinberg, b.1942, The Whitehead Institute of Biomedical Research and Department of Biology, The Massachusetts Institute of Technology, Cambridge, MA, USA.

Summary box 10.1

Features of malignant transformation

- Establish an autonomous lineage
  - Resist signals that inhibit growth
  - Sustain proliferative signalling
- Obtain replicative immortality
- Evade apoptosis
- Acquire angiogenic competence
- Acquire ability to invade
- Acquire ability to disseminate and implant
- Evocation of inflammation
- Evade detection/elimination
- Jettison excess baggage
- Subvert communication to and from the cellular environment
- Develop ability to change energy metabolism

Establish an autonomous lineage

Cells develop independence from the normal signals that control supply and demand. The healing of a wound is a physiological process; the cellular response is exquisitely coordinated so that proliferation occurs when it is needed and ceases when it is no longer required. The whole process is controlled by a series of signals telling cells when, and when not, to divide. Cancer cells escape from this normal system of checks and balances: they grow and proliferate in the absence of external stimuli; they proliferate and grow regardless of signals telling them to desist. Oncogenes, aberrant forms of normal cellular genes, are key factors in this process. They were originally identified as sequences within the genome of viruses that could cause cancer and were thought to be of viral origin but, surprisingly, turned out to be parts of the normal genome that were hitchhiking between cells, using the virus as a vector. Viral oncogenes (*v-onc*) had sequence homology with normal cellular genes (*c-onc*) and are now presumed to be mutated versions of genes concerned with normal cellular husbandry. The implication of this is that we all carry within us the seeds of our own destruction: genetic sequences that, through mutation, can turn into active oncogenes and thereby cause malignant transformation.

Obtain immortality

According to the Hayflick hypothesis, normal cells are permitted to undergo only a finite number of divisions. For humans this number is between 40 and 60. The limitation is imposed by the progressive shortening of the end of the chromosome (the telomere) that occurs each time a cell divides. Telomeric shortening is like a molecular clock and, when its time is up, the lineage will die out. Cancer cells can use the enzyme telomerase to rebuild the telomere at each cell division; there is no telomeric shortening, and the lineage will never die out. The cancer cell has achieved immortality.

Evade apoptosis

Apoptosis is a form of programmed cell death which occurs as the direct result of internal cellular events instructing the cell to die. Unlike necrosis, apoptosis is an orderly and internally driven process. The cell dismantles itself neatly for disposal (**Figure 10.1**). There is minimal inflammatory response. Apoptosis is a physiological process. Cells that find themselves in the wrong place normally die by apoptosis and this is an important self-regulatory mechanism in growth and development: cells in the web space of the embryo die by apoptosis, as do lymphocytes that could react to self. The process was rediscovered in 1972, and named apoptosis from the Greek αποπτωσις, indicating leaf fall. Genes, such as *p53*, that can activate apoptosis function as tumour suppressor genes. Loss of function in a tumour suppressor gene will contribute to malignant transformation. Cancer cells will be able to evade apoptosis, which means that the wrong cells can be in the wrong places at the wrong times.

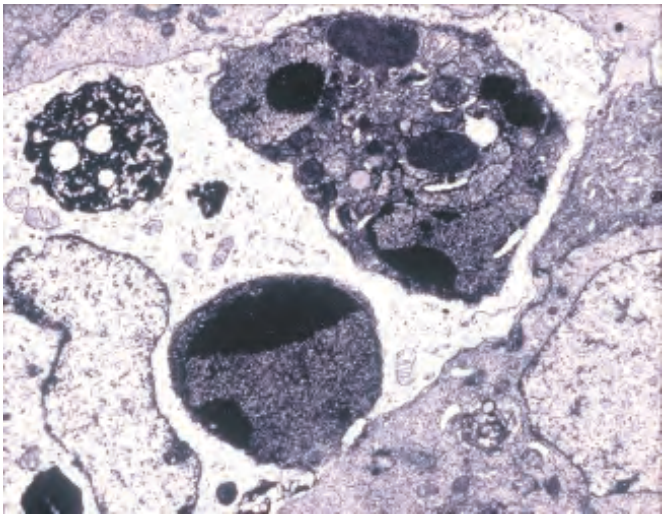

Figure 10.1 Electron micrograph of apoptotic bodies engulfed by a macrophage.

Acquire angiogenic competence

A mass of tumour cells cannot, in the absence of a blood supply, grow beyond a diameter of about 1 mm. This places a severe restriction on the capabilities of the tumour: it cannot grow much larger or spread widely within the body. If, however, the mass of tumour cells is able to attract or to construct a blood supply then it is able to quit its dormant state and behave in a far more aggressive fashion. The ability of a tumour to form blood vessels is termed 'angiogenic competence' and is a key feature of malignant transformation.

Acquire ability to invade

Cancer cells have no respect for the structure of normal tissues. They acquire the ability to breach the basement

Leonard Hayflick, b.1928, while working at the Wistar Institute in Philadelphia in 1962, he noted that normal mammalian cells growing in culture had a limited, rather than an indefinite, capacity for self-replication.

membrane and gain direct access to blood and lymph vessels. Cancer cells use three main mechanisms to facilitate invasion: (1) they cause a rise in the interstitial pressure within a tissue; (2) they secrete enzymes that dissolve extracellular matrix; and (3) they become mobile. Unrestrained proliferation and a lack of contact inhibition enable cancer cells to exert pressure directly on the surrounding tissue and push beyond the normal limits. They secrete collagenases and proteases that chemically dissolve any extracellular boundaries that would otherwise limit their spread through tissues and, by modulating the expression of cell-surface molecules called integrins, are able to detach themselves from the extracellular matrix. The abnormal integrins associated with malignancy can also transmit signals from the environment to the cytoplasm and nucleus of the cancer cells ('outside-in signalling') and these signals can induce increased motility. These processes are similar to those involved in normal development, in the migration of the neural crest or the formation of the heart. Epithelial cells behave as if they were mesenchymal cells and the process is termed 'epithelial–mesenchymal transition' (EMT). EMT is a crucial step in malignant transformation and many of the genes and proteins implicated in the formation of cancer control processes are involved in EMT, for example *Src*, *Ras*, integrins, *Wnt /b* –catenin, Notch.

Acquire ability to disseminate and implant, evocation of inflammation

Once cancer cells gain access to vascular and lymphovascular spaces, they have acquired the potential to use the body's natural distribution system. This is not, of itself, sufficient to cause tumours to develop at distant sites. The cells also need to acquire the ability to implant. As Paget pointed out over a century ago, there is a crucial relationship here between the seed (the tumour cell) and the soil (the distant tissue). Most of the cancer cells discharged into the circulation probably do not form viable metastases: circulating cancer cells can be identified in patients who never develop clinical evidence of metastatic disease. Clumping may be important in permitting metastases, the outer cells protecting the inner cells from immunological attack. These outer protective cells may, on occasion, be normal lymphocytes.

Cancer can spread in this embolic fashion but can also spread when individual cells migrate and implant. Whether spread occurs in groups or as individual cells there is still the problem of crossing the vascular endothelium (and basement membrane) to gain access to the tissue itself. Cancer cells probably implant themselves in distant tissues by exploiting, and subverting, the normal inflammatory response. By expressing inflammatory cytokines the cancer cells can fool the endothelium of the host tissue into becoming activated and allowing cancer cells access to the extravascular space. Activated endothelium expresses receptors that bind to integrins and selectins on the surface of cells, allowing them to move across the endothelial barrier.

Evade detection/elimination

Cancer cells are simultaneously both 'self' and 'not self'. Although derived from normal cells ('self') they are, in terms of their genetic make up, behaviour and characteristics, foreign ('not self'). As such, they ought to provoke an immune response and be eliminated, and it is entirely possible that malignant transformation is a more frequent event than the emergence of clinical cancer. The possible role of the immune system in eliminating nascent cancers was proposed by Paul Ehrlich in 1909 and revisited by both Sir Frank McFarlane Burnet and Lewis Thomas in the late 1950s. Cancer cells, or at least those that give rise to clinical disease, appear to gain the ability to escape detection by the immune system. This may be through suppressing expression of tumour associated antigens or it may be through actively co-opting one part of the immune system to help the tumour escape detection by other parts of the immune surveillance system.

Jettison excess baggage

Cancer cells are geared to excessive and remorseless proliferation. They do not need to develop or retain those specialised functions that make them good cellular citizens. They can therefore afford to repress or permanently lose those genes that control such functions. They become leaner and meaner. This may bring some short-term advantages. The longer-term disadvantage is that what is today superfluous may, tomorrow, be essential. This can leave cancer cells vulnerable to external stressors and may, in part, explain why some cancer treatments work.

Subvert communication to and from the environment/milieu

Providing false information is a classic military strategy. Degrading the command and control systems of the enemy is an essential component of modern warfare. Cancer cells almost certainly use similar tactics in their battle for control over their host. Given the complexity of communication between and within cells, this is not an easy statement either to disprove or to prove. Nor does it offer any easy targets for therapeutic manipulation.

Stephen Paget, 1855–1926, surgeon, The West London Hospital, London, UK. Paget's 'seed and soil' hypothesis is contained in his paper 'The distribution of secondary growths in cancer of the breast', in the *Lancet*, 1889.

Paul Ehrlich, 1854–1915, Professor of Hygiene, The University of Berlin, and later Director of The Institute for Infectious Diseases, Berlin, Germany. In 1908, he shared the Nobel Prize for Physiology or Medicine with **Elie Metchnikoff**, 1845–1916, 'in recognition of his work on immunity'. Metchnikoff was Professor of Zoology at Odessa in Russia, and later worked at the Pasteur Institute in Paris, France.

Sir Frank McFarlane Burnet, 1899–1985, Australian virologist, Walter and Eliza Hall Institute, Melbourne, Australia. Burnett shared the 1960 Nobel Prize for Physiology or Medicine with **Sir Peter Brian Medawar**, 1915–1987, Jodrell Professor of Zoology, University College, London, UK, 'for their discovery of acquired immunological tolerance'.

Lewis Thomas, 1913–1993, American pathologist and immunologist, who became President of the Sloan Kettering Memorial Institute, New York, NY, USA.

Develop ability to change energy metabolism

Blood flow in tumours is often sporadic and unreliable. As a result, cancer cells may have to spend prolonged periods starved of oxygen – in a state of relative hypoxia. Compared with the corresponding normal cells, some cancer cells may be better able to survive in hypoxic conditions. This ability may enable tumours to grow and develop despite an impoverished blood supply. Cancer cells can alter their metabolism even when oxygen is abundant; they break down glucose but do not, as normal cells would do, send the resulting pyruvate to the mitochondria for conversion, in an oxygen-dependent process, to carbon dioxide. This is the phenomenon of aerobic glycolysis, or the Warburg effect, and leads to the production of lactate. In an act of symbiosis, lactate-producing cancer cells may provide lactate for adjacent cancer cells which are then able to use it, via the citric acid cycle, for energy production. This cooperation is similar to that which occurs in skeletal muscle during exercise.

Malignant transformation

The characteristics of the cancer cell arise as a result of mutation. Only very rarely is a single mutation sufficient to cause cancer; multiple mutations are usually required. Colorectal cancer provides the classical example of how multiple mutations are necessary for the complete transformation from normal cell to malignant cell. Vogelstein and his colleagues identified the genes required and also postulated not only that it is necessary to have mutations in all the relevant genes, but also that these mutations must be acquired in a specific sequence.

Cancer is usually regarded as a clonal disease. Once a cell has arisen with all the mutations necessary to make it fully malignant, it is capable of giving rise to an infinite number of identical cells, each of which is fully malignant. These cells divide, invade, metastasise and destroy but, ultimately, each is the direct descendant of that original, primordial, transformed cell. There is certainly evidence, mostly from haematological malignancies, to support the view that tumours are monoclonal in origin, but recent evidence challenges the universality of this assumption. Some cancers may arise from more than one clone of cells. Epigenetic modification refers to hereditable changes in DNA that are not related to the nucleotide sequence of the molecule. Epigenetic modification may give rise to distinct cancer cell lineages with differing biological properties. The interactions between cells from each lineage and the tissue within which such cells find themselves may determine the overall clinical behaviour of a tumour.

Two mechanisms may help to sustain and accelerate the process of malignant transformation: genomic instability and tumour-related inflammation.

Genomic instability

A cancer is in a genetic ferment. Cells are dividing without proper checks and balances. Mutations are arising all the time within tumours and some of these mutations, particularly those in tumour suppressor genes, may have the ability to encourage the development and persistence of further mutations. This gives rise to the phenomenon of genomic instability – as it evolves, a cancer contains an increasing variety and number of genetic aberrations. The greater the number of such abnormalities, the greater the chance of increasingly deviant behaviour, and the pace of malignant transformation accelerates.

Tumour-related inflammation

If a tumour provokes an inflammatory response then the cytokines and other factors produced as a result of that response may act to promote and sustain malignant transformation. Growth factors, mutagenic ROS (reactive oxygen species), angiogenic factors and antiapoptotic factors may all be produced as part of an inflammatory process and all may contribute to the progression of a tumour.

A recurring theme in the molecular biology of cancer is that systems and pathways can behave unpredictably – activation may sometimes promote, and sometimes inhibit, growth and transformation. This has important implications for therapy: treatments designed to inhibit the growth and spread of cancer may, occasionally, have precisely the opposite effect. The most consistent feature of cancer is its lack of consistency.

The growth of a tumour

If it is accepted that a cancer starts from a single transformed cell then it is possible, using straightforward arithmetic, to describe the progression from a single cell to a mass of cells large enough to kill the host. The division of a cell produces two daughter cells. The relationship 2^n will describe the number of cells produced after n generations of division. There are between 10^{13} and 10^{14} cells in a typical human being. A tumour 10 mm in diameter will contain about 10^9 cells. Since $2^{30} = 10^9$ this implies that it would take 30 generations to reach the threshold of clinical detectability and, as $2^{45} = 3 \times 10^{13}$, it will take fewer than 15 subsequent generations to produce a tumour that, through sheer bulk alone, would be fatal. This is an oversimplification because cell loss is a feature of many tumours, and for squamous cancers as many as 99% of the cells produced may be lost, mainly by exfoliation. It will, in the presence of cell loss, take many cellular divisions to produce a clinically evident tumour – abundant opportunity for further mutations to occur during the preclinical phase of tumour growth. The growth of a typical human tumour can be described by an exponential relationship, the doubling time of which increases exponentially – so-called Gompertzian growth (**Figure 10.2**). This

Otto Warburg, 1883–1970, chemist, Director of the Kaiser Wilhelm Institute for Cell Physiology, Berlin-Dahlem. Awarded the Nobel Prize for Physiology or Medicine in 1931 for 'his discovery of the nature and mode of action of the respiratory enzyme'.

Bert Vogelstein, b.1949, molecular biologist, Johns Hopkins Hospital, Baltimore, MD, USA.

Benjamin Gompertz, 1779–1865, an insurance actuary who was interested in calculating annuities. To do this, he needed to describe mathematically the relationship between life-expectancy and age. He was able to do this using the function that bears his name. The Gompertzian function provides an excellent fit to data points plotting tumour size against time.

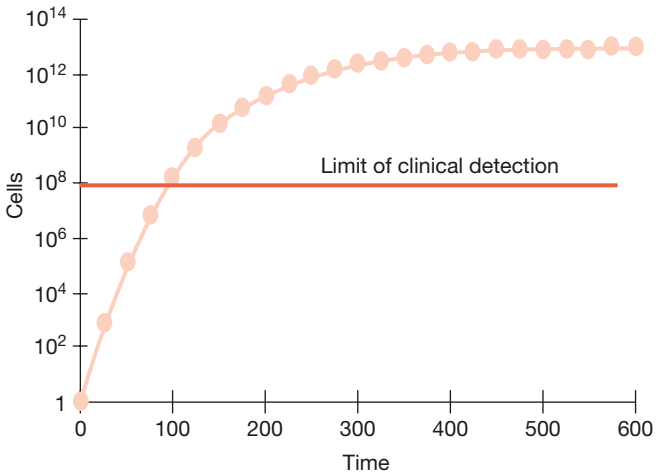

Figure 10.2 The Gompertzian curve describing the growth of a typical tumour. In its early stages, growth is exponential but, as the tumour grows, the growth rate slows. This decrease in growth rate probably arises because of difficulties with nutrition and oxygenation. The tumour cells are in competition: not only with the tissues of the host, but also with each other.

Gompertzian pattern has several important implications for the diagnosis and treatment of cancer.

Summary box 10.2

The implications of Gompertzian growth

- The majority of the growth of a tumour occurs before it is clinically detectable
- By the time they are detected, tumours have passed the period of most rapid growth, that period when they might be most sensitive to antiproliferative drugs
- There has been plenty of time, before diagnosis, for individual cells to detach, invade, implant, and form distant metastases. In many patients cancer may, at the time of presentation, be a systemic disease
- 'Early tumours' are genetically old, yielding many opportunities for mutations to occur, mutations that might confer spontaneous drug resistance (a probability greatly increased by the existence of cell loss)
- The rate of regression of a tumour will depend upon its age (the Norton–Simon hypothesis extends this: chemotherapy results in a rate of regression in tumour volume that is proportional to the rate of growth for an unperturbed tumour of that size)

THE CAUSES OF CANCER

The interplay between nature and nurture

Both inheritance and environment are important determinants of cancer development. Neither influence is totally dominant. Using a familiar example, not all smokers develop lung cancer; lung cancer can occur in people who have never smoked. The debate concerning the relative importance of the two factors has recently become polarised, Tomasetti and Vogelstein claiming that cancer is largely a random process ('bad luck); the contrary view, expressed by Wu, Powers and colleagues, is that extrinsic risk factors make a substantial contribution to the development of cancer. The likelihood is that both sides are correct, but each only partially.

Knowledge about the causes of cancer can be used to design appropriate strategies for prevention or earlier diagnosis. As we find out more about the genes associated with cancer, genetic testing and counselling will play an increasing role in the prevention of cancer. These considerations are incorporated into *Table 10.1*, on the inherited cancer syndromes, and in *Table 10.2*, on the environmental contribution to cancer.

THE MANAGEMENT OF CANCER

Management is more than treatment

The traditional approach to cancer concentrates on diagnosis and active treatment. This is a very limited view that, in terms of the public health, may not have served society well. It implies a fatalistic attitude to the occurrence of cancer and an assumption that, once active treatment is complete, there is little more to be done. Prevention is forgotten and rehabilitation is ignored.

A more comprehensive view considers the management of cancer as taking place along two axes: one is an axis of scale, from the individual to the world population; the other is an axis based on the unnatural history of the disease, from prevention through to rehabilitation or palliative care (**Figure 10.3**).

Figure 10.3 The management of cancer spans the natural history of the disease and all humankind, from the individual to the population of the world.

Prevention

The World Cancer Research Fund has published an extensive view of the evidence on the preventable causes of cancer; their conclusion is that many cancers could be prevented if

TABLE 10.1 Inherited syndromes associated with cancer.

Syndrome	Gene(s) implicated	Inheritance	Associated tumours and abnormalities	Strategies for prevention/ early diagnosis
Familial adenomatous polyposis (FAP)/ Gardner syndrome	*APC* gene	D	Colorectal cancer under the age of 25 Papillary carcinoma of the thyroid Cancer of the ampulla of Vater Hepatoblastomas Primary brain tumours (Turcot syndrome) Osteomas of the jaw CHRPE (congenital hypertrophy of the retinal pigment epithelium)	Prophylactic panproctocolectomy
Hereditary non-polyposis colorectal cancer (HNPCC)	DNA mismatch repair genes (*MLH1*; *MSH2*; *MSH6*)	D	Colorectal cancer (typically in 40s and 50s)	Surveillance colonoscopies / polypectomies Non-steroidal anti-inflammatory drugs
HNPCC1	*MSH2*		Endometrium, stomach, hepatobiliary (Lynch syndrome 1)	
HNPCC2	*MLH1*			
HNPCC3	*PMS1*			
Peutz–Jeghers syndrome	*STK11*	D	Bowel cancer; breast cancer; freckles round the mouth	Surveillance colonoscopy; mammography
Cowden* syndrome	*PTEN*	D	Multiple hamartomas of skin, breast and mucous membranes Breast cancer Neuroendocrine tumours Endometrial cancer Thyroid cancer	Active surveillance
Retinoblastoma	*RB*	D	Retinoblastoma Pinealoma Osteosarcoma	Surveillance of uninvolved eye
Multiple endocrine neoplasia (MEN) Type 1	*Menin*	D	Parathyroid tumours Islet cell tumours Pituitary tumours	Awareness of associations and paying attention to relevant symptoms
MEN Type 2A	*RET*	D	Medullary carcinoma of the thyroid Phaeochromocytoma Parathyroid tumours	Regular screening of blood pressure, serum calcitonin and urinary catecholamines Prophylactic thyroidectomy
MEN2b	*RET*	D	Medullary carcinoma of the thyroid; phaeochromocytoma; mucosal neuromas; ganglioneuromas of the gut	Regular screening of blood pressure, serum calcitonin and urinary catecholamines; Prophylactic thyroidectomy
Li–Fraumeni	*P53*	D	Sarcomas Leukaemia Osteosarcomas Brain tumours Adrenocortical carcinomas	Very difficult, since pattern of tumours is so heterogeneous and varies from patient to patient
Familial breast cancer	*BRCA1; BRCA2*	D	Breast cancer Ovarian cancer Papillary serous carcinoma of the peritoneum Prostate cancer	Screening mammography; pelvic ultrasound; PSA (in males) Prophylactic mastectomy; prophylactic oophorectomy

TABLE 10.2 Environmental causes of cancer (and suggested measures for reducing their impact) – *continued*.

Environmental/behavioural factor			Associated tumours	Strategy for prevention/early diagnosis
Viral infections	Human papillomavirus (HPV)		Cervical cancer Penile tumours	Avoid unprotected sex Vaccination
	Human immunodeficiency virus (HIV)		Kaposi's sarcoma Lymphomas Germ cell tumours Anal cancer	Avoid unprotected sex Antiretroviral therapy
	Hepatitis B		Hepatoma	Avoid contaminated injections/ infusions Vaccination
Other infections	Bilharzia		Bladder cancer	Treatment of infection Cystoscopic surveillance
	Helicobacter pylori		Stomach cancer	Eradication therapy
Inhaled particles	Asbestos		Mesothelioma	Protect workers from inhaled dusts and fibres
	Wood dust		Paranasal sinus cancers	
Chemicals	Environmental pollutants/chemicals used in industry		Angiosarcoma (vinyl chloride) Bladder cancer (aniline dyes, vulcanisation of rubber) Lung, nasal cavity (nickel) Skin (arsenic) Lung (beryllium, cadmium, chromium) All sites (dioxins)	Protection of exposed workers; avoid chemical discharge and spillages
	Medical	Alkylating agents used in cytotoxic chemotherapy	Leukaemia Lymphoma Lung cancer	Avoid over-treatment; only combine drugs with ionising radiation when absolutely necessary
		Immunosuppressive treatment	Kaposi's sarcoma	As low a dose as possible, for as short a period as possible
		Stilboestrol	Adenocarcinoma of vagina in daughters of treated mothers	Use of stilboestrol curtailed
		Tamoxifen	Endometrial cancer	Biopsy if patient on tamoxifen develops uterine bleeding
Fungal and plant toxins	Aflatoxins		Hepatoma	Appropriate food storage, screen for fungal contamination of foodstuffs
Obesity/lack of physical exercise			Breast Endometrium Kidney Colon Oesophagus	Maintain ideal body weight, regular exercise

people ate sensibly and exercised more. This advice supplements the preventative measures outlined in *Table 10.2*.

Screening

Screening involves the detection of disease in an asymptomatic population in order to improve outcomes by early diagnosis. It follows that a successful screening programme must achieve early diagnosis and that the disease in question has a better outcome when treated at an early stage. The criteria which must be fulfilled for the disease, screening test and the screening programme itself are given in *Summary box 10.3*. Merely to prove that screening picks up disease at an early stage, and that the outcome is better for patients with screen-detected disease than for those who present with symptoms, is an insufficient criterion for the success of a screening programme. This is because of inherent biases in screening (lead time bias, selection bias and length bias) which make screen-detected disease appear to be associated with better outcomes than symptomatic disease.

Lead time bias describes the phenomenon whereby early detection of a disease will always prolong survival from the time of diagnosis when compared to disease picked up at a later stage in its development whether or not the screening process has altered the progression of the tumour (**Figure 10.4**). Selection bias describes the finding that individuals who accept an invitation for screening are, in general, healthier than those who do not. It follows that individuals with screen-detected disease will tend to live longer, independently of the condition for which screening is being

Moritz Kaposi (originally Kohn), 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

Summary Box 10.3

Criteria for screening

The disease:

- Recognisable early stage
- Treatment at early stage more effective than at later stage
- Sufficiently common to warrant screening

The test:

- Sensitive and specific
- Acceptable to the screened population
- Safe
- Inexpensive

The programme:

- Adequate diagnostic facilities for those with a positive test
- High quality treatment for screen-detected disease to minimise morbidity and mortality
- Screening repeated at intervals if disease of insidious onset
- Benefit must outweigh physical and psychological harm

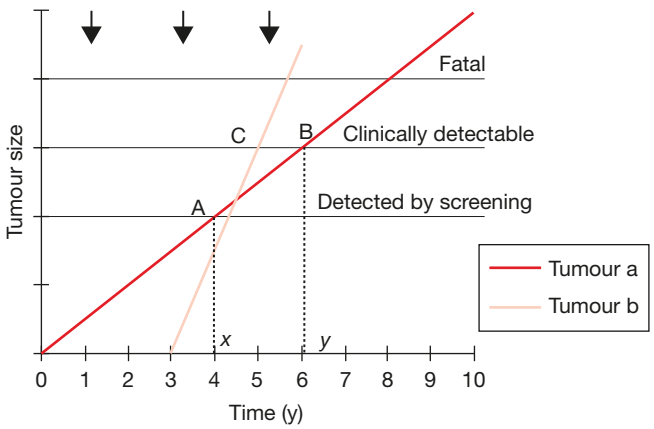

Figure 10.4 An illustration of lead-time and length bias. Tumour a is a steadily growing tumour, its progress is uninfluenced by any treatment. The arrows indicate the timing of tests in a screening programme. The horizontal lines indicate three thresholds: detectability by screening; clinical detectability; and death due to tumour progression. Point A indicates the time at which the tumour would be diagnosed in a screening programme, and point B indicates the time at which the tumour would be diagnosed clinically, that is, in the absence of any screening programme. If the date of diagnosis is used as the start time for measuring survival, then it is clear that, in the absence of any effect from treatment, the screening programme will, artefactually, add to the survival time. The amount of 'increased' survival is equal to $y - x$ years, in this example just over 2 years. This artefactual inflation of survival time is referred to as lead-time bias.

Tumour b is a rapidly growing tumour, again its progress is uninfluenced by treatment. It grows so rapidly that, in the interval between two screening tests, it can cross both the threshold for detectability by screening and that of clinical detectability. It will continue to progress rapidly after diagnosis and the measured survival time will be short. This phenomenon, whereby those tumours that are 'missed' by the screening programme are associated with decreased survival, is called length time bias.

performed. Length bias occurs because slow-growing tumours are likely to be picked up by screening whereas fast-growing tumours are likely to arise and produce symptoms in between screening rounds. Screen-detected tumours will therefore tend to be less aggressive than symptomatic tumours. Because of these biases it is essential to carry out population-based randomised controlled trials and to compare the mortality rate in a whole population offered screening (including those who refuse to be screened and those who develop cancer after a negative test) with the mortality rate in a population which has not been offered screening. This research design has been applied to both breast cancer and colorectal cancer: in both cases there was reduction in disease-specific mortality.

Diagnosis and classification

Accurate diagnosis is the key to the successful management of cancer. Precise diagnosis is crucial to the choice of correct therapy; the wrong operation, no matter how superbly performed, is useless. An unequivocal diagnosis is the key to an accurate prognosis. Only rarely can a diagnosis of cancer be confidently made in the absence of tissue for pathological or cytological examination. Cancer is a disease of cells and, for accurate diagnosis, the abnormal cells need to be seen. Different tumours are classified in different ways: most squamous epithelial tumours are simply classed as well (G1), moderate (G2) or poorly (G3) differentiated. Adenocarcinomas are also often classified as G1, 2 or 3 but prostate cancer is an exception, with widespread use of the Gleason system. The Gleason system grades prostate cancer according to the degree of differentiation of the two most prevalent architectural patterns. The final score is the sum of the two grades and can vary from 2 (1+1) to 10 (5+5) with the higher scores indicating poorer prognosis.

The management of malignant lymphomas is based firmly upon histopathological classification: the first distinction is between Hodgkin's lymphoma (HL) and the non-Hodgkin's lymphomas (NHL). Each of these main types of lymphoma is then subclassified according to a different scheme. The World Health Organization/Revised European–American Lymphoma (WHO/REAL) system classifies Hodgkin's lymphoma into classical HL (nodular sclerosis HL; mixed-cellularity HL; lymphocyte depletion HL; lymphocyte-rich classical HL) and nodular lymphocyte-predominant HL. The WHO/REAL classification of NHL is considerably more complex and recognises 27 distinct pathological subtypes. It is perhaps no coincidence that the non-surgical treatment of lymphomas is, by and large, more successful than the non-surgical treatment of solid tumours. This suggests that precise and accurate subtyping of tumours enables appropriate selection of treatment and, in turn, this is associated with better outcome. The development, over the next decade, of molecular classifiers will profoundly alter our approach. Diseases such as breast cancer and colorectal cancer will become subdivided into a plethora of molecularly distinct entities.

Donald F Gleason, b.1920, pathologist, The University of Minnesota, Minneapolis, MN, USA.
Thomas Hodgkin, 1798–1866, curator of the Museum and demonstrator of Morbid Anatomy, Guy's Hospital, London, UK, described lymphadenoma in 1832.

Investigation and staging

It is not sufficient simply to know what a cancer is; its site and extent must also be known. If it is localised, then locoregional treatments such as surgery and radiation therapy may be curative. If the disease is widespread then, although such local interventions may contribute to cure, they will be insufficient and systemic treatment, for example with drugs or hormones, will also be required.

Staging is the process whereby the extent of disease is mapped out. Staging used to be a fairly crude process based on clinical examination, chest x-ray and the occasional ultrasound; nowadays it is a highly sophisticated process, heavily reliant on the technology of modern imaging. These technological advances bring with them the implication that patients staged as having localised disease in 2017 are not comparable to patients described in 1985 as having localised disease. Many of these latter patients would, had they been imaged using the technology of 2017, have had occult metastatic disease detected. This leads to the paradox of stage shift, also named, by Alvan Feinstein, the Will Rogers phenomenon. A change in staging system, or in the techniques used to provide baseline information concerning staging, can produce 'benefits' to patients in all stages of the disease. These benefits are, however, entirely artefactual and depend simply upon patients in each stage being enriched by patients with improved prognosis. The important cross-check to protect against being misled by stage shift is that the prognosis for the entire group (i.e. all stages pooled) has not been changed. *Table 10.3* shows a worked example of stage shift.

The UICC (International Union against Cancer) is responsible for the TNM (tumour, nodes, metastases) staging system for cancer. This system is compatible with, and relates to, the American Cancer Society (AJCC) system for stage grouping of cancer. Examples of clinicopathological staging systems for colon cancer are shown in *Tables 10.4 and 10.5*.

Therapeutic decision making and the multidisciplinary team

As the management of cancer becomes more complex, it becomes impossible for any individual clinician to have the intellectual and technical competence that is necessary to manage all patients presenting with a particular type of tumour. The formation of multidisciplinary teams represents an attempt to make certain that each and every patient with a particular type of cancer is managed appropriately. Teams should not only be multidisciplinary, they should be multiprofessional. The advantages and disadvantages of multidisciplinary teams are summarised in *Table 10.6*.

Summary box 10.4

The composition of the multidisciplinary team

- Site-specialist surgeon
- Surgical oncologist
- Plastic and reconstructive surgeon
- Clinical oncologist/radiotherapist
- Medical oncologist
- Diagnostic radiologist
- Palliative care physician
- Pathologist
- Speech therapist
- Physiotherapist
- Prosthetist
- Clinical nurse specialist (rehabilitation, supportive care)
- Macmillan nurse (symptom control, palliative care)
- Social worker/counsellor
- Medical secretary/administrator
- Audit and information coordinator

Principles of cancer surgery

For most solid tumours, surgery remains the definitive treatment and the only realistic hope of cure. However, surgery has several roles in cancer treatment including diagnosis, removal of primary disease, removal of metastatic disease, palliation, prevention and reconstruction.

Diagnosis and staging

In most cases the diagnosis of cancer has been made before definitive surgery is carried out but occasionally a surgical

TABLE 10.3 Stage shift: the cure rate improves in both Stage I and Stage IV, and there is no change in cure rates for Stage II and Stage III, after the introduction of a new staging investigation. The overall cure rate is, however, unchanged.

Before new staging test				After new staging test				
Stage	Distribution	Cure rate	Number cured	Stage	Distribution	Cure rate	Number cured	% 'improvement' in cure rate
I	70%	90%	63	I	50%	94%	47	4%
II	10%	80%	8	II	10%	80%	8	0%
III	10%	80%	8	III	10%	80%	8	0%
IV	10%	50%	5	IV	30%	70%	21	20%
All	100%		84	All	100%		84	0%

Alvan Feinstein, 1926–2001, American clinician and epidemiologist.
Will Rogers (properly William Penn Adair Rogers), 1879–1935, American actor, humorist and wit.
There is much confusion about the use of the terms '**multidisciplinary**' and '**multiprofessional**': we use 'multidisciplinary' to imply the presence of various medically qualified specialists (pathologists, radiologists, etc.) and 'multiprofessional' implies the presence of specialists from non-medical backgrounds (nurses, social workers, radiographers).

TABLE 10.4 Staging of colorectal cancer.

TNM	
TX, Primary tumour cannot be assessed	
T0, No evidence of primary tumour	
Tis, Intraepithelial or intramucosal carcinoma	
T1, Tumour invades submucosa	
T2, Tumour invades muscularis propria	
T3, Tumour invades through the muscularis propria into the subserosa or into retroperitoneal (pericolic or perirectal) tissues	a, Minimal invasion: <1 mm beyond muscularis
	b, Slight invasion: 1–5 mm beyond muscularis
	c, Moderate invasion: >5–15 mm beyond muscularis
	d, Extensive invasion: >15 mm beyond muscularis
T4, Tumour directly invades beyond bowel	a, Direct invasion into other organs or structures
	b, Perforates visceral peritoneum
NX, Regional lymph nodes cannot be assessed

procedure is required to make the diagnosis. This is particularly true of patients with malignant ascites where laparoscopy has an important role in obtaining tissue for diagnosis. Laparoscopy is also widely used for the staging of intra-abdominal malignancy, particularly oesophageal and gastric cancer. By this means it is often possible to diagnose widespread peritoneal disease and small liver metastases that may have been missed on cross-sectional imaging. Laparoscopic ultrasound is a particularly useful adjunct for the diagnosis of intrahepatic metastases. Other examples where surgery is central to the diagnosis of cancer include orchidectomy where a patient suspected of testicular cancer and lymph node biopsy in a patient with lymphoma. Recently, sentinel node biopsy in melanoma and breast cancer has attracted a great deal of interest. Here a radiolabelled colloid is injected into or around the primary

TABLE 10.6 The advantages and disadvantages of the multidisciplinary team.

Advantages	Disadvantages
Open debate concerning management	An opportunity for rampant egotism and showing-off
Patient has advantage of many simultaneous opinions from many different specialities	Less confident and less articulate members of the team may not be able to express their views, even though their views may be extremely important
Decision-making is open, transparent and explicit	May degenerate into a rubber-stamping exercise in which the class solutions implied by guidelines are unthinkingly applied to disparate individuals
Team members educate each other	Decisions are made in the absence of patients and their carers: the commodification of the person
A useful educational experience for trainees and students	Clinicians are able to avoid having to take responsibility for their decisions and their actions: the fig-leaf of 'corporate responsibility'
Performance can be monitored by managers	Time-consuming and resource-intensive: takes busy clinicians away from clinical practice for hours at a time

Vernon B Astler, surgeon, The Medical School of the University of Michigan, Ann Arbor, MI, USA.
Frederick A Coller, pathologist, The Medical School of the University of Michigan, Ann Arbor, MI, USA.
Cuthbert Esquire Dukes, 1890–1977, pathologist, St Mark's Hospital, London, UK.

tumour and the regional lymph nodes are then scanned with a gamma camera which will pinpoint the lymph node nearest to the tumour. This lymph node can then be removed for histological diagnosis. Staging laparotomy used to be an important aspect of the staging of lymphomas but with more accurate cross-sectional imaging and the more widespread use of chemotherapy this practice is now largely redundant.

Removal of primary disease

Radical surgery for cancer involves removal of the primary tumour and as much of the surrounding tissue and lymph node drainage as possible in order not only to ensure local control but also to prevent spread of tumour through the lymphatics. Although the principle of local control is still extremely important, it is now recognised that ultra-radical surgery probably has little effect on the development of metastatic disease, as evidenced by the randomised trials of radical versus simple mastectomy for breast cancer. It is important, however, to appreciate that high quality, meticulous surgery taking care not to disrupt the primary tumour at the time of excision is of the utmost importance in obtaining a cure in localised disease and in preventing local recurrence.

Removal of metastatic disease

Under certain circumstances surgery for metastatic disease may be appropriate. This is particularly true for liver metastases arising from colorectal cancer where successful resection of all detectable disease can lead to long-term survival in about one-third of patients. With multiple liver metastases, it may still be possible to take a surgical approach by using *in situ* ablation with cryotherapy or radiofrequency energy. Another situation in which surgery may be of value is pulmonary resection for isolated lung metastases, particularly from renal cell carcinoma.

Palliation

In many cases surgery is not appropriate for cure but may be extremely valuable for palliation. A good example of this is the patient with a symptomatic primary tumour who also has distant metastases. In this case, removal of the primary will increase the patient's quality of life but will have little effect on the ultimate outcome. Other situations where surgical palliation is appropriate include bypass procedures such as an ileo-transverse anastomosis to alleviate symptoms of obstruction caused by an inoperable caecal cancer or bypassing an unresectable carcinoma at the head of the pancreas by cholecysto- or choledocho-jejunostomy to alleviate jaundice.

Principles underlying the non-surgical treatment of cancer

The relationship between dose and response and the principle of selective toxicity

Non-surgical treatments, in common with surgery, have the potential to cause harm as well as benefit. Surgery is difficult to quantify: it is hard to describe a mastectomy in units of measure. Both drugs and radiation can be expressed in reproducible units: milligrams, in the case of drugs; Grays (Gy), in the case of radiation. Thus, in contrast to surgery, it is possible to construct dose–response relationships for both the benefits (such as tumour cure rate) and the harms (such as tissue damage that is both severe and permanent) associated with non-surgical interventions. These curves (see **Figure 10.5**) have the same general shape: they are sigmoidal. The practical consequence of this is that, over a relatively narrow dose range, we move from failure to success, from tolerability to disaster. It is theoretically possible to use dose–response curves to calculate an optimal dose for treating each tumour: the dose is that which is associated with the maximal probability of an uncomplicated cure. Lying behind the concept of the probability of an uncomplicated cure is the principle of selective toxicity: the treatment should be selectively toxic to the tumour and, as far as possible, should spare the normal tissues from damage. It is this simple principle that underpins both the selection of agents used to treat cancer and the schedules used to deliver them. Although the graphical representations of the relationships between, dose, response and the probability of uncomplicated cure are conceptually simple and intuitively appealing they are, in clinical practice, completely impractical. The construction of full dose–response curves for all possible combinations of tumours and normal tissues is neither feasible nor ethical. We have to rely, when it comes to defining optimal doses and schedules, upon incomplete clinical data and a knowledge of the general shape of the relationship between dose and response.

Personalised (precision) medicine

Advances in molecular biology and pharmacogenomics are providing insights into the ways in which tumours and normal tissues might behave in response to treatment. Employing this knowledge, at the level of the individual patient, has become known as **personalised medicine**, or **precision medicine**. *Table 10.7* summarises how a personalised approach, based on knowledge of the relative sensitivities of tumour and normal tissues, might modify therapeutic decisions.

TABLE 10.7 Personalised dose adjustment.

Normal tissue	Tumour	Dose
N	N	Usual dose
N	S	Lower dose
N	R	Use different Rx
S	N	Use different Rx
S	S	Lower dose
S	R	Use different Rx
R	N	Use higher dose
R	S	Usual dose
R	R	Use different Rx

N, normal sensitivity; R, resistant to treatment; Rx, treatment; S, increased sensitivity.

in situ is Latin for 'in the place'.

Louis Harold Gray, 1905–1965, Director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, UK. A Gray (Gy) is the SI unit for the absorbed dose of ionising radiation.

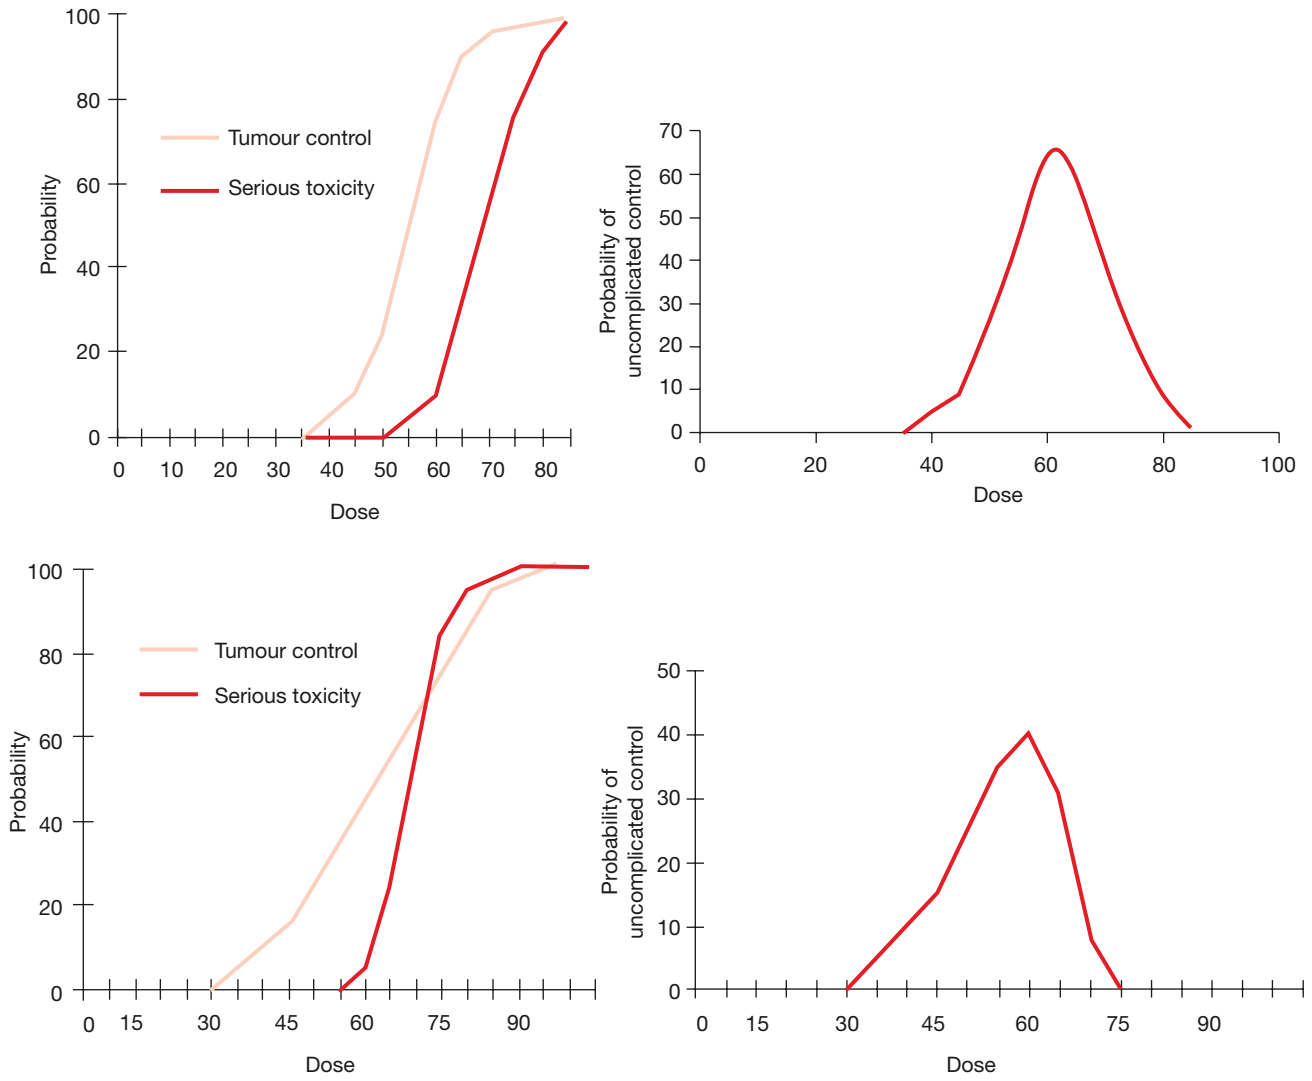

Figure 10.5 A schematic illustration of the relationship between dose, response and the probability of uncomplicated cure. The upper figures show ideal circumstances, with steep dose–response relationships for both normal tissue damage and tumour control. The lower figures show something more like the real world. The dose–response relationship for tumour control is flatter, because tumours are heterogeneous and, consequently, the probability of uncomplicated cure is lower – even for the optimal dose (40% in the lower figure compared with 70% in the upper figure).

General strategies in the non-surgical management of cancer

Curative surgery for cancer is guided by one simple principle: the physical removal of all identifiable disease. The principles underlying the non-surgical management of cancer are more complex. First, the spatial distribution of treatment must be considered: surgery and radiotherapy are local or, at best, locoregional treatments; drugs offer systemic therapy (**Figure 10.6** and *Table 10.8*).

Second, there is the question of the intent underlying the treatment. Radiotherapy, chemotherapy, or the combination of the two, may be used with curative intent. More usually, chemotherapy or radiotherapy is used to lower the risk of recurrence after primary treatment with surgery, so-called adjuvant therapy. Implicit within the concept of adjuvant therapy is the realisation that much of what is done

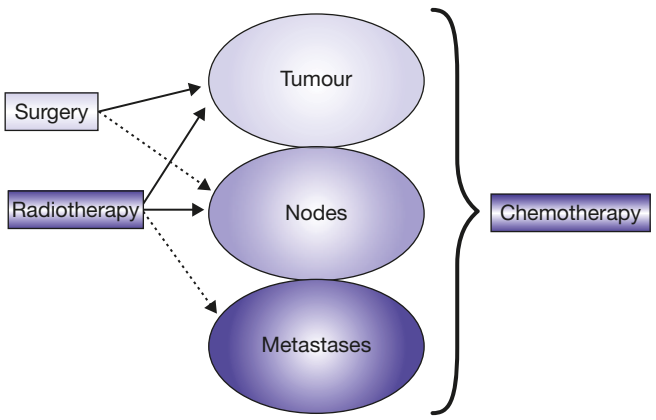

Figure 10.6 Schematic diagram to show the spatial scope of cancer treatments. Chemotherapy is systemic, surgery is mainly a local treatment. Radiotherapy is usually local or locoregional, but can, as in radioiodine therapy for thyroid cancer, be systemic.

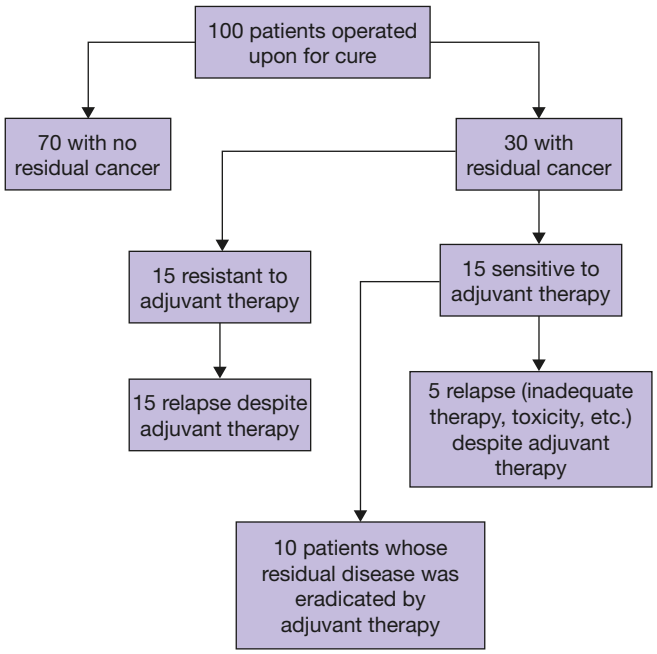
TABLE 10.8 Examples of malignancies that may be cured without the need for surgical excision.

Malignancy	Potentially curative treatment
Leukaemia	Chemotherapy (+/– Radiotherapy)
Lymphoma	Chemotherapy (+/– Radiotherapy)
Small cell lung cancer	Chemotherapy (+/– Radiotherapy)
Tumours of childhood (rhabdomyosarcoma, Wilm's tumour)	Chemotherapy (+/– Radiotherapy)
Early laryngeal cancer	Radiotherapy
Advanced head and neck cancer	Chemo-radiation (synchronous chemotherapy and radiotherapy)
Oesophageal cancer	Chemo-radiation (synchronous chemotherapy and radiotherapy)
Squamous cell cancer of the anus	Chemo-radiation (synchronous chemotherapy and radiotherapy)
Advanced cancer of the cervix	Radiotherapy (+/– chemotherapy)
Medulloblastoma	Radiotherapy (+/– chemotherapy)
Skin tumours (BCC, SCC)	Radiotherapy

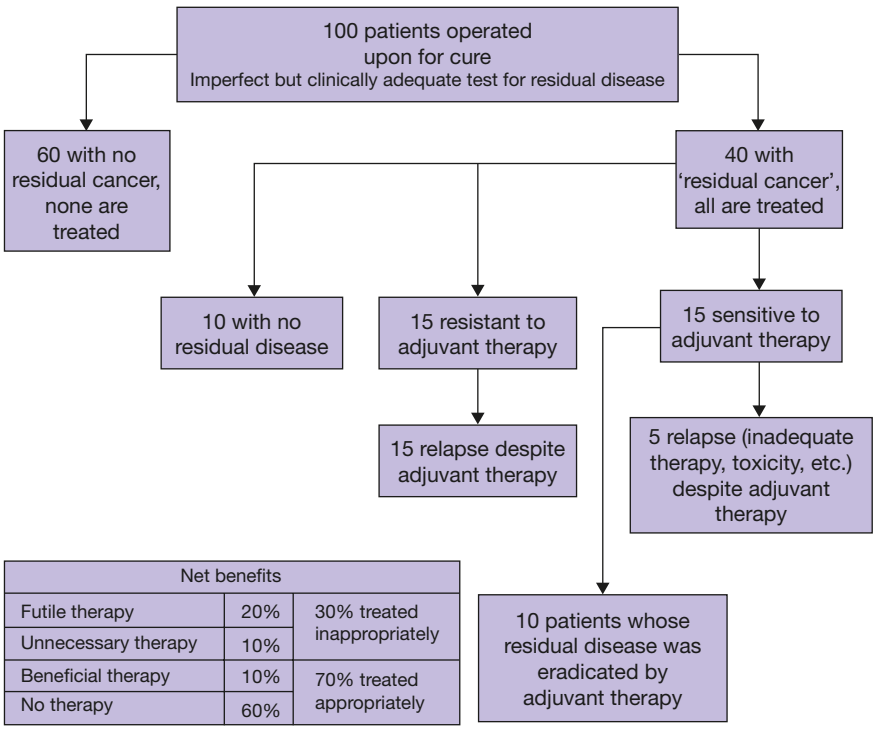
BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

is unnecessary, or futile, or both. The need for adjuvant therapy, to treat the risk that residual disease might be present after apparently curative surgery, is an acknowledgement of the current inability to detect or predict, with sufficient precision, the presence of residual disease. It also explains why the incremental benefits from adjuvant treatments are so small, and why the existence of these benefits can only be proven using randomised controlled trials including many thousands of patients. As illustrated in Figures 10.7 and 10.8,



Net benefits		
Futile therapy	20%	90% treated inappropriately
Unnecessary therapy	70%	
Beneficial therapy	10%	10% treated appropriately
No therapy	0%	

Figure 10.7 The concept of adjuvant chemotherapy.



Net benefits		
Futile therapy	20%	30% treated inappropriately
Unnecessary therapy	10%	
Beneficial therapy	10%	70% treated appropriately
No therapy	60%	

Figure 10.8 The concept of adjuvant chemotherapy and testing for minimal residual disease.

Max Wilms, 1867–1918, Professor of Surgery, Heidelberg, Germany.

the current approach to the selection of patients for postsurgical adjuvant treatment is both intellectually impoverished and inefficient. Patients might have been far better off if, rather than so much time and effort being invested in attempting to discover new 'cures' for cancer, equivalent resources had been devoted to devising clinically useful tests to detect residual cancer cells persisting after apparently successful initial therapy. Had this been the case, we might now be better able to distinguish between those patients with systemic disease at presentation and those with truly localised disease.

Radiotherapy

Within a month of their discovery in 1895, x-rays were being used to treat cancer. Despite over 100 years of use, and despite some outstanding clinical achievements, it is still not known how best to use radiation to treat cancer. In part this arises because it is not known precisely how radiation treatment affects tumours and normal tissues. Until about 30 years ago it was assumed that the biological effects of radiation resulted from radiation-induced damage to the DNA of dividing cells. Nowadays it is known that, although this undoubtedly explains some of the biological effects of radiation, it does not provide a full explanation. Radiation can, both directly and indirectly, influence gene expression: over 100 radiation-inducible effects on gene expression have now been described. These changes in gene expression are responsible for a considerable proportion of the biological effects of radiation upon tumours and normal tissues. In this sense, radiotherapy is a precisely targeted form of gene therapy for cancer.

The practicalities of radiation therapy are reasonably straightforward: define the target to treat; design the optimal technical set up to provide uniform irradiation of that target; and choose that schedule of treatment that delivers radiation to that target so as to maximise the therapeutic ratio (**Figure 10.9**). Modern radiotherapy uses sophisticated computer programmes and algorithms to sculpt the shape of the treatment volume. A decade ago it was possible only to treat simple geometric forms, nowadays, with techniques such as intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT), it is possible safely to deliver high doses to irregularly shaped target volumes. The ability to give high fractional doses in this way has lead to the development of stereotactic ablative radiotherapy (SABR) in which a small number of fractions can be used to treat primary tumours, or isolated metastases, to curative dose levels.

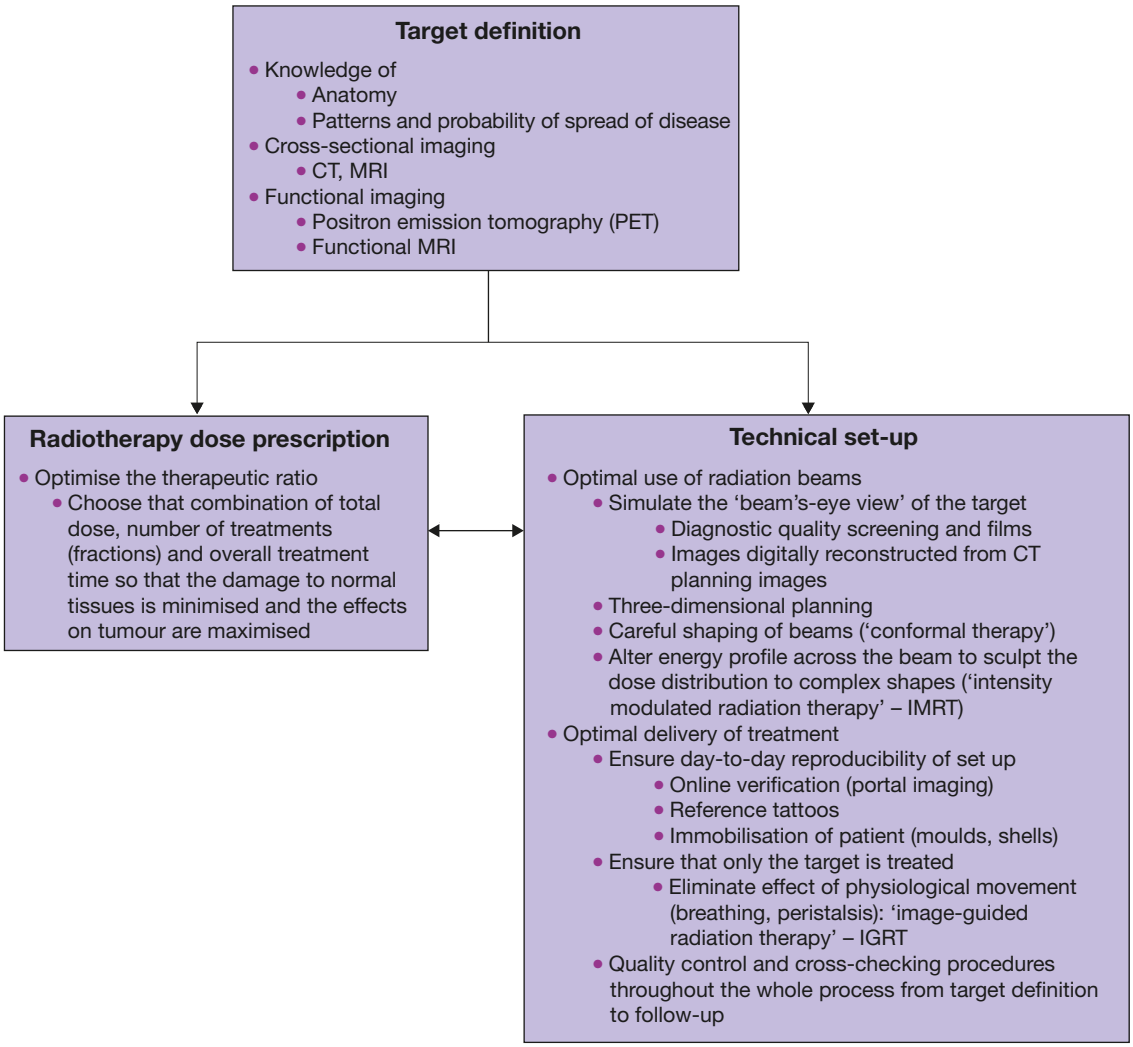


Figure 10.9 The processes involved in clinical radiotherapy. CT, computed tomography; MRI, magnetic resonance imaging.

One of the main problems with assessing a therapeutic ratio for a given schedule of radiation is that there is a dissociation between the acute effects on normal tissues and the late damage. The acute reaction is not a reliable guide to the adverse consequences of treatment in the longer term. Since the late effects following irradiation can take over 20 years to develop, this poses an obvious difficulty: if a radiation schedule is changed it will be known within two or three years whether or not the new schedule has improved tumour control; it may, however, be two decades before it is known, with any degree of certainty, whether or not the new technique is safe. Fractionated radiotherapy selectively spares late, as opposed to immediate, effects. For any given total dose, the smaller the dose per treatment (the larger the number of fractions), the less severe the late effects will be. The problem is that the greater the number of fractions of daily treatment, the longer the overall treatment time, and the greater the opportunity for the tumour to proliferate during treatment. All fractionation is a compromise. Thirty years ago, Withers defined the 4 Rs of radiotherapy; subsequently, a fifth 'R' (intrinsic radiosensitivity) has been added. The clinical practice of radiation oncology operates within the limits defined by these 5 Rs.

Summary box 10.5

The five Rs of radiotherapy

- **Repair**. If given sufficient time between fractional doses of radiation, cells will repair the radiation-induced damage. Repair half-times are typically 3–6 hours. Fractionation offers a means whereby we may be able to exploit any differentials in repair capacity between tumour cells and normal cells.
- **Reoxygenation**. Hypoxic cells are, compared with well-oxygenated cells, relatively radioresistant. Normal tissues are well oxygenated, tumours are often hypoxic. This is an obvious therapeutic disadvantage. The problem may be mitigated if a sequence of daily treatments is used. Cells dying as a result of radiation treatment will not use oxygen; this means that more oxygen is available to the, previously hypoxic, surviving cells. These cells become oxygenated and are therefore more susceptible to the next dose of radiation treatment.
- **Repopulation**. As radiotherapy kills cancer cells within a tumour it may provide a stimulus to rapid proliferation of tumour cells. Thus, during protracted treatment, production of cells by the tumour may equal, or even exceed, radiation-induced cell loss. This provides an argument for keeping the overall treatment time as short as possible.
- **Redistribution**. The sensitivity of cells to radiation varies according to their position within the cell cycle. This may lead to a degree of synchronisation of cellular division within the tumour: ideally, fractions of radiotherapy would be timed to coincide with vulnerable phases of the cell cycle (late G2 and M) in a partially synchronised population of tumour cells.
- **Radiosensitivity**. Experiments using low dose-rate irradiation demonstrate that, for reasons distinct from those summarised above, cells derived from tumours differ in their intrinsic sensitivity to radiation. There may be cells so intrinsically resistant to treatment that no clinically viable schedule of radiation therapy would be able to eliminate them. Conversely, some cells may be so sensitive that virtually any schedule would be successful – the majority of cells will lie somewhere between these extremes.

Chemotherapy and biological therapies

Selective toxicity is the fundamental principle underlying the use of chemotherapy in clinical practice. The importance of the principle is further emphasised by the fact that, by itself, chemotherapy is rarely sufficient to cure cancer. Chemotherapy is often (in effect, if not in intent) a palliative rather than a curative intervention. As such, its use should be influenced by the cardinal principle of palliative treatment: treatment aimed at relieving symptoms should not, itself, produce unacceptable symptoms. The cure of a disease should not be more grievous than its endurance. There are now over 120 different drugs licensed by the US Food and Drug Administration (FDA) for the treatment of cancer; 30 of them were approved between 2013 and 2015. The majority are cytotoxic drugs, hormonal therapies account for around 10%, and an increasing number have been designed to interact with specific molecular targets – so-called targeted therapies. There are now many more options than there were 20 years ago and, perhaps more importantly, lessons have been learned about how better to deploy resources. The classes of chemotherapeutic drugs, their modes of action and clinical indications are summarized in *Table 10.9*.

The newer, 'targeted' therapies (*Tables 10.9* and *10.10*) now available for treating cancer present particular dilemmas. They offer modest prolongation of survival, often with minimal toxicity, but at considerable financial cost. When compared with conventional therapies, these drugs typically cost over £50 000 ($94 000) per quality adjusted life-year gained and, when overall resources are limited, may be considered unaffordable. *Table 10.11* puts into context the cost-effectiveness of various clinical interventions. The current cost of targeted therapies should not obscure their importance: they represent the first attempts to translate advances in molecular biology into clinical practice. The discoveries of the mid-twentieth century are finally bearing fruit. One feature that is emerging is the exquisite selectivity of these treatments – they will only target specific subsets of tumours. The kinase inhibitor vemurafenib will only be effective in patients with melanoma whose tumours have the V600E BRAF mutation; cetuximab is only effective in patients with colorectal cancer who have wild-type (non-mutated) *ras*; imatinib is particularly effective in patients with gastrointestinal stromal tumours (GIST) who have mutations in exon 11 of the *Kit* gene, patients with mutations in exon 9 may still respond to imatinib but will require higher doses, and patients without mutations in *Kit* are far less likely to respond to imatinib.

The next decade will see a major shift in the medical management of cancer – from cell killing to cellular reprogramming. Sophisticated manipulations of the immune system will also become increasingly important. As a result, cancer therapies are likely to become less acutely toxic, but the longer-term consequences of such sophisticated manipulations will be both uncertain and unpredictable.

Hubert Rodney ('Rod') Withers, Professor of Radiation Oncology at the University of California, Los Angeles.

TABLE 10.9 A summary of chemotherapeutic and biological agents currently used in cancer treatment.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs which interfere with mitosis	Vincristine, Vinblastine	Interfere with formation of microtubules: 'spindle poisons'	Lymphomas Leukaemias Brain tumours Sarcomas
	Taxanes: Taxol, Paclitaxel	Stabilise microtubules	Breast cancer Non-small cell lung cancer Ovarian cancer Prostate cancer Head and neck cancer
Drugs which interfere with DNA synthesis (antimetabolites)	5-Fluorouracil (5-FU)	Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer GI cancer
	Capecitabine	Orally active prodrug which is metabolised to 5-FU. Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer GI cancer
	Methotrexate	Inhibition of dihydrofolate reductase	Breast cancer Bladder cancer Lymphomas Cervical cancer
	6-Mercaptopurine	Inhibits ***de novo*** purine synthesis	Leukaemias
	6-Thioguanine	Inhibits ***de novo*** purine synthesis	Leukaemias
	Cytosine arabinoside	False substrate in DNA synthesis	Leukaemias Lymphomas
	Gemcitabine	Inhibits ribonucleotide reductase	Non-small lung cancer Pancreatic cancer
Drugs which directly damage DNA or interfere with its function	Mitomycin C	DNA cross-linking, preferentially active at sites of low oxygen tension (a bioreductive drug)	Anal cancer Bladder cancer Gastric cancer Head and neck cancer Rectal cancer
	Cis-platinum	Forms adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer Oesophageal cancer
	Carboplatin	Forms adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer
	Oxaliplatin	Forms adducts between DNA strands and interferes with replication	Colorectal cancer
	Doxorubicin	Intercalates between DNA strands and interferes with replication	Breast cancer Lymphomas Sarcomas Kaposi's sarcoma
	Cyclophosphamide	A prodrug converted via hepatic cytochrome p450 to phosphoramide mustard. Causes DNA cross links	Breast cancer Lymphomas Sarcomas
	Ifosfamide	Related to cyclophosphamide, causes DNA cross links	Small-cell lung cancer Sarcomas
	Bleomycin	DNA strand breakage via formation of metal complex	Germ cell tumours Lymphomas
	Irinotecan	Inhibits topoisomerase 1 and thereby prevents the DNA from unwinding and repairing during replication	Colorectal cancer
	Etoposide	Inhibits topoisomerase 2, prevents DNA from unwinding and repairing during replication	Small-cell lung cancer Germ cell tumours Lymphomas

Continued

TABLE 10.9 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs which directly damage DNA or interfere with its function – *continued*	Dacarbazine	A nitrosourea which requires activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Brain tumours Sarcoma Melanoma
	Temozolomide	A nitrosourea but, unlike dacarbazine, does not require activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Glioblastoma multiforme Melanoma
	Actinomycin D	Intercalation between DNA strands, DNA strand breaks	Rhabdomyosarcoma Wilm's tumour
Hormones	Tamoxifen	Blocks oestrogen receptors	Breast cancer
	Anastrazole	An aromatase inhibitor than blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Exemestane	An aromatase inhibitor than blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Letrozole	An aromatase inhibitor than blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Leuprolide	Analogue of gonadotrophin-releasing hormone, continued use produces downregulation of the anterior pituitary with consequent fall in testosterone levels	Prostate cancer
	Goserelin	Analogue of gonadotrophin-releasing hormone, continued use produces downregulation of the anterior pituitary with consequent fall in testosterone levels	Prostate cancer
	Buserelin	Analogue of gonadotrophin-releasing hormone, continued use produces downregulation of the anterior pituitary with consequent fall in testosterone levels	Prostate cancer
	Cabergoline	Blocks prolactin release, a long-acting dopamine agonist	Prolactin-secreting pituitary tumours
	Bromocriptine	Dopamine agonist, blocks stimulation of anterior pituitary	Pituitary tumours
	Cyproterone acetate	Blocks the effect of androgens	Prostate cancer
	Flutamide	Blocks the effect of androgens	Prostate cancer
	Nilutamide	Blocks the effect of androgens	Prostate cancer
	Bicalutamide	Blocks the effect of androgens	Prostate cancer
Inhibitors of receptor tyrosine kinases	Gefitinib	Inhibits EGFR tyrosine kinase	Non-small cell lung lancer
	Imatinib	Blocks ability of mutant BCR–ABL fusion protein to bind ATP	Chronic myeloid meukaemia
		Inhibition of mutant c-KIT	Gastrointestinal stromal tumours (GIST)
	Erlotinib	Inhibits EGFR tyrosine kinase	Non-small cell lung cancer Pancreatic cancer
	Sunitinib, Sorafenib, Regorafenib, Lenvatinib	Promiscuous tyrosine kinase inhibitors (PDGFR, VEGFR, KIT, FLT)	Renal cancer GIST refractory to Imatinib, colorectal cancer, thyroid cancer
	Lapatinib	Inhibits tyrosine kinases associated with EGFR and HER2	Breast cancer
	Axitinib	Inhibits tyrosine kinase associated with VEGF receptor	Renal cancer
Protease inhibitors	Bortezomib	Interferes with proteasomal degradation of regulatory proteins, in particular prevents NF kappa B from preventing apoptosis	Multiple myeloma
Differentiating agents	All ***trans***-retinoic acid	Induces terminal differentiation	Acute promyelocytic leukaemia

TABLE 10.9 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Farnesyl transferase inhibitors	Lonafarnib	Inhibition of farnesyl transferase and consequent inactivation of ***ras***-dependent signal transduction	Leukaemia
	Tipifarnib	Inhibition of farnesyl transferase and consequent inactivation of ***ras***-dependent signal transduction	Acute leukaemia Myelodysplastic syndrome
Antibodies directed to cell surface antigens	Trastuzumab	Antibody directed against HER2 receptor	Breast cancer
	Cetuximab	Antibody directed against EGFR receptor	Colorectal cancer Head and neck cancer
	Bevacizumab	Antibody directed against VEGFR	Colorectal cancer
	Rituximab	Antibody against CD20 antigen	Lymphomas
	Alemtuzumab	Antibody against CD52 antigen	Lymphomas
Inducers of apoptosis	Arsenic trioxide	Induces apoptosis by caspase inhibition Inhibition of nitric oxide	Acute promyelocytic leukaemia
Immunological mediators	Ipilumumab	Blocks cytotoxic T lymphocyte-associated protein 4 (CTLA-4) and thus releases the brakes on the activation of T cells	Melanoma
	Pembrolizumab Nivolumab	Block the PD-1 receptor on T lymphocytes and thereby prevents the inhibition of T cell activation	Melanoma
	MEDI6383	OX40 agonist: enhances T cell survival and production of cytokines	In phase I trials
	Interferon alpha-2b	Activates macrophages, increases the cytotoxicity of T lymphocytes, inhibits cell division (and viral replication)	Renal carcinoma Melanoma Hairy-cell leukaemia
	Thalidomide	Anti-inflammatory, stimulates T cells, anti-angiogenic	Myeloma
HDAC inhibitors	Panobinostat Vorinostat	Acetylation of histones is associated with increased transcription of genes; inhibiting deacetylation can decrease expression of mutated or dysregulated genes	Cutaneous T cell lymphoma
	Entinostat		Melanoma
PI3K inhibitors	Idelalisib	Inhibit signalling via the PI3K/AKT/mTOR pathway and thereby switch off stimulus to cellular proliferation	B cell lymphomas
mTOR inhibitors	Temsirolimus	Inhibit the mammalian target of Rapamycin (mTOR) a key component in the PI3K/AKT/mTOR pathway	Renal cancer Neuroendocrine Tumours
	Everolimus		Gastric cancer
MEK inhibitors	Trametinib Selumetinib	Inhibit the mitogen-activated protein kinase pathway (MAPK)	Melanoma
RAF inhibitors	Dabrafenib	Inhibit the mitogen-activated protein kinase pathway (MAPK)	Melanoma
	Vemurafenib		Melanoma

CML, chronic myeloid leukaemia; EGFR, epidermal growth factor receptor; FLT3, FMS-like tyrosine kinase; GI, Gastrointestinal; HDAC, Histone deacetylase; mTOR , mammalian target of rapamycin; NF, nuclear factor; PDGFR, platelet-derived growth factor receptor; PI3K, phosphoinositide 3-kinase; TKI, tyrosine kinase inhibitor; VEGFR, vascular endothelial growth factor receptor.

Principles of combined treatment

Cytotoxic drugs are rarely used as single agents; radiotherapy and chemotherapy are often given together. The rationale behind combination, as opposed to single-agent, drug therapy is straightforward and is somewhat analogous to that used for combined antibiotic therapy: it is a strategy designed to combat drug resistance. By the time of diagnosis many tumours will contain cancer cells that, through spontaneous mutation, have acquired resistance to cytotoxic drugs. Unlike antibiotic resistance, there is no need for previous exposure to the drug. Spontaneous mutation rates are high enough to allow the play of chance to permit the occurrence, and subsequent expansion, of clones of cells resistant to drugs to which they have never been exposed. If drugs were used as single agents then the further expansion of these *de novo* resistant subclones would limit cure. The problem can be mitigated by, from the outset of treatment, combining drugs.

There are three main principles upon which the choice of drugs for combination therapy is based: (1) use drugs active against the diseases in question; (2) use drugs with distinct modes of action; (3) use drugs with non-overlapping toxicities. By using drugs with different biological effects, for

TABLE 10.10 Targeted treatments mapped to the hallmarks of cancer. It is noteworthy that those agents that specifically target the hallmarks of cancer are not widely used in clinical practice. This may simply reflect the novelty of these agents, but could also suggest that an approach based on hallmarks is of more relevance to cancer biologists than to oncologists.

Hallmark	Drug classes	Specific drugs
Resist signals that inhibit growth	Cyclin-dependent kinase inhibitors	Dinaciclib Palbociclib Ronaciclib Seliciclib
Sustaining proliferative signalling	EGFR inhibitors	Trastuzumab Cetuximab
Avoid immune detection/destruction	Immune activators: antagonists of CTLA4, PD1, PD-L1 OX40 agonists	Ipilumumab Pembrolizumab Nivolumab MEDI6383
Obtain replicative immortality	Telomerase inhibitors	Imetelstat
Evoke inflammation	Anti-inflammatory drugs	Aspirin
Acquire ability to invade	Inhibition of Wnt/β-catenin	Resveratrol
Acquire ability to disseminate and implant	IGF-1 inhibitors	Linsitinib
Acquire angiogenic competence	Inhibitors of VEGF	Ramucirumab Bevacizumab Aflibercept
Genomic instability	PARP inhibitors	Olaparib Niraparib Rucaparib Veliparib
Evade apoptosis	BH3 mimetics	Navitoclax Venetoclax
Deregulate cellular energy supply & transfer	Aerobic glycolysis inhibitors	Metformin

BH3, B cell lymphoma gene 2 homology region 3; CTLA4, cytotoxic T lymphocyte associated protein 4; EGFR, epidermal growth factor receptor; IGF-1, insulin-like growth factor 1; OX40, also known as CD134, is expressed on activated T cells and is a tumour necrosis factor receptor; PARP, poly ADP ribose polymerase; PD1, programmed death-1 receptor; PD-L1, ligand for programmed death-1 receptor; VEGF, vascular endothelial growth factor.

example by combining an antimetabolite with an agent that actively damages DNA, it may be possible to obtain a truly synergistic effect. It is inadvisable to combine drugs with similar adverse effects: combining two highly myelosuppressive drugs may produce an unacceptably high risk of neutropenic sepsis. Where possible, combinations should be based upon a consideration of the toxicity profiles of the drugs concerned.

In considering the combination of radiotherapy and chemotherapy, radiation could be considered as just another drug. There is, in addition to synergy and toxicity, another factor to consider in the combination of drugs and radiation – the concept of spatial cooperation. Chemotherapy is a systemic treatment, radiotherapy is not. Radiotherapy is, however, able to reach sites, such as the central nervous system and testis, that drugs may not reach effectively. This is why, for example in patients treated primarily with chemotherapy for leukaemias, lymphomas, and small-cell lung cancer, prophylactic cranial irradiation may be part of the treatment protocol.

TABLE 10.11 Comparison of various estimates of cost-effectiveness for selected clinical interventions. Currently, in the United Kingdom, interventions costing less than $60 000 US (2002) are considered 'affordable', that is, they fall below the WTP ('willingness to pay') threshold.

Intervention	Cost (in 2002 US dollars) per quality-adjusted life-year (QALY)
Annual CT chest screening for lung cancer in a 60-year-old male ex-smoker versus no screening	2.4 million
Laparoscopic inguinal hernia repair versus expectant management in adults with inguinal hernia	610
Stroke unit care versus usual care in survivors of acute stroke	1600
Lifetime vitamin D + calcium supplements versus no supplements to prevent/treat osteoporosis in 70-year-old women	8500
Letrazole versus tamoxifen in the first-line management of postmenopausal women with advanced breast cancer	120 000
Erlotinib versus usual care in the treatment of relapsed non-small cell lung cancer	104 000

Data from CEA (Tufts-New England Medical Center) register (accessed via http://www.tufts-nemc.org/cearegistry/ on 15 November 2006) and the UK National Institute for Health and Clinical Excellence (accessed via http://www.nice.org.uk/page.aspx?c=153 on 15 November 2006).

Summary box 10.6

Principles of combined treatment

- Use effective agents
- Use agents with different modes of action (synergy)
- Use agents with non-overlapping toxicities
- Consider spatial cooperation

Palliative therapy

The distinction between palliative and curative treatment is not always clear cut and will become increasingly blurred as professional and public attitudes to towards the management of cancer change. Twenty years ago cancer was perceived as a disease that was either cured or it was not; patients either lived or died. There was little appreciation that, for many patients, cancer might be a chronic disease. Nowadays, it is appreciated that many of the so-called curative treatments are simply elegant exercises in growth delay. Five-year survival is not necessarily tantamount to cure. With the development

A **synergistic effect** is one in which the damage caused by giving the agents together is greater than the damage caused when the drugs are given separately.

of targeted therapies which regulate, rather than eradicate, cancer this state of affairs is likely to continue. The aim of treatment will be growth control rather than the extirpation of every last cancer cell. Patients will live with their cancers, perhaps for years. They will die **with** cancer, but not necessarily **of** cancer. Against this background, the distinction between curative and palliative therapy seems somewhat arbitrary; nevertheless, the control and relief of symptoms is crucial to the successful management of patients with cancer. Much of the fear associated with cancer is due to past failures to control patients' symptoms.

Patients fear the symptoms, distress and disruption associated with cancer almost as much as they fear the disease itself. Palliative treatment has as its goal the relief of symptoms. Sometimes this will involve treating the underlying problem, as with palliative radiotherapy for bone metastases, sometimes it will not. Sometimes it may be inappropriate to treat the cancer itself, but that does not imply that there is nothing more to be done, it simply means that there may be better ways to assuage the distress and discomfort caused by the tumour. Palliative medicine in the twenty-first century is about far more than optimal control of pain: its scope is wide, its impact immense (*Table 10.12*). The most important factor in the successful palliative management of a patient with cancer is early referral. Transition between curative and palliative modes of management should be seamless.

End-of-life care

End-of-life care is distinct from palliative care. Patients treated palliatively may survive for many years; end-of-life care concerns the last few months of a patient's life. Many issues, such as symptom control, are common to both palliative care and to end-of-life care but there are also problems which are specific to the sense of approaching death. These include a heightened sense of spiritual need, profound fear and the specific needs of those who are facing bereavement. The concept of the 'good death' has been embedded in many cultures over many centuries. Healthcare professionals deal with many deaths and sometimes forget that the patient who hopes for a good death has only one chance to get it right. This is why end-of-life care is worth considering in its own right and not as a mere appendage to palliative care.

Summary box 10.7

Issues at the end of life

- Appropriateness of active intervention
- Euthanasia
- Physician-assisted suicide
- Living wills
- Bereavement
- Spirituality
- Support to allow death at home
- The problem of the medicalisation of death

TABLE 10.12 An outline of the domains and interventions included within palliative and supportive care.

Symptom assessment	Pain, anorexia, fatigue, dyspnoea, etc.	
	Treatment-related toxicity	
Quality of life assessment		
Symptom relief	Drugs	
	Surgery	
	Radiotherapy	
	Complementary therapies:	Acupuncture
		Homeopathy
		Aromatherapy etc.
Psychosocial interventions	Psychological support	
	Relaxation techniques	
	Cognitive behavioural therapy	
	Counselling	
	Group therapy	
	Music therapy	
	Emotional support	
Physical and practical support	Physiotherapy	
	Occupational therapy	
	Speech therapy	
Information and knowledge	Cancer backup	
	Maggie's centres	
Nutritional support	Dietary advice	
	Nutritional supplements	
Social support	Patients	
	Relatives and carers	
Financial support	Ensure uptake of entitlements	
	Grants from charities e.g. Cancer Relief, Macmillan	
Spiritual support

Chapter 11

Surgical audit and research

Learning objectives

To understand:

- The planning and conduct of audit and research
- How to write up a project
- How to review a journal article and determine its value

INTRODUCTION

It is essential for a surgeon to understand the educational and legal framework in which he or she works. The agenda for medical education and both clinical and research governance requires surgeons to expand their skills to encompass audit and clinical research capabilities as useful tools for continued outcome measurement, service improvement and innovations for the benefit of patient care.

The aim of this chapter is to enable improvements in patient experience as a result of a successful audit cycle or by recognising the need for clinical research to determine a new and innovative way of treatment. It will also show how to keep track of personal clinical results. In addition, much clinical work is tedious and repetitive. Rigorous evaluation of even the most simple techniques and conditions can help to keep a surgeon stimulated throughout a long career and ensure good outcomes for patients, with cost benefits to the provider and a benefit to society as a whole.

Large numbers of clinical papers appear in the surgical literature every year. Many are flawed, and it is important that a surgeon has the skills to examine publications critically. The best way to develop a critical understanding of the research and audit undertaken by others is to perform studies of one's own. The hardest part of audit and research is writing it up, and the hardest article to write is the first. This chapter contains the information required to write a surgical paper and to evaluate the publications of others.

AUDIT OR RESEARCH?

Health professionals are expected to undertake audit and service evaluation as part of quality assurance. These usually involve minimal additional risk, burden or intrusion for participants. It is important to determine at an early stage whether a project is audit or research, and sometimes that is not as easy as it seems. The decision will determine the framework in which the study is undertaken. In the UK the Health Research Authority (HRA) has developed a decision tool to help decide whether your project is classified as research (http://www.hra-decisiontools.org.uk/research/). The HRA leaflet 'Differentiating clinical audit, service evaluation, research and usual practice/surveillance work in public health' is also helpful (*Table 11.1*).

AUDIT AND SERVICE EVALUATION

Clinical audit is a process used by clinicians who seek to improve patient care. The process involves comparing aspects of care (structure, process and outcome) against explicit criteria and defined standards. Keeping track of personal outcome data and contributing to a clinical database ensures that a surgeon's own performance is monitored continuously and can be compared with a national data set to ensure compliance with agreed standards. It is also an essential component of revalidation for the individual surgeon in the UK. If the care falls short of the criteria chosen, some change in the way that care is organised should be proposed. This change may be required at one of many levels. It might be an individual who needs training or surgical equipment that needs replacing. At times, the change may need to take place at the team level. Sometimes, the only appropriate action is change at an institutional level (e.g. a new antibiotic policy), regional level (provision of a tertiary referral centre) or, indeed, national level (screening programmes and health education campaigns).

Essentially, two types of audit may be encountered: national audits (e.g. in the UK, NHS England) and local/hospital audits. Both are designed to improve the quality of care. In an ideal world, national audits should be driven by needs identified in local and hospital-based audits that are closest to

TABLE 11.1 Research, audit or service evaluation? (Based on information by the National Research Ethics Service.)

Research	Clinical audit	Service evaluation
The attempt to derive generalisable new knowledge including studies that aim to generate hypotheses as well as studies that aim to test them	Designed and conducted to produce information to inform the delivery of best care	Designed and conducted solely to define or judge current care
Quantitative research – designed to test a hypothesis	Designed to answer the question: 'Does this service reach a predetermined standard?'	Designed to answer the question: 'What standard does this service achieve?'
Qualitative research – identifies/explores themes following established methodology;		
Addresses clearly defined questions, aims and objectives	Measures against a standard	Measures current service without reference to a standard
Quantitative research – may involve evaluating or comparing interventions, particularly new ones	Involves an intervention in use ONLY. (The choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)	Involves an intervention in use ONLY. (The choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)
Qualitative research – usually involves studying how interventions and relationships are experienced		
Usually involves collecting data that are additional to those for routine care but may include data collected routinely. May involve treatments, samples or investigations additional to routine care	Usually involves analysis of existing data but may include administration of simple interviews or questionnaires	Usually involves analysis of existing data but may include administration of simple interviews or questionnaires
Quantitative research – study design may involve allocating patients to intervention groups	No allocation to interventions: the health professional and patient have chosen intervention before clinical audit	No allocation to intervention: the health professional and patient have chosen intervention before service evaluation
Qualitative research uses a clearly defined sampling framework underpinned by conceptual or theoretical justifications		
May involve randomisation	No randomisation	No randomisation

Although any of the above may raise ethical issues, under current guidance, research requires ethics committee review, whereas audit and service evaluation do not. Advice (in the UK) from National Research Ethics Service (http://www.nres.npsa.nhs.uk/).

the patient. For example, hospital topics are often identified at the departmental morbidity and mortality meetings, where issues related to patient care are discussed. The reporting process might identify a possible national issue, and a national audit could be designed to be completed by the local audit department and surgical teams. The Vascular Society of Great Britain and Ireland is working continually with all its members in an evaluation of process and outcomes for major vascular operations. This is driven through the Vascular Society Quality Improvement Programme (VSQIP), where recently, individual surgeon outcomes for elective aortic aneurysm and carotid surgery are recorded (www.vsqip.org.uk). Audits are formal processes that require a structure. The following steps are essential to establish an audit cycle:

1 define the audit question in a multidisciplinary team;
2 identify the body of evidence and current standards;
3 design the audit to measure performance against agreed standards based on strong evidence. Seek appropriate advice (local audit department in UK) and ensure institutions have agreed to undertake the audit;
4 measure over an agreed interval;
5 analyse results and compare performance against agreed standards;
6 undertake gap analysis:
   a. if all standards are reached, reaudit after an agreed interval;
   b. if there is a need for improvement, identify possible interventions such as training, and agree with the involved parties;
7 reaudit.

Research study

During the design of the audit project, it might become apparent that there is a limited body of evidence available. In this case, the study should be structured as a research proposal. Research is designed to generate new knowledge and might involve testing a new treatment or regimen.

IDENTIFYING A RESEARCH TOPIC

Once an idea has been formed, or a question asked, it needs to be transformed into a hypothesis. It is helpful to approach surgeons who regularly publish articles and who have a special interest in the surgical area being considered. As ideas are suggested, it is important to consider whether the question posed really matters, and to spend some time refining the question (hypothesis) as this is probably the most important part of the process. Choosing the wrong topic at this stage can lead to many wasted hours. Once a topic has been identified, it is also

important not rush into the study. The worst possible outcome is to find at the end of a long arduous study that the research has already been done or that the chosen methodology did not support investigation of the primary/secondary outcomes.

The first port of call for information is the internet (with assistance as needed from a medical librarian). Current articles about the proposed research should be retrieved; review articles and meta-analyses can be particularly helpful. At this stage, most clinicians go to an electronic library and perform a database search. It is very important to learn how to do an accurate and efficient search as early as possible. Details are beyond the scope of this chapter, but most librarians will be of assistance. Current techniques involve searching on Medline or other collected databases such as Google Scholar, but as electronic information advances and the world wide web (www) becomes more user friendly, new search strategies may emerge. Collections of reviews are becoming available – the Cochrane Collaboration brings together evidence-based medical information and is available in most libraries (*Table 11.2*).

Once information on the subject has been obtained and the relevent literature identified, it is important that these are carefully perused. It is not sufficient to read the abstract on Medline! If the proposed project is still looking good after some thorough reading, it is worth further discussion with colleagues who have written a paper on a similar subject. All scientists are flattered by interest in their work. It is important to ensure the cooperation of any other specialties or clinicians who will be involved in the study and to agree on the sharing of responsibility for the trial. This will help to prevent disagreement about who takes the credit once a study is ready for presentation and publication.

It is also helpful to seek support from specific networks set up to support health research. In the UK, the National Institute for Health Research Collaboration for Leadership in Applied Health Research and Care (NIHR CLAHRC) works with partner organisations, including the NHS, local authorities and universities, to conduct applied health research and implement research evidence, to improve health and healthcare. There are also a number of training courses in research methodology and application.

Once the forgoing has been completed, it should be possible to start to plan the research project.

PROJECT DESIGN

During the first phase, it is important to keep in the mind some important questions (*Summary box 11.1*).

Summary box 11.1

Questions to answer before undertaking research

- Why do the study?
- Will it answer a useful question?
- Is it practical?
- Can it be accomplished in the available time and with the available resources?
- Will the project benefit from collaboration to increase numbers or make best use of high tech equipment?
- What findings are expected?
- What are the research governance requirments?
- What are the ethical issues?
- What impact could it have?

TABLE 11.2 Electronic information sites.

Database	Producer	Coverage	Availability
Pubmed http://www.ncbi.nlm.nih.gov/pubmed	US National Library of Medicine (NLM)	PubMed comprises more than 25 million citations for biomedical literature from MEDLINE, life science journals, and online books. The **Cochrane Collaboration** was formed in 1993 and named after Archibald Leman Cochrane, 1909–1988, Director of the Medical Research Council Epidemiology Unit, Cardiff, and later the first President of the Faculty of Community Medicine (now the Faculty of Public Health) of the Royal College of Physicians of London, UK.

Time spent carefully designing a potential project is never wasted. There are many different types of scientific study. The design used depends on the study. A randomised controlled trial (RCT) is regarded as one of the best methods of scientific research; however, much surgical practice has been advanced through other different types of study such as those listed in *Table 11.3*. For example, testing a new type of operation often requires a pilot study to assess feasibility, which is then followed by a formal RCT. The introduction of innovative surgical techniques may require novel handling, and recomendations have been made by the IDEAL collaborators (see Further reading).

Research can be qualitative or quantitative. Quantitative research allows hard facts to speak for themselves. A medical condition is analysed systematically using hard, objective endpoints such as death or major complications, which should be clearly defined. For example, surgical complications are now classified using the Dindo–Clavien system. In qualitative research, data often come from patient narratives, and the psychosocial impact of the disease and its treatment are analysed; for example, narratives from patients with breast cancer. These kinds of data are often collected using quality-of-life measurements. A variety of different quality-of-life questionnaires exist to suit several different clinical situations. Much of the best research is both quantitative and qualitative. Recently, the importance of outomes from the patient's perspective has been emphasised; Patient Reported Outcome Measures (PROMs) are now an important component of the evaluation of surgical procedures.

Research should be focused according to institutional, national and international strategies. As finances for health care are always limited, it is important to consider including a cost–benefit analysis in any major area of research so that the value of the proposed intervention or change in treatment can be assessed. The National Institute for Health Research (NIHR) provides the framework through which the Department of Health maintains and manages the research, research staff and research infrastructure of the NHS in England.

TABLE 11.3 Types of study.

Type of study	Definition
Observational	Evaluation of condition or treatment in a defined population
	Retrospective: analysing past events
	Prospective: collecting data contemporaneously
Case–control	Series of patients with a particular disease or condition compared with matched control patients
Cross-sectional	Measurements made on a single occasion, not looking at the whole population but selecting a small similar group and expanding results
Longitudinal	Measurements are taken over a period of time, not looking at the whole population but selecting a small similar group and expanding results
Experimental	Two or more treatments are compared. Allocation to treatment groups is under the control of the researcher
Randomised	Two randomly allocated treatments
Randomised controlled	Includes a control group with standard treatment

Sample size

Calculating the number of patients required to perform a satisfactory investigation is an important prerequisite to any study. An incorrect sample size is probably the most frequent reason for research being invalid. Often, surgical trials are marred by the possibility of error caused by the inadequate number of patients investigated.

- **Type I error.** Benefit is perceived when really there is none (false positive).
- **Type II error.** Benefit is missed when it was there to be found (false negative).

Calculating the number of patients required in the study can overcome this bias. Unfortunately, it often reveals that a larger number of patients is needed for the study than can possibly be obtained from available resources. This often means expanding enrolment by using a multicentre study. There is no point in embarking on a trial if it will never be possible to recruit an adequate population to answer the research question. More patients will need to be randomised than the final sample size to take into account patients who die, drop out or are lost to follow-up.

The following is an example calculation for a study to recruit patients into two groups. In order to calculate a sample size, it is common practice to set the level of power for the study at 80% with a 5% significance level. This means that, if there is a difference between study groups, there is an 80% chance of detecting it. Based on previous studies, realistic expectations of differences between groups should be used to calculate the sample size. The formula below uses the figures of a reduction in event rate from 30% to 10% (e.g. a new treatment expected to reduce the complication rate such as wound infection from 30% = r to 10% = s).

$$8 \times \frac{[r(100 - r) + s(100 - s)]}{(r - s)^2}$$

$$\text{e.g. } 8 \times \frac{[30(100 - 30) + 10(100 - 10)]}{(30 - 10)^2}$$

$$= 60 \text{ needed in each group}$$

Eliminating bias

It is important to imagine how a study could be invalidated by thinking of things that could go wrong. One way to eliminate any bias inherent in the data collection is to have observers or recorders who do not know which treatment has been used (blinded observer). It might also be possible to ensure that the patient is unaware of the treatment allocation (single blind). In the best randomised studies, neither patient nor researcher is aware of which therapy has been used until after the study

has finished (double blind). Randomised trials are essential for testing new drugs. In practice, however, in some surgical trials, randomisation may not be possible or ethical.

Study protocol

Now that the question to pose has been decided, and it has been checked that sufficient patients should be available to enrol into the study, it is time to prepare the detail of the trial. At this stage, a study protocol should be constructed to define the research strategy. It should contain a paragraph on the background of the proposed study, the aims and objectives, a clear methodology, definitions of population and sample sizes and methods of proposed analysis. It should include the patient numbers, inclusion and exclusion criteria and the timescale for the work. It is useful to construct a flow diagram giving a clear summary of the research protocol and its requirements (**Figure 11.1**). It is helpful to imagine the paper that will be written about the study, before it is performed. This may prevent errors in data collection.

When a study is planned, sufficient time should be reserved at the beginning for fund-raising and obtaining ethical, regulatory and or other approvals (e.g. HRA). Time for data analysis and preparation of publication needs to be included in funding applications. The cost of any non-routine investigations and extra treatments should be identified and covered by the research grant in line with national guidance (in the UK, the Attributing the costs of health and social care Research and Development (AcoRD) guidance). It is essential to discuss this with institutional leads well in advance of the grant submission date to ensure appropriate authorisation from institutions.

A data collection form should be designed or a computer collection package developed. If data are collected on computer, appropriate safeguards for privacy, confidentiality and data quality will be necessary to comply with legislation. At this stage it is important to consider any validation requirements and needs for open access either in a recognised archive (e.g. the UK Data Archive) or an institutional repository. Any form of data collection needs to be quality assured. The quality assurance process will include training, Standard Operating Procedures as well as monitoring and checking a certain sample of the data. At the end of data collection and analysis, a final data base with all data should be locked and kept for future reference in a safe location. A data archiving policy with a nominated data custodian should be in place.

Research is no longer confined by institutional or even geographical boundaries. Communication by the internet can be a valid way to co-ordinate internalional research. The Global Surgical Outcomes Collaboration (www.globalsurg.org) is a group of young surgeons performing collaborative research with internet data collection.

Some publishers require registration of a study at the time of study set up on a publically available database (e.g. ISRCTN). It is becoming increasingly popular to consider publication of a protocol paper.

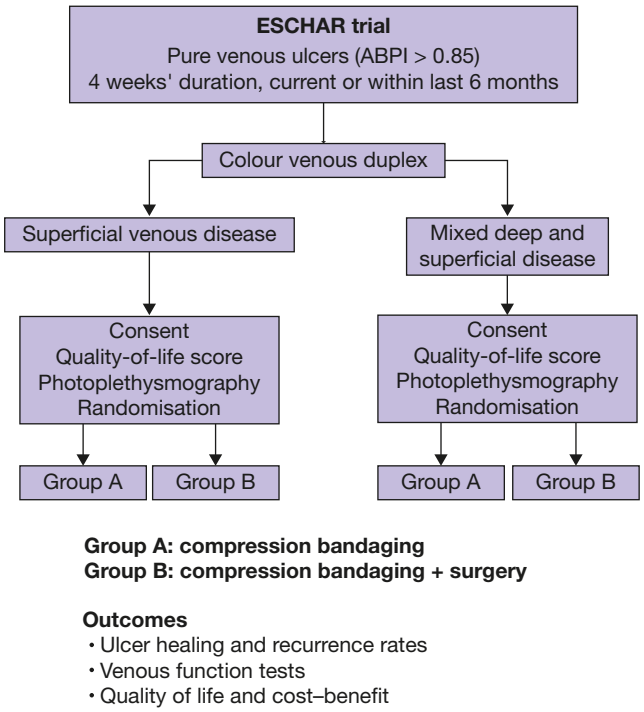

Figure 11.1 ESCHAR trial: completed in Gloucestershire, UK (Gohel MS *et al. British Journal of Surgery 2005*; **92**: 291–7. Copyright British Journal of Surgery Society Ltd. Permission is granted by John Wiley & Sons Ltd on behalf of the BJSS Ltd.) ABPI, ankle–brachial pressure index.

Regulatory framework

In the UK, the implementation of the research governance framework by the Department of Health, or its planned successor UK Policy Framework for Health and Social Care, provides a framwork that enhances the integrity of the study and includes requirements for sponsorship by an institution to ensure the following: peer review, independent ethics review, compliance with data protection principles, financial probity, dissemination and management of intellectual property.

Sponsorship is defined by the HRA as the individual, company, institution or organisation that takes on ultimate responsibility for the initiation, management (or arranging the initiation and management) of and/or financing (or arranging the financing) for that research. The sponsor takes primary responsibility for ensuring that the design of the study meets appropriate standards and that arrangements are in place to ensure appropriate conduct and reporting. http://www.hra.nhs.uk/resources/before-you-apply/roles-and-responsibilties/sponsor/

Peer review

Once the protocol is finalised, formal peer review is needed. In the UK, evidence of peer review will be needed before submitting an application to a research ethics committee and for HRA approval.

- If the research is part of a university course, the university (usually the student supervisor) should undertake this review.
- Surgeons working for the NHS can arrange their own peer review by experts who are not connected with the study.

Alternatively, most Research and Development Support Units (NHS) will give guidance through the review process.
- Many funders of research will undertake their own independent peer review. There is usually feedback from this process that can provide valuable advice about the study.

Ethics

In the first instance, common sense is the best guide to whether or not a study is ethical. It is still important to seek advice from an independent research ethics committee whenever research is contemplated.

In the UK the requirement is that a NHS Research Ethics Committee (NHS REC) provides an independent ethical review of all health and social care research if it involves patients and/or carers. The Government arrangment for Research Ethics Commitees (GafREC) provide detailed guidance about NHS REC review requirements. The application for NHS REC review should be made using the Integrated Research Administraion System (IRAS). IRAS is a single system for applying for the permissions and approvals for health and social care/community care research in the UK. It enables entry of information about the project once instead of duplicating information in separate application forms. IRAS captures the information needed for the relevant approvals from the following review bodies:

- Administration of Radioactive Substances Advisory Committee (ARSAC);
- Confidentiality Advisory Group (CAG);
- Gene Therapy Advisory Committee (GTAC);
- Health Research Authority (HRA) for projects seeking HRA approval;
- Medicines and Healthcare products Regulatory Agency (MHRA);
- NHS/HSC R&D offices;
- NHS/HSC Research Ethics Committees;
- National Offender Management Service (NOMS);
- Social Care Research Ethics Committee.

Once all the relevant forms and associated study documentation have been completed, guidance provided by the HRA and the Research Ethics Service should be followed for submission of the request for ethical review and HRA approval. If the study does not require review by an NHS REC, the need for an independent ethical review should still be considered. Universities have developed their own ethical review infrastructure and this will be institute specific and location specific. For collaborative research, local ethical review should be obtained where possible, and developing a local ethics infrastructure should be considered if it does not already exist. Duplicaton of ethical review should be avoided.

Ethics committees prefer to see fully developed trial protocols but it is often possible to get some preliminary advice from the NHS REC Manager. Ethics committee forms may seem long and detailed, but it is important that these are filled in correctly and it helps to prepare the investigators for all practical aspects of the project. All dealings with ethics committees should be intelligent and courteous. It is important to attend the meeting at which the study will be discussed, if invited, as it provides a forum for direct communication in relation to the study. It can save time as possible concerns of the ethics committee can be addressed at the time, avoiding lengthy correspondence.

Regulatory approvals

In the case of interventional clinical or device trials, the European Union Clinical Trial Directives apply, which are regulated by the Medicines and Health Care products Regulatory Agency (MHRA) in the UK. A clinical trial should be registered with the European Clinical Trials Database before applying to the MHRA for a Clinical Trial Authorisation via the common European submission portal. This can be a complicated and trying process, and support should be sought from the investigators' employing institution. Editors of the major surgical journals now agree that all clinical trials should have been registered before an article relating to a trial can be published.

All studies undertaken with NHS patients and/or carers will need HRA approval and confrmation of capacity and capability from NHS sites. Studies involving animals require approval from statutory licensing authorities. Reporting on animal research should employ ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments).

Research integrity

The principles and responsibilities set out in the Singapore Statement on Research Integrity in 2010 was the first international effort to encourage the development of unified policies, guidelines and codes of conduct, with the long-term goal of fostering greater integrity in research worldwide. The European Code of Conduct followed and in 2012 Universities UK, in collaboration with major funders of research, developed 'the Concordat to support research integrity', which sets out key commitments to ensure a high standard in research. All highlight the principles and professional responsibilities of researchers and research instituions that are fundamental to the integrity of research wherever it is undertaken. These centre around:

- honesty in all aspects of research;
- accountability and transparentcy in the conduct of research;
- professional courtesy and fairness in working with others;
- good stewardship of research.

A study should not under any circumstances commence until the correct approval has been granted and compliance with the principles of research integrity is ensured. Any challenge to the integrity of research can be time-consuming and career-limiting.

STATISTICAL ANALYSIS

Both audit and research commonly require statistical analysis. Many surgeons find the statistical analysis of a project the most difficult part. It is also the most commonly criticised part

of papers written by clinicians. There are many useful books about statistics that can be consulted (see Further reading); if in any doubt, a statistician will be pleased to give assistance. Statisticians like to be consulted before research or audit has been conducted rather than being presented with the data at the end; they often give helpful advice over study design and can be an important part of the project team.

The following terms are frequently used when summarising statistical data:

- **Mean:** the result of dividing the total by the number of observations (the average);
- **Median:** the middle value with equal numbers of observations above and below – used for numerical or ranked data;
- **Mode:** the value with the highest frequency observed – used for nominal data collection;
- **Range:** the largest to the smallest value.

The most important decision for analysis is whether the distribution of the data is normal (i.e. parametric or non-parametric). Normally, distributed data have a symmetrical, bell-shaped curve, and the mean, median and mode all lie at the same value. The type of data collected determines which statistical test should be used.

1 Numerical and normally distributed (e.g. blood pressure) – use unpaired *t*-test to compare two groups or paired *t*-test to assess whether a variable has changed between two time points.
2 Numerical but not normally distributed (e.g. tumour size) – use Mann–Whitney *U*-test to compare two groups or a Wilcoxon signed rank test to assess whether a variable has increased/stayed the same/decreased between two time points.
3 Categorical (e.g. admitted or not admitted to an intensive care unit) – can use chi-squared test to compare two groups.

(**Note:** the use of these and any other statistical tests may benefit from professional advice.)

Confidence intervals are the best guide to the possible range in which the true differences are likely to lie. A confidence interval that includes zero usually implies a lack of statistical significance.

Scientists usually employ probability (*P*-values) to describe statistical chance. A *P*-value <0.05 is commonly taken to imply a true difference. It is important not to forget that $P = 0.05$ simply means there is only a 1:20 chance that the differences between the variables would have happened by chance when in fact there is no real difference. If enough variables are examined in any study, significant differences will occur simply by chance. Trials with multiple endpoints or variables require more sophisticated analysis to determine the significance of individual risk factors. Univariable or multivariable logistic regression analysis techniques may be appropriate.

Statistics simply deal with the chance that observations between populations are different and should be treated with caution. Clinical results should show clear differences. If statistics are required to demonstrate differences between results, it is possible that they are unlikely to have major clinical significance.

Computer software packages available

Statistical computer packages offer a quick way of analysing descriptive statistics such as mean, median and range, as well as the most commonly used statistical tests such as the chi-squared test. Various packages are available commercially and are useful tools in data analysis.

ANALYSING A SCIENTIFIC ARTICLE

The simplest way to analyse an article from a scientific journal is to look at the checklist of requirements for good scientific research. A group of scientists and editors developed the CONSORT (Consolidated Standards of Reporting Trials) statement to improve the quality of reporting of RCTs. Looking in detail at the study design is often the best way of deciding whether a trial is any good. The CONSORT document includes a checklist for the conduct of good randomised trials (*Table 11.4*). Often clinicians overlook biases that others

TABLE 11.4 Checklist for authors.

Heading	Sub-heading	Descriptor
Title		Identify as randomised trial
Abstract		Structured format
Introduction		Prospectively defined hypotheses, clinical objective
Methods	Protocol	Study population
		Intervention, timing
		Primary and secondary outcome
		Statistical rationale
		Stopping rules
	Assignment	Unit of randomisation
		Method: allocation schedule
	Masking (blinding)	
Results	Participant flow and follow-up	Trial profile, flow diagram
	Analysis	Estimated effect of intervention
		Summary data with appropriate inferential statistics
		Protocol deviation
Comment		Specific interpretation of study
		Sources of bias
		External validity
		General interpretation

find obvious to detect, which can have a profound influence on the outcome of any study. Even the randomised design does not always guarantee quality, and a core component of systematic review is the grading of trial quality; several scoring systems have been developed (e.g. Jadad Score). Recent guidelines have been published formalising the methods of systematic review and meta-analysis (PRISMA guidelines), and also many other types of article. These can be found in the instructions to authors of most surgical journals, which will now only accept articles that follow the rules.

PRESENTING AND PUBLISHING AN ARTICLE

There is no point in conducting a research or audit project and then leaving the results unreported. Even when results are negative, they are worth distributing; no project if properly conducted is worthless. Under-reporting of negative outcomes causes a systematic bias in the literature in favour of positive trials. Most studies do not provide dramatic results, and few surgeons publish seminal articles.

The key to both presentation and publication is to decide on the message and then aim for an appropriate forum. Big important randomised studies or national audits merit presentation at national meetings and publication in international journals. Small observational studies and audits are more often accepted for presentation at regional or hospital meetings and for publication in smaller specialist journals. Help and advice from clinicians familiar with presentation and publication are invaluable at this stage. The most important piece of advice is to follow accurately the instructions for journal submission. Most international meetings will accept presentations eagerly (especially by poster) as this increases the attendance at a conference.

Most surgeons publish research in peer-reviewed journals. The work that is submitted is checked anonymously by other surgeons before publication. If in doubt about whether to submit to a journal, many editors will give advice about the suitability of an article for submission to their journal. It is usually free to publish in surgical journals, since the cost of refereeing and editing is born by the journal subscriber. A second model of publication is becoming more prevalent: open access, author pays. This ensures all research is visible to anyone, by pushing the costs of the editorial process onto the study budget. It may well become standard in future.

Convention dictates that articles are submitted in IMRAD form – introduction, methods, results and discussion. Increasingly, electronic publication and the Internet may change the face of scientific publication and, in the next decade, these restrictions on style may disappear. For now, the IMRAD format remains inviolable. The length of an article is important: a paper should be as long as the size of the message. Readers of big randomised multicentre trials wish to know as much detail about the study as possible; reports on small negative trials should be brief.

- **Introduction.** This should always be short. A brief background of the study should be presented and then the aims of the trial or audit outlined.
- **Methods.** The methodology and study design should be given in detail. It is important to own up to any biases. Any new techniques or investigations should be detailed in full; if they are common practice or have been described elsewhere, this should be referenced instead of described.
- **Results.** Results are almost always best shown diagrammatically using tables and figures if possible. Results shown in the form of a diagram need not then be duplicated in the text.
- **Discussion.** It is important not to repeat the introduction or reiterate the results in this section. The study should be interpreted intelligently and any suggestions for future studies or changes in management should be made. It is important not to indulge in flights of fantasy or wild imagination about future possibilities; most journal editors will delete these. Recently, a standard format for the discussion section has been promoted, and journals such as the *British Medical Journal* are keen that authors use it.
- **References.** This section should include all relevant papers recording previous studies on the subject in question. The number should reflect the size of the message and the importance of the work. The reference section does not usually have to be exhaustive, but should include up-to-date articles. Remember to present the references in the style of the journal of submission.

EVIDENCE-BASED SURGERY

Surgical practice has been considered an art: ask 50 surgeons how to manage a patient and you will probably get 50 different answers. There is so much clinical information available that no surgeon can know it all. Evidence-based surgery is a move to find the best ways of managing patients using clinical evidence from collected studies. It was estimated that sufficient evidence to justify routine myocardial thrombolysis for heart attacks was available years before the randomised clinical studies that finally made it clinically acceptable. No one had gathered all the available information together. Centres such as the Cochrane Collaboration have been collecting randomised trials and reviews to provide up-to-date information for clinicians. The Cochrane Library presently includes a database of systematic reviews, reviews of surgical effectiveness and a register of controlled trials. The *BJS* has been collecting surgical randomised trials on its website archive for 10 years (www.bjs.co.uk). There are now almost 1500 annotated references that can be a valuable resource for scientific authors. As evidence accumulates, it is expected that this will gradually smooth out the differences between clinicians as the best way of managing patients becomes more obvious. Collecting published evidence together and analysing it often requires reviews of multiple randomised trials. These meta-analyses involve complex statistical analyses designed to interpret multiple findings and synthesise the results of multiple studies.

Chapter 12

Surgical ethics and law

Learning objectives

To understand:

- The importance of autonomy in good surgical practice
- The moral and legal boundaries and practical difficulties of informed consent
- Good practice in making decisions about the withdrawal of life-sustaining treatment
- The importance and boundaries of confidentiality in surgical practice
- The importance of appropriate regulation in surgical research
- The importance of rigorous training and maintenance of good practice standards

INTRODUCTION

This chapter incorporates references to English common and statute law. Nevertheless, these legal and ethical principles have much in common with many other jurisdictions across the world.

Surgery, ethics and law go hand in hand. In any other arena of public or private life, if someone deliberately cuts another person, draws blood, causes pain, leaves scars and disrupts everyday activity, then the likely result will be a criminal charge. If the person dies as a result, the charge could be manslaughter or even murder. Self evidently, the difference between the criminal and the surgeon is that their intentions differ. While a criminal intentionally (or recklessly) inflicts harm, the surgeon's intention is limited to the treatment of illness. Any harm that ensues is either unintentional, or is necessary (such as an incision), to facilitate treatment.

Patients submit to surgery because they trust their surgeons. What should consent entail in practice and what should surgeons do when patients need help but are unable or unwilling to agree to it? When patients do consent to treatment, surgeons are provided with a wide discretion. The end result may be cure, but disfigurement, disability and death may also result. How should such surgical 'power' be regulated to reinforce the trust of patients and to ensure that surgeons practise to an acceptable professional standard? Are there circumstances, in the public interest, in which it is acceptable to sacrifice the trust of individual patients through revealing information that was communicated in what patients believed to be conditions of strict privacy?

These questions about what constitutes good professional practice concern medical ethics and law relating to consent, confidentiality and the underlying concept of personal autonomy.

In addition, these principles need to be applied to surgical activities, including professional matters relating to governance, regulation and the process of revalidation, in its different guises around the world. Surgical training is starting to embrace the 'basic science' of surgical law, to offer surgeons assistance in the resolution of such ethical dilemmas. This chapter is evidence of that process.

RESPECT FOR AUTONOMY

Surgeons have a duty of care towards their human patients that goes beyond just protecting their life and health. Their additional duty of care is to respect the autonomy of their patients and their ability to make choices about their treatments, and to evaluate potential outcomes in light of other life plans. Such respect is particularly important for surgeons because, without it, the trust between them and their patients may be compromised, along with the success of the surgical care provided. We are careful enough in everyday life about whom we allow to touch us and to see us unclothed. It is hardly surprising that many people feel strongly about exercising the same control over a potentially hazardous activity, such as surgery.

For all these reasons, there is a wide moral and legal consensus that patients have the right to exercise choice over their surgical care. In this context, a right should be interpreted as a claim that can be made on the surgeon. The surgeon, therefore, accepts the strict duty to respect the patient's choice, regardless of personal preferences. Thus, to the degree that patients have a right to make choices about proposed surgical treatment, it then follows that they should be allowed to refuse treatments that they do not want, even when surgeons think that they are wrong. The right to make an unwise

decision was exemplified in a recent case[1], where a woman with capacity refused renal replacement therapy. The court reminded doctors that notwithstanding the fact that other citizens might consider her decision unreasonable, illogical or even immoral, none of these criticisms of the decision by themselves provide evidence of a lack of capacity. Patients can refuse surgical treatment that will save their lives, either at present or in the future, the latter through the formulation of advance decisions or lasting powers of attorney specifying the types of life-saving treatments that they do not wish to have, notwithstanding that they may later become incompetent to refuse them.

INFORMED CONSENT

In surgical practice, respect for autonomy translates into the clinical duty to obtain informed consent before the commencement of treatment.

It is easy to underestimate the gap in understanding between a surgeon and his or her patient.[2] How many patients would recognise that unilateral eye surgery might lead to contralateral blindness? The risks and side effects of many operations are not intuitive, and the surgeon is not in the position to guess how the patient's plans for employment, leisure and family life may be inadvertently affected by a forseeable complication. A budding Olympic gymnast might choose to forgo surgery on a quiescent posterior triangle lesion if he or she knew the potentially consequences of division of the accessory nerve. That is why patients need to be informed, beforehand, so they can choose whether to take the risk.

To establish valid consent to treatment, patients need to be given appropriate and accurate information. In England and Wales, the Department of Health's Reference Guide to Consent should be consulted.

Such information, disclosed during a formal and tangible discussion, must include:

- the condition and the reasons why it warrants surgery;
- the type of surgery proposed and how it might correct the condition;
- the anticipated prognosis and expected side effects of the proposed surgery;
- the unexpected hazards of the proposed surgery;
- any alternative and potentially successful treatments other than the proposed surgery;
- the consequences of no treatment at all.

With such information, patients can link their clinical prospects with the management of other aspects of their life and the lives of others for whom they may be morally and/or professionally responsible. Good professional practice dictates that obtaining informed consent should occur in circumstances that are designed to maximise the chances of patients understanding what is said about their condition and proposed treatment, as well as giving them an opportunity to ask questions and express anxieties.

Where possible:

- a quiet venue for discussion should be found;
- written material in the patient's preferred language should be provided to supplement verbal communication, together with diagrams where appropriate;
- patients should be given time and help to come to their own decision;
- the person obtaining the consent should ideally be the surgeon who will carry out the treatment. It should not be – as is sometimes the case – a junior member of staff who has never conducted such a procedure and thus may not have enough understanding to counsel the patient properly.

Good communication skills go hand in hand with properly obtaining informed consent for surgery. It is not good enough just to go through the motions of providing patients with the information required for considered choice. Attention must be paid to:

- whether or not the patient has understood what has been stated;
- avoiding overly technical language in descriptions and explanations;
- the provision of translators for patients whose first language is not English;
- asking patients if they have further questions.

When there is any doubt about their understanding, patients should be asked questions by their surgeon about what has supposedly been communicated to see if they can explain the information in question for themselves.

Surgeons have a legal as well as a moral obligation to obtain consent for treatment based on appropriate disclosure. Failure to do so could result in one of two civil proceedings, assuming the absence of criminal intent. First, in law, intentionally to touch another person without their consent is a battery, remembering that we are usually touched by strangers as a consequence of accidental contact. Surgeons have an obligation to give the conscious and competent patient sufficient information 'in broad terms' about the surgical treatment being proposed and why. If the patient agrees to proceed, no other treatment should ordinarily be administered without further explicit consent.

The second legal action that might be brought against a surgeon for not obtaining appropriate consent to treatment is in the tort (civil wrong) of negligence. Patients may have been given enough information about what is surgically proposed to agree to be touched in the ways suggested. However, surgeons may still be in breach of their professional duty if they do not provide sufficient information about the risks that patients will encounter through such treatment. Although standards of how much information should be provided about risks vary between nations, as a matter of good practice, surgeons should inform patients of the hazards that any reasonable person in the position of the patient would wish to know. In UK law, this level and style of disclosure has been most recently reviewed in the case of *Montgomery v Lanarkshire Health Board*.[2]

Finally, surgeons now understand that, when they obtain consent to proceed with treatment, patients are expected to sign a consent form of some kind. The detail of such forms can differ, but they often contain very little of the information

supposedly communicated to the patient who signed it. Partly for this reason, the process of formally obtaining consent can become overly focused on obtaining the signature of patients rather than ensuring that appropriate types and amounts of information have been provided and have been understood.

Both professionally and legally, it is important for surgeons to understand that a signed consent form is not proof that valid consent has been properly obtained. It is simply a piece of evidence that consent may have been attempted. Even when they have provided their signature, patients can and do deny that appropriate information has been communicated or that the communication was effective. Surgeons are therefore well advised to make brief notes of what they have said to patients about their proposed treatments, especially information about significant risks. These notes should be placed in the patient's clinical record, perhaps by referring to the disclosure in the letter to the family doctor, copied to the patient. In addition, information sheets describing the generic risks, benefits and complications associated with the proposed procedure can be provided.

PRACTICAL APPLICATION

Thus far we have examined the moral and legal reasons why the duty of surgeons to respect the autonomy of patients translates into the specific responsibility to obtain informed consent to treatment. For consent to be valid, adult patients must:

- have capacity to give it – be able to understand, remember and deliberate about whatever information is provided to them about treatment choices, and to communicate those choices;
- not be coerced into decisions that reflect the preferences of others rather than themselves;
- be given sufficient information for these choices to be based on an accurate understanding of reasons for and against proceeding with specific treatments.

Surgical care would grind to a halt if it were always necessary to obtain explicit informed consent every time a patient is touched in the context of their care. Fortunately, it is an elementary step merely to ask the patient whether they mind being examined – the usual response will be acceptance. This simple transaction illustrates that the legal and ethical 'rules' that govern a surgeon are often no more than an expression of good clinical practice; in this case, politeness.

Some patients will not be able to give consent because of temporary incapacity. This may result from their presenting illness or intoxication, or an unanticipated situation may be encountered midway through a general anaesthetic. The moral and legal rules that govern such situations are clear. The doctrine of medical necessity enables the surgeon, in an emergency, to save life and prevent permanent disability, operating without consent. This is employed daily, where unconsious emergency patients undergo surgery to save 'life and limb'. No consent has been provided and none is required, providing the treatment is in the patient's best interests.

However, if the patient has made a legally valid advance decision refusing treatment of the specific kind required, their decision must be honoured, providing it is applicable to the current clinical situation. Where possible, surgery on patients who are temporarily incapacitated should be postponed until their capacity is restored and they are able to give informed consent or refusal for themselves.

Surgeons must take care to respect the distinction between procedures that are necessary to prevent death or irremediable harm, and those that are done merely out of convenience. If the patient consents only to a dilatation and currettage, do not consider performing an additional hysterectomy 'in her best interests', simply because she is anaesthetised.

Consent may be made impossible by incompetence of other kinds. In the case of children, parents or someone with parental responsibility are ordinarily required to provide consent on their behalf. This said, surgeons should:

- take care to explain to children what is being surgically proposed, and why;
- always consult with children about their response;
- where possible, take the child's views into account and note that even young children can be competent to consent to treatment provided that they too can understand, remember, deliberate about and believe information relevant to their clinical condition. Plainly, it is almost always appropriate in addition to discuss the treatment with their parents.

When such *Gillick* competence is present, under English law, children can provide their own consent to surgical care, although they cannot unconditionally refuse it until they are 18 years old. These provisions illustrate the importance of respecting as much autonomy as is present among child patients and remembering that, for the purposes of consent to medical treatment, they may be just as autonomous as adults.

If capacity in adults is erased by psychiatric illness or mental handicap, other moral and legal provisions hold. If patients lack the autonomy to choose how to protect themselves as regards the consequences of their illness, then others charged with protecting them must assume the responsibility. However, care must be taken not to abuse this duty. Even when such patients have been legally detained for compulsory psychiatric care, it does not follow that such patients are unable to provide consent for surgical care. Their capacity should be assumed and consent should be sought. Only if it is established with the help of their carers that such patients also lack capacity to provide consent for surgery, and that they are at risk of death or serious and permanent disability, can therapy then proceed in their best interests. However, if treatment can be postponed, then this should be done until, as a result of their psychiatric care, patients become able either to consent or to refuse. If this recovery is not predicted, then legal steps may be taken to make elective surgery lawful. As with children, respect should always be shown for as much autonomy as is present.

Absence of capacity in adults does not vitiate the requirement, where possible, to take into account their sentiments during clinical decision making. In a recent case, a judge declared that an elderly man with a septic leg, although incapacitated by his mental illness, had feelings, beliefs and values that weighed so heavily in the consideration of his best

interests that they outweighed the clinical desire to save his life by amputation.[3] Although an unusual judgement in this context, it reflects the growing determination to give incapacitated adults an opportunity to influence their fate, as best they can.

In adult patients who are permanently incapacitated, and thus unable to provide consent for surgery, as noted above, the doctrine of necessity obtains and surgery can proceed in an emergency to save life, to prevent serious and permanent injury. Elective treatment for less grave complaints can also be provided, and in England and Wales is done so under the auspices of the Mental Capacity Act 2005. The associated Code of Practice guides the surgeon in matters of capacity and disclosure, and in dealing with those who have taken steps to influence their treatment, anticipating the time that they will have lost their capacity. These arrangements may manifest either in documentary form, as Advance Decisions, or in person, in the form of persons appointed with a Lasting Power of Attorney.

It is not possible for relatives of incapacitated adult patients to sign consent forms for surgery on their behalf. Indeed, to make such requests can be a disservice to relatives, who may feel an unjustified sense of responsibility if the surgery fails. This said, relatives play a vital role in providing background information about the patient, allowing the clinician to assess and then determine what treatment is in the best interests of the patient.

MATTERS OF LIFE AND DEATH

It has been noted that the right of an adult with capacity to consent to and refuse lawful treatment is unlimited, including the refusal of life-sustaining treatment. Probably the example of this most familiar to surgeons is Jehovah's Witnesses, who may refuse blood transfusions at the risk of their own lives.

There will be some circumstances in which sustaining the life and health of incapacitated adult patients is judged to be inappropriate. They are no longer able to be consulted and may not have expressed a view about what their wishes would be in such circumstances. Here, if possible after discussion and consensus with the next of kin, a decision may be made to withhold or to withdraw life-sustaining treatment on behalf of the incapacitated patient. The fact that such decisions can be seen as omissions to act does not excuse surgeons from morally and legally having to reconcile them with their ordinary duty of care. Ultimately, this can only be done through arguing that such omissions to sustain life are in the patient's best interests.

The determination of best interests in these circumstances will rely on one of three objective criteria, over and above the subjective perception by the surgeon that the quality of life of the patient is poor. There is no obligation to provide or to continue life-sustaining treatment:

- if doing so is futile, when clinical consensus dictates that it will not achieve the goal of extending life. Thought of in this way, judgements about futility exclude considering patient's quality of life, and thus can be difficult to justify as long as treatment might stand even a very small chance of success;
- if a patient is imminently and irreversibly close to death – in such circumstances, it would not be in the patient's best interests to prolong life slightly (e.g. through the application of intensive care) when, again, there is no hope of any sustained success. Declining needlessly to interfere with the process of a dignified death can be just as caring as the provision of curative therapy;
- if patients are so permanently and seriously brain damaged that, lacking awareness of themselves or others, they will never be able to engage in any form of self-directed activity. The argument here is backed up by moral and legal reasoning: that further treatment other than effective palliation cannot be in the best interests of patients as it will provide them with no benefit.

When any of these principles are employed to justify an omission to provide or to continue life-sustaining treatment, the circumstances should be carefully recorded in the patient's medical record, along with a note of another senior clinician's agreement.

Furthermore, the decision to discontinue life-sustaining tretament may go hand in hand with a decision not to attempt cardiopulmonary resuscitation, in the event of cardiorespiratory arrest. In England, it is settled law that before finally making this decision, doctors must discuss it with patients or their relatives.[4] The reason for this insistence is that the patient may have personal circumstances, unbeknown to the surgeon, which might yet influence this final (and for the patient, portentous) decision. The only exclusion to this legal rule is where discussion of this matter with the patient may cause them not merely distress, but harm.

Finally, surgeons will sometimes find themselves in charge of the palliative care of patients whose pain is increasingly difficult to control. There may come a point in the management of such pain when effective palliation is possible at the risk of shortening a patient's life because of the respiratory effects of the palliative drugs. In such circumstances, surgeons can with legal justification administer a dose that might be dangerous, although experts in palliative care are sceptical that this is ever necessary with appropriate training. In any case, the argument employed to justify such action refers to its 'double effect': that both the relief of pain and death might follow from such an action. Intentional killing (active euthanasia) is rejected as unlawful malpractice throughout most of the world. A foreseeably lethal analgesic dose is thus regarded as appropriate only when it is solely motivated by palliative intent, and this motivation can be documented. Recent authority from criminal law indicates that if an analgesic injection is 'virtually certain' also to kill the patient, a court might deduce that the person giving the injection had an intention to kill. The key to the defence of double effect is the absolute absence of such an intention.

A **Jehovah's Witness** is a member of a millenarian fundamentalist Christian sect founded in America in 1884. They have their own translation of the Bible, which they interpret literally.

TRANSPLANTATION

The law and ethics of organ transplantation require more space than this chapter allows. In common with other nations, the UK has a statutory framework for transplantation, but even amongst this small group of nations, there is no unanimity of legislation, thus rules for deceased and live donor transplants differ. In general, the rules for defining a dead donor, for compensating a living donor and for legitimising a market in organs differ widely. It is strongly recommended that you refer to the rules within your own jurisdiction.

CONFIDENTIALITY

Respect for autonomy does not entail only the right of capacitous patients to consent to treatment. Their autonomous right extends to control over their confidential information, and surgeons must to respect their privacy, not communicate information revealed in the course of treatment to anyone else without consent. Generally speaking, such respect means that surgeons must not discuss clinical matters with relatives, friends, employers and others unless the patient explicitly agrees. To do otherwise is regarded by all the regulatory bodies of medicine and surgery as a grave offence, incurring harsh penalties. For breaches of confidentiality are not only abuses of human dignity, they again undermine the trust between surgeon and patient on which successful surgery and the professional reputations of surgeons depend.

Important as respect for confidentiality is, however, it is not absolute. Surgeons are allowed to communicate private information to other professionals who are part of the healthcare team, provided that the information has a direct bearing on treatment. Here, it is argued that patients have given their implied consent to such communication when they explicitly consent to a treatment plan. Whether implied consent can ever be valid is a matter for public debate, as government attempts to apply the doctrine to tissue donation and access to electronic health records. Such examples of implied 'consent' are better viewed as mere aquiescence of patients, ignorant of and not objecting to decisions made about them.

Patients cannot expect strict adherence to the principle of confidentiality if it poses a serious threat to the health and safety of others. There will be some circumstances in which confidentiality either must or may be breached in the public interest. For example, it must be breached as a result of court orders or in relation to the requirements of public health legislation. Confidentiality may be waived in the interests of preventing serious crime or to protect the safety of other known individuals who are at risk of serious harm.

RESEARCH

As part of their duty to protect life and health to an acceptable professional standard, surgeons have a subsidiary responsibility to strive to improve operative techniques through research, to assure themselves and their patients that the care proposed is the best that is currently possible. Yet there is moral tension between the duty to act in the best interests of individual patients and the duty to improve surgical standards through exposing patients to the unknown risks that any form of research inevitably entails.

The willingness to expose patients to such risks may be further increased by the professional and academic pressures on many surgeons to maintain a high research profile in their work. For this reason, surgeons (and physicians, who face the same dilemmas) now accept that their research must be externally regulated to ensure that patients give their informed consent, that any known risks to patients are far outweighed by the potential benefits, and that other forms of protection for the patient are in place (e.g. proper indemnity) in case they are unexpectedly harmed. The administration of such regulation is through research ethics committees, and surgeons should not participate in research that has not been approved by such bodies. Equally, special provisions will apply to research involving incompetent patients who cannot provide consent to participate, and research ethics committees will evaluate specific proposals with great care.

In practice, it is not always clear as to what constitutes 'research' that should be subjected to regulation, as compared with a minor innovation dictated by the contingencies of a particular clinical situation. Surgeons must always ask themselves in such circumstances whether or not the innovation in question falls within the boundaries of standard procedures in which they are trained. If so, what may be a new technique for them will count not as research but as an incremental improvement in personal practice. Nevertheless, major innovations in operative procedure are scrutinised by national regulatory authorities; in the UK by the National Institute for Health and Care Excellence. This process of scrutiny has been designed to ensure that the innovation is safe, efficacous and cost effective. It is regarded (by the NHS) as a mandatory step when introducing a new interventional procedure.

Equally, surgeons know that exigencies of operative surgery sometimes demand a novel and hitherto undecsribed manoeuvre to get the surgeon (and the patient) out of trouble. Providing your solution is necessary, proportionate to the circumstances, performed in good faith and would pass the scrutiny of your peers as reasonable, it is unlikely that any subsequent criticism of your actions could be sustained.

If a proposed innovation passes the criteria for research, it should be approved by a research ethics committee. Such surgical research should also be subject to a clinical trial designed to ensure that findings about outcomes are systematically compared with the best available treatment and that favourable results are not the result of arbitrary factors (e.g. unusual surgical skill among researchers) that cannot be replicated.

MAINTAINING STANDARDS OF EXCELLENCE

To optimise success in protecting life and health to an acceptable standard, surgeons must only offer specialised treatment in which they have been properly trained. To do so will entail sustained further education throughout a surgeon's career in the wake of new surgical procedures. While training, surgery should be practised only under appropriate supervision by someone who has appropriate levels of skill. Such skill can

be demonstrated only through appropriate clinical audit, to which all surgeons should regularly submit their results. When these reveal unacceptable levels of success, no further surgical work of that kind should continue unless further training is undergone under the supervision of someone whose success rates are satisfactory. To do otherwise would be to place the interest of the surgeon above that of their patient, an imbalance that is never morally or professionally appropriate.

Surgeons also have a duty to monitor the performance of their colleagues. To know that a fellow surgeon is exposing patients to unacceptable levels of potential harm and to do nothing about it is to incur some responsibility for such harm when it occurs. Surgical teams and the institutions in which they function should have clear protocols for exposing unacceptable professional performance and helping colleagues to understand the danger to which they may expose patients. If necessary, offending surgeons must be stopped from practising until they can undergo further appropriate training and counselling. Too often, such danger has had to be reported by individuals whose anxieties have not been properly heeded and who have then been professionally pilloried rather than acknowleged for their contribution to patient safety. Those who participate in closing ranks, and ostracism, share the moral responsibility for any resulting harm to patients. If something goes wrong with surgical treatment, the UK health regulators unanimously insist that the patient should be told what has happened; in many senses, a similar disclosure to that which occurred during the consent process, but now with the benefit of hindsight. Again, this candid disclosure is designed to put the patient in the same position as the surgeon, with respect to information about their health.[5]

CONCLUSION

Surgeons have combined duties to their patients; to protect life and health and to respect autonomy, both to an acceptable professional standard. The specific duties of surgeons are shown to follow from these: reasonable practice concerning informed consent; confidentiality; decisions not to provide, or to omit, life-sustaining care; surgical research; and the maintenance of good professional standards. The final duty of surgical care is to exercise all these general and specific responsibilities with fairness and justice, and without arbitrary prejudice. Now, at least partly either enshrined in statute or echoed in the English common law, these duties closely reflect the guidance of the General Medical Council.

The conduct of ethical surgery illustrates good citizenship: protecting the vulnerable and respecting human dignity; and equality. To the extent that the practice of individual surgeons is a reflection of such sustained conduct, they deserve the civil respect that they often receive. To the extent that it is not, they should not practise the honourable profession of surgery.

Chapter 13

Human factors, patient safety and quality improvement

Learning objectives

To learn:

- The reasons why contemporary healthcare, despite all its advances, is often less than satisfactory
- The importance of understanding human behaviour if patient care is to improve
- 'Human factors', what they are, and their importance in understanding and rectifying error and working together as teams
- The importance of patient safety and the scale of the problem
- Medical error and its definitions including adverse events and near misses
- Patient safety strategies and solutions
- Applying the science of patient safety into clinical practice
- Patient safety as it relates to the surgeon
- Quality improvement as an overarching activity designed to address gaps in the quality of healthcare delivery
- The different kinds of quality measures
- The patient's surgical journey and its potential for inefficiency and waste
- Some of the methodologies, tools and skills needed for quality improvement
- The need for system thinking and leadership
- The importance of quality improvement, its place in education and as a strategy to address significant healthcare challenges

INTRODUCTION

During the last century improving public health is credited with adding 25 years to the average life expectancy of populations in resource-rich countries. Contributing achievements include immunisation, motor vehicle safety, workplace safety, control of infectious disease, declines in deaths from heart disease and stroke, safer and healthier foods, healthier mothers and babies, family planning and the recognition of tobacco as a health hazard. At the same time the array of surgical, medical, diagnostic and remedial possibilities that can be offered to patients is well illustrated in the chapters of this book with many of the newer innovations developed, not just in the last century, but in the last 20–30 years. This has, in turn, led to greater specialisation. A combination of these three factors presents today's healthcare with two big challenges: greater demand due to greater volumes of patients who are older and have more chronic diseases often requiring multidisciplinary care; and an increasing volume of treatment options often of increasing complexity and cost.

However, the acquisition of newly learnt abilities to manage and treat all these patients and conditions does not mean that these tasks are performed well. Added to this, financial outlay on healthcare is struggling to meet the supply of healthcare providers and this leaves the long-term implications for the quality of patient care uncertain. According to the Institute of Medicine (IoM), patients do not always receive the most suitable care, at the best time or in the best place. Its influential report, '*Crossing the Quality Chasm: A New Health System for the 21st Century*', emphasised the need to redesign healthcare processes and systems in response to this quality gap. It called on providers to ensure more efficient, safe, timely, effective, patient-centred and equitable care.

HUMAN FACTORS

Healthcare largely depends on direct human interventions. It has many goals, which span from preserving life and relieving distress to a wide range of more mundane services all of which society demands must be performed safely and efficiently and achieve broad-based user satisfaction. It is arguably more complex than any other broadly equivalent industry, and because it is extremely resource sensitive, it critically requires a strong evidence base. Even then the return on investment is often difficult to measure. As patient safety and quality improvement are dependent on human behaviour, as well as the systems and processes designed by health care workers,

any discussion on these issues is helped by first addressing those 'human factors'.

Human factors (HF) is the study of the interrelationship between humans, the tools they work with and the environment in which they work. A greater understanding of these relationships in healthcare should enhance performance through a better understanding of the effects of teamwork, tasks, equipment, workspace, culture and organisation on human behaviour in clinical settings The SHELL model was designed to help understand these relationships (**Figure 13.1**).

The SHELL concept is named after the initial letters of its components – **S**oftware, **H**ardware, **E**nvironment and two **L**ivewares. In the centre of the model is the human operator, or the first Liveware, represented by 'L'. This may be any individual whose job is relevant to patient care. It is the most flexible component in the system but may be unpredictable due to individual factors such as personality, motivation, stress tolerance, skills, knowledge and attitudes. To overcome these intrinsic limitations the interface with the other components of the SHELL model must be adapted and matched to the Liveware component for optimum performance.

The first interface, Liveware–Hardware, has much to do with the ergonomic design of the tools and medical devices that are used and designed in such a way that they should, for example, make it difficult for the user to make a mistake.

The Liveware–Software interface encompasses the non-physical aspects of the system such as manuals, checklists and computer programs. An adequate Liveware–Software interface should produce a situation where procedural omissions are difficult to make.

The Liveware–Environment interface may include stressors in the physical environment that have to be coped with such as noise, poor acoustics and overcrowding.

The second Liveware–Liveware interface is the interface of interpersonal communication. It embraces concepts such as team coordination, conflict resolution and the continuity of information flow in the care of patients.

In the SHELL model diagram the edges of the blocks are uneven. This is to illustrate the fact that the interdependent components are constantly changing and will never match perfectly. HF are concerned with minimising the mismatch between the different components.

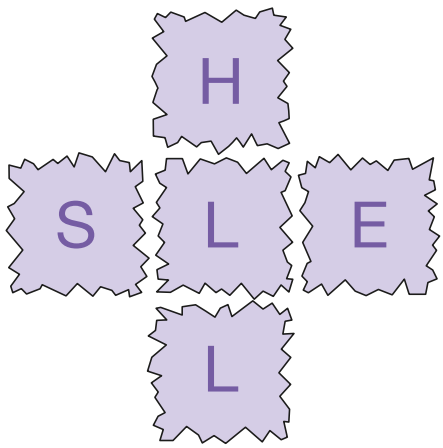

Figure 13.1 SHELL model.

HF was conceived in the 1940s in the aviation industry and is where its principles have been most successfully applied. HF training in healthcare enhances clinical performance through an understanding of the effects of teamwork, tasks, equipment, workspace, culture and organisation on human behaviour in clinical settings. An HF approach to patient safety differs from traditional safety training in that the focus is less with the technical knowledge and skills required to perform specific tasks, but rather with the cognitive and interpersonal skills needed to effectively manage a team-based, high-risk activity.

Crew Resource Management (CRM) training is another term used to describe HF training. In the CRM context, cognitive skills are the mental processes used for gaining and maintaining situational awareness, for solving problems and making decisions. Interpersonal skills are the communications and behavioural activities associated with teamwork. CRM training develops effective communication skills and a cohesive environment among team members, and builds an atmosphere in which all personnel feel empowered to speak up when they suspect a problem. Team members are trained to cross-check each other's actions, offer assistance when needed and address errors in a non-judgmental fashion. Debriefing and providing feedback are also components of CRM training. It also emphasises the role of fatigue, perceptual errors (such as misreading monitors or mishearing instructions) and the impact of management styles and organisational cultures.

It is now widely recognised that HF training, specialist HF groups and the integration of HF into systems, processes and incident investigation is extremely important for achieving the highest standards of patient safety. However, safety is just one aspect of a wider HF systems approach to equipment, task, environment and organisational design. HF training can also significantly contribute to the quality, accessibility and cost of healthcare services.

Summary box 13.1

Acknowledging the gap between medical progress and the delivery of quality patient care

- The need to recognise the things that are wrong
- Understanding that HF among care givers often provides both the causes and the potential solutions
- The different factors that impact on human behaviour can be identified
- Team working is a prerequisite of contemporary healthcare
- The place of CRM training

PATIENT SAFETY

Medicine will never be a risk-free enterprise. From the beginning of training, doctors are taught that errors are unacceptable and that the philosophy of *primum non nocere* (first, do no harm) should permeate all aspects of treatment. Yet, worldwide, despite all the improvements in treatment and investment in technologies, training and services, there

remains the challenge of dealing with unsafe practices, incompetent healthcare professionals, poor governance of healthcare service delivery, errors in diagnosis and treatment and non-compliance with accepted standards.

When errors do occur there continue to be inadequate systems in place to ensure that all those affected are informed and cared for, and that there is a process of analysis and learning to uncover the cause and prevent recurrence of such events. Patient safety has become an established healthcare discipline in its own right thus formalising approaches to these inadequacies, directing research and offering solutions for the future.

THE PREVALENCE OF ADVERSE HEALTHCARE EVENTS

The aviation and nuclear industries have a much better safety record than healthcare. This became abundantly clear when, in 1999, the Institute of Medicine of the National Academy of Sciences released a report, '*To Err is Human: Building a Safer Health System*', that drew widespread attention to the alarming statistics that there were between 44,000 and 98,000 preventable deaths annually due to medical error in American hospitals with some 7,000 preventable deaths related to medication errors alone. This experience has been found to be similar in other resource-rich countries and was emphasised by the Bristol Royal Infirmary Inquiry of 2001 into a series of unacceptable paediatric cardiac surgical deaths. The World Health Organization (WHO) estimates that, even in advanced hospital settings, one in ten patients receiving health care will suffer preventable harm.

The financial burden of unsafe care globally is also compelling, resulting as it does in prolonged hospitalisation, loss of income, disability and litigation costing many billions of dollars every year.

In the years since the Institute of Medicine report there have been many initiatives to improve patient safety. Some interventions have been shown to reduce errors but many have still not been rigorously evaluated. Overall, it remains doubtful whether efforts to reduce errors at national, regional and local levels have yet translated into significant improvements in the safe care of patients. The Francis report (2013) of the Mid Staffordshire NHS Foundation Trust Public Inquiry identified multiple problems relating to that institutions safety culture.

It has also been stated recently that if medical error was a disease it would rank as the third leading cause of death in the United States after heart disease and cancer, although this information is not currently captured or coded on death certificates. This has led to a call for human and system errors to become part of disease coding systems, such as the ICD system – the International Classification of Diseases coding system – that is used by 117 countries for patient administrative purposes.

COMMON CAUSES OF ADVERSE HEALTHCARE EVENTS

Most medical care entails some level of risk to the patient either from their underlying condition or its treatment which, of itself, may lead to recognised complications or side effects. These episodes are different from **patient safety incidents**, which have been described as preventable events or circumstances that could have, or did, result in unnecessary harm to the patient. This might be an adverse event, a near miss or a no-harm event (*Table 13.1*).

The most frequent contributing factors that lead to patient safety incidents are listed in *Table 13.2*. Of these, inadequate communication between healthcare staff, or between medical staff and their patients or family members, ranks highest in frequency.

TABLE 13.1 Patient safety incidents.

Definitions	
An adverse event	An incident that results in harm to the patient
A near miss	An incident that could have resulted in unwanted consequences but did not, either by chance or through a timely intervention preventing the event from reaching the patient
A no-harm event	An incident that occurs and reaches the patient but results in no injury to the patient. Harm is avoided by chance or due to mitigating circumstances

TABLE 13.2 Factors that contribute to patient safety incidents.

Human factors	Inadequate patient assessment; delays or errors in diagnosis
	Failure to use or interpret appropriate tests
	Error in performance of an operation, treatment or test
	Inadequate monitoring or follow-up of treatment
	Deficiencies in training or experience
	Fatigue, overwork, time pressures
	Personal or psychological factors (e.g. depression or drug abuse)
	Patient or working environment variation
	Lack of recognition of the dangers of medical errors
System failures	Poor communication between healthcare providers
	Inadequate staffing levels
	Disconnected reporting systems or over-reliance on automated systems
	Lack of coordination at handovers
	Drug similarities
	Environment design, infrastructure
	Equipment failure due to lack of parts or skilled operators
	Cost-cutting measures by hospitals
	Inadequate systems to report and review patient safety incidents
Medical complexity	Advanced and new technologies
	Potent drugs, their side effects and interactions
	Working environments – intensive care, operating theatres

UNDERSTANDING PATIENT SAFETY INCIDENTS

Understanding the concepts underlying patient safety incidents is useful because it helps to anticipate situations that are likely to lead to errors and highlights areas where preventative action can be taken. The problem of error can be viewed in two ways – from a person approach or from a system approach.

The person approach

Human performance principles tell us that humans are fallible and that errors can occur through doing the wrong thing – errors of commission; failure to act – errors of omission; or errors of execution – doing the right thing incorrectly. These principles also tell us that, by understanding the reasons why adverse events and near misses occur and by applying the lessons learnt from past events, future errors can be prevented. However, for most errors the person approach on its own tends to blame the individual and restricts learning.

The system approach

Health systems add complex organisational structures to human fallibility thus substantially increasing the potential for errors. A systems approach to error recognises that adverse events rarely have a single isolated cause and that they are best addressed by examining why the system failed rather than who made the mistake. James Reason, former Professor of Psychology at Manchester University, has stated that, "We cannot change the human condition but we can change the conditions under which people work so as to make error less provoking."

Heinrich's safety pyramid

Developed in 1931, Heinrich's safety pyramid (**Figure 13.2**) theorised that unsafe acts or near misses lead to minor injuries and, over time, to a major injury. The accident pyramid proposes that for every 300 near misses there are 29 minor injuries and one major injury. **Risk assessment**, which is a step in risk management that calculates the value of risk related to a situation or hazard, has shown us that what prevents patients from being hurt is not only by reducing the number of mistakes but rather by increasing the number of defences set up against the consequences of mistakes. The key message is that near misses provide the best data about the reliability of safety systems. It is, therefore, most important to report near misses as well as adverse events to ensure that defences against adverse events are built and sustained.

Swiss cheese model

Reason's theory of accident causation, often referred to as the Swiss Cheese Model (**Figure 13.3**), is as well known in the aviation and nuclear power industries as it is in healthcare. His model takes Heinrich's concept forward and proposes the notion of **active failures** – acts that are committed by those at the coal face such as slip-ups, lapses or mistakes – and **latent conditions** – created by decisions taken at a higher level within the organisation leading, for example, to staff shortages or time pressures

Reason hypothesised that all organisations operating in potentially harmful environments tend to build up defences against potential damage and that these defences can be broken down by active failures or latent conditions. Although latent conditions are not harmful in themselves, they lie dormant within the system before combining with active failures to bypass the defences.

The defences in this model are represented as slices of Swiss cheese. This is because, instead of being intact, they are, in reality, full of holes or defects that represent either active failures or latent conditions. In addition, these gaps in the defences may not be static but can open and close and change position over time. Danger arises when a set of holes line up for a brief window, allowing a potential hazard to become a fully blown accident. Each slice of cheese or defence is an opportunity to prevent an accident and the more slices there are and the fewer holes the less likely it is that an accident will occur or harm be done to a patient.

While healthcare workers are often at the sharp end of an error they are also often error catchers. It is the clinician's responsibility to observe, discuss and highlight latent conditions before adverse events occur and ensure the appropriate defences are in place.

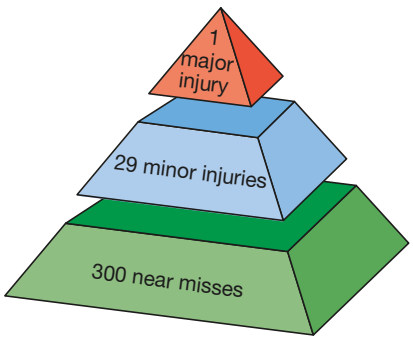

Figure 13.2 Heinrich's pyramid.

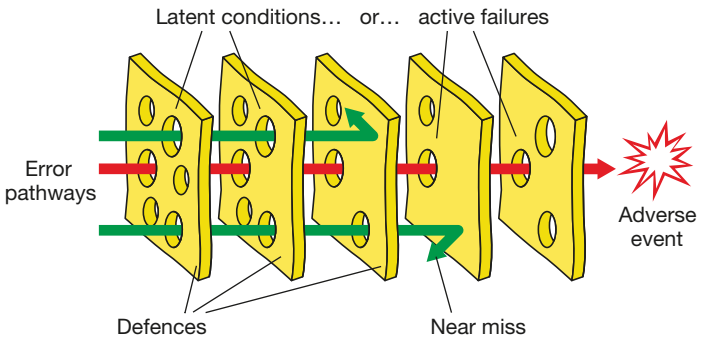

Figure 13.3 Reason's Swiss cheese model.

Herbert William Heinrich, 1886–1962, Assistant Superintendent, Engineering and Inspection Division of Travellers Insurance Co., Hartford, Connecticut, USA. He was a pioneer in industrial safety and developed his pyramid in 1931 when he published the book Industrial Accident Prevention: A Scientific Approach.
James T Reason, contemporary, Professor of Psychology, University of Manchester, proposed in 1990 'The Swiss Cheese Model of Accident Causation'.

Summary box 13.2

Understanding patient safety incidents

- Errors can be viewed from a person-centred or a system approach
- The majority of near misses or adverse events are due to system factors
- Understanding why these errors occur and applying the lessons learnt will prevent future injuries to patients
- It is important to report all near misses or adverse events so that we can constantly learn from mistakes
- Error models can help us understand the factors that cause near misses and adverse events and also direct us to where our defences against harm need to be improved

STRATEGIES FOR PATIENT SAFETY

International

Safety is everybody's business. Since the Institute of Medicine report the WHO has adopted a strong leadership role with many initiatives aimed at addressing safety challenges, notably '*WHO SAVE LIVES: Clean Your Hands campaign*' to ensure sustainable hand hygiene and which has now been adopted by almost 18,000 health facilities in 179 countries, and, '*WHO Guidelines for Safe Surgery 2009*' which includes the Surgical Safety Checklist aimed at decreasing the incidence of operative complications.

In low- and middle-income countries the WHO has also identified priority areas for patient safety such as the Pulse Oximetry Project set up to improve surgical safety and the Global Initiative for Emergency and Essential Surgical Care, a collaboration to reduce death and disability from injuries, pregnancy-related complications, congenital anomalies, disasters and other surgical conditions.

Resource-rich countries

Many governments and national organisations in such countries have developed important strategies aimed at delivering safety and quality in healthcare. These include:

- regulating and licensing of physicians and healthcare institutions;
- developing and adopting policies for patient safety and quality improvement;
- providing patient safety education programmes;
- instituting national clinical audits;
- reporting (and learning from) adverse events;
- setting up agencies to resolve concerns about the practice of doctors by providing case and incident management services.

Resource-poor countries

Resource-poor countries share many of the aspirations and challenges of richer countries. However, they also face issues that are different and require different strategies. The probability of a patient being harmed in hospital is higher with, for example, the risk of healthcare-associated infection being as much as 20 times higher than in richer countries. At least 50% of medical equipment in resource-poor countries is unusable or only partly usable and often the equipment is not used due to lack of parts or necessary skills. In some countries, the proportion of injections given with syringes or needles reused without sterilisation is as high as 70%. Each year, unsafe injections cause 1.3 million deaths, primarily due to transmission of hepatitis viruses and human immunodeficiency virus. Clearly these issues need to be met with a specific range of initiatives.

Institutional or hospital

Team working and training

In order to decrease errors and increase patient safety many medical team training programmes have now been developed internationally, often based on CRM or HF programmes. Some of these programmes are domain-specific (such as in anaesthesia), others are multidisciplinary (emergency department or operating room based), some rely on state-of-the-art simulators (critical care) and others rely primarily on classroom instruction.

Motivated and well prepared healthcare workers who are educated and trained to work together can reduce risks to patients, themselves and their colleagues, especially if they manage incidents positively and make the most of opportunities to learn from adverse events and near misses. Increasingly, healthcare institutions will have to provide this kind of educational support for their workforce.

Teams can work as **clinical microsystems**, which are quality improvement units that can be defined as a small group of people who work together, usually on a regular basis, to provide care. The individuals who receive that care can also be recognised as members of a discrete subpopulation of patients. Clinical microsystems have clinical and business aims, linked processes, a shared information environment and produce services and care that can be measured as performance outcomes. These systems evolve over time and are aimed to become embedded into the larger macrosystems or organisations. As with any living adaptive system, the microsystem must carry out the work, meet the staff needs and maintain its coherence as a clinical unit. Clinical microsystems can be assessed on their evidence base, leadership, patient and staff focus and information systems. In the delivery of healthcare, clinical microsystems invariably come into contact with other microsystems and interactions at their boundaries are common and should be understood and accommodated.

Using information technology

A major barrier to providing quality care to patients is the way health information is collected and stored in paper-based records, often in locations remote from where care is provided. Paper-based record systems are more susceptible to errors and permit fewer checks than electronic systems. There is now good evidence that the routine use of information and

communication technology (ICT) will contribute greatly to the use of real time data to support clinical decisions, thereby supporting healthcare workers and patients to more easily access reliable health information and reduce medical errors. Good examples include electronic patient records and physician order entry systems for medication prescribing. However, there are drawbacks to the introduction of these systems including the high capital costs, underestimation of the change management and redesign of clinical processes required, and concern that systems will become obsolete.

Summary box 13.3

Strategies for patient safety

- The WHO has established a number of international initiatives for patient safety
- Various national approaches are being undertaken by countries
- In resource-poor countries patient safety issues are more acute, due to a lack of resource, and face different challenges
- Hospitals or institutions that will offer the greatest patient safety systems in the future will include those that foster team working, maximise the use of information technology and are prepared to realign their systems and processes

PATIENT SAFETY AT THE COAL FACE

Communicating openly with patients and their carers and obtaining consent

A patient-centred approach by medical staff, with involvement of patients and their carers as partners, is now recognised as being of fundamental importance. There are better treatment outcomes and fewer errors when there is good communication while poor communication is a common reason for patients taking legal actions.

Involving patients in and respecting their right to make decisions about their care and treatment is crucial. Explaining risk is a difficult but important part of good communication. It requires skill to explain the potential for harm of a procedure so that it is fully understood because patients vary in their perception and understanding and it is often difficult to assess the trade-offs between harm and benefit.

Obtaining consent for surgery requires that surgeons provide information to help patients to understand the positives and negatives of their various treatment options (*Table 13.3*). If only for the purposes of defending claims, hospitals invariably make signed consent mandatory. However, patients should be allowed to make these informed decisions without coercion or manipulation. Consent should be obtained by someone who is capable of performing the surgery and this should be taken when the patient is fully aware, especially in the non-urgent situation, well before the surgical procedure (see also Chapter 12, Surgical ethics and law).

TABLE 13.3 Information to be provided when seeking consent for surgery.

Details and uncertainties of the diagnosis
The purpose and details of the proposed surgery
Known possible side effects and potential complications
The likely prognosis
Other options for treatment, including the option not to treat
Explanation of the likely benefits and probabilities of success for each option
The name of the doctor who will have overall responsibility
A reminder that the patient can change his or her mind at any time

Communicating honestly with patients after an adverse event, or **open disclosure**, includes a full explanation of what happened, the potential consequences and what will be done to fix the problem. Safe care also involves taking care of the patient after the event, ensuring that the problem does not happen again and sincerely offering regret or an apology, as appropriate. As a consequence of the Francis Report there is now a statutory duty of candour on all healthcare providers who work within the National Health Service.

Professional behaviour and maintaining fitness to practice

Professionalism is an important component of patient safety. This embraces those attitudes and behaviours that serve the patient's best interests above and beyond other considerations. Organisations responsible for maintaining ethical standards include professionalism as one of those standards by which healthcare workers are judged.

Fitness to work or practice – **competence** – refers not just to knowledge and skills but also to the attitudes required to be able to carry out one's duties. Monitoring their own fitness for work is a responsibility of each individual and also their employers and professional organisations. Healthcare workers are now required to have transparent systems in place to identify, monitor and assist them to maintain their competence. **Credentialing** is one way that is used to ensure that clinicians are adequately prepared to safely treat patients with particular problems or to undertake defined procedures.

Reporting adverse events and near misses

Adverse events and near misses go unreported for many reasons including a fear of blame and the potential for litigation. **Clinical risk management** is a specific task, based on risk identification, analysis and control of events, carried out within a 'blame-free' environment. Data collected from these episodes should be collated and learnt both institutionally and by uploading to a national database. Doctors should be familiar with the systems that operate within their own working environment.

Complaints from a patient or carer often highlight a problem that, when analysed, provides opportunities for reducing adverse events and near misses. Poor communication is

often the cause and knowing how to manage complaints is an important part of providing better health care. There is wide acceptance for the need for complaints to be made easily and effectively, such that now, more and more **patient advocacy** units provide a range of options for resolving complaints including the provision of information, mediation and the setting up of conciliation meetings between the parties.

Staff communication, understanding the work environment and working well within it

Nowhere is team working more important than in managing the flow of information within healthcare. Poor communication can lead to misinformation to patients and staff, delays in diagnosis, treatment and discharge as well as in failures to follow up on test results. On the other hand, good team work, good communication and continuity of care reduce errors and improve patient care and staff satisfaction within a team.

Stress, tiredness and mental fatigue in the workplace are significant occupational health and safety risks in healthcare. There is good evidence linking tiredness with medical errors. Fatigue can also affect wellbeing by causing depression, anxiety and confusion, all of which negatively impact on clinician performance. Organisations and individuals each bear the responsibility for managing working environments and practices so as to reduce fatigue and stress. This is reflected in the legal restriction of working hours that is now adopted in many countries.

Prescribing safely

Prescribing medication is common to almost all strands of medical practice and patients are vulnerable to mistakes being made in any one of the many steps involved in the ordering, dispensing and administration of medications. Accuracy requires that all steps are correctly executed. Unfortunately, medication errors are common and their many causes include:

- poor assessment or inadequate knowledge of patients and their clinical conditions;
- inadequate knowledge of the medications;
- dosage calculation errors;
- illegible hand writing;
- confusion regarding the name or the mixing up medications.

Summary box 13.4

Patient safety at the coal face

- Communicating well with patients and their carers
- Professionalism, as another essential component of patient safety
- Clinical risk management and patient advocacy and their roles in adverse events and patient complaints
- Team working and information flow as well as managing the work environment
- Recognising the pitfalls to safe prescribing

PATIENT SAFETY AND THE SURGEON

Surgery is one of the most intrusive healthcare interventions that can be visited on patients. More than 100 million people worldwide require surgical treatment every year for different reasons. Problems associated with surgical safety in resource-rich countries account for half of the avoidable adverse events that result in death or disability.

The 'more than one cause' theory of accident causation can be aptly applied to many aspects of surgical patient care during the perioperative period. Cuschieri and others have described **coal-face errors** as those that can potentially be committed by surgeons during the care of their patients and include:

- diagnostic and management errors;
- resuscitation errors,
- prophylaxis errors;
- prescription/parenteral administration errors;
- situation awareness, identification and teamwork errors;
- technical and operative errors.

Situation awareness – identifying teamwork errors

Operating rooms have been described as "among the most complex political, social and cultural structures that exist, full of ritual, drama, hierarchy and too often conflict". In such an environment, systems should seek to prevent error by improving workplace preparedness and by incorporating defences so as to reduce human error or minimise its consequence. Well recognised and potential errors include:

- the wrong patient in the operating room;
- surgery performed on the wrong side or site;
- the wrong procedure performed;
- failure to communicate changes in the patient's condition;
- disagreements about proceeding;
- retained instruments or swabs **(Figure 13.4)**.

All these events are catastrophic for the patient and almost invariably occur through a lack of communication (see Never events below). This means that all theatre staff should follow protocols and be familiar with the underlying principles supporting a uniform approach to caring for patients.

Checklists

Checklists in the operating theatre environment are now accepted as standard safety protocols since the '*Safe Surgery Saves Lives*' Study Group at the WHO published their results. The use of a perioperative surgical safety checklist in eight hospitals around the world was associated with a reduction in perioperative mortality from 1.5% to 0.7% and major inpatient complications from 11.0% before, to 7.0% after, the introduction of the checklist. A more recent study from two hospitals in Norway (2015) showed a decrease in complications from 19.9% to 11.5%, a fall in mean length of stay of 2 days and a significant fall in hospital mortality from 1.9% to 0.2% in one hospital.

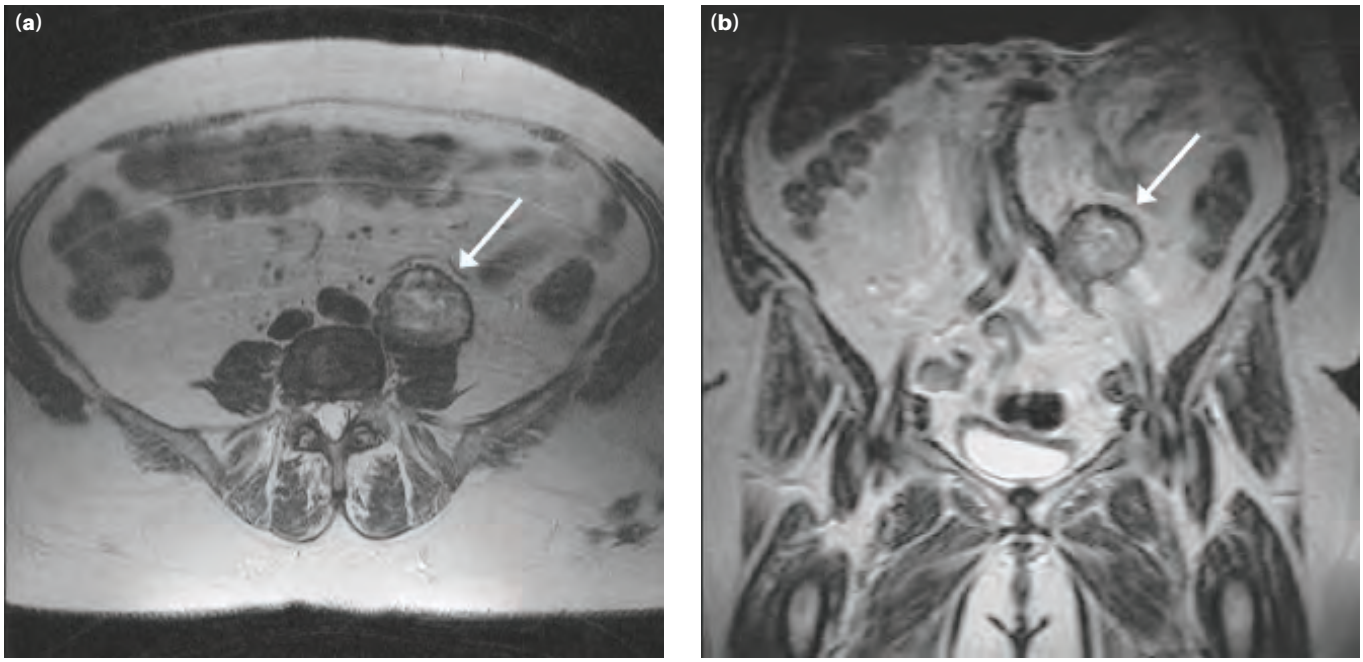

Figure 13.4 Axial **(a)** and coronal **(b)** magnetic resonance images demonstrating a well-defined abdominal mass with whorled stripes in a fluid filled central cavity (arrows). This 60-year-old lady had had an abdominal hysterectomy 10 years previously and presented with pyrexia and flank pain. The cause was due to the late presentation of a retained surgical swab.

The surgical safety checklist identifies specific checks to be carried out at three obligatory time points (**Figure 13.5**). The checklist items are not intended to be comprehensive and additions and modifications are encouraged.

The benefits of standardisation of surgical processes need not be limited to the operating room. Several studies have shown that the majority of surgical errors (53–70%) occur outside the operating room, before or after surgery, and that a more substantial improvement in safety can be achieved by targeting the entire surgical pathway.

There is no question that checklists are tools that improve outcomes provided they are correctly implemented. However, there are some important considerations. Checklists are suited to solving specific kinds of problems, but not others.

Before induction of anaesthesia

SIGN IN

☐ **Patient has confirmed**
- Identity
- Site
- Procedure
- Consent

☐ **Site marked/not applicable**

☐ **Anaesthesia safety check completed**

☐ **Pulse oximeter on patient and fuctioning**

Does patient have a:

Known allergy?
☐ No
☐ Yes

Difficult airway/aspiration risk?
☐ No
☐ Yes, and equipment/assistance available

Risk of >500 mL blood loss (7 mL/kg in children)?
☐ No
☐ Yes, and adequate intravenous access and fluids planned

Before skin incision

TIME OUT

☐ **Confirm all team members have introduced themselves by name and role**

☐ **Surgeon, anaesthesia professional and nurse verbally confirm**
- Patient
- Site
- Procedure

Anticipated critical events

☐ **Surgeon reviews:** what are the critical or unexpected steps, operative duration, anticipated blood loss?

☐ **Anaesthesia team reviews:** are there any patient-specific concerns?

☐ **Nursing team reviews:** has sterility (including indicator results) been confirmed? are there equipment issues or any concerns?

Has antibiotic prophylaxis been given within the last 60 minutes?
☐ Yes
☐ Not applicable

Is essential imaging displayed?
☐ Yes
☐ Not applicable

Before patient leaves operating room

SIGN OUT

Nurse verbally confirms with the team:

☐ **The name of the procedure recorded**

☐ **That instrument, sponge and needle counts are correct**(or not applicable)

☐ **How the specimen is labelled** (including patient name)

☐ **Whether there are any equipment problems to be addressed**

☐ **Surgeon, anaesthesia professional and nurse review the key concerns for recovery and management of this patient**

Figure 13.5 World Health Organisation Surgical Safety Checklist (First Edition).

Even in comparison to aviation, managing patients involves an enormous amount of coordinated, time-pressured decision making and potential delays. Checklists are simple reminders of what to do, and unless they are coupled with attitude change and efforts to remove barriers to actually using them, they will have limited impact. Finally, if one begins to believe that safety is simple and that all it requires is a checklist, there is a danger of abandoning other important efforts to achieve safer, higher quality care.

Technical and operative errors

In surgery, the person rather than systems approach emphasises the accountability of the surgeon who, unlike colleagues in other medical disciplines, when operating, is an instrument of the treatment. During a surgical procedure, for example, there may be a specific action that, of itself, may be the error, such as the inadvertent cutting of the common bile duct during a cholecystectomy (**Figure 13.6**). The practical value of this kind of interpretation is that, provided latent conditions are excluded, it gives a sense of responsibility to the surgeon and it may also help to point to the most effective pathway for remediation, by counselling or retraining, as against reassessing the system and putting in place further safeguards.

Figure 13.6 Radiograph showing an iatrogenic bile duct injury.

Central to operative performance is proficiency, which is an acquired state, honed by sound teaching, practice and repetition, by which a surgeon consistently performs operations with good outcomes. In cognitive psychology, high surgical proficiency is a state of automatic unconscious processing, with the execution being effortless, intuitive and untiring, as opposed to non-proficient execution which is characterised by conscious control processing requiring constant attention and resulting in slow, deliberate execution and inducing fatigue. The transition from one state to the other is better known as the 'learning curve'. This should not carry negative connotations for trainee surgeons who might be at the conscious processing stage but still perform a perfectly good operation, although it might take longer and be more tiring.

Failures in operative technique include:

- cognitive errors of judgment, such as failure or late conversion of a difficult laparoscopic procedure into an open one;
- procedural, when the steps of an operation are not followed or omitted;
- executional, when, for example, too much force is used which may result in damage that may or may not have consequences;
- misinterpretation, which is unique to minimal access surgery and is a function of the misreading of a two dimensional image;
- misuse of instrumentation, such as with energised dissection modalities (e.g. diathermy);
- missed iatrogenic injury either at the time of surgery or diagnosed late.

Never events

Many national health services and institutions now require that all incidents are managed, reported and investigated. Incidents can be defined as events that could have or did result in unintended and/or unnecessary serious harm.

One subset of serious incidents is a Never or Serious Reportable Event. These events are wholly preventable; for example, a retained abdominal swab or instrument, where guidance providing strong systemic protective barriers should have been implemented, namely checklists. Each Never Event type has the potential to cause serious patient harm or death. However, serious harm or death is not required to have occurred for that incident to be categorised as a Never or Serious Reportable Event.

Newer concepts of approaches to safety

Safety I is the approach to patient safety that has been described so far. It is predicated on identifying errors after the event and aims to prevent them from occurring or recurring in the future. Because healthcare is much more complex than such a linear model suggests, it is felt that that there is a need to switch our efforts to enable getting things to go right more often – a concept called **Safety II**. This acknowledges that healthcare work is resilient and that everyday performance succeeds much more often than it fails. This is because clinicians constantly adjust what they do to match the conditions. Working flexibly, and actively trying to increase their capacity to deliver more care more effectively, is key to this new approach. At its heart, proactive safety management focuses on how everyday performance usually succeeds rather than why it occasionally fails, and actively strives to improve the former rather than simply preventing the latter.

Summary box 13.5

Patient safety and the surgeon and newer concepts on safety

- Errors that can be made by surgeons in their overall management of patients
- Errors that occur in the operating theatre and how they can be mitigated
- The role of checklists in patient safety
- Performance proficiency and understanding technical and operative failures
- Getting things right more often may be a better approach than identifying errors after the event

QUALITY IMPROVEMENT

Quality improvement (QI) comes into play when we need to design or redesign healthcare processes and systems in response to a quality gap in order to ensure more efficient, safe, timely, effective, patient-centred and equitable care. Although safety is just a single aspect, it is self-apparent that improving any one of these components will likely have a beneficial effect on the other. Cost is also an important adjunct to quality improvement. The concept of value – the quotient of what is delivered divided by the cost – is an increasingly important metric in healthcare.

The scope for QI is enormous and can range from redesigning how teams deliver care in clinical microsystems that make up healthcare organisations to large-scale reconfigurations of specialist services such as stroke care and cancer care. It may even extend to redesigning training, budgeting processes and information systems and it requires leadership and cultures that both understand and value quality improvement. Improvements come from the intentional actions of staff equipped with the skills and data needed to bring about changes in patient care either directly or indirectly, and they require substantial and sustained commitment of time and resource.

QUALITY MEASURES

Quality measures are tools that help us measure or quantify healthcare processes, outcomes, patient perceptions and organisational structures or systems that are associated with the ability to provide high-quality health care and/or that relate to one or more quality goals for healthcare. Measurement is important to determine whether changes that are believed to lead to improvements in quality do in fact result in improvements. Improvement efforts require different methods from those used in research, being concerned more with testing of how to introduce best practice rather than determining what that developing best practice should be.

Process measures reflect the procedures and practices implemented by staff in the planning prescribing, delivery and evaluation of care – these may be specific to a clinical process, a service or administrative process. An example of a clinical process might be the starting times of operating lists. Process improvement measures should be associated with better outcomes of care and, ideally, should be important from a patient's perspective – reducing delays in starting times in the example cited.

The patient's surgical journey is a composite of multiple processes. Measurement for improvement less commonly involves comparisons among sites and against thresholds but more commonly involves tracking processes and outcomes in the same site over time.

Outcome indicators are specific, observable and measurable changes that represent the achievement of an outcome of a quality improvement measure. **Clinical outcome measures** refer specifically to outcomes of healthcare interventions whether they are to do with diagnosis, treatment or that care received by service users. Ideally, they should be outcomes that are important to patients rather than to the health provider, and there should be evidence that they reflect the quality of the interventions and their effect. Outcome measures are what are commonly used in **clinical audit** when compared with evidenced-based standards of clinical care.

Patient perception and the principles of patient centred-care should be an important part of QI particularly in those areas that directly affect their care, such as:

- the speed of their access to reliable health advice;
- the effectiveness of their treatment delivered by trusted professionals;
- the continuity of their care and its smooth transitions;
- the involvement of, and support for, their family and carers;
- the availability of clear, comprehensible information and support for self-care;
- their involvement in decisions and the respect for their preferences;
- the emotional support, empathy and respect provided;
- the attention paid to their physical and environmental needs.

Organisational structure and systems refers to the availability of resources required to deliver care. These include the care environment and facilities, the available equipment and the organisation's documented policies, procedures, protocols and guidelines.

The consistent consensus view is that good-quality improvement or clinical audit has to have at least four essential stages of activity to be considered high quality:

- preparation and planning,
- measuring performance;
- implementing change;
- sustaining improvement (including reaudit).

The collection and interpretation of reliable data is of fundamental importance to any QI exercise (*Table 13.4*).

CLINICAL OUTCOMES AND AUDIT

Put simply, clinical audit is that part of clinical governance that finds out if healthcare is being provided in line with standards and it allows care providers and patients know how

TABLE 13.4 Three pioneers of quality improvement and their quotes on data.

William Edwards Denning (1900–1993)	American engineer, statistician, professor, author, lecturer and management consultant. Pioneered the PDSA (Plan, Do, Study, Act) cycle	"In God we trust, all others bring data."
Peter Ferdinand Drucker (1909–2005)	Austrian-born American management consultant and educator	"What gets measured gets improved."
Donald Berwick (Born 1946)	American paediatrician. Former President and Chief Executive Officer of the Institute of Health Care Improvement	Sequence of reactions that challenge data: "The data are wrong." "The data are right but it's not a problem." "The data are right; it is a problem but not my problem." "I accept the burden of improvement."

their service is doing and where there could be improvements. The aim is to allow quality improvement to take place where it will be most helpful and will improve outcomes for patients. Clinical audits can look at care nationwide or locally within hospitals and their departments, in GP practices or anywhere healthcare is provided.

Measuring clinical outcomes as part of the quality improvement cycle aims to:

- improve the quality of clinical care with shorter hospital stays, better outcomes and fewer complications, reduced readmissions and greater patient satisfaction;
- inform the development of national clinical audits, including driving participation, data completeness and accuracy;
- support shared decision making and empowerment of patients, including their treatment options and choice of provider;
- improve the oversight and management of clinicians, their teams and practises and thus reassuring patients that their clinical care is being actively monitored and improved;
- help medical specialty associations to become increasingly transparent and patient focused;
- support team and individual quality improvement including providing information for appraisal and revalidation;
- learn from, spread and celebrate best practice.

'Best practice' dictates that surgeons should not just be aware of their clinical activity and outcomes but also endeavour to benchmark their activity against national and international norms. (Surgical audit is further addressed in Chapter 11.)

There is limited evidence that audit as presently defined and used is meeting health policy makers' aspirations. The alternative, systems-based QI methods, discussed below, although they have produced many successful improvements within healthcare services, have still not yet been scientifically proven to be more impactful.

THE PROCESS OF SURGICAL CARE

The process of QI can perhaps be best illustrated by understanding and optimising the efficiency of the patient journey at each step across the healthcare domains from the patient's home and primary care through the hospital system and then back out into the community. For example, while many illnesses and injuries require hospitalisation, a QI exercise might be the introduction of an admission avoidance policy for selected, appropriate patients attending Emergency Departments who could be better managed at home or in the community, thus providing an overall benefit to those patients in terms of safety, economy and choice.

Patients attend surgeons in many different settings depending on whether they present **electively or urgently** (scheduled or unscheduled). An elective journey is usually predictable and starts out as a referral from primary care and commonly requires an outpatient visit and investigations. If a surgical procedure is required, then we recognise that it is best that the patient is fully assessed from a surgical and anaesthetic perspective prior to admission within a pre-admission assessment clinic. Once assessed, the patient should be admitted as a day case, wherever possible, or on the day of surgery or as short a time as possible before surgery as an inpatient. Preoperative checking is followed by the theatre journey, which includes reception, anaesthesia, the surgery itself and recovery – each, in their own way, a series of complex interventions. Returning to the ward and recovery demands another set of skills, procedures and processes followed by a final 'discharge from hospital' process.

The urgent or unscheduled journey is different because it is unpredictable for any single individual, although patterns of presentation do emerge when managing large numbers. The patient commonly presents at the Emergency Department of a hospital either as a self-referral, primary care referral or by ambulance. The journey begins with triage by a team who assess the severity of the illness (using, for example, the Manchester scoring system) and then directing the patient to the appropriate area, which might include, for example, a resuscitation unit, a rapid assessment and treatment unit, an acute surgical assessment unit (or medical assessment for medical patients), a minor injuries unit or an ambulatory care unit. The objective is to be seen as soon as possible by a senior decision maker, so that the patient can be treated or discharged as expeditiously as possible or, if admission and surgery is required, then this too can be expedited. Thereafter the journey follows a similar course to that of an elective admission.

This simple outline of surgical patients' journeys serves to illustrate the very many individual steps or processes in that journey. The scope for errors, delays and inefficiencies from a patient's perspective is almost limitless. Instituting QI aims at their mitigation.

Good surgical practice has, for many years, dictated that surgeons should be aware of their clinical outcomes including their complications, re-admission rates and standardised mortality rates. It is now also incumbent on surgeons and their teams to measure the performance of their surgical processes against best practice. These include the average length of stay of their patients, their day case and day of admission rates, bed occupancy and, as activity-based funding becomes more prevalent, their consumption of institutional costs.

THE QUALITY IMPROVEMENT PATHWAY

QI can be applied to almost any step, process or activity. The Scottish Improvement Hub recommends seven stages that might be undertaken in a QI exercise:

- discovering – is about defining the aims and vision; for example, what the problem is and what data is available;
- exploring – is about defining the present state and visualising the future state;
- designing – is about defining how to move from the present state to the future state and identifying the priorities;
- refining – is about testing change, learning from the data and identifying the benefits;
- introducing – is about managing communications and building the will and culture to change;
- spreading – is about showing the improvements, telling the story and disseminating the message;
- closing – is about capturing and sustaining the learning.

Each step can then be accompanied by any number of established organisational and graphical tools and methodologies appropriate to the design and planning of each step and suitable for the QI improvement exercise being undertaken (*Table 13.5*).

Emergency departments, wards and operating theatres are fertile grounds for process and performance improvement. Bundled educational programmes, such as the Productive Series (for wards and theatres, for example) introduced by the former NHS Institute for Innovation and Improvement, supports teams to redesign and streamline the way they manage and work within specific areas.

Lean

Arguably, the most successful example of system redesign in an industrial setting has been the Toyota Production System from which much of the thinking can be applied to healthcare. 'Kaizen' is the Japanese for improvement. At Toyota, production line personnel are expected to stop the production line when an abnormality is noticed and, along with their supervisor, initiate kaizen. A single cycle of kaizen activity is defined as 'plan, do, study and act', also known as the PDSA cycle. The same application can be used in healthcare, with many sequential cycles growing to 'continuous improvement'.

Lean manufacturing is a management philosophy that is also derived mostly from the Toyota Production System. Defining Lean is difficult; it is in essence the elimination of waste through continuous improvement. Identifying waste leads inevitably to the need to define customer value and reducing waste requires elimination of error. This approach has found widespread application in industry. In medical settings, there is extensive evidence of its benefits in improving efficiency, reducing costs and improving patient satisfaction.

Operating theatres provide a good example of how lean principles can be applied in healthcare. Lean states that, in manufacturing, there are broadly seven types of waste that need eliminating in order to improve productivity: the same could be applied to perioperative care. For example:

- *Overproduction*. Such as: ordering unnecessary preoperative tests. Solution: optimising evidence-based preassessment.
- *Inventory*. Such as: purchasing of excessive drug stock before it is required. Solution: alphabetically ordered drug cupboards with only 1–2 boxes of commonly used drugs.
- *Waiting*. Such as: surgeons waiting for a patient to come down to theatre and sitting in the coffee room doing nothing. Solution: improve communications and, maybe, engage more porters.
- *Waste of transportation*. Such as: wasting time transferring patients from the admitting ward to the theatre or vice versa. Solutions: better design of the theatre complex to optimise patient flow, simplifying mode of transport and better communications and handover.
- *Waste of overprocessing*. Such as: giving patients a nerve block, a spinal and a general anaesthetic for a joint replacement. Solution: general anaesthetic and local infiltration may be equivalent and quicker.
- *Defect*. Such as: patients arrive in theatre with incomplete or inappropriate preoperative paperwork. Solution: more robust checking systems before patients come to theatre.
- *Motion*. Such as: constant repetitive movement around theatre and the anaesthetic room to get drugs, equipment and disposal of waste. Solution: a 'motion efficient' theatre where everything is easily available with minimal movement, and similar layouts in multitheatre complexes.

Six sigma

Six sigma is another scientific business performance methodology that has been adopted for use in healthcare. The fundamental objective of the Six Sigma methodology is the implementation of a measurement-based strategy that focuses on process improvement and variation reduction. One of its sub-methodologies is DMAIC (**D**efine, **M**easure, **A**nalyse, **I**mprove, **C**ontrol), which is an improvement system for

existing processes falling below specification and requiring incremental improvement.

Systems thinking and leadership

In a system as fraught with complexity as healthcare, 'systems' thinking allows the whole system to be viewed and the relationships of the parts rather than just the isolated parts. Healthcare is a shared resource with many interdependencies; for surgery these include anaesthesia and critical care and all those specialties we require to work with to manage comorbid patients.

If quality problems exist primarily because of system problems, solutions are more likely in those systems where relationships and integration are considered important, where emphasis is placed on communication, team building, conflict management, behavioural and skill competencies, process management, and education; many of the features discussed under HF. Systems frameworks should never be punitive. They should have leaders who are systems thinkers and foster a culture of continuous QI. Those leaders should be visible at the front line and be champions of a supportive practice environment.

Improvement in the quality of care does not occur by chance. Nor will a programme team, armed with just organisational and graphical tools succeed in producing sustainable change. The underlying, central and agreed principles must include the creation of value for the patient, a constancy of purpose and systems thinking. These should be enabled by the intentional actions of trained staff supported by humble leadership and respect for individuals. Such a culture adjustment also requires integrated and coherent strategies and a sustained commitment of time, patience and resources.

INVESTING IN QI AND ITS EDUCATION

Healthcare as a sector has been late in recognising the important contribution that the theory and practice of QI are able to make in delivering better value care. The experience of a relatively small number of healthcare organisations that have successfully done so, such as the Virginia Mason Medical Centre in Seattle, is a challenge to others to invest in acquiring the necessary skills and capabilities.

A recent report of the Academy of the Medical Royal Colleges of UK and Ireland (2016) has argued that QI should be at the heart of medical training and that there is a pressing need to develop QI learning across the continuum of medical education. Their report sets out to enable education bodies to embed QI education into their curricula while asserting that it is as important as learning anatomy, biochemistry and physiology and a skill as important as CPR.

Summary box 13.6

Understanding QI and its application in healthcare

- The definition of QI and its relationship to clinical audit
- The different kinds of quality measures
- The patient surgical journey and its potential for improvement
- Examples of QI pathways, organisational methodologies and tools
- What system thinking is and its importance alongside leadership
- The requirement for more education and training in QI

PART 2

Investigation and diagnosis

Chapter 14

Diagnostic imaging

Learning objectives

To understand:

- The advantages of good working relationships and close collaboration with the imaging department in planning appropriate investigations
- The basic principles of radiation protection and know the law in relation to the use of ionising radiation
- The principles of different imaging techniques and their advantages and disadvantages in different clinical scenarios
- The role of imaging in directing treatment in various surgical scenarios

INTRODUCTION

Appropriate surgical management of the patient relies on correct diagnosis. While clinical symptoms and signs may provide a firm diagnosis in some cases, other conditions will require the use of supplementary investigations including imaging techniques. The number and scope of imaging techniques available to the surgeon have dramatically increased within a generation, from a time when radiographs alone were the mainstay of investigation. The development of ultrasound and colour Doppler, computed tomography (CT) and magnetic resonance imaging (MRI) has enabled the surgeon to make increasingly confident diagnoses and has reduced the need for diagnostic surgical techniques such as explorative laparotomy. Faced with such a plethora of imaging to choose from, it is important that the patient is not sent on a journey through multiple unnecessary examinations.

As a basic principle, the simplest, cheapest test should be chosen that it is hoped will answer the clinical question. This necessitates knowledge of the potential complications and diagnostic limitations of the various methods. For example, in a patient presenting with the clinical features of biliary colic, an ultrasound examination alone may give enough information to enable appropriate surgical management. In more complex cases, it may be more efficient to opt for a single, more expensive investigation, such as CT, rather than embarking on multiple simpler and cheaper investigations that may not yield the answer. The choice of technique is often dictated by equipment availability, expertise and cost, as well as the clinical presentation. However, it must be emphasised that, not infrequently, the most valuable investigation is prior imaging; this not only reduces the cost and the amount of radiation a patient receives but very often improves patient care.

HOW TO REQUEST IMAGING

Best practice depends on close collaboration between the radiologist and the referrer and must take into account local expertise and access to facilities. When requesting imaging, consider what it is that you want to know from the investigation. Give a provisional diagnosis or state the clinical problem. If there is uncertainty over the best method to answer the clinical problem, then discussion with a radiologist is always worthwhile, informally or within the context of a clinicoradiological meeting or a multidisciplinary team (MDT) meeting.

As well as the basic demographic information stored on the radiology information system (RIS), it is important to provide relevant past medical history, e.g. diabetes, epilepsy, renal failure, allergies and anticoagulation, all of which can affect which contrast agent can be given safely, and the date of the last menses in women of childbearing potential.

INTERPRETING IMAGES

While the role of the Imaging department is to provide radiological reports for imaging examinations performed, it is nevertheless good clinical practice to be able to evaluate your patients' examinations, and a systematic approach is encouraged.

The systematic approach to examining a radiograph varies according to the part of the body being imaged. For instance, for a radiograph of an extremity, the alignment, the cortices and the medullary cavity of the individual bones, the joints and the soft tissues all need to be assessed on each view.

Summary box 14.1

A simple system for checking radiographs

Label	Name of patient
Site	Date of examination
Side (check marker)	
	What part is the film centered on?
	Does the film cover the whole area required?
	Is there more than one view?
Quality	Is the penetration appropriate?
Compare	How have the appearances changed from previous images?
Conclude	Is the diagnosis clear?
	Is further imaging needed?

HAZARDS OF IMAGING

Contrast media

There has been a dramatic increase in the use of contrast agents in recent years, mainly related to the increasing use of CT. Potential problems include allergic reaction and nephrotoxicity. Reactions are rare: serious reactions occur in about 1:2500 cases and life- threatening reactions in about 1:25 000 cases. The risk of sudden death, however, has not changed with the new agents. Local policies for dealing with patients at increased risk vary between departments and, indeed, between countries. Advice from the Royal College of Radiologists (RCR) in the UK does not recommend routine steroid prophylaxis for patients at increased risk of allergic reaction, but rather the use of low osmolality contrast media(LOCM) or iso-osmolar media, and observation of the patient for 30 minutes after injection with the intravenous cannula still in situ, since most serious reactions occur shortly after injection. Guidelines from the European Society of Uroradiology (ESUR), however, continue to advocate the use of steroids.

In patients with diabetes or renal impairment, a recent creatinine level should be available. The radiologist should be informed of any history of renal impairment, as all contrast media are nephrotoxic in patients with impaired renal function. The risks and benefits of contrast administration need to be carefully assessed in these patients and, if contrast is given, the patient should be well hydrated and the lowest dose of a LOCM should be given. The British RCR does not recommend the routine use of *N*-acetylcysteine for renal protection.

Concerns about lactic acidosis in patients on metformin receiving contrast led to various recommendations for stopping the metformin. The latest RCR recommendations are that it can be continued in patients with normal renal function. If there is a raised creatinine or reduced estimated glomerular filtration rate (eGFR) below 60 then any decision to stop metformin should be made with the radiologist and the physician managing the patient's diabetes. Gadolinium-containing contrast agents are used in MRI examinations. Allergic reactions to these agents are very rare. However, they can be nephrotoxic in patients with renal failure. In addition, they are associated with a risk of nephrogenic systemic fibrosis (NSF), an extremely rare but serious life-threatening condition whereby connective tissue forms in the skin causing it to become coarse and hard. NSF may also affect other organs, including joints, muscle, liver and heart. High-risk gadolinium-containing contrast agents are contraindicated in severe renal failure, in neonates and in the perioperative period of liver transplantation, and are not recommended in pregnancy. However, lower-risk gadolinium preparations are available that may be used with caution.

Liver-specific contrast agents for MRI, selectively taken up by hepatocytes, are increasingly used to characterise liver lesions and in cancer staging.

HAZARDS OF IONISING RADIATION

The majority of ionising radiation comes from natural sources on the earth and cosmic rays, and this makes up the background radiation. However, medical exposure accounts for around 15% of the total received by humans. The effects of ionising radiation can be broadly divided into two groups. The first group comprises predictable, dose-dependent tissue effects and includes, for example, the development of cataracts in the lens of the eye. These effects are important for those chronically exposed to radiation, including those using image intensifiers regularly. The second group comprises the all-or-nothing effects such as the development of cancer (termed stochastic). These effects are not dose dependent, but increase in likelihood with increased radiation dose.

The risk of radiation-induced cancer for plain films of the chest or extremities is very small, of the order of 1:1 000000. However, that risk rises considerably for high-dose examinations such as CT of the abdomen or pelvis, where the estimated lifetime excess risk of cancer increases to the order of 1:1000. Use of CT has increased dramatically in the last 20 years, with a 12-fold increase in the UK, and it has been estimated that up to 30% of these examinations may be unnecessary. Obviously, the risk of such examinations has to be balanced against the benefit to the patient in terms of increased diagnostic yield, and must also be viewed in the context that the lifetime risk of cancer for people generally is about 1:3. Nevertheless, the increased risk is important since it is iatrogenic and applied to a large population. Therefore, techniques that do not use ionising radiation, such as ultrasound and MRI, should be carefully considered as alternatives, particularly in children and young people.

CURRENT LEGISLATION

In the UK, the Ionising Radiation (Medical Exposure) Regulations (IRMER) introduced in 2000, and amended in 2006, impose on the radiologist the duty to the patient to make sure that all studies involving radiation (plain radiographs, CT and nuclear medicine) are performed appropriately and to the highest standards. Inappropriate use of radiation is a criminal offence, so investigations involving radiation need careful consideration in order to prevent wasteful use of radiology.

Summary box 14.2

Wasteful use of radiology

Results unlikely to affect patient management	
Positive finding unlikely	
Anticipated finding probably irrelevant for management	Do I need it?
Investigating too often	
Before disease could be expected to have progressed or resolved	Do I need it now?
Repeating investigations done previously	
Other hospital (?)	
GP (?)	Has it been done already?
Failing to provide adequate information	
Therefore wrong test performed or essential view omitted	Have I explained the problem?
Requesting wrong investigation	
Discuss with radiologist	Is this the best test?
Over-investigating	Are too many investigations being performed?

After: IRefer gudelines, *Making the best use of radiology*, 7th edition. Royal College of Radiologists, 2012.

Summary box 14.3 gives a summary of the responsibilities of both the radiologist and the referrer.

The RCR produces an evidence-based guidance tool, called iRefer, which is widely available on line. *Table 14.1*, showing the radiation doses for common procedures, is taken from this publication, now in its seventh edition.

Summary box 14.3

Responsibilities

- Radiologists have a legal responsibility to keep imaging as safe as possible
- The referrer has a duty to balance risk against benefit
- The referrer must provide adequate clinical details to allow justification of the examination
- Avoid using portable (mobile) x-ray machines whenever practical
- Take all precautions when using an image intensifier
- The gonads, eyes and thyroid are especially vulnerable to radiation and should be protected

There are special considerations for portable and fluoroscopy units. The longer an operator keeps the fluoroscopy unit running, the higher the dose of radiation to all in the vicinity. Portable x-ray machines and fluoroscopic imaging equipment use much more radiation to achieve the same result. The staff, and patients in the next bed, are at risk

TABLE 14.1 Typical effective doses from diagnostic medical exposure in the 2000s.

Diagnostic procedure	Typical effective dose (mSv)	Equivalent no. of chest radiographs	Approximately equivalent period of natural background radiation[a]
Radiographic examinations			
Limbs and joints (except hip)	<0.01	<0.5	<1.5 days
Chest (single posteroanterior film)	0.02	1	3 days
Skull	0.07	3.5	11 days
Thoracic spine	0.7	35	4 months
Lumbar spine	1.3	65	7 months
Hip	0.3	15	7 weeks
Pelvis	0.7	35	4 months
Abdomen	1.0	50	6 months
Intravenous urography (IVU)	2.5	125	14 months
Barium swallow	1.5	75	8 months
Barium meal	3	150	16 months
Barium follow-through	3	150	16 months
Barium enema	7	350	3.2 years
CT head	2.3	115	1 year
CT chest	8	400	3.6 years
CT abdomen or pelvis	10	500	4.5 years
Radionuclide studies			
Lung ventilation (133Xe)	0.3	15	7 weeks
Lung perfusion (99mTc)	1	50	6 months
Kidney (99mTc)	1	50	6 months
Thyroid (99mTc)	1	50	6 months
Bone (99mTc)	4	200	1.8 years
Dynamic cardiac (99mTc)	6	300	2.7 years
PET head (18F-FDG)	5	250	2.3 years

[a]UK average background radiation = 2.2 mSv per year; regional averages range from 1.5 to 7.5 mSv.
18F-FDG, 18F-2-fluoro-2-deoxy-D-glucose; CT, computed tomography; ^{99m}Tc, ^{99m}technetium; PET, positron emission tomography. From *Making the Best Use of a Department of Clinical Radiology*, 7th edn. Royal College of Radiologists, 2012. By kind permission.

when portable equipment is used. The result is also of lower quality, so portable x-ray machines should not be used unless absolutely necessary.

When using the image intensifier, lead aprons, thyroid shields, lead glasses and radiation badges should always be worn. Pregnancy in the female patient or staff must be excluded.

DIAGNOSTIC IMAGING

Basic principles of imaging methods

Conventional radiography

Although it is over 120 years since the discovery of x-rays by Roentgen in 1895, conventional radiography continues to play a central role in the diagnostic pathway of many acute surgical problems and particularly in chest disease, trauma and orthopaedics.

X-rays emitted from an x-ray source are absorbed to varying degrees by different materials and tissues and therefore cause different degrees of blackening of radiographic film, resulting in a radiographic image. This differential absorption is dependent partly on the density and the atomic number of different substances. In general, higher-density tissues result in a greater reduction in the number of x-ray photons and reduce the amount of blackening caused by those photons. In terms of conventional radiographs, a large difference in tissue structure and density is required before an appreciable difference is manifested radiographically. The different densities visible consist of air, fat, soft tissue, bone and mineralisation, and metal. Different soft tissues cannot be reliably distinguished as, in broad terms, they possess similar quantities of water (**Figure 14.1**). Manipulation of x-ray systems and x-ray energies, as used in circumstances such as mammography, may allow better differentiation between some soft-tissue structures.

Despite this inherent lack of soft-tissue contrast, conventional radiography has many advantages. It is cheap, universally available, easily reproducible and comparable with prior examinations and, in many instances, has a relatively low dose of ionising radiation in contrast to more complex examinations. However, injudicious repeat radiography, particularly of the abdomen, pelvis and spine, can easily result in doses similar to CT.

The lack of soft-tissue contrast allows little assessment of the internal architecture of many abdominal organs. To obviate this problem, techniques employing the administration of contrast material combined with radiography have long been used. These techniques include intravenous urography and barium examinations (**Figure 14.2**). Intravenous urography involves a series of radiographs taken before and after contrast injection, but has been largely superseded by CT urography, which is more accurate in detecting and defining pathology (**Figure 14.3**).

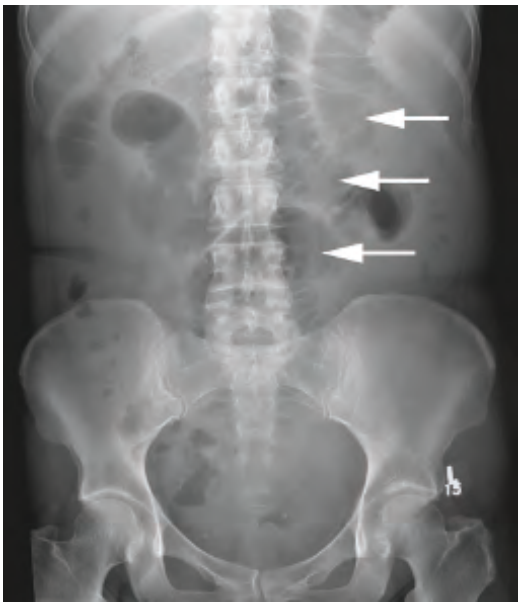

Figure 14.1 Supine abdominal radiograph of a patient with small bowel obstruction demonstrates multiple dilated small bowel loops (arrows). The different densities visible are air (within the bowel), bones, soft tissues and fat. The different soft tissues, subcutaneous and intra-abdominal, cannot be differentiated.

Figure 14.2 Barium swallow examination showing a malignant stricture (arrow) due to an oesophageal carcinoma.

Wilhelm Conrad Roentgen, 1845–1923, Professor of Physics, Wurtzburg (1888–1900), and then at Munich, Germany. He was awarded the Nobel Prize for Physics in 1901 for his work on x-rays.

Figure 14.3 Coronal computed tomography intravenous urogram shows a transitional cell carcinoma in the bladder (long arrow) and right hydronephrosis (short arrow).

A further modification of conventional x-rays uses fluorescent screens to allow real-time monitoring of organs and structures as opposed to the 'snapshot' images obtained with radiographs. This is used to follow the passage of barium through the bowel, obtaining dedicated images at specific points of interest only. Motility of the bowel can also be assessed in this way. Fluoroscopy is used extensively in interventional radiology, allowing the operator to guide catheters and wires into the patient while monitoring their position in real time.

Naturally, with the more sustained use of ionising radiation, the cumulative doses tend to be greater than when obtaining a conventional radiograph.

Ultrasound

Ultrasound is the second most common method of imaging. It relies on high-frequency sound waves generated by a transducer containing piezoelectric material. The generated sound waves are reflected by tissue interfaces and, by ascertaining the time taken for a pulse to return and the direction of a pulse, it is possible to form an image. Medical ultrasound uses frequencies in the range 3–20 MHz. The higher the frequency of the ultrasound wave, the greater the resolution of the image, but the less depth of view from the skin. Consequently, abdominal imaging uses transducers with a frequency of 3–7 MHz, while higher- frequency transducers are used for superficial structures, such as musculoskeletal and breast ultrasound. Dedicated transducers have also been developed for endocavitary ultrasound, such as transvaginal scanning and transrectal ultrasound of the prostate, allowing high-frequency scanning of organs by reducing the distance between the probe and the organ of interest **(Figure 14.4)**. A further application of dedicated probes has been in the field of endoscopic ultrasound, allowing exquisite imaging of the wall of a hollow viscus and the adjacent organs such as the biliary tree and pancreas.

Reflection of an ultrasound wave from moving objects such as red blood cells causes a change in the frequency of the ultrasound wave. By measuring this frequency change, it is possible to calculate the speed and direction of the movement. This principle forms the basis of Doppler ultrasound, whereby velocities within major vessels, as well as smaller vessels in organs such as the liver and the kidneys, can be measured. Doppler imaging is widely used in the assessment of arterial and venous disease, in which stenotic lesions cause an alteration in the normal velocity. Furthermore, diffuse parenchymal diseases, such as cirrhosis, may cause an alteration in the normal Doppler signal of the blood vessels of the affected organ.

Figure 14.4 Longitudinal transvaginal ultrasound scan of the uterus demonstrates thickening of the endometrium in a patient during the secretory phase of the menstrual cycle.

The advantages of ultrasound are that it is cheap and easily available. It is the first-line investigation of choice for assessment of the liver, the biliary tree and the renal tract **(Figures 14.5 and 14.6)**. Ultrasound is also the imaging method of choice in obstetric assessment and gynaecological disease. High-frequency transducers have made ultrasound the best imaging technique for the evaluation of thyroid and testicular disorders, in terms of both diffuse disease and focal mass lesions. It is also an invaluable tool for guiding needle placement in interventional procedures such as biopsies and drainages, allowing direct real-time visualisation of the needle during the procedure.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

Figure 14.5 Transverse ultrasound image of the liver in a patient with colorectal cancer shows a solitary liver metastasis.

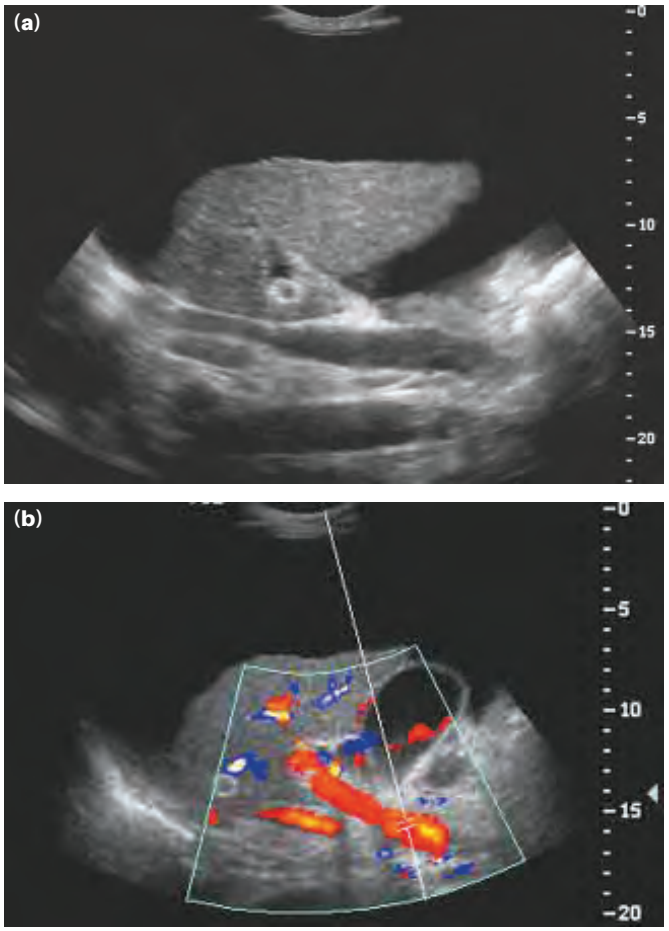

Figure 14.6 Sagittal ultrasound image of the liver **(a)** in a patient with cirrhosis demonstrates nodularity of the liver surface and extensive ascites. Doppler ultrasound **(b)** illustrates portal vein flow with a normal direction.

Ligament, tendon and muscle injuries are also probably best imaged in the first instance by ultrasound **(Figure 14.7)**. The ability to stress ligaments and to allow tendons to move during the investigation gives an extra dimension, which greatly improves its diagnostic value. The use of 'panoramic' or 'extended field of view' ultrasound **(Figure 14.8)** provides

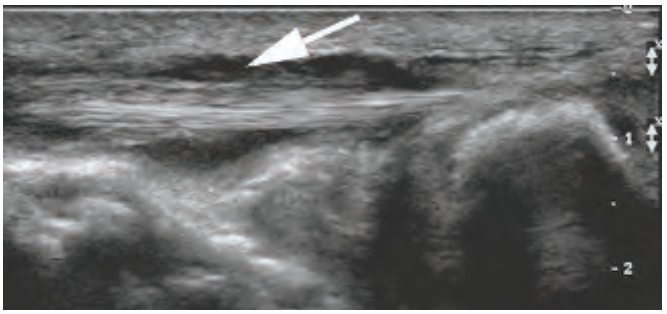

Figure 14.7 Ultrasound of the dorsal surface of the wrist shows the normal fibrillar pattern of the extensor tendons. There is increased fluid (arrow) within the tendon sheath in this patient with extensor tenosynovitis.

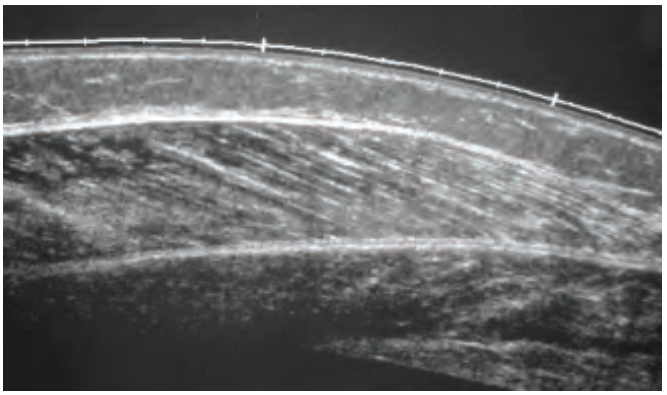

Figure 14.8 Panoramic ultrasound of the calf. The normal muscle fibres and the fascia can be identified over an area measuring approximately 12 cm.

images that are more easily interpreted by an observer not performing the examination, and are of particular assistance to surgeons planning a procedure. Ultrasound will demonstrate most foreign bodies in soft tissues, including those that are not radio-opaque.

The disadvantages of ultrasound are that it is highly operator dependent, and most of the information is gained during the actual process of scanning as opposed to reviewing the static images. Another drawback is that the ultrasound wave is highly attenuated by air and bone and, thus, little information is gained with regard to tissues beyond bony or air-filled structures; alternative techniques may be required to image these areas.

Computed tomography

There has been a great deal of development in CT technology over the last 30 years from the initial conventional CT scanners through to helical or spiral scanners and the current multidetector machines. CT scanners consist of a gantry containing the x-ray tube, filters and detectors, which revolve around the patient, acquiring information at different angles and projections. This information is then mathematically reconstructed to produce a two-dimensional grey-scale image of a slice through the body. This technique overcomes the problem of superimposition of different structures, which is inherent in conventional radiography. Improvements in

Summary box 14.4

Ultrasound

Strengths

- No radiation
- Inexpensive
- Allows interaction with patients
- Superb soft-tissue resolution in the near field
- Dynamic studies can be performed
- First-line investigation for hepatic, biliary and renal disease
- Endocavitary ultrasound for gynaecological and prostate disorders
- Excellent resolution for breast, thyroid and testis imaging
- Good for soft tissue, including tendons and ligaments
- Excellent for cysts and foreign bodies
- Doppler studies allow assessment of blood flow
- Good real-time imaging to guide interventional biopsies and drainages

Weaknesses

- Interpretation only possible during the examination
- Long learning curve for some areas of expertise
- Resolution dependent on the machine available
- Images cannot be reliably reviewed away from the patient

gantry design, advances in detector technology using more sensitive detectors and an increase in the number of detectors have resulted in an increase in spatial resolution, as well as the speed at which the images are acquired. In early CT scanners, the table on which the patient was positioned moved in between the gantry revolution to allow imaging of an adjacent slice. Modern scanners allow for continuous movement of the table and the patient during the gantry revolution, thus greatly reducing the scan time. With modern equipment, it is now not only possible to obtain images of the chest, abdomen and pelvis in under 20 seconds, but these axial images can be reformatted in multiple planes with practically no degradation in image quality.

In addition, CT has a far higher contrast resolution than plain radiographs, allowing the assessment of tissues with similar attenuation characteristics. As with radiographs, the natural contrast of tissues is further augmented by the use of intravenous contrast medium. Rapid scanning of a volume of tissue also allows the scans to be performed at different phases of enhancement, which is advantageous in identifying different diseases. For instance, very early scanning during the arterial phase is ideally suited to the examination of the arterial tree and hypervascular liver lesions, whereas scanning performed after a delay may be better suited to the identification of other solid organ pathology such as renal masses. Furthermore, it is possible to obtain scans during several phases including the arterial and venous phases in the same patient, which may aid in the identification and characterisation of lesions.

CT is widely used in thoracic, abdominal (Figure 14.9), neurological (Figure 14.10), musculoskeletal (Figure 14.11) and trauma imaging. The thinner collimation and improved spatial resolution have also resulted in the development of newer techniques such as CT angiography, virtual colonoscopy and virtual bronchoscopy. Furthermore, three-dimensional images can be reconstructed from the raw data to aid in surgical planning. The disadvantage of CT compared with ultrasound and conventional radiography lies largely in the increased costs and the far higher doses of ionising radiation. For instance, a CT scan of the abdomen and pelvis has a radiation dose equivalent to approximately 500 chest radiographs.

Summary box 14.5

Computed tomography

Strengths

- High spatial and contrast resolution
- Contrast resolution enhanced by ability to image in multiple phases, including arterial, venous and delayed
- Rapid acquisition of images in one breath-hold
- Imaging of choice for the detection of pulmonary masses
- Allows global assessment of the abdomen and pelvis
- Excellent for liver, pancreatic, renal and bowel pathology
- Three-dimensional reconstruction allows complex fracture imaging
- Multiplanar reconstruction and three-dimensional imaging,
- e.g. CT angiography and colonoscopy
- Ability to guide intervention such as percutaneous biopsy and drainage

Weaknesses

- High radiation dose
- Poor soft-tissue resolution of the peripheries and superficial structures
- Patient needs to be able to lie flat and still

Figure 14.9 Axial computed tomography scan through the pelvis with oral contrast administration illustrates loops of distal ileum with mural thickening in a patient with Crohn's disease (arrow).

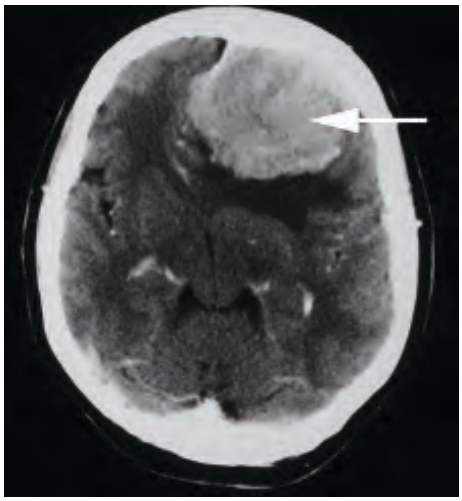

Figure 14.10 Axial computed tomography scan of the head following intravenous contrast demonstrates a large mass lesion in the left frontal region (arrow) in a patient with a large left frontal meningioma.

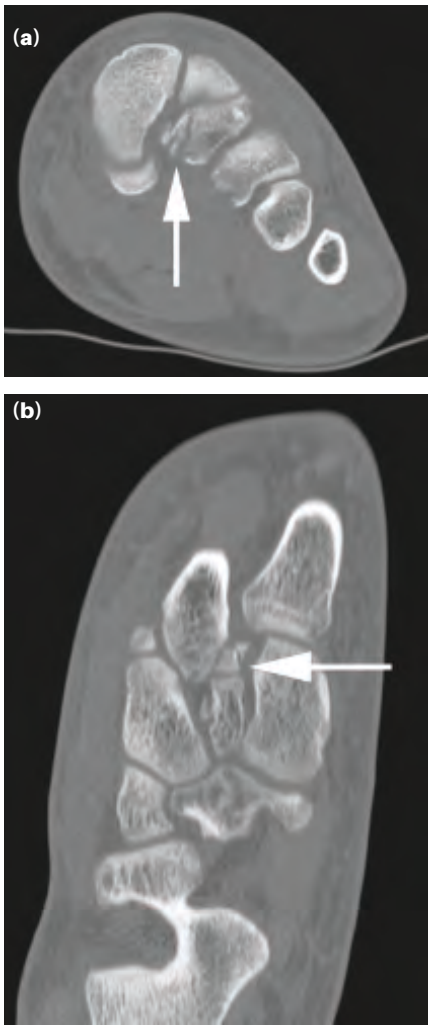

Figure 14.11 Coronal computed tomography **(a)** and axial reformats **(b)** of the foot in a patient involved in a road traffic accident demonstrates Lisfranc fracture dislocation with a comminuted fracture of the base of the second metatarsal (arrows).

Magnetic resonance imaging

Over the last 20 years, MRI has become an integral part of the imaging arsenal with ever-expanding indications. MRI relies on the fact that nuclei containing an odd number of protons have a characteristic motion in a magnetic field (precession) and produce a magnetic moment as a result of this motion. In a strong uniform magnetic field such as an MRI scanner, these nuclei align themselves with the main magnetic field and result in a net magnetic moment. A brief radiofrequency pulse is then applied to alter the motion of the nuclei. Once the radiofrequency pulse is removed, the nuclei realign themselves with the main magnetic field (relaxation) and in the process emit a radiofrequency signal that can be recorded, spatially encoded and used to construct a grey-scale image. The specific tissue characteristics define the manner and rate at which the nuclei relax. This relaxation is measured in two ways, referred to as the T1 and T2 relaxation times. The relaxation times and the proton density determine the signal from a specific tissue.

There are a large number of imaging sequences that can be used by applying radiofrequency pulses of different strengths and durations. The image characteristic and signal intensity from different tissues are governed by the pulse sequence employed and whether it is T1 weighted or T2 weighted. For instance, fat, methaemoglobin and mucinous fluid are bright on T1-weighted images, whereas water and thus most pathological processes, which tend to increase tissue water content, are bright on T2-weighted images. Cortical bone, air, haemosiderin and ferromagnetic materials are of very low signal on all pulse sequences. In general, T1-weighted images are superior in the delineation of anatomy, while T2-weighted images tend to highlight pathology better. For added tissue contrast, intravenous gadolinium may be administered. Other more specific contrast media are also available for liver, bowel and lymph node imaging.

MRI's exquisite contrast resolution, coupled with a lack of ionising radiation, is very attractive in imaging, particularly of tissues that have relatively little natural contrast. MRI also has the advantage of multiplanar imaging, as images can be acquired in any plane prescribed. It has traditionally been used extensively in the assessment of intracranial, spinal and musculoskeletal disorders **(Figures 14.12, 14.13 and 14.14)**, allowing a global assessment of bony and soft-tissue structures. More recent developments have resulted in new indications and applications. Today, MRI is commonly used in oncological imaging, such as staging of rectal carcinoma and gynaecological malignancies, identification and characterisation of hepatic masses and assessment of the biliary tree (magnetic resonance cholangiopancreatography (MRCP) **(Figure 14.15)**). MRI has become increasingly important in imaging of the small bowel, for example in Crohn's disease, where repeated imaging with ionising radiation can incur a significant radiation dose over time.

MR angiographic techniques allow non-invasive angiographic assessment of the cranial and peripheral circulation **(Figure 14.16)**, and cardiac imaging.

Jacques Lisfranc de St. Martin, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

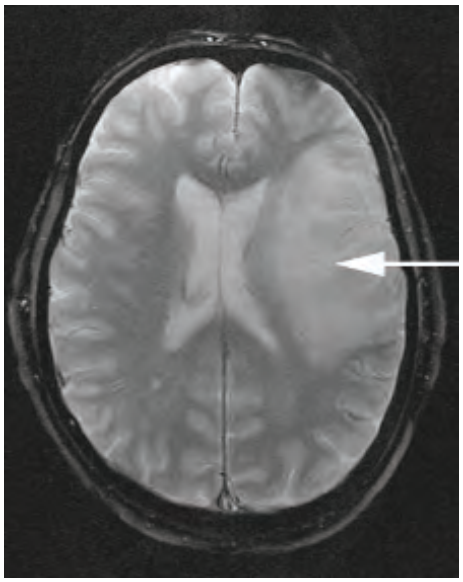

Figure 14.12 T2-weighted axial magnetic resonance imaging scan of the head in a patient with a large left-sided oligodendroglioma (arrow).

Figure 14.13 Sagittal T2-weighted magnetic resonance imaging scan of the lumbar spine demonstrates disc herniation (arrow) in a patient with acute back pain.

Figure 14.14 Coronal magnetic resonance imaging scan of the knee demonstrates extensive serpiginous areas of altered signal intensity in the distal femur and proximal tibia (arrows) in a patient with bone infarcts secondary to oral corticosteroids.

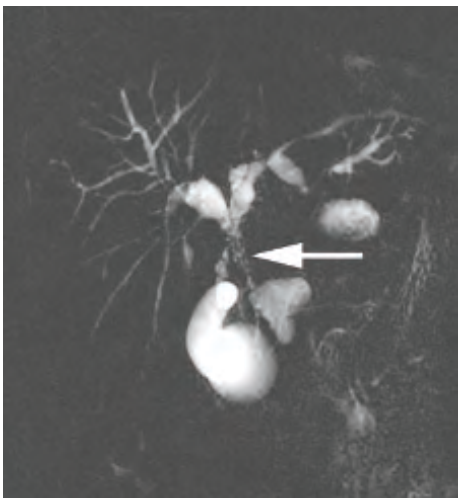

Figure 14.15 Magnetic resonance cholangiopancreatography demonstrates dilated central intrahepatic bile ducts and a stricture of the common bile duct (arrow) in a patient with obstructive jaundice and cholangio-carcinoma.

Diffusion weighted imaging is a relatively new type of MRI sequence that exploits the different rates of Brownian motion between different tissues. Tissues with greater cellular density have lower rates of diffusion of water molecules, and this difference can be exploited to distinguish benign and malignant lesions in a variety of organs as malignant lesions tend to have greater density of cells.

However, the availability of MRI is still relatively limited in comparison with other imaging techniques, and it is time-consuming with respect to image acquisition and interpretation. Images are easily degraded by motion, including respiratory and cardiac motion. The use of respiratory and cardiac gating can minimise this, although bowel peristalsis can still be a problem. The long acquisition times require a cooperative patient who can lie very still, which can be difficult especially in claustrophobic individuals or those in pain. Furthermore, because of the use of high-strength magnetic fields, patients with some metallic implants, such as some aneurysm clips and prosthetic heart valves, and those with implanted electronic devices, such as pacemakers and defibrillators, cannot be examined. Some newer implants may, however, be MRI compatible, and patients with joint replacements can be studied safely.

Figure 14.16 Maximum intensity projection image from a magnetic resonance angiogram demonstrates the abdominal aorta, common and external iliac arteries as well as parts of the pulmonary, mesenteric and renal vasculature.

Summary box 14.6

Magnetic resonance (MR) imaging

Strengths

- No ionising radiation
- Excellent soft-tissue contrast
- Best imaging technique for
  - Intracranial lesions
  - Spine
  - Bone marrow and joint lesions

Evolving use

- Staging
- MRCP
- MR angiography
- Breast malignancy
- Pelvic malignancy
- Cardiac imaging
- MR enterography
- Diffusion-weighted imaging

Weaknesses

- Absolute contraindications
  - Ocular metallic foreign bodies
  - Pacemakers
  - Cochlear implants Cranial aneurysm clips
- Relative contraindications
  - First trimester of pregnancy
  - Claustrophobia
- Long scan times so patients may not be able to keep still, especially if in pain
- Limited availability
- Expensive

Nuclear medicine

In other imaging techniques using ionising radiation such as CT and conventional radiography, the individual is exposed to ionising radiation from an external source and the radiation transmitted through the patient is recorded. In nuclear medicine, however, a radioactive element or radionuclide such as technetium, gallium, thallium or iodine is administered to the patient as part of a radiopharmaceutical agent, and a detector such as a gamma camera is then used to record and localise the emission from the patient, thus forming the image. The radionuclide is chosen and coupled with other compounds such that it is distributed and taken up in the tissues of interest. Therefore, a variety of radionuclides are required for imaging of different tissues. Nuclear medicine also differs from other means of imaging, which are largely anatomically based, as it also provides functional information.

Radionuclide imaging is widely used in bone imaging with very high sensitivity for assessing metastatic disease, metabolic bone disease, established arthropathies and occult infection and traumatic injuries (**Figure 14.17**), although many of these applications are being replaced by MRI. In

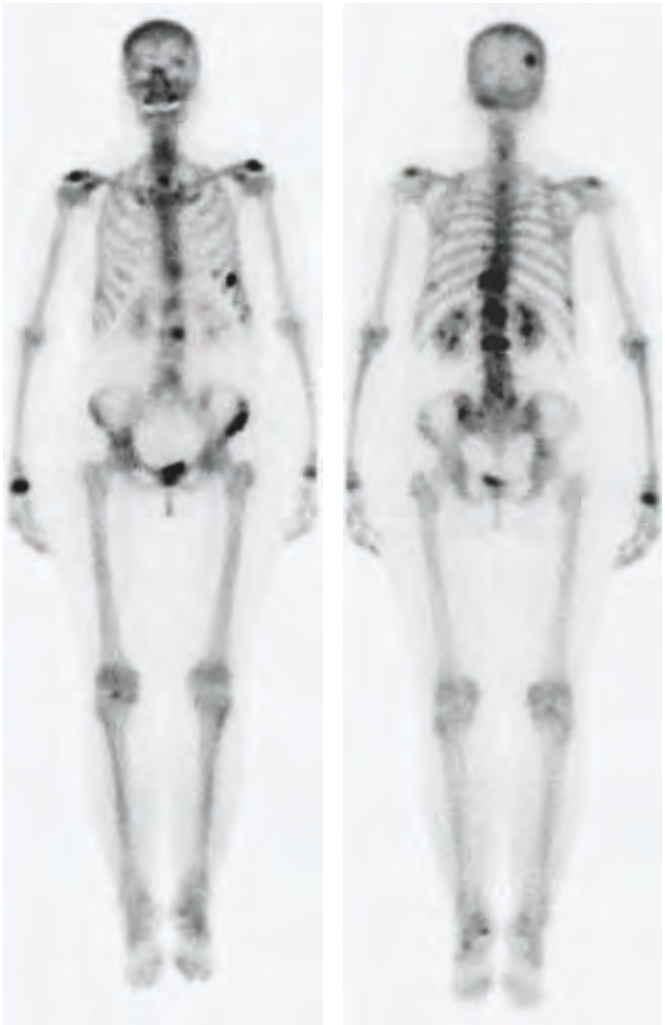

Figure 14.17 Bone scintigraphy in a patient with carcinoma of the breast illustrates bony metastatic deposits involving multiple vertebrae, the skull, pelvis and ribs.

genitourinary disease, dynamic imaging can be performed to assess renal perfusion and function including obstruction, investigate renovascular hyper- tension and evaluate renal transplants. Radionuclide imaging is also commonly used in thyroid and parathyroid disorders, ischaemic cardiac disease, detection of pulmonary emboli and assessment of occult infection and inflammatory bowel disease.

Positron emission tomography (PET) is an extension of nuclear medicine, in which a positron-emitting substance such as 18F is tagged and used to assess tissue metabolic characteristics. The most commonly used radiolabelled tracer is 18F-2-fluoro-2-deoxy-D-glucose (FDG), although other tracers can also be used in order to assess metabolic functions such as oxygen and glucose consumption and blood flow. Radioisotope decay causes the emission of a positron, which subsequently, within a few millimetres, collides with and annihilates an electron to produce a pair of annihilation photons. The drawbacks have been high cost, very limited availability and relatively low spatial resolution. The last of these has been addressed by PET/CT systems combining simultaneous PET imaging and CT, allowing the two sets of images to be registered so that the anatomical location of the abnormality can be localised more precisely.

Summary box 14.7

Radionuclide imaging

Strengths

- Allows functional imaging
- Allows imaging of the whole body
- Bone scan has a high sensitivity for metastatic bone disease, fractures and infection
- PET scanning is valuable in the detection of metastatic cancer

Weaknesses

- Specific agents are required for specific indications
- Often non-specific and an abnormal result may require further imaging
- Generally poor spatial resolution

IMAGING IN ORTHOPAEDIC SURGERY

Introduction

Imaging is an intricate part of musculoskeletal diagnosis, and image-guided, minimally invasive techniques also play a major role in treatment. In broad terms, radiographs are the best method of looking for bony lesions or injuries, MRI shows bone marrow disease, muscle tendon and soft-tissue disorders and ultrasound has better resolution than MRI for small structures, with the added advantage of showing dynamic changes. CT enables visualisation of the fine detail of bony structures, clarifying abnormalities seen on plain radiographs.

There are occasions when a combination of techniques will be important, and due consideration should be given to reducing the ionising radiation burden to the patient, using ultrasound and MRI as primary investigations whenever appropriate.

Summary box 14.8

Types of imaging

- Radiographs are the best first-line test for bone lesions and fractures
- MRI is good for diagnosing bone marrow disease, occult fractures and tendon and soft-tissue disorders
- CT enables visualisation of the fine detail of bony structures
- CT gives the best three-dimensional information on fractures
- Ultrasound has better resolution in accessible soft tissues and can be used dynamically
- Ultrasound is the best method of distinguishing solid from cystic lesions
- Ultrasound is the only method for locating non-metallic foreign bodies
- Ultrasound is the best method for detecting muscle hernias

Skeletal trauma

Musculoskeletal trauma is best imaged by an initial plain radiograph. All skeletal radiographs should be taken from two different angles, usually at right angles to each other. This is important in trauma because a fracture or dislocation may not be visible on a single view (**Figure 14.18**). Occasionally, and in specific locations such as the scaphoid, more than two views are routinely performed. If this fails to make a clear diagnosis, or if there is suspicion of soft-tissue injuries, then cross-sectional studies are indicated.

Increasingly in the assessment of spinal trauma, CT is replacing radiographs as the first-line investigation for two main reasons: the first is that the sensitivity of CT is superior, the second is that it is quicker, enabling treatment to commence sooner).

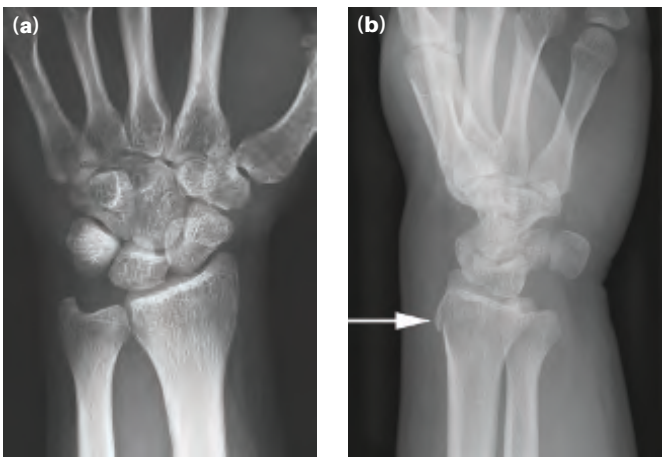

Figure 14.18 Anteroposterior radiograph of the wrist **(a)** in a patient following a fall does not show an acute bony injury. It is only on the second view **(b)** that a fracture of the dorsal cortex of the distal radius is visualised (arrow).

Summary box 14.9

Trauma imaging

- Initial imaging is either radiography or CT
- At least two views are needed for radiographs
- Use CT for spine, intra-articular or occult fractures

Axial CT images alone may fail to diagnose some fractures, so three-dimensional reformatting is important to prevent errors. Sections should be thin, but care must be taken not to cover too wide an area, as the radiation burden may be excessive, particularly with multislice CT.

Degenerative disease

Synovitis

Radiographs are usually the first-line imaging investigation performed for the examination of joints. Typical changes of a degenerative or an erosive arthropathy are well known and understood. However, early arthropathy will be missed on radiographs and, with the advent of disease-modifying drugs, it is important to detect early synovitis before it is even apparent on clinical examination. Gadolinium diethyl triamine penta-acetic (DTPA)-enhanced MRI is the most sensitive method for detecting synovial thickening of numerous joints, but ultrasound is also sensitive, albeit more laborious to perform. Ultrasound shows effusions and synovial thickening clearly, and shows the increased blood flow around the affected joints without the use of contrast agents (**Figures 14.19** and **14.20**).

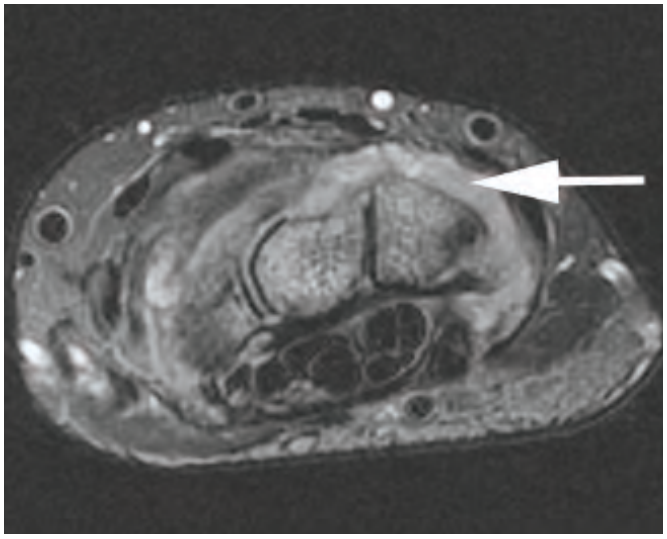

Figure 14.19 Axial T2-weighted fat-suppressed image of the wrist in a patient with rheumatoid arthritis demonstrates synovitis manifested as increased signal dorsal to the carpal bones (arrow).

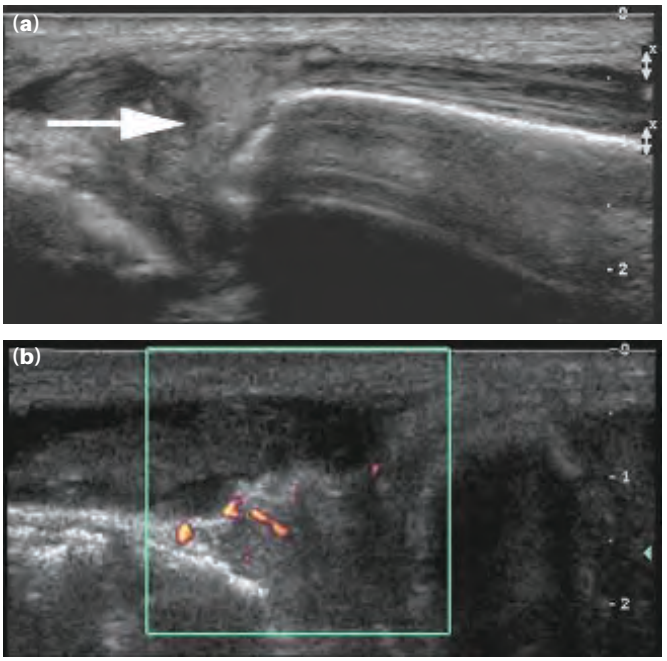

Figure 14.20 Ultrasound of the wrist **(a)** shows thickening of tissues on the dorsal aspect of the radiocarpal joint (arrow). **(b)** There is increased flow on power Doppler ultrasound in this patient with wrist synovitis and rheumatoid arthritis.

Articular cartilage damage

Articular surface disease is difficult to detect using non-invasive techniques. MRI is probably the best method, although it is not sensitive to early chondral changes (**Figure 14.21**). Higher field strength magnets (3 Tesla and above) with dedicated surface coils provide more precise assessment; however, MR arthrography

Figure 14.21 Coronal magnetic resonance imaging of the knee demonstrates a focal osteochondral abnormality of the medial femoral condyle, with full-thickness loss of the articular cartilage and abnormality of the subchondral bone (arrow).

Nikola Tesla, 1856–1943, American physicist and electrical engineer who worked for the Westinghouse Company. A Tesla is the SI unit of magnetic flux density.

is currently the imaging 'gold standard'. Saline mixed with a dilute quantity of gadolinium DTPA is introduced into the joint by needle puncture, which is followed by an MRI examination. Using this technique, more subtle changes in the articular surface can be seen, including thinning, fissuring and ulceration. However, early softening of articular cartilage will not be visible. MR arthrography is also useful for detecting labral tears in the shoulder or hip, and in the assessment of patients who have undergone a previous meniscectomy. The triangular fibrocartilage of the wrist is also difficult to assess fully without MR or CT arthrography (Figure 14.22).

Figure 14.22 Coronal CT arthrogram of the wrist showing a central perforation of the triangular fibrocartilage with contrast extending into the distal radioulnar joint and radiocarpal articulation (arrow).

In the shoulder, rotator cuff trauma and degenerative changes can be studied using ultrasound or MRI. In experienced hands, ultrasound has a higher accuracy rate, because image resolution is better and because the mechanical integrity of the cuff can be tested by dynamically stressing it (Figure 14.23). MRI has the advantage of being able to show abnormalities in the subcortical bone.

In the majority of arthropathies and degenerative disorders, serial imaging is useful. Changes in films taken weeks or months apart are far easier to see and interpret than a single snap-shot study.

Aggressive bone disease

The radiograph is the first imaging technique for destructive lesions in bones. There is considerable experience required in the interpretation of these films, especially with regard as to whether the lesion is benign or malignant (Figure 14.24).

Summary box 14.10

Imaging techniques for joint disease

- Radiographs are good for assessing established articular disease
- Synovitis can be detected using ultrasound or contrast-enhanced MRI
- Early damage to articular cartilage is difficult to image by conventional methods
- Rotator cuff lesions are best studied using ultrasound or MRI
- Destructive lesions are best studied first on plain radiographs
- MRI is best for staging tumours
- Biopsy can be guided by fluoroscopy, CT or ultrasound

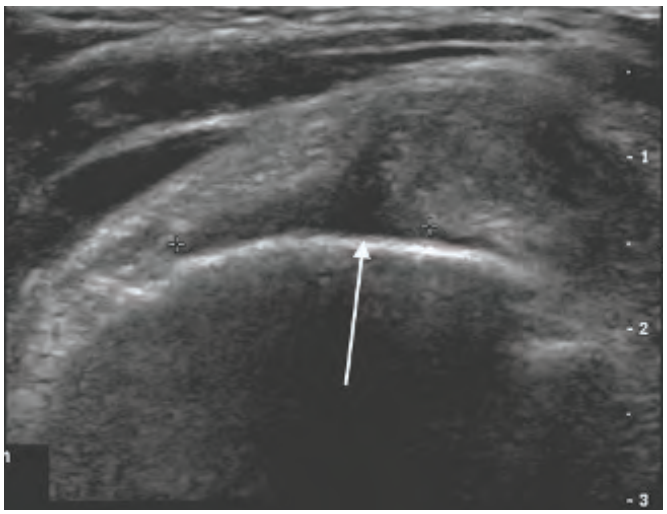

Figure 14.23 Ultrasound of the supraspinatus tendon identifies a partial tear of the tendon (arrow), which is predominantly articular sided but with a component that is nearly full thickness.

Radiographs are also vital in the assessment of soft-tissue calcification in tumours of muscle, tendon and subcutaneous fat. When a lesion is detected, there needs to be an early decision as to whether this is benign or malignant. If there is a suspicion of malignancy on the radiograph, or any uncertainty, then local staging is indicated. This is best performed by MRI for both bone and soft-tissue lesions (Figure 14.25). At this stage, it is likely that a biopsy will be indicated, and preferably under image guidance. Soft-tissue and bone biopsy needles may be guided by CT, ultrasound or interventional MRI systems. The route of puncture should avoid vital structures and must be agreed with the surgeon, who will perform local excision if the lesion proves to be malignant. Care should be taken to avoid contaminating other compartments. In all circumstances, samples are best sent for both histopathological and microbiological examination. It may be difficult to tell on imaging whether or not a lesion is infected, and histology often provides a clear diagnosis in inflammatory conditions. Bone scintigraphy is useful in detecting whether a lesion is solitary or multiple, although whole-body MRI is becoming available.

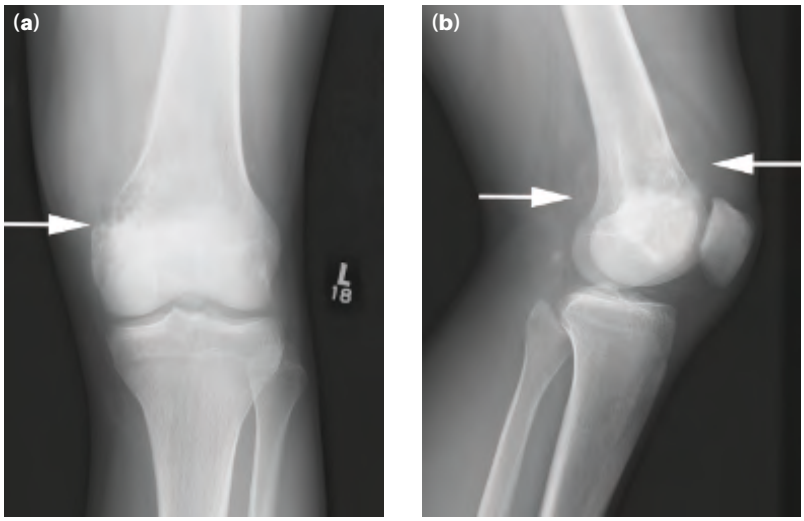

Figure 14.24 Anteroposterior **(a)** and lateral **(b)** radiographs of the left knee in a young patient with knee pain. There is a mixed lucent and sclerotic lesion of the distal femur with breach of the cortex medially and soft-tissue extension seen anteriorly and posteriorly (arrows). The location and appearances are consistent with osteosarcoma.

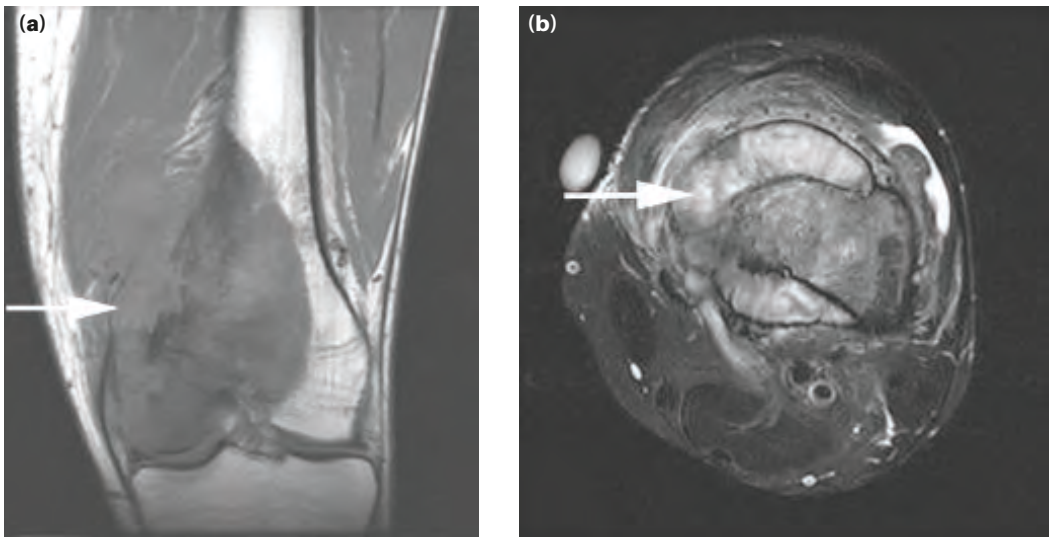

Figure 14.25 Coronal T1- **(a)** and axial T2-weighted fat-suppressed **(b)** images through the distal femur of the patient in Figure 14.24 illustrates the bony area involved, the soft-tissue extent of the tumour and the relationship of the neurovascular structures to the mass (arrows).

Summary box 14.11

Imaging of aggressive lesions in bone

- Plain radiographs are important as a first investigation
- MRI is best for local staging
- Bone scintigraphy or whole-body MRI for solitary or multiple lesion determination
- CT detects lung metastases
- Fluoroscopy, CT, MRI or ultrasound can be used to guide the biopsy

Mass lesions

Mass lesions in muscle and soft tissue are examined by ultrasound, which can be diagnostic in the majority of cases, thereby avoiding the need for further imaging. This is most often the case when a lesion is purely cystic and, as most soft-tissue masses are cysts, ultrasound is a very effective screening test. There are occasions when no mass lesion is found at the site of concern, and then reassurance can be offered. If the ultrasound examination is normal, this effectively excludes soft-tissue neoplasia. A reasonable protocol is to perform ultrasound on all palpable 'lesions' to exclude cysts, and on patients without any identifiable mass, and to proceed to MRI only when there is a solid or partly solid element to an unidentifiable lesion. Tumour vascularity is best assessed by Doppler ultrasound. It can be studied by intravenous gadolinium DTPA-enhanced MRI; however, this is a more expensive and invasive technique, providing no more information than Doppler ultrasound.

Summary box 14.12

Imaging of soft-tissue lesions

- Ultrasound is the best for screening; it is often the only imaging required
- MRI is best for local staging and follow-up
- Doppler ultrasound can assess vascularity cheaply and effectively
- Ultrasound is useful for biopsy

Infection

In the early stages of joint infection, the plain films may be normal, but they should still be performed to exclude bony erosions, in case a painful joint is the first sign of an arthropathy. Ultrasound examination is the easiest and most accurate method of assessing joint effusions, although, when an effusion is identified, it is not possible to discriminate between blood and pus. Aspiration guided by ultrasound is the best method of making this distinction. MRI may be required to assess early articular cartilage and bone involvement.

Radiographs should also be used to examine patients with suspected osteomyelitis. Although they may not detect early infection, they will demonstrate or exclude bony destruction, calcification and sequestrum formation. CT may be needed to give a cross-sectional view, in order to assess the extent of bony sequestrum.

MRI is perhaps the most sensitive method for detecting early disease and is the preferred technique to define the activity and extent of infection, as it shows not only the bony involvement but also the extent of oedema and soft-tissue involvement (Figure 14.26). Abscesses may be detected or excluded, and subperiosteal oedema is readily visible. MRI can be used as a staging procedure to plan treatment, including surgical intervention. Serial examinations can be used to follow the response to intravenous antibiotics and are very useful in the management of complex osteomyelitis. In cases of negative or equivocal MRI, nuclear medicine techniques such as bone scintigraphy can be very sensitive, and specialised studies using tracers such as gallium citrate or indium-labelled white cells increase specificity.

Figure 14.26 **(a)** The plain films of this 13-year-old are close to normal. On close inspection, there is a fine periosteal reaction on the fibula. **(b)** The coronal T1-weighted magnetic resonance image shows little more, but **(c)** the coronal fast STIR (short tau inversion recovery) images and **(d)** axial T2 fast spin echo with fat suppression show the oedema in bone as white and the extensive periosteal fluid with soft-tissue inflammation. The diagnosis is acute osteomyelitis.

Summary box 14.13

Imaging of potentially infected bone and joint

- Plain radiographs may be needed to exclude bone erosion
- Ultrasound is sensitive for an effusion, periosteal collections and superficial abscesses and can be used for guided aspiration
- CT is useful in established infection to look for sequestrum
- MRI is useful to define the activity of osteomyelitis, early infection and soft-tissue collections
- Bone scans are sensitive but of low specificity
- Complex nuclear medicine studies are useful in negative MR examinations or equivocal cases

Metabolic bone disease

Plain radiographs should be the first images of patients with metabolic bone disease. They may detect the subperiosteal erosions in hyperparathyroidism or, more commonly, the osteopenia in osteoporosis, but they cannot be used to quantify osteoporosis. The apparent density of the bone on the film is linked to the penetration of the rays, among other variables, as well as to the bone density. If a quantitative method is needed, however, bone mineral density using dual x-ray absorptiometry (DEXA) is the most accurate and practical. However, fractures will cause erroneously high readings, and they tend to occur in the vertebrae used for DEXA measurements. Quantitative CT is an alternative technique, although this is less readily available. Ultrasound transmission measurement in the extremities has its advocates, as it arguably measures factors that better represent the strength of bone rather than its density. Its limitations are that it cannot be used to study the vertebrae or hip, and these are the sites where osteoporotic fractures occur most frequently. MRI may be useful in detecting fractures and is an essential prerequisite to percutaneous vertebroplasty.

IMAGING IN MAJOR TRAUMA

Introduction

Trauma remains a major cause of mortality and morbidity in all age groups. Presented with a multiply injured patient, rapid and effective investigation and treatment are required to maximise the chances of survival and to reduce morbidity. Imaging plays a major role in this assessment and in guiding treatment. As with the clinical assessment, imaging is carried out according to the principles of primary and secondary surveys, identifying major life-threatening injuries of the airway, respiratory system and circulation before a more detailed and typically time-consuming assessment of other injures. At no point should imaging delay the treatment of immediately life-threatening injuries. As in other settings, the quickest and least invasive examinations should be performed first. A radiologist present in the trauma room at the time of patient assessment is able to evaluate the radiographs rapidly, relay this information back to the team and guide further imaging, which may include further plain films, CT, ultrasound and MRI.

Plain radiographs

Conventional radiography allows rapid assessment of the major injuries and can be carried out in the trauma room while the patient is clinically assessed and treated. Despite the time constraints, the number of staff involved and the restricted mobility of the patient, high-quality images can be routinely obtained with due care and attention.

There is no routine set of radiographs to be obtained, and the decision is based on the mechanism of injury, the stability of the patient's condition and whether the patient is intubated. The most commonly performed initial radiographs are a chest radiograph, a single anteroposterior view of the pelvis and a cervical spine series.

The supine chest radiograph should encompass an area from the lung apices to the costophrenic recesses and include the ribs laterally. Chest radiographs give valuable information in both blunt and penetrating trauma. Evaluation of the radiograph should be undertaken in a systematic manner to minimise the chances of missing an injury. In the first instance, the position of line and tubes, including the endotracheal tube, should be assessed followed by assessment of the central airways. Following this, the lungs should be evaluated for abnormal focal areas of opacification, which may represent aspiration, haemorrhage, haematoma or oedema, as well as more diffuse opacification reflecting a pleural collection. Alternatively, relative focal or unilateral lucency may reflect a pneumothorax in the supine position. Evaluation of the mediastinum should include its position, which may be altered by tension pneumothoraces or large collections, as well as its contour, an alteration of which may reflect a mediastinal haematoma due to aortic or spinal injury. Finally, the skeleton and the soft tissue should be carefully examined for rib, vertebral, scapular and limb fractures, as well as evidence of surgical emphysema and paraspinal haematomas (**Figure 14.27**).

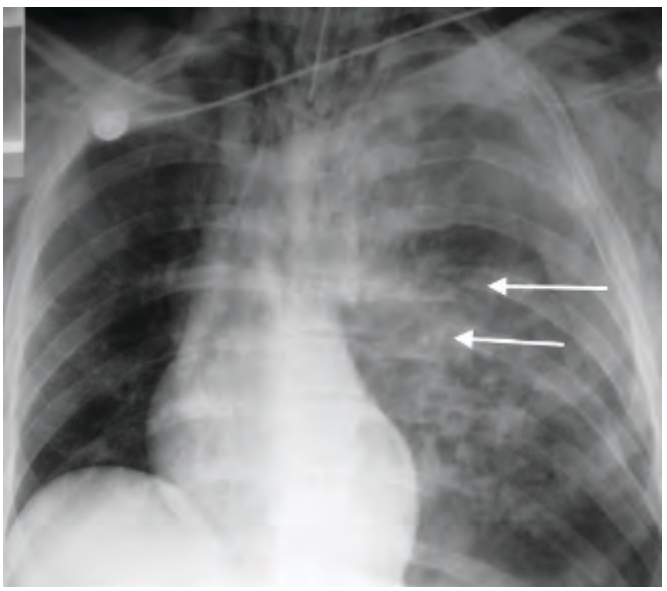

Figure 14.27 Supine chest radiograph of a patient involved in a road traffic accident. The patient is intubated. There are multiple left-sided rib fractures (arrows) and extensive surgical emphysema. Depression of the left hemidiaphragm and mediastinal shift to the right suggest that there is a tension pneumothorax present.

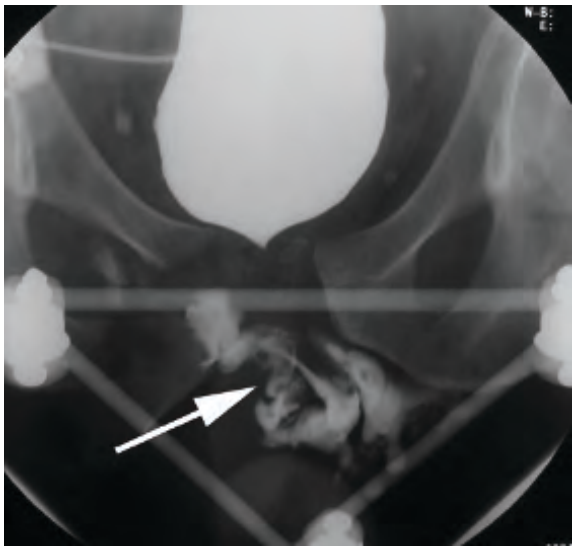

Figure 14.28 Retrograde urethrogram in a patient who sustained extensive pelvic fractures following a fall. The pelvic injuries have been stabilised using an external fixation device. The urethrogram identifies extensive injury to the urethra with extravasation of contrast (arrow).

Pelvic radiographs are also commonly performed to screen for, and assess, fractures of the bony pelvis. The image should include the iliac crests in their totality and extend inferiorly to below the lesser trochanters. When assessing the film, the alignment of the sacroiliac joints and the symphysis pubis should be carefully examined, as some fractures, especially those of the sacral arcades, can be very subtle on the pelvic radiograph. The presence of pubic fractures raises the possibility of urethral injury and should alert clinicians to exercise caution with bladder catheterisation **(Figure 14.28)**.

The utility of cervical spine x-rays depends on the consciousness level of the patient and the presence of distracting injuries. In fully conscious patients with an isolated neck injury, clinical assessment can be used to guide the need for x-rays. In patients with distracting injuries and/or altered consciousness, including intubated patients, CT is preferred **(Figure 14.29)**.

Further radiographs of the thoracic and lumbar spine and the peripheral skeleton may be required, depending on the clinical setting. As with all skeletal radiographs, two perpendicular views are required for adequate assessment. However, with the increasing use of CT in assessment of the torso the need for plain films is diminishing.

Radiographs of the skull or facial bones have no role in the immediate assessment of the multitrauma individual, except for immediate localisation of a penetrating object.

Ultrasound

Ultrasound has an evolving role in the assessment of acutely traumatised patients. The main current roles of ultrasound include the assessment of intraperitoneal fluid and haemo-pericardium (focused assessment with sonography for trauma, FAST), the evaluation of pneumothoraces in supine patients and in guiding intervention.

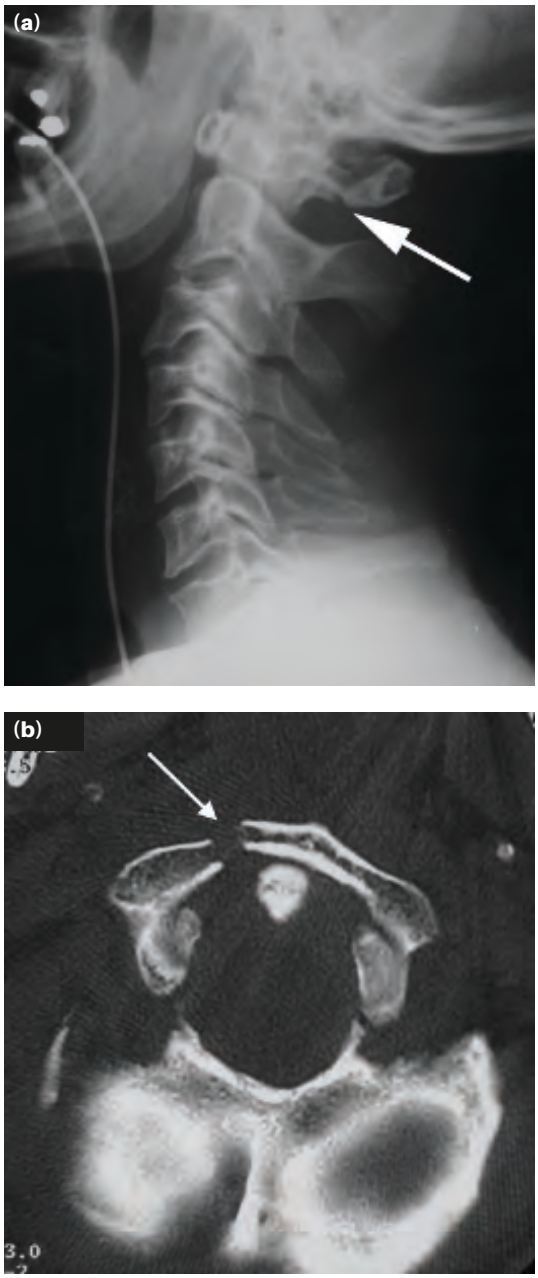

Figure 14.29 Lateral view of the cervical spine **(a)** fails to demonstrate the cervicothoracic junction. In addition, there appears to be a break in the posterior arch of C1 (arrow). Computed tomography of the cervical spine **(b)** demonstrates a fracture of the anterior arch as well as the posterior arch of C1 (arrow).

FAST ultrasound is a limited examination directed to look for intraperitoneal fluid or pericardial injury as a marker of underlying injury. This avoids the invasiveness of diagnostic peritoneal lavage. In the presence of free intraperitoneal fluid and an unstable patient, the ultrasound allows the trauma surgeon to explore the abdomen as a cause of blood loss. In the presence of fluid and a haemodynamically stable individual, further assessment by way of CT can be performed. However, it is important to realise that ultrasound has limitations in the identification of free fluid. This includes obscuration of fluid by bowel gas or extensive surgical emphysema. More

organised haematoma may be more difficult to visualise. It must also be emphasised that the principal role of ultrasound is not to identify the primary solid organ injury, although this may be visualised. Occasionally, a second ultrasound scan may show free fluid in the presence of an initially negative FAST scan.

The detection of a pneumothorax on a supine radiograph can be very difficult. Ultrasound examination may be used to identify a radiographically occult pneumothorax. With a high-resolution linear probe, the pleura can be visualised as an echogenic stripe, and its motion with respiration can also be assessed. In the presence of a pneumothorax, the sliding motion of the pleura is lost. Ultrasound may also be used to detect a haemothorax or haemopericardium.

Finally, ultrasound may be of value in guiding the placement of an intravascular line by direct visualisation of the vessels. This can be especially advantageous in shocked patients.

Computed tomography

CT is the main imaging method for the investigation of intracranial and intra-abdominal injuries and vertebral fractures. With current multidetector scanners a comprehensive examination of the head, spine, chest, abdomen and pelvis can be completed in less than 5 minutes. However, much more time is taken up in transferring the patient and the associated monitoring equipment onto the scanner. Therefore, the total time can be in excess of 30 minutes, and CT should be reserved for individuals whose condition is stable.

CT examination of the head is accurate in identifying treatable intracranial injuries **(Figures 14.30 and 14.31)** and should not be delayed by radiography of peripheral injuries, as there is declining success in cases of intracranial collection when treated after the initial 3–4 hours. In comparison, identification of more widespread injuries, such as diffuse axonal injury, is relatively poor. Examination of facial injuries and

Figure 14.30 Computed tomography of the head in a patient with head injury shows bilateral large frontal extradural collections (arrow).

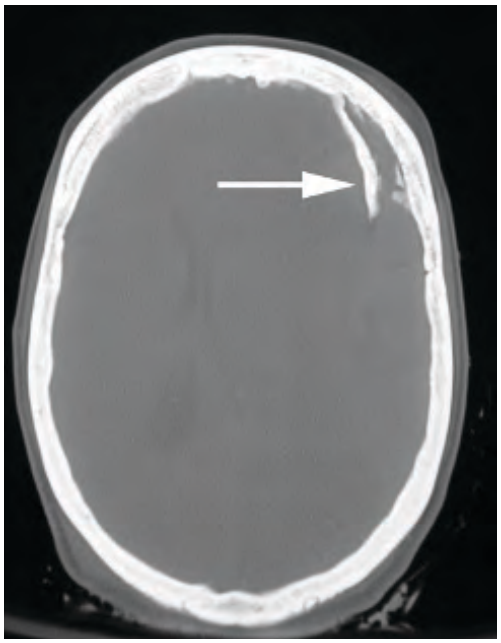

Figure 14.31 Computed tomography of the head following head trauma shows a skull fracture with a large depressed component (arrow).

cervical spine fractures can also be carried out at the same time as this only adds seconds to the examination. There is evidence that CT of the abdomen and pelvis is of benefit in multiple trauma when there is a head injury, as it often shows unexpected abnormalities, and this may affect the immediate management, especially if the patient deteriorates.

Chest CT with intravenous contrast agent is valuable in identifying vascular and lung injuries and is the most accurate way of demonstrating haemothorax and pneumothorax. The position of chest drains can be identified, allowing adjustment of position if necessary. Abdominal and pelvic CT is usually undertaken as an extension to the chest CT. If an abdominal examination is performed, the pelvis should be included to avoid missing pelvic injuries and free pelvic fluid. CT is an excellent means of identifying hepatic, splenic **(Figure 14.32)** and renal injuries. Delayed examination after the administration of intravenous contrast agents allows assessment of the pelvicalyceal system in cases of renal trauma. Pancreatic and duodenal injuries may also be identified, but detection of these injuries may be more problematic. Using CT, the accuracy of detection of bowel or mesenteric injuries is less than it is for solid organ injury, and these injuries should be suspected when there is free intraperitoneal fluid without an identifiable cause **(Figure 14.33)**.

The image data may be reconstructed into thinner slices for the diagnosis of injuries to the thoracic and lumbar spine and for the better delineation of pelvic and acetabular fractures. Complex intra-articular fractures of the peripheral skeleton, such as calcaneal and tibial plateau fractures, may be usefully examined by dedicated thin-section studies provided this does not delay the treatment of other more serious injuries **(Figure 14.34)**. CT angiography may be used to demonstrate vascular injuries in the limbs in those with penetrating injuries or complex displaced fractures.

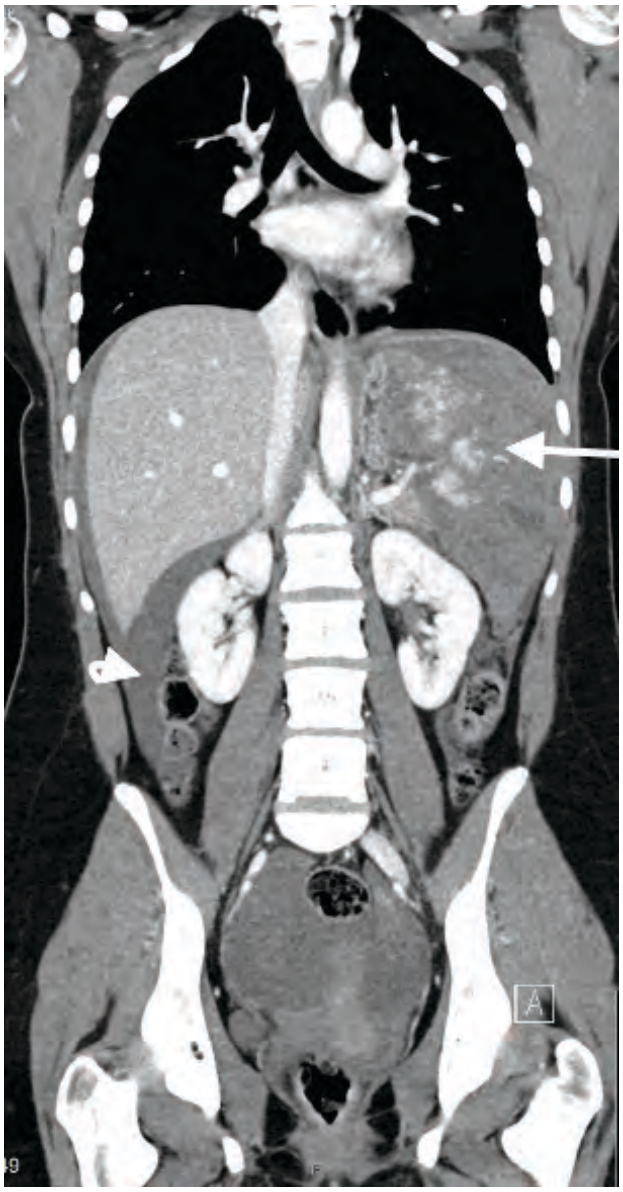

Figure 14.32 Coronal computed tomography image of the body shows a grade V splenic injury ('shattered spleen', arrow) with vascular injury at the hilum and free fluid around the spleen and liver (arrowhead).

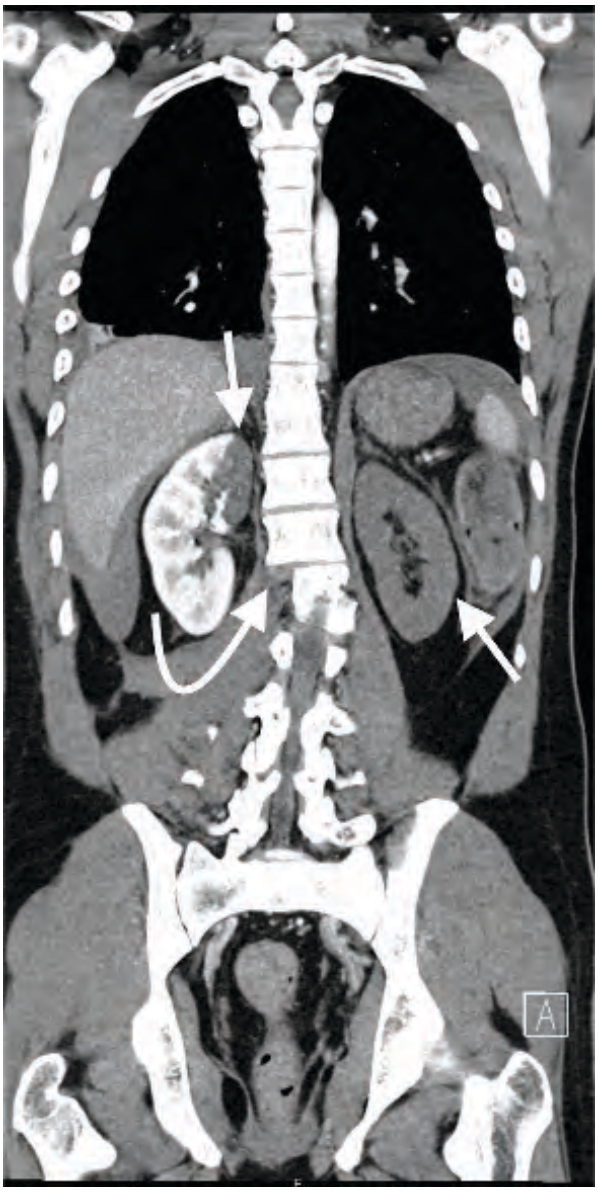

Figure 14.33 Coronal computed tomography demonstrating free fluid around the liver. The upper pole of the right kidney and left kidney demonstrate no contrast uptake in keeping with acute vascular injury (arrows). In addition there is a distraction injury with lateral dislocation of the T11–T12 intervertebral junction (curved arrow).

Figure 14.34 Sagittal reformats of computed tomography of the calcaneus in a patient following a fall illustrate a comminuted calcaneal fracture with intra-articular extension into the posterior facet of the subtalar joint (arrow).

Magnetic resonance imaging

The value of immediate MRI in trauma is relatively limited and is largely confined to the imaging of spinal injuries (Figure 14.35).

Access to urgent MRI is not widely available, and there are major practical problems in imaging patients who require ventilation or monitoring. MRI is therefore only practical in stable patients. All monitoring equipment must be MRI compatible, and ventilation support should be undertaken by staff skilled and experienced in these techniques as applied to the MRI environment. MRI may be used to diagnose injuries of the spinal cord and associated perispinal haematomas in patients with neurological signs or symptoms. MRI can supplement CT in spinal injuries by imaging soft-tissue injuries to the longitudinal and interspinous ligaments. MRI is mandatory in patients in whom there is facetal dislocation if surgical reduction is being considered, to minimise the risk of displacing soft-tissue or disc material into the spinal canal during reduction procedures. Subtle fractures may be difficult to identify, particularly if they are old, but an acute injury is normally identified by the surrounding oedema. Bony abnormalities should be reviewed using CT, as fracture lines are hard to identify with MRI and unstable injuries may be overlooked. In the less acute setting, MRI may also be used to assess diffuse axonal injuries, with an accuracy exceeding CT.

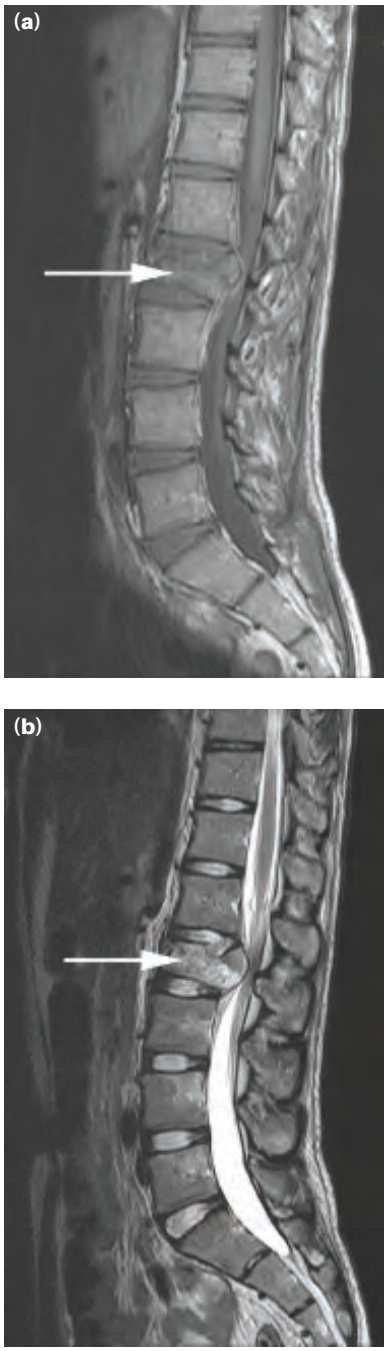

Figure 14.35 Sagittal T1-weighted **(a)** and T2-weighted **(b)** magnetic resonance imaging of the spine demonstrate a burst fracture of L2 causing neural compression (arrows).

Vascular interventional radiology

With the development and refinement of CT angiography techniques, the diagnostic role of formal angiography has become limited. CT angiography is the first-line investigation for aortic trauma and for penetrating and non-penetrating peripheral vascular trauma.

Endovascular techniques play an important role in the treatment of acute solid organ injuries, and the interventional radiologist should be consulted early in the decision-making process. Using coaxial catheter systems and a variety of available embolic agents such as soluble gelatine sponge and microcoils, selective embolisation and reduction of blood flow to the injured segment can be achieved without causing infarction. Selective embolisation techniques are also suitable for the treatment of patients with pelvic fractures with ongoing blood loss and volume issues. With penetrating and non-penetrating extremity trauma, balloon occlusion and embolisation may be employed to control haemorrhage, while the application of stent grafts can aid in re-establishing the circulation to the affected extremity.

IMAGING IN ABDOMINAL SURGERY

The acute abdomen

The term 'acute abdomen' encompasses many diverse entities.

IMAGING IN COMMON SURGICAL CLINICAL SCENARIOS

In this section the roles of different radiological modalities in common surgical scenarios are discussed, with a brief rationale behind their use and typical appearances of various pathological processes.

Bowel obstruction

The plain abdominal radiograph is a useful tool in diagnosing bowel obstruction. Small bowel obstruction can generally be distinguished from large bowel obstruction by virtue of the following: small bowel lies centrally in the abdomen while large bowel lies peripherally; the valvulae conniventes (folds) of the small bowel traverse the entire width of the lumen while the haustra of the large bowel do not; and the calibre of the small bowel is typically less than the large, even when obstructed (typical measurements in obstruction: small bowel 3.5–5 cm, large bowel 5–8 cm).

However, it must be stressed that a normal plain radiograph does not exclude an obstruction and if there is persistent concern, further imaging is indicated; CT is the modality of choice having largely superseded the contrast follow-through or enema, particularly in the acute setting. The key to diagnosis of a mechanical obstruction of either small or large bowel on CT, and differentiation from paralytic ileus, is identification of a transition zone from dilated proximal bowel to collapsed distal bowel. In small bowel obstruction if no obvious cause such as a mass, volvulus or intussusception is identified, then the most likely aetiology is adhesional. There is no need to give oral contrast for a suspected bowel obstruction CT as fluid in the lumen is a natural contrast agent and, in any case, oral contrast may well not reach the point of obstruction by the time of the scan. CT is also invaluable to diagnose complications of bowel obstruction such as perforation and ischaemia.

Closed loop obstruction, where the bowel is obstructed at two points, often in close proximity to each other and frequently related to an internal hernia or adhesional band, is a particular type of small bowel obstruction prone to developing ischemia, and should be suspected at CT if the bowel is dilated distal to a transition point with a further transition point more distally **(Figure 14.36)**.

Figure 14.36 Coronal computed tomography showing a failed renal transplant in the right iliac fossa and second transplant in the left iliac fossa. There has also been a right hemicolectomy. There is proximal small bowel obstruction with dilated fluid filled small bowel loops. Distal to the first point of obstruction (large arrow) there are dilated thick walled fluid filled loops in the pelvis with some adjacent free fluid, which could be followed to a second point of obstruction (small arrow). The patient was taken to surgery, which confirmed a closed loop obstruction secondary to an adhesive band with ischaemia in the segment of small bowel between the points of obstruction.

Perforation

The erect chest x-ray (CXR) is the ideal first test for hollow organ perforation and as little as 10–20 mL of free air can be detected under the diaphragm, with the following caveats **(Figures 14.37 and 14.38)**: about 10 minutes should be left between sitting the patient upright to allow air time to rise; the free air must be sought under the right hemidiaphragm to prevent misinterpretation of the gastric air bubble; and the reviewer must be able to recognise Chilaiditi's syndrome, the harmless and asymptomatic interposition of large bowel between the liver and diaphragm. Caution must also be exercised in interpreting any free air in the context of recent abdominal surgery, as air can persist for up to 5–7 days in the peritoneal cavity.

If the erect CXR is equivocal or a possible walled-off perforation is suspected, a CT is the optimal modality, which may show tiny quantities of free air but may also show the cause, e.g. peptic ulcer, diverticulitis or a neoplastic lesion. As with suspected obstruction, oral or rectal contrast is unnecessary if perforation is suspected as making the diagnosis should prompt appropriate management even if the precise site of perforation is not identified. Also, it cannot be overstressed that if there is any possibility of a leak from the gastrointestinal tract (including an anastomotic leak after surgery), then the use of barium is absolutely contraindicated as it can induce a serious and potentially fatal peritonitis.

Figure 14.37 Erect chest radiograph showing marked bilateral elevation of the hemidiaphragms with a large volume of subdiaphragmatic free gas.

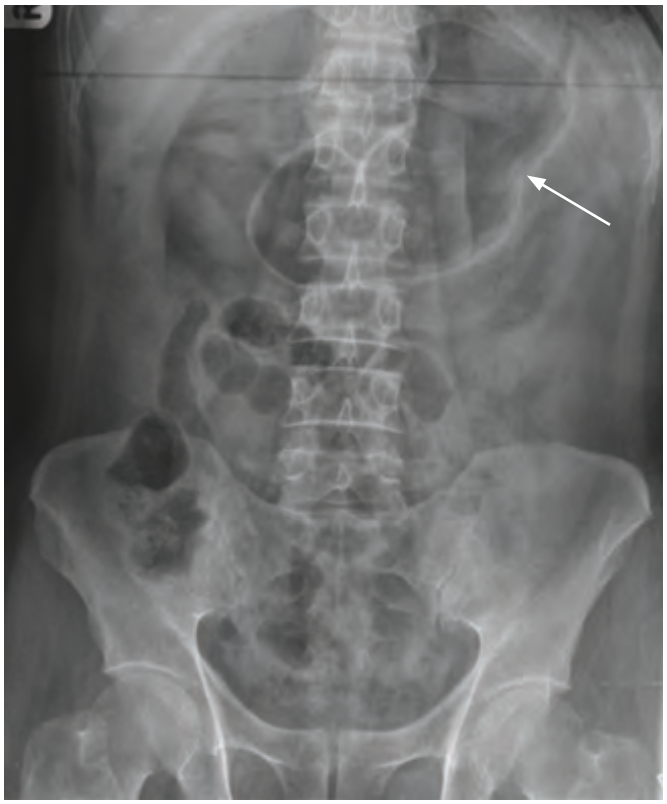

Figure 14.38 Plain abdominal radiograph showing an abnormal appearance to the gastric wall, which is very clearly visualised due to the presence of gas both inside the lumen and also outside the lumen (arrow). This is Rigler's sign of hollow organ perforation, in this case due to a duodenal ulcer.

Ischaemia/infarction

The most useful test when bowel ischaemia or infarction is suspected is a CT scan. Intravenous contrast administration is essential to look for thrombus/embolus in the mesenteric vessels, though ischaemia due to low flow states can still occur in their absence. Ischaemia can be a difficult diagnosis to make radiologically but is suspected, in the appropriate clinical context, by bowel wall thickening, submucosal oedema and free fluid between the folds of the mesentery (particularly if haemorrhagic). Ischaemia must be strongly suspected if these findings are seen in association with a closed loop obstruction or strangulated hernia. Ischaemic colitis typically affects the 'watershed area', which is the junction of the areas supplied by the superior and inferior mesenteric arteries, typically in the region of the splenic flexure.

When bowel wall ischaemia proceeds to transmural infarction, the diagnosis is usually more straightforward with evidence of pneumatosis (air in the bowel wall) typically identified. The air in the bowel wall can then track into mesenteric veins and thence to the portal vein, a CT sign of grave prognostic significance in an adult as it implies widespread and relatively long-standing bowel infarction.

Gastrointestinal haemorrhage

The aetiology of acute gastrointestinal haemorrhage varies between the upper gastrointestinal tract (GIT) (common causes including peptic ulcer disease, varices and Mallory Weiss tears) and the lower GIT (common causes including angiodysplasia, diverticular haemorrhage and neoplastic lesions). While endoscopy is a useful first-line investigation for both, in refractory or occult gastrointestinal (GI) haemorrhage radiology can also contribute to diagnosis and management. Nuclear medicine scans using radioisotope-labelled red blood cells are useful when bleeding is intermittent, but for patients suspected of active bleeding the best investigation is a CT mesenteric angiogram. Non-contrast scans to look for bright blood in the bowel lumen should be supplemented with scans in the arterial phase to assess for a blush due to active extravasation, and portal venous phase to optimise detection of wall thickening and masses and to look for sites of venous bleeding. If non-invasive imaging is effective, catheter angiography can be used to embolise a bleeding point.

Inflammatory processes

Appendicitis

Historically, a straightforward clinical diagnosis of appendicitis obviated any need for imaging, but with the proven accuracy of available modalities imaging has become increasingly popular to reduce negative appendicectomy rates and to make alternative diagnoses. While a plain radiograph may demonstrate a calcified appendicolith in the right iliac fossa, it is insufficiently sensitive or specific to be reliable. In children ultrasound is the best test, to reduce radiation exposure and due to typically favourable body habitus. This also applies to females of childbearing age, again to reduce radiation exposure, but also as the symptoms may be mimicked by gynaecological pathology, such as ectopic pregnancy, haemorrhagic ovarian cyst and tubo-ovarian abscess, all diagnoses best made with ultrasound. The definitive exclusion of appendicitis, however, hinges on the identification of a normal appendix, measuring less than 6 mm diameter. Retrocaecal appendicitis can readily escape detection with ultrasound, and thus CT is the next modality of choice and indeed frequently the first requested in most adults **(Figure 14.39)**. The diagnosis of appendicitis on CT requires the identification of a thickened appendix (>7 mm), with periappendiceal inflammatory change as evidenced by stranding in the surrounding fat. Other signs that may be sought include free fluid, thickening of the caecal pole, possible localised small bowel ileus and right iliac fossa lymphadenopathy. Both CT and ultrasound can also identify collections if an inflamed appendix ruptures, and can be used to guide percutaneous drainage as a bridge to definitive surgery.

Diverticulitis

Inflammation of an obstructed diverticulum typically presents with left iliac fossa pain and pyrexia **(Figure 14.40)**. While some authors have promoted the use of focused ultrasound

Leo George Rigler, 1896–1979, American radiologist, described the double wall sign in pneumoperitoneum.

Figure 14.39 Acute appendicitis. Contrast enhanced CT scan reconstructed in the coronal plane demonstrates a thickened appendix in the right iliac fossa (arrow) with inflammatory changes in the surrounding fat and reactive thickening of the caecal pole.

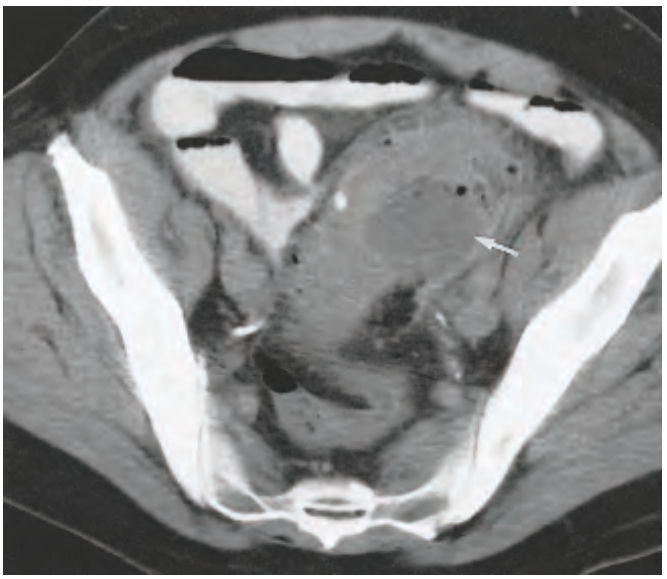

Figure 14.40 Computed tomography scan showing a segment of thickened sigmoid colon with a paracolic abscess (arrow) in a patient with diverticulitis.

for this indication, in general it is best diagnosed with a CT scan. The typical CT appearance is of pericolic inflammatory change around a diverticulum, most commonly in the sigmoid colon. Complications of diverticulitis include perforation, abscess formation, fistulation to adjacent structures and strictures in the bowel; CT is also the modality of choice to identify these, and as with appendicitis can be used to guide percutaneous abscess drainage as a bridge to definitive surgery.

Inflammatory bowel disease

The diagnosis of inflammatory bowel disease is made histologically, though a barium study of the small bowel, either a follow-through (where barium is ingested orally) or enteroclysis (where dilute barium is infused via a nasojejunal (NJ) tube) is often used as a screening tool if symptoms are vague. If the diagnosis of Crohn's disease is established, barium studies are useful to demonstrate the extent of disease, particularly to demonstrate the length and number of strictures if surgery is planned, although increasingly this role is being superseded by MRI enterography, which entails an abdominopelvic MRI scan after ingestion of an agent such as lactulose or mannitol to distend the small bowel. The other obvious advantage of MRI is the lack of radiation, particularly relevant in young patients with Crohn's disease who often undergo multiple imaging studies over their lifetime, and for this reason it is gaining in popularity for inflammatory bowel disease follow-up.

An acute flare up may also require imaging, and an ultrasound is usually a good first test to look for dilated bowel loops and any abscess, though CT may ultimately be required as gas-filled bowel loops can obscure visualisation of an abscess on ultrasound. MRI is the imaging modality of choice to assess perianal fistulae and abscesses.

Acute pancreatitis

As with acute appendicitis, when the diagnosis is straightforward clinically there may be no need for imaging, though increasingly it is used to confirm the diagnosis, to assess the severity of the process and to look for complications. While ultrasound may show gallstones and can demonstrate an enlarged pancreas with peripancreatic fluid and inflammatory changes, the optimal modality is CT. CT performed too early in the course of the attack, e.g. in the first 12 hours, can be equivocal and the optimal timing of imaging is 48–72 hours.

In mild acute pancreatitis, CT may be normal or may show an enlarged oedematous gland, but in more severe attacks other findings which should be sought include peripancreatic fluid collections, vascular complications such as arterial pseudo- aneurysm formation or venous thrombosis and necrosis either of the gland itself or of the surrounding fat. Necrosis typically develops 48–72 hours after the onset of symptoms, and is manifest on CT as lack of enhancement of the necrotic areas. CT with intravenous contrast is therefore essential to look for necrosis, which is potentially catastrophic particularly if it becomes infected. While CT is not always reliable to diagnose infected necrosis, it is suggested by bubbles of air in the necrotic segment. As with other intra-abdominal inflammatory processes, either ultrasound or more usually CT can be used to guide percutaneous drainage of inflammatory fluid collections.

Acute cholecystitis/biliary colic/jaundice

While acute cholecystitis is usually due to mechanical obstruction of the cystic duct or gallbladder neck by a gallstone, acute acalculous cholecystitis can occur in critically

ill patients from a number of causes. In any case ultrasound is the modality of choice should this diagnosis be suspected, and the classic diagnostic features are of gallbladder distension with wall thickening (>3 mm). A gallstone obstructing the gallbladder neck or cystic duct may be visualised; alternatively, in acalculous cholecystitis sludge may be seen layering in the gallbladder lumen. Associated signs include pericholecystic fluid and hyperaemia on Doppler examination. Ultrasonographic Murphy's sign refers to tenderness over the gallbladder when pressure is applied while scanning and is a supportive finding in making the diagnosis. As a second-line investigation CT is also accurate for this condition, demonstrating similar signs of gallbladder distension and wall thickening with surrounding inflammatory changes. CT is also useful to diagnose complications such as gangrenous cholecystitis, gallbladder perforation and emphysematous cholecystitis, which may necessitate emergency cholecystectomy. If cross-sectional studies are equivocal, hepatobiliary scintigraphy can be useful, with the diagnosis of acute cholecystitis suggested by non-visualisation of the gallbladder 3 hours after radioisotope administration.

A frequent limitation of ultrasound is failure to visualise the common bile duct throughout its length due to overlying bowel gas, and elective cholecystectomy was typically accompanied by bile duct exploration to look for duct calculi. Increasingly, however, MRCP has been shown to be highly accurate in excluding bile duct calculi before surgery.

Ultrasound is also a useful first-line investigation for jaundice of unknown cause as it can demonstrate duct dilatation and gallstones. If a definitive cause is not shown with ultrasound, or a mass is identified but its precise nature and extent is uncertain, CT is indicated to look for common causes including stones, cholangiocarcinoma and pancreatic carcinoma. CT can not only identify malignant lesions but can also demonstrate the extent of local infiltration and the presence of metastases to determine potential resectability. If the ducts are of normal calibre in a jaundiced patient, liver biopsy should be considered.

Renal colic

The historical methods of imaging for renal colic all have their limitations. Plain film radiography may not demonstrate all calculi, will not show renal tract obstruction and is unreliable for alternative diagnoses. Intravenous urography (IVU) necessitates the administration of intravenous contrast and, if a level of obstruction is sought, delayed films up to 8 hours after injection may be required; it also will not provide alternative diagnoses. Ultrasound will demonstrate hydronephrosis and hydroureter, and calculi in the kidneys and either the proximal or distal ureters can usually be identified as echogenic foci with posterior acoustic shadowing; however, the ureter from just below the kidneys to the pelvis is usually obscured by bowel gas, which significantly impairs stone detection.

For these reasons the optimal investigation is now CT KUB, a non-contrast, low dose (2–3 MSv if a low mA scan is performed, equivalent to the dose from a limited IVU series) scan from the upper poles of the kidneys to the pubic symphisis. Contrast administration, either orally or intravenously, is not employed as it does not aid stone detection and may even impair it. Stones are readily identified as high attenuation (typically calcific) foci, and the secondary signs of acute ureteric obstruction may also be seen, including hydronephrosis and hydroureter, renal enlargement and perinephric fat stranding. The most common sites for stones to be seen are at the areas of ureteric narrowing, namely the pelvi-ureteric junction, the pelvic brim and vesico-ureteric junction. CT also offers unrivalled capability for making alternative diagnoses when compared with other modalities.

Abdominal aortic aneurym

If a pulsatile mass is felt in the abdomen and the diagnosis of a possible abdominal aortic aneurysm (AAA) is suspected, ultrasound is a useful modality and provided the aorta is not obscured by bowel gas an aneurysm can usually reliably be excluded. If, however, ultrasound visualisation is suboptimal and the diagnosis is as a result equivocal, or if an aneurysm is identified and information regarding the extent and exact size is required, for example for surgical or endovascular repair planning, CT angiography is indicated, with the aorta typically scanned from the arch to the pubic symphisis in the arterial phase after intravenous contrast. MR angiography is a useful alternative if iodinated contrast is contraindicated.

In the case of suspected aneurysm rupture, provided the patient is sufficiently haemodynamically stable to undergo CT, CT angiography should be urgently performed; a supplementary non-enhanced initial scan is useful to look for retroperitoneal haematoma, which is typically of relatively high attenuation compared to the blood in the lumen on a non-contrast scan.

IMAGING IN ONCOLOGY

Modern surgical treatment of cancer requires an understanding of tumour staging systems, as in many instances the tumour stage will define appropriate management. The development of stage-dependent treatment protocols involving neoadjuvant chemotherapy and preoperative radiotherapy relies on the ability of imaging to determine stage accurately before surgical and pathological staging. Once a diagnosis of cancer has been established, often by percutaneous or endoscopic biopsy, new imaging techniques can considerably improve the ability to define the extent of tumour, although the pathological specimen remains the 'gold standard'. Many staging systems are based on the tumour–node–metastasis (TNM) classification.

Tumour

In most published studies, cross-sectional imaging techniques (CT, ultrasound, MRI) are more accurate in staging advanced (T3, T4) than early (T1, T2) diseases, and the staging of early disease remains a challenge. In gut tumours, endoscopic ultrasound is more accurate than CT or MRI in the local staging of early disease (T1 and T2) by virtue of its ability to demonstrate the layered structure of the bowel wall and the depth of tumour penetration (**Figure 14.41**). Developments in MRI may also improve the staging accuracy of early disease. MRI is extremely valuable in bone and soft-tissue tumour staging and in intracranial and spinal disease.

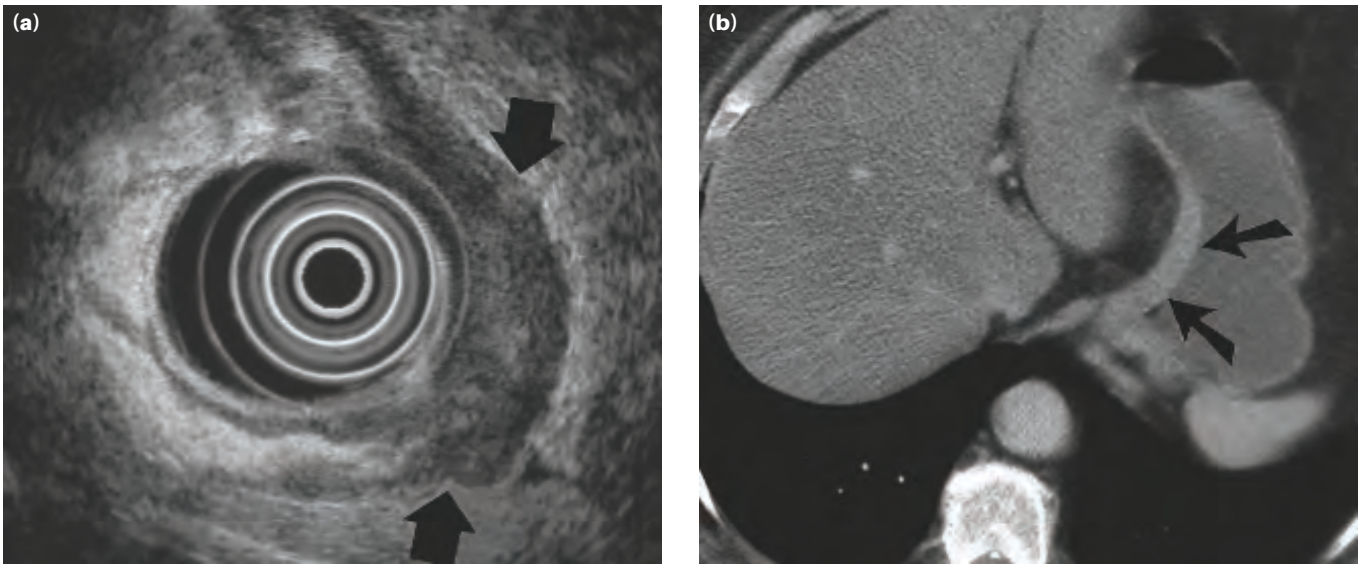

Figure 14.41 **(a)** Echo endoscopy in gastric cancer. The hypoechoic tumour (arrows) is destroying the layered structure of the gastric wall and extending out beyond the serosa. **(b)** Computed tomography scan demonstrates thickening and enhancement of the gastric wall in the same area (arrows). The stomach is distended with water to provide low-density contrast.

Nodes

Accurate assessment of nodal involvement remains a challenge for imaging. Most imaging techniques rely purely on size criteria to demonstrate lymph node involvement, with no possibility of identifying micrometastases in normal-sized nodes. A size criterion of 8–10 mm is often adopted, but it is not usually possible to distinguish benign reactive nodes from infiltrated nodes. This is a particular problem in patients with intrathoracic neoplasms, in whom enlarged benign reactive mediastinal nodes are common. The echo characteristics of nodes at endoscopic ultrasound have been used in many centres to increase the accuracy of nodal staging, and nodal sampling is possible via either mediastinoscopy or transoesophageal biopsy under endoscopic ultrasound control. PET-CT is of increasing use in detecting nodal metastases from a wide range of malignancies, with the capacity to coregister the area of increased FDG uptake with a precise anatomical location. Novel MRI contrast agents may help in the identification of non-enlarged tumour-infiltrated nodes.

Metastases

The demonstration of metastatic disease will usually significantly affect surgical management. Modern cross-sectional imaging has greatly improved the detection of metastases, but occult lesions will be overlooked in between 10% and 30% of patients. CT is the most sensitive technique for the detection of lung deposits, although the decision to perform CT will depend on the site of the primary tumour, its likelihood of intrapulmonary spread and the effect on staging and subsequent therapy of the demonstration of intrapulmonary deposits.

Ultrasound and CT are most frequently used to detect liver metastases. Contrast-enhanced CT can detect most lesions greater than 1 cm, although accuracy rates vary with the technique used and range from 70% to 90%. Recent studies suggest that MRI may be more accurate than CT in demonstrating metastatic disease. Preoperative identification of the segment of the liver involved can be determined by translation of the segmental surgical anatomy, as defined by Couinaud, to the cross-sectional CT images **(Figure 14.42)**.

The technique of PET/CT with FDG, an analogue of glucose, is becoming a powerful tool in oncological imaging. This functional and anatomical imaging technique reflects tumour metabolism and allows the detection of otherwise occult metastases. The most common indications for PET/CT have been staging of lymphoma, lung cancer, particularly non-small cell lung cancer, and preoperative assessment of potentially resectable liver metastases, such as colorectal carcinoma metastases **(Figure 14.43)**.

Intraoperative ultrasound is an additional method of staging that provides superb high-resolution imaging of subcentimetre liver nodules that may not be palpable at surgery. This is often used immediately prior to resection of liver metastases.

Chapter 15

Gastrointestinal endoscopy

Learning objectives

To gain an understanding of:

- The role of endoscopy as a diagnostic and therapeutic tool
- The basic organisation of an endoscopy unit and its equipment
- Consent and safe sedation
- Special situations: the key points in managing endoscopy in at-risk patients
- The indications for diagnostic and therapeutic endoscopic procedures including endoscopic ultrasound
- The recognition and management of complications
- Novel techniques for endoscoping the small bowel
- Advances in diagnostic ability

INTRODUCTION

The gastrointestinal tract has a myriad of functions, such as digestion, absorption and excretion, as well as the synthesis of an array of hormones, growth factors and cytokines. In addition, a complex enteric nervous system has evolved to control its function and communicate with the central and peripheral nervous systems. Finally, as the gastrointestinal tract contains the largest sources of foreign antigens to which the body is exposed, it houses well-developed arms of both the innate and acquired immune system. Therefore, it is not surprising that malfunction or infection of this complex organ results in a wide spectrum of pathology. However, its importance in disease pathogenesis is matched only by its inaccessibility to traditional examination.

Few discoveries in medicine have contributed more to the practice of gastroenterology than the development of diagnostic and therapeutic endoscopy. Although spectacular advances in radiology have occurred recently with the introduction of multislice spiral computed tomography (CT) and magnetic resonance imaging (MRI), the ability to take targeted mucosal biopsies remains a unique strength of endoscopy. Historically, radiological techniques were required to image areas of jejunum and ileum inaccessible to the standard endoscope; however, the introduction of both capsule endoscopy and single/double-balloon enteroscopy allows both diagnostic and therapeutic access to the entire gastrointestinal tract. Image enhancement with techniques such as chromoendoscopy, magnification endoscopy and narrow band imaging allows increased resolution at the mucosal level and increases diagnostic yield. Endoscopic ultrasound can examine all layers of the intestinal wall as well as extraintestinal structures. Finally, experimental techniques such as confocal laser endomicroscopy give resolution at a level compatible with standard histology. The advances in the diagnostic accuracy of endoscopy lend themselves to disease surveillance for specific patient groups as well as population screening for gastrointestinal malignancy. Likewise, there has been a rapid expansion in the therapeutic capability of endoscopy with both luminal and extraintestinal surgery being performed via endoscopic access.

As in all areas of interventional practice, competent endoscopists must match a thorough grounding in anatomy and physiology with a clear understanding of the capabilities and limitations of the rapidly advancing techniques available. Perhaps most importantly they must appreciate all aspects of patient care including preprocedural management, communication before and during the procedure and the management of endoscopic complications. This chapter aims to guide the reader through these areas in addition to providing an introduction to the breadth of procedures that are currently performed.

HISTORY OF ENDOSCOPY

Over the last 50 years, endoscopy has become a powerful diagnostic and therapeutic tool. However, its development required two obvious but formidable barriers to be overcome. First, the gastrointestinal tract is rather long and tortuous and, second, no natural light shines through the available orifices! Therefore, successful visualisation of anything beyond the distal extremities requires a flexible instrument with an intrinsic light source that can transmit images to the operator. The illumination issue was solved in 1879 by

Thomas Edison, but 25 years elapsed before a light source was incorporated into the primitive rigid endoscopes available at that time. The first approach to gastrointestinal tortuosity was an instrument with articulated lenses and prisms, proposed by Hoffmann in 1911. Again, approximately two decades elapsed before this concept was incorporated into a semiflexible gastroscope by Wolf, a fabricator of medical instruments, and Schindler, a physician.

The real breakthrough was the discovery that images could be transmitted using flexible quartz fibres. Although this was first described in the late 1920s, it was not until 1954 that Hopkins built a model of a flexible fibre imaging device. The availability of highly transparent optical quality glass led to the development in 1958 of the first flexible fibreoptic gastroscope by Larry Curtiss, a graduate student in physics, and Basil Hirschowitz, a trainee in gastroenterology. Over the next 30 years, the fibrescope evolved to allow examination of the upper gastrointestinal tract, the biliary system and the colon. In parallel with advances in diagnostic ability, a range of therapeutic procedures was developed (*Table 15.1*). Although the fibreoptic endoscope has been the workhorse of many endoscopy units over the last three decades, its obsolescence was guaranteed by the invention of the charge coupled device (CCD) in the 1960s, which allowed the creation of a digital electronic image, permitting endoscopic images to be processed by a computer and transmitted to television screens. Thus, the modern endoscope was born (**Figure 15.1**).

History does not sit still, and endoscopic evolution will continue with the replacement of much diagnostic endoscopy with capsule endoscopy and virtual imaging. Enhanced resolution using chromoendoscopy and even histological grade images have increased the diagnostic yield of surveillance procedures. Endoscopic ultrasound allows diagnosis and therapy to extend beyond the mucosal surface of the intestine.

Traditional endoscopy will therefore become increasingly therapeutic and historical divisions between medicine, radiology and surgery will become progressively blurred. As the complexity of the procedures increase, the distinction between specialist and general endoscopists will become more definite. This reinforces the need for all endoscopic practitioners to have a detailed understanding of the units in which they work and the instruments that they use.

THE MODERN ENDOSCOPY UNIT

Organisation

A well-designed endoscopy unit staffed by trained endoscopy nurses and dedicated administrative staff is essential to support good endoscopic practice and training. Clinical governance with regular appraisal and assessment of performance should be a routine process embedded within the unit philosophy. Endoscopist training demands particular attention, with a transparent process of skills- and theory-based education centred on practical experience and dedicated training courses. Experienced supervision of all trainee endoscopists is essential until competency has been obtained and assessed by an appropriately validated technique, such as direct observation of practical skills (DOPS) and review of procedure logbooks. However, all endoscopists should keep an on-going log to record diagnostic and therapeutic procedure numbers and markers of competency such as colonoscopy completion rates, polyp detection rates, mean sedation use and complication rates. Central to this is an efficient data management system that provides outcome analysis for all aspects of endoscopy including adherence to guidelines, near misses, patient satisfaction, decontamination processes and scope tracking, as well as the more obvious completion and complication rates.

In the UK the Joint Advisory Group (JAG) provide guidance for endoscopist competence assessment and operate a

Thomas Alva Edison, 1847–1931, American physicist and inventor of Menlo Park, New Jersey, NJ, USA, produced the first carbon filament electric light bulb in 1879.

Basil I. Hirschowitz, Professor of Medicine, Birmingham, AL, USA.

certification system of individual endoscopic competencies, based on procedure numbers, key performance indicators (e.g. caecal intubation rate, adenoma detection, sedation levels, complications), course attendance and peer assessment.

Equipment

A full description of all available endoscopic equipment is beyond the scope of this chapter. However, each unit should have a sufficient range of endoscopes, processors and accessories as dictated by the local case mix and sufficient endoscope numbers to ensure smooth service provision. These should include both forward- and lateral-viewing gastroscopes, an enteroscope for proximal small bowel visualisation and a range of adult and paediatric colonoscopes to aid examination of both redundant and fixed colons. Dedicated small bowel centres require capsule endoscopy and a single/double-balloon enteroscope for ileojejunal visualisation and therapeutics. Larger centres will require linear and radial endoscopic ultrasound, particularly if they specialise in gastrointestinal and hepatobiliary malignancy. An electrosurgical unit is the cornerstone of many therapeutic procedures and this may be supplemented by an argon plasma coagulation (APC) unit and laser units for advanced therapeutics in specialised centres.

Instrument decontamination

Endoscopes will not withstand steam-based autoclaving and therefore require high-level disinfection between cases to prevent transmission of infection. Although accessories may be autoclaved, best practice requires the use of disposable single-use items whenever possible. All equipment should be decontaminated to an identical standard whether for use on immunocompromised/infected patients or not. This process involves two equally important stages: first, removal of physical debris from the internal and external surfaces of the instrument and, second, chemical neutralisation of all microbiological agents. A variety of agents are available and endoscopists should familiarise themselves with the agent in use in their department. In 2014 the British Society of Gastroenterology has updated guidelines for decontamination of endoscopes (http://www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/decontamination_2014_v2.pdf). Particular care should be applied to the decontamination of duodenoscopes due to reports of transmission of multiresistant bacteria.

Key points in endoscope decontamination are shown in *Summary box 15.1*.

There are currently no reliable means of decontaminating scopes from contact with prion-associated conditions such as variant Creutzfeldt–Jakob disease (vCJD), although risk of transmission of this is considered very low. If an 'invasive' procedure (where gut mucosa is breached and an unsheathed accessory withdrawn through the endoscope working channel) is conducted in a patient with known or possible vCJD, the endoscope needs to be quarantined after use. The performance of an invasive procedure in a patient at risk of vCJD due to receipt of pooled plasma concentrates is no longer deemed to confer a high risk of endoscope contamination. A single quality assured decontamination cycle is considered sufficient, but the endoscope should be decontaminated separately from others with a single-use disinfectant. There is no longer a requirement to quarantine the endoscope provided that routine traceability data can be demonstrated.

Summary box 15.1

Disinfection of endoscopes

- All channels must be brushed and irrigated throughout the disinfection process
- All instruments and accessories should be traceable to each use, patient and cleaning cycle
- All staff should be trained and protected (particularly if glutaraldehyde is used in view of its immune-sensitising properties)
- Regular monitoring of disinfectant power and microbiological contamination should be performed

CONSENT IN ENDOSCOPY

Approximately 1% of medical negligence claims in the USA relate to the practice of endoscopy. Many of these could have been avoided by a careful explanation of the procedure, including an honest discussion of the risks and benefits. Therefore, obtaining informed consent is a cornerstone of good endoscopic practice. It preserves a patient's autonomy, facilitates communication and acts as a shield against future complaints and claims of malpractice.

The most important aspect of the consent procedure is that a patient understands the nature, purpose and risk of a particular procedure. Current guidelines would suggest that a patient should be informed of minor adverse events with a risk of more than 10% and serious events with an incidence of more than 0.5%. The key risks of endoscopy are summarised in *Summary box 15.2*. The 2008 British Society of Gastroenterology Guidelines for consent can be found using the link http://www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/consent08.pdf.

Summary box 15.2

The risks of endoscopy

- Sedation-related cardiorespiratory complications
- Damage to dentition
- Aspiration
- Perforation or haemorrhage after endoscopic dilatation/therapeutic endoscopic ultrasound
- Perforation, infection and aspiration after percutaneous endoscopic gastrostomy insertion
- Perforation or haemorrhage after flexible sigmoidoscopy/colonoscopy with polypectomy
- Pancreatitis, cholangitis, perforation or bleeding after endoscopic retrograde cholangiopancreatography

Hans Gerhard Creutzfeldt, 1885–1964, neurologist, Kiel, Germany.
Alfons Marie Jakob, 1884–1931, neurologist, Hamburg, Germany.

SAFE SEDATION

If performed competently the majority of diagnostic endoscopy and colonoscopy can be performed without sedation or with pharyngeal anaesthesia alone. However, therapeutic procedures may cause pain and patients are often anxious; thus, in most countries sedation and analgesia are offered to achieve a state of conscious sedation (not anaesthesia). Medication-induced respiratory depression in elderly patients or those with comorbidities is the greatest cause of endoscopy-related mortality and, therefore, safe sedation practices are essential. The involvement of anaesthetists to advise on appropriate protocols is recommended. Endoscopy in certain situations (particularly paediatric endoscopy) requires a general anaesthetic – this should only be undertaken by appropriately trained staff with adequate equipment available.

Summary box 15.3

Sedation in endoscopy

- Pharyngeal anaesthesia may increase the risk of aspiration in more heavily sedated patients
- Comorbidities must be identified so that sedation can be individualised
- All sedated patients require secure intravenous access
- Benzodiazepines reach their maximum effect 15–20 min after administration – doses should be titrated carefully, particularly in the elderly or those with comorbidities
- Coadministration of opiates and benzodiazepines has a synergistic effect – opiates should be given first and doses need to be reduced
- The use of supplementary oxygen is essential in all sedated patients
- Sedated patients require pulse oximetry to monitor oxygen saturation; high-risk patients or those undergoing high-risk procedures also require blood pressure and electrocardiogram monitoring
- A trained assistant should be responsible for patient monitoring throughout the procedure
- Resuscitation equipment and sedation reversal agents must be readily available
- The use of anaesthetic agents such as propofol for complex procedures requires specialist training
- The halflife of benzodiazepines is 4–24 hours – appropriate recovery and monitoring is essential. Postprocedural consultations may not be remembered, and patients must be advised not to drink alcohol or drive for 24 hours

ENDOSCOPY IN DIABETIC PATIENTS

As approximately 2% of the population is diabetic, managing glycaemic control before and after endoscopy is an essential aspect of endoscopic practice. Each unit should develop a policy for managing diabetic control during endoscopy. Factors influencing management include the type of diabetes, the procedure that is planned, the preparation/recovery time, and the history of diabetic control in the individual patient. Thus, a poorly controlled insulin-dependent diabetic undergoing colonoscopy will require more input than a type 2 diabetic on oral hypoglycaemic medication undergoing upper gastrointestinal endoscopy. All patients should bring their own medication to the unit and should be advised not to drive in case there is an alteration in their glycaemic control. The majority of patients can be managed using clear protocols on an outpatient basis; however, elderly patients and those with brittle control should be admitted. In general, diabetic patients should be endoscoped first on the morning list. In complex cases the diabetic team should be involved.

ANTIBIOTIC PROPHYLAXIS

The majority of endoscopy can be performed safely without the need for routine antibiotic prophylaxis. However, given that certain endoscopic procedures are associated with a significant bacteraemia (*Table 15.2*), there are several specific situations where antibiotic cover is required to prevent either bacterial endocarditis, infection of surgical prostheses or systemic sepsis. In general, the risk of infection relates to the level of bacteraemia and the risk of the underlying medical condition. Traditionally, patients with a previous history of endocarditis or a metallic heart valve received antibiotic prophylaxis for all endoscopic procedures, and some national guidelines still reflect this. However, in 2009 UK guidelines changed in response to the low reported incidence of infective endocaritis in this patient group undergoing endoscopy (http://www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/prophylaxis_09.pdf). Patients with severe neutropenia may also require antibiotic prophylaxis for

TABLE 15.2 Approximate incidence of bacteraemia in immunocompetent individuals following various procedures involving the gastrointestinal tract.

Procedure	Incidence of bacteraemia (%)[a]
Rectal digital examination	4
Proctoscopy	5
Barium enema	11
Tooth brushing	25
Dental extraction	30–60
Colonoscopy	2–4
Diagnostic upper gastrointestinal endoscopy	4
Sigmoidoscopy	6–9
ERCP (no duct occlusion)	6
ERCP (duct occluded)	11
Oesophageal varices band ligation	6
Oesophageal varices sclerotherapy	10–50[b]
Oesophageal dilatation/prosthesis	34–54
Oesophageal laser therapy	35
EUS +/– fine needle aspirate	0–6

[a] Summary of published data.
[b] Higher after emergency than after elective management. ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound.

endoscopy. The antibiotic regime used will depend on local guidelines. Procedures such as endoscopic percutaneous gastrostomy are associated with a significant incidence of wound or stoma infection, particularly if inserted for malignancy. There is excellent evidence that antibiotic prophylaxis reduces this complication and a single intravenous injection of coamoxiclav should be administered before the procedure. Ciprofloxacin is routinely used during endoscopic manipulation of an obstructed biliary tree in which it is unlikely that complete drainage will be achieved or there is significant comorbidity. When cystic cavities are aspirated at endoscopic ultrasound, a one-off dose of broad spectrum antibiotic (e.g. co-amoxiclav) is recommended to prevent cyst infection. Patients with chronic liver disease and ascites undergoing variceal sclerotherapy should receive antibiotic prophylaxis to prevent bacterial peritonitis.

ANTICOAGULATION IN PATIENTS UNDERGOING ENDOSCOPY

Many patients undergoing endoscopy may be taking medication that interferes with normal haemostasis, such as warfarin, heparin, direct oral anticoagulants, clopidogrel or aspirin. The key points to remember when managing anticoagulants in patients undergoing endoscopy are given in *Summary box 15.4*.

Summary box 15.4

Managing anticoagulants in patients undergoing endoscopy

It is important to recognise and understand:

- The risk of complications related to the underlying gastrointestinal disease from anticoagulant therapy
- The risk of haemorrhage related to an endoscopic procedure in the setting of anticoagulant therapy
- The risk of a thromboembolic/ischaemic event related to interruptions of anticoagulant therapy

Urgent endoscopy for gastrointestinal bleeding in the anticoagulated patient

The risk of clinically significant gastrointestinal bleeding in patients on warfarin is increased, particularly in patients with a past history of similar events, if the international normalised ratio (INR) is above the therapeutic range or if they are taking concomitant aspirin/non-steroidal anti-inflammatory drugs (NSAIDs). In these situations the risk of reversing the anticoagulation must be weighed against the risk of on-going haemorrhage. If complete reversal is not appropriate, correction of the INR to approximately 1.5 is usually sufficient to allow endoscopic diagnosis and therapy. Anticoagulation can often be resumed 24 hours after successful endoscopic therapy. If rapid resumption of anticoagulation is required, intravenous heparin should be used.

Elective endoscopy in patients on anticoagulants and antiplatelet agents

Endoscopic procedures vary in their potential to produce significant or uncontrolled bleeding. Diagnostic oesophagogastroduodenoscopy (OGD), colonoscopy, enteroscopy, diagnostic endoscopic ultrasound and endoscopic retrograde cholangiopancreatography (ERCP) without sphincterotomy are considered low risk, as is mucosal biopsy. High-risk procedures include colonoscopic polypectomy (1–2.5%), gastric polypectomy (4%), laser ablation of tumour (6%), endoscopic sphincterotomy (2.5–5%), EMR and ESD, stent placement and procedures with the potential to produce bleeding that is inaccessible or uncontrollable by endoscopic means, such as dilatation of benign or malignant strictures, percutaneous gastrostomy insertion and endoscopic ultrasound (EUS)-guided fine-needle aspiration. Likewise, the probability of a thromboembolic complication during temporary cessation of anticoagulant or antiplatelet therapy depends on the underlying medical condition (*Table 15.3*).

TABLE 15.3 The risk of a thromboembolic event varies according to the underlying medical condition.

Condition	Risk
Atrial fibrillation with valvular heart disease	High
Mechanical mitral valve	High
Mechanical valve and previous thromboembolic event	High
Deep vein thrombosis	Low
Uncomplicated atrial fibrillation	Low
Bioprosthetic valve	Low
Mechanical aortic valve	Low

Summary box 15.5

Recommendations concerning P2Y12 antiplatelet drugs (clopidogrel, prasugrel, ticagrelor)

Low-risk procedures

- Continue therapy

High-risk procedures, low-risk indication for antiplatelet therapy

- Stop 5 days before procedure (continue aspirin if taken)

High-risk procedures, high-risk indication for antiplatelet therapy (e.g. coronary artery stent)

- Liaise with cardiologist (consider stopping for 5 days if drug-eluting stent older than 12 months or bare metal stent older than 1 month)

Summary box 15.5 – *contd*

Recommendations concerning warfarin anticoagulant management

Low-risk procedures

- No adjustment to anticoagulation required
- Check INR within the week before procedure
- Avoid elective procedures when anticoagulation is above the therapeutic range

High-risk procedure in a patient with a low-risk condition

- Discontinue warfarin 5 days before the procedure
- Check INR on day of procedure to ensure <1.5
- Restart warfarin on evening after procedure if uncomplicated and recheck INR in 1 week

High-risk procedure in a patient with a high-risk condition

- Discontinue warfarin 5 days before the procedure
- Start low molecular weight heparin (LMWH) 2 days after stopping warfarin
- Check INR on day of procedure to ensure <1.5
- Omit LMWH on day of procedure
- Warfarin may be resumed the night of the procedure
- LMWH should be continued until INR adequate
- The decision to administer intravenous heparin should be individualised

Recommendations concerning direct oral anticoagulants (e.g. dabigatran, rivaroxaban, apixaban)

Low-risk procedures

- Omit on the morning of procedure

High-risk procedures

- Take last dose ≥48 h before procedure (for dabigatran ≥72 h before if estimated glomerular filtration rate (eGFR) 30–50 mL/min)

Aspirin

Aspirin and NSAIDs inhibit platelet cyclo-oxygenase resulting in suppression of thromboxane A_2-induced platelet aggregation. Limited published data do not suggest an increased bleeding risk in patients taking standard doses and, therefore, there is no need to discontinue therapy before endoscopic procedures.

UPPER GASTROINTESTINAL ENDOSCOPY

OGD is the most commonly performed endoscopic procedure. Excellent visualisation of the oesophagus, gastrooesophageal junction, stomach, duodenal bulb and second part of the duodenum can be obtained **(Figure 15.2)**. Retroversion of the gastroscope in the stomach is essential to obtain complete views of the gastric cardia and fundus **(Figure 15.2)**. Traditional forward-viewing endoscopes do not adequately visualise the ampulla, and a side-viewing scope should be used if this is essential. Likewise, although it is possible to reach the third part of the duodenum with a standard 120 cm instrument, a longer enteroscope is required if views beyond the ligament of Treitz are required. In addition to clear mucosal views, diagnostic endoscopy allows mucosal biopsies to be taken, which may either undergo processing for histological examination or be used for near-patient detection of *Helicobacter pylori* infection using a commercial urease-based kit. In addition, brushings may be taken for cytology and aspirates for microbiological culture.

Indications for oesophagogastroduodenoscopy

A full assessment of the role of OGD is outside the scope of this chapter. It will vary with local circumstances and the availability of alternative diagnostic techniques. OGD is usually appropriate when a patient's symptoms are persistent despite appropriate empirical therapy or are associated with warning signs such as intractable vomiting, anaemia, weight loss, dysphagia or bleeding. It is also part of the diagnostic work-up for patients with anaemia, symptoms of malabsorption and chronic diarrhoea. However, increasing ease of access to OGD with the availability of 'open access' endoscopy has resulted in a significant number of unnecessary procedures being performed in young patients with dyspepsia or gastro-oesophageal reflux disease (GORD). This has led to a number of international gastroenterology societies proposing guidelines for the management of dyspepsia and GORD, including the empirical use of acid suppression and non-invasive *H. pylori* tests, such as urease breath tests and stool antigen assay (e.g. the National Institute for Health and Care Excellence guidelines on dyspepsia: https://www.nice.org.uk/guidance/cg184/chapter/1-recommendations). In addition to the role of OGD in diagnosis, it is also commonly used in the surveillance of neoplasia development in high-risk patient groups. Whereas there is consensus about its role in genetic conditions such as familial adenomatous polyposis and Peutz–Jeghers syndrome, controversy remains about the role and frequency of endoscopic surveillance in premalignant conditions such as Barrett's oesophagus and gastric intestinal metaplasia (although ongoing studies will hopefully answer some of these uncertainties).

Therapeutic oesophagogastroduodenoscopy

Increasing technological advances have revolutionised the therapeutic applications of upper gastrointestinal endos-

Wenzel Treitz, 1819–1872, Professor of Pathology, Prague, The Czech Republic.
John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.
Norman Rupert Barrett, 1903–1979, surgeon, St. Thomas's Hospital, London, UK.

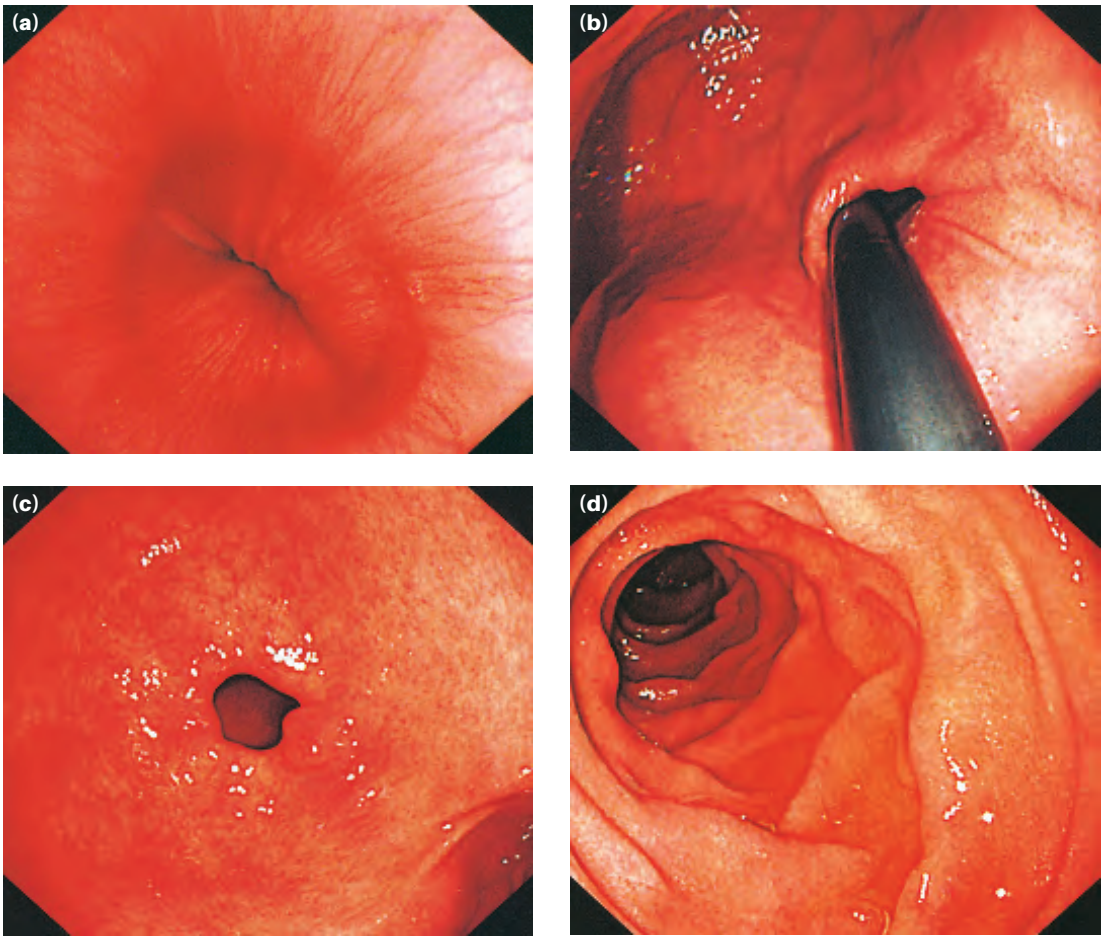

Figure 15.2 A normal upper gastrointestinal endoscopy showing the gastro-oesophageal junction **(a)**, the gastric fundus in the 'J' position **(b)**, the gastric antrum **(c)** and the second part of the duodenum **(d)**.

copy. However, appropriate patient selection and monitoring is essential to minimise complications. The most common therapeutic endoscopic procedure performed as an emergency is the control of upper gastrointestinal haemorrhage of any aetiology. Band ligation has replaced sclerotherapy in the management of oesophageal varices **(Figure 15.3)**, whereas sclerotherapy using thrombin-based glues can be used to control blood loss from gastric and duodenal varices. Injection sclerotherapy with adrenaline coupled with a second haemostatic technique such as heater probe vessel obliteration or haemoclip application, remains the technique of choice for a peptic ulcer with an active arterial spurt or high-risk stigmata

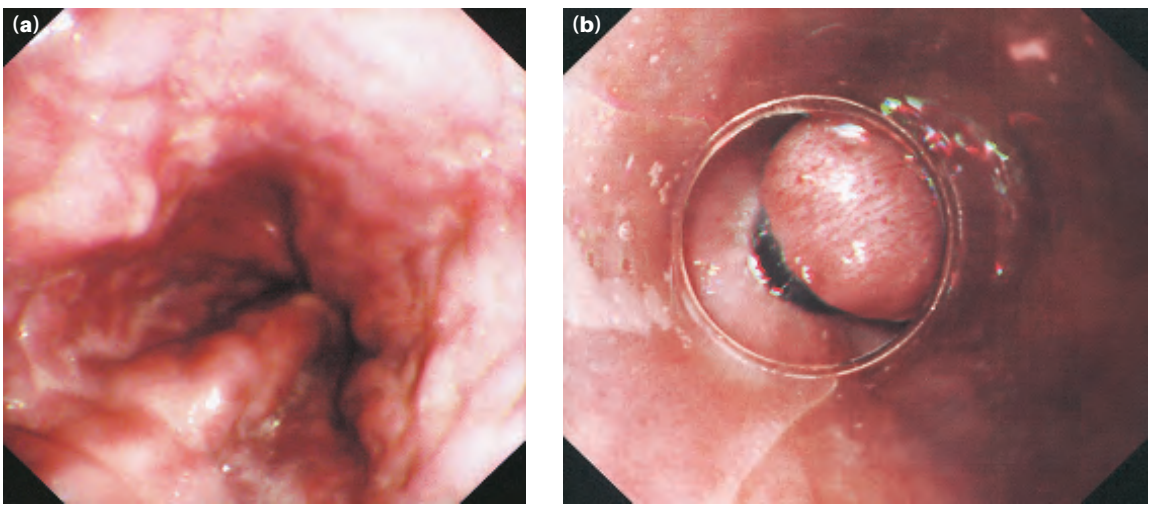

Figure 15.3 Grade 2 oesophageal varices **(a)**, which can be treated by the application of bands to ligate the vessel and reduce blood flow **(b)**.

of haemorrhage **(Figure 15.4)**. Such high-risk bleeds should be followed by 72 hours of intravenous proton pump inhibition in all cases. Chronic blood loss from angioectasia is most safely treated with APC because of the controlled depth of burn compared with alternative thermal techniques **(Figure 15.5)**.

Benign oesophageal and pyloric strictures may be dilated under direct vision with 'through-the-scope' (TTS) balloon dilators or the more traditional guidewire-based systems such as Savary–Guillard bougie dilators **(Figure 15.6)**. On occasion, more difficult benign strictures can be treated by the insertion of a fully-covered removable stent, or with a biodegradeable stent. Likewise, the non-relaxing lower oesophageal sphincter associated with achalasia can be treated by pneumatic balloon dilatation with a 30–40 mm balloon. Endoscopic dissection techniques (see below) are now being employed to treat achalasia by natural orifice myotomy (per-oral endoscopic myotomy, POEM) with good early follow-up results. An alternative in patients unfit to suffer endoscopic complication is the injection of botulinum toxin into the lower oesophageal sphincter, although this has a limited (3–6 month) duration of benefit.

There are a limited number of endoscopic techniques available to reduce gastro-oesophageal reflux, which rely on tightening the loose gastro-oesophageal junction by plication or by the application of radial thermal energy. These techniques may have a role in some patients, but are yet to demonstrate benefit over surgical fundoplication. Likewise, endoscopic techniques to tackle obesity, such as gastric balloon insertion, have not been associated with evidence of long-lasting benefit. In contrast, there is clear evidence that the insertion of a percutaneous endoscopic gastrostomy (PEG) tube enhances nutritional and functional outcome in patients unable to maintain oral nutritional intake **(Figure 15.7)**. PEG insertion is often a prelude to treatment of

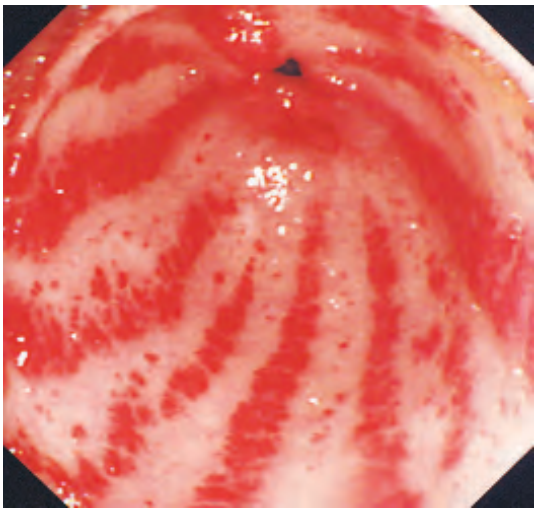

Figure 15.5 The classic appearance of gastric antral vascular ectasia (GAVE), which is often treated with argon plasma coagulation.

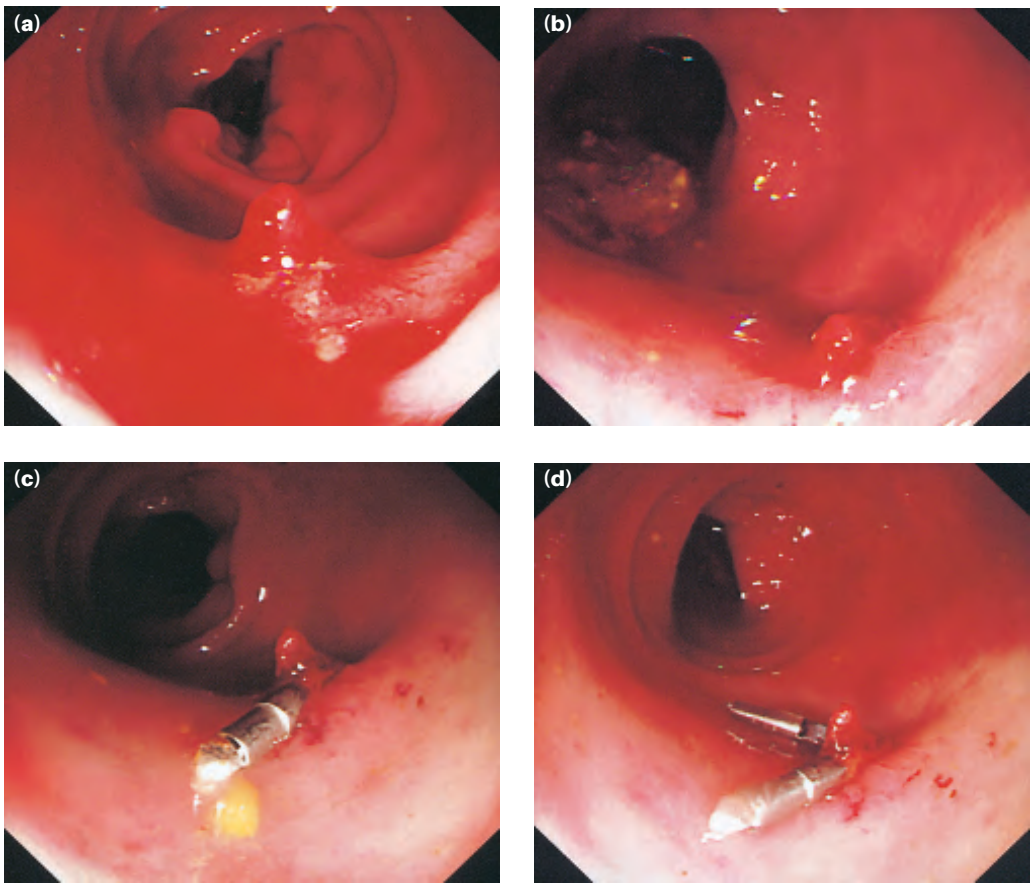

Figure 15.4 A gastric ulcer with active bleeding **(a)** is initially treated with adrenaline injection to achieve haemostasis **(b)**. Two haemoclips are then applied to prevent rebleeding **(c and d)**.

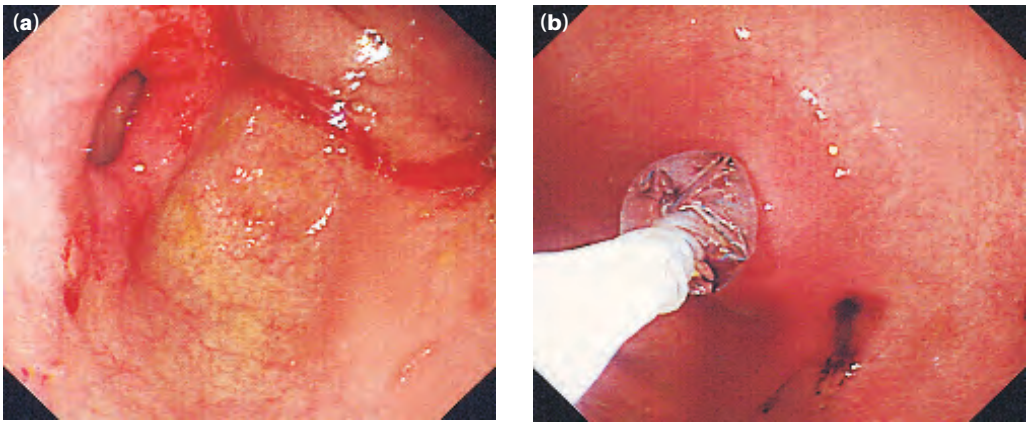

Figure 15.6 A pyloric stricture **(a)** can be dilated using a 'through-the-scope' balloon under direct vision to minimise complications **(b)**.

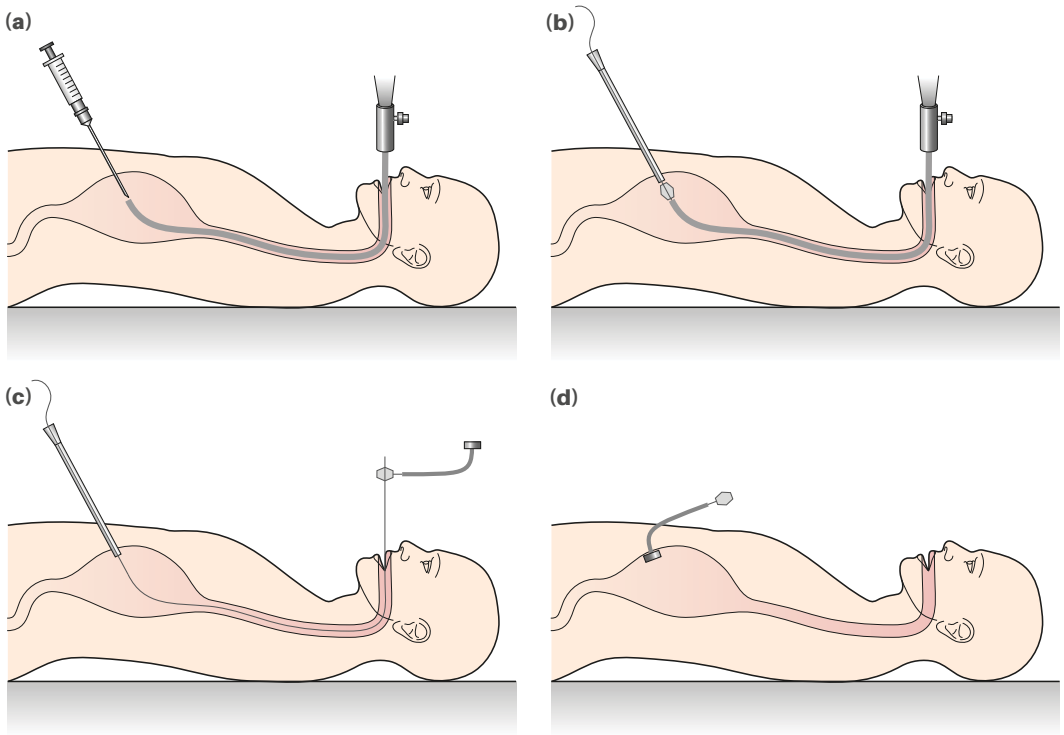

Figure 15.7 A schematic diagram of percutaneous endoscopic gastrostomy insertion. A standard endoscopy is performed to ensure that there are no contraindications to gastrostomy insertion. The stomach is insufflated with air and a direct percutaneous needle puncture made at a point where the stomach abuts the abdominal wall. Lignocaine is infused on withdrawal **(a)**. A trochar is inserted and a wire passed into the stomach, which can be caught with a snare **(b)**. The scope is withdrawn, pulling the wire out through the mouth, at which point it is attached to the gastrostomy tube **(c)**. The gastrostomy is pulled through into the stomach and out through the track created by the trochar insertion **(d)**.

complex orofacial malignancy, and may be used to support nutrition in patients with alternative malignant, degenerative or inflammatory diseases.

The deployment of self-expanding metal stents with or without a covering sheath inserted over a stiff guidewire leads to a significant improvement in symptomatic dysphagia and quality of life in patients with malignant oesophageal and gastric outlet obstruction **(Figure 15.8)**. Covered stents are the mainstay of treatment for benign or malignant tracheo-oesophageal fistulae.

Perhaps the area of greatest progress over recent years has been in the endoscopic management of early oesophageal and gastric neoplasia with endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). These techniques require specialist training, but have allowed endoscopic management of mucosal lesions that were previously subject to surgical intervention **(Figure 15.9)**. A prime example has been improved endoscopic treatment of Barrett's high-grade dysplasia and early oesophageal adenocarcinoma. Destruction of residual Barrett's epithelium in cases of low- or high-grade dysplasia is possible with endoscopic ablation, and has been shown to reduce risk of progression to cancer. The most commonly used technique for this purpose is radiofrequency ablation, where 360° ablation can be achieved with a balloon catheter, or more focused ablation with smaller probes. Cryotherapy and APC can also be used for ablation, but photodynamic therapy is now used much less often.

Complications of diagnostic and therapeutic oesophagogastroduodenoscopy

Diagnostic upper gastrointestinal endoscopy is a safe procedure with minimal morbidity as long as appropriate patient

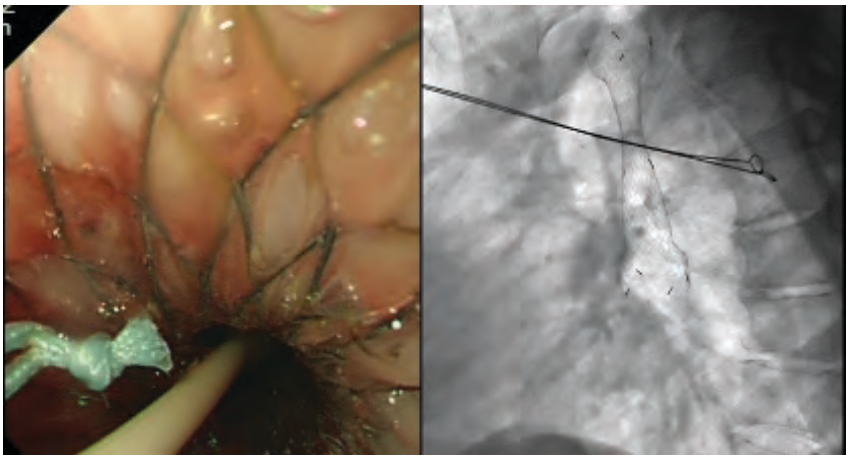

Figure 15.8 A self-expanding metal stent may alleviate symptoms relating to malignant oesophageal strictures. The left panel shows an endoscopic view of a deployed stent, and the right panel shows the radiographic image.

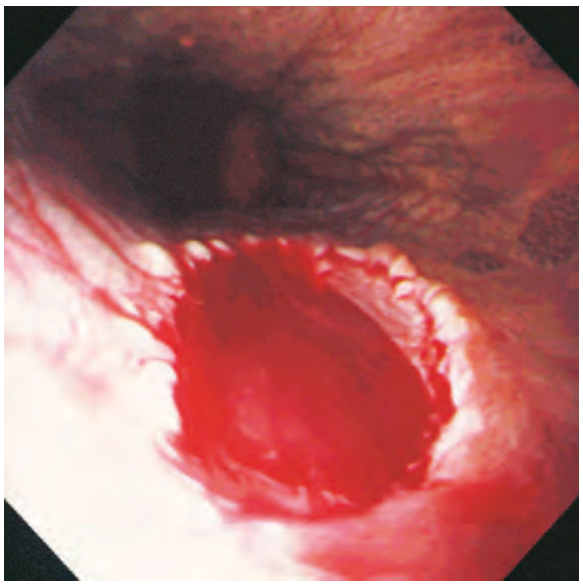

Figure 15.9 Novel upper gastrointestinal therapeutic uses of oesophagogastroduodenoscopy include the use of endoscopic mucosal resection to remove early gastric cancer leaving a clean base.

selection and safe sedation practices are embedded in the unit policy. The mortality rate is estimated to be less than 1:10 000, with a complication rate of approximately 1:1000. As mentioned above, the majority of adverse events relate to sedation and patient comorbidity. Particular caution should be exercised in patients with recent unstable cardiac ischaemia and respiratory compromise. Perforation can occur at any point in the upper gastrointestinal tract, including the oropharynx. It is rare during diagnostic procedures and is often associated with inexperience. Perforation is more common in therapeutic endoscopy, particularly oesophageal dilatation and EMR/ESD for early malignancy. Early diagnosis significantly improves outcome and thus all staff must be alert to the symptoms.

Prompt management includes radiological assessment using CT/water-soluble contrast studies, strict nil by mouth, intravenous fluids and antibiotics and early review by an experienced upper gastrointestinal surgeon.

Summary box 15.6

Symptoms of endoscopic oesophageal perforation

- Neck/chest pain
- Dysphagia/drooling saliva
- Abdominal pain
- Increasing tachycardia
- Hypotension
- Surgical emphysema

ENDOSCOPIC ASSESSMENT OF THE SMALL BOWEL

Introduction and indications

The requirement to visualise, biopsy and treat the small bowel is far less than in the stomach, biliary tree or colon, resulting in a time lag in technological advances. The most frequent indication is the investigation of gastrointestinal blood loss, which may present with either recurrent iron deficiency anaemia (occult haemorrhage) or recurrent overt blood loss per rectum (cryptic haemorrhage) in a patient with normal OGD (with duodenal biopsies) and colonoscopy. Other indications include the investigation of malabsorption; the exclusion of cryptic small bowel inflammation such as Crohn's disease in patients with diarrhoea/abdominal pain and evidence of an inflammatory response; targeting lesions seen on radiological investigations; and surveillance for neoplasia in patients with inherited polyposis syndromes.

A standard enteroscope is able to reach and biopsy lesions detected in the proximal small bowel; however, even in the most experienced hands this is limited to approximately 100 cm distal to the pylorus, although the use of a stiffening overtube may increase this somewhat. The procedure takes approximately 45 min and may be uncomfortable, requiring high doses of sedation with the attendant increased risk of perforation and sedation-related morbidity. Sonde endoscopy, in theory, has the potential to examine the entire small bowel. In this procedure a long thin endoscope is inserted transnasally into the stomach and pushed through the pylorus with a gastroscope passed through the mouth. It is carried distally by peristalsis, which propels a balloon inflated at the tip. The technique has several limitations including a long examination time (6–8 hours),

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

patient discomfort, the danger of perforation and the inability to perform therapeutic procedures. For these reasons it is not widely performed and will soon become obsolete.

Therefore, until recently, barium follow-through or enteroclysis were the most effective imaging modalities to visualise the distal duodenum, jejunum and ileum. Obviously these techniques do not give true mucosal views, and outside specialist centres their decreasing use has led to diminished expertise and a reduced diagnostic yield. There have been rapid advances in axial radiological techniques such as MRI and CT enteroclysis, which demonstrate excellent diagnostic accuracy in this area (see Chapter 14). However, although these techniques may yield information about vascularity and bowel wall thickening, they do not allow direct mucosal views, have no biopsy capability and have limited scope in terms of therapeutics. Historically, if an area of interest was outside the reach of a standard enteroscope, direct access via enterotomy under either laparoscopic or open surgery was required. Two major clinical advances over the last decade have revolutionised small bowel diagnosis and therapeutics. First, the development of the capsule endoscope allows diagnostic mucosal views of the entire small bowel to be obtained with minimal discomfort in unsedated patients. Second, the novel technique of single/double-balloon enteroscopy allows endoscopic access to the entire small bowel for biopsy and therapeutics (*Table 15.4*).

TABLE 15.4 Comparison of the advantages and disadvantages of the currently available modalities to endoscope the small intestine.

Technique	Advantages	Disadvantages
Traditional enteroscopy	Simple technique with wide availability Full range of therapeutics available Performed under sedation	Some discomfort Can only access proximal small bowel
Capsule endoscopy	Able to visualise the entire small bowel Preferable for patients No sedation Painless	No biopsies Not controllable and no accurate localisation Variable transit Incomplete studies due to battery life Not suitable for patients with strictures Large capsule to swallow
Double/single-balloon enteroscopy	Able to visualise the entire small bowel Full range of therapeutics	Requires sedation/general anaesthesia Patient discomfort May take 3–4 hours; may require admission Specialist centres only Complications include perforation

Capsule endoscopy

The prototype capsule endoscope was developed at the Royal London Hospital in the UK by Professor Paul Swain. Several companies have developed different systems for routine clinical use, but the basic principles remain identical. The technique requires three main components: an ingestible capsule, a portable data recorder and a workstation equipped with image-processing software. The capsule consists of an optical dome and lens, two light-emitting diodes, a processor, a battery, a transmitter and an antenna encased in a resistant coat the size of a large vitamin pill (**Figure 15.10**). It acquires

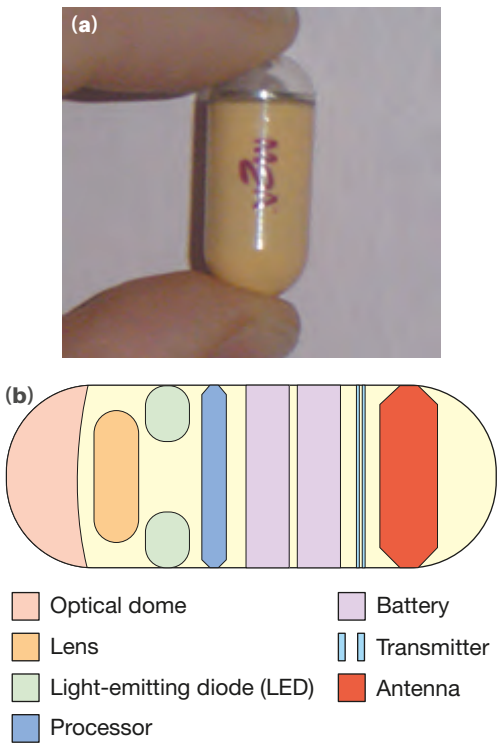

Figure 15.10 Complete diagnostic visualisation of the small bowel can be achieved with capsule endoscopy **(a)**. The structure of the capsule is shown in **(b)**. Clear mucosal pictures can be achieved here showing angioectasias (arrow) **(c)** and small bowel Crohn's disease **(d)**.

Christopher Paul Swain, Professor of Gastroenterology, The Royal London Hospital, London, UK.

video images during natural propulsion through the digestive system that it transmits via a digital radiofrequency communication channel to the recorder unit worn outside the body; this also contains sensors that allow basic localisation of the site of image capture within the abdomen. Upon completion of the examination, the physician transfers the accumulated data to the workstation for interpretation via a high-capacity digital link. The workstation is a modified personal computer required for off-line data storage, interpretation and analysis of the acquired images and report generation.

The small bowel capsule provides good visualisation from mouth to colon with a high diagnostic yield. It compares favourably with the 'gold standard' techniques for the localisation of cryptic and occult gastrointestinal bleeding and the diagnosis of small bowel Crohn's disease. Use of the capsule endoscope is contraindicated in patients with known small bowel strictures in which it may impact, resulting in acute obstruction requiring retrieval at laparotomy or via laparoscopy. Severe gastroparesis and pseudo-obstruction are also relative contraindications to its use. Some units advocate a barium follow-through or small bowel MRI to exclude stricturing disease in all patients before capsule endoscopy. However, there are well-reported episodes of capsule impaction in a stricture that was not visualised on prior imaging. Therefore, a 'dummy' patency capsule that can be tracked via a handheld device or conventional radiology as it passes through the intestine should be used in all patients where there is a possibility of stricturing disease. The patency capsule will dissolve after 40 hours if it becomes impacted. Technology in this field is rapidly advancing, with capsule systems designed to image the oesophagus and colon nearing the market. Prototype capsules that can be directed, take biopsies and deliver thermal therapy to angioectasia are in development.

Single/double-balloon enteroscopy

This technique allows the direct visualisation of and therapeutic intervention for the entire small bowel and may be attempted via either the oral or rectal route. Double-balloon enteroscopy was developed in 2001 in Japan; it involves the use of a thin enteroscope and an overtube, which are both fitted with a balloon. The procedure is usually carried out under general anaesthesia, but may be undertaken with the use of conscious sedation. The enteroscope and overtube are inserted through either the mouth or anus and steered to the proximal duodenum/terminal ileum in the conventional manner. Following this the endoscope is advanced a small distance in front of the overtube and the balloon at the end is inflated. Using the assistance of friction at the interface between the enteroscope and intestinal wall, the small bowel is accordioned back to the overtube. The overtube balloon is then deployed and the enteroscope balloon is deflated.

The process is then continued until the entire small bowel is visualised **(Figure 15.11)**. In single-balloon enteroscopy, developed more recently, an enteroscope and overtube are used, but only the overtube has a balloon attached. A full range of therapeutics including diagnostic biopsy, polypectomy, APC and stent insertion are available for balloon enteroscopy. Some experts advocate routine capsule endoscopy before balloon enteroscopy in an attempt to localise any lesions and plan whether oral or rectal access is more appropriate. The indications for single/double-balloon endoscopy are given in *Summary box 15.7*.

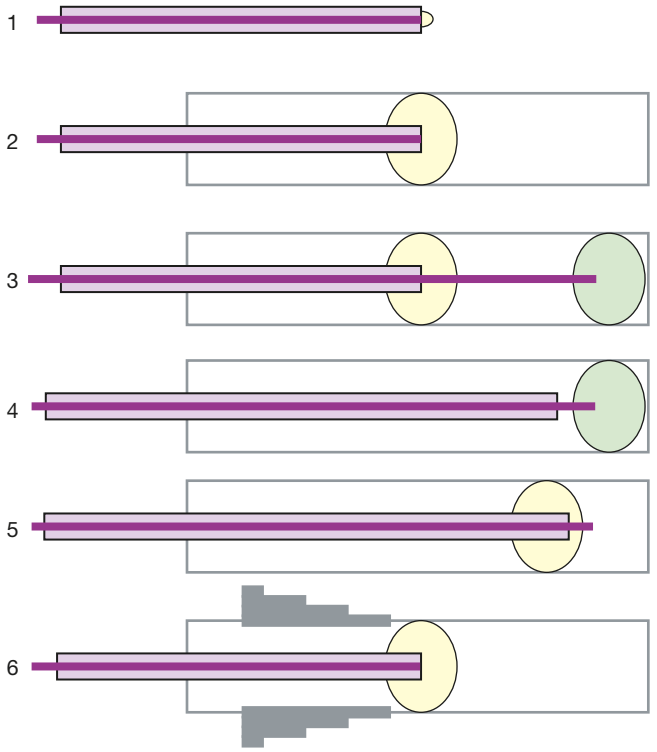

Figure 15.11 The technique of double-balloon enteroscopy is performed with an adapted enteroscope and overtube, both of which have inflatable balloons at their tip.

Summary box 15.7

Current established indications for single/double-balloon endoscopy

- Bleeding from the gastrointestinal tract of obscure cause
- Iron deficiency anaemia with normal colonoscopy and gastroscopy
- Visualisation of and therapeutic intervention for abnormalities seen on traditional small bowel imaging/capsule endoscopy

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

This procedure involves the use of a side-viewing duodenoscope, which is passed through the pylorus and into the second part of the duodenum to visualise the papilla. This is then cannulated, either directly with a catheter or with the help of a guidewire **(Figure 15.12)**. Occasionally a small precut is required to gain access. By altering the angle of approach one can selectively cannulate the pancreatic duct or biliary tree, which is then visualised under fluoroscopy after contrast injection. The significant range of complications associated with this procedure and improvements in radiological

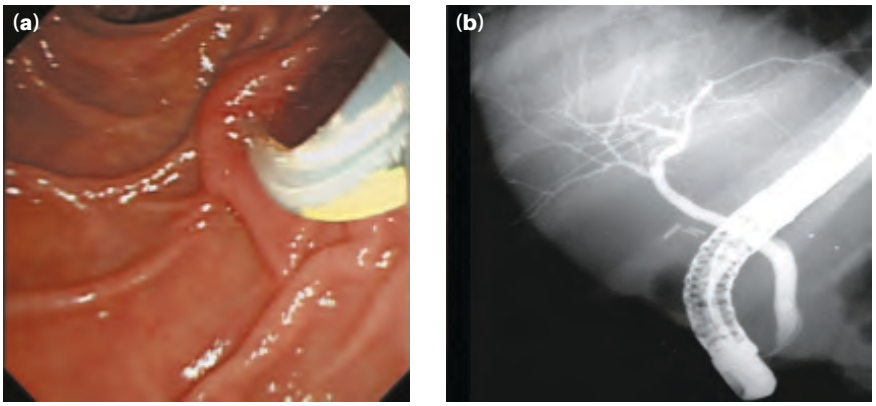

Figure 15.12 During endoscopic retrograde cholangiopancreatography a side-viewing duodenoscope is positioned opposite the papilla, which can then be cannulated using either a catheter or a guidewire **(a)**. Contrast is injected to achieve a cholangiogram **(b)**.

imaging using magnetic resonance cholangiopancreatography (MRCP) have rendered much diagnostic ERCP obsolete, and thus most procedures are currently performed for therapeutic purposes. There is still a role for accessing cytology/biopsy specimens.

Therapeutic endoscopic retrograde cholangiopancreatography

It is essential to ensure that patients have appropriate assessment prior to therapeutic ERCP, which is associated with a significant morbidity and occasional mortality. All patients require routine blood screening including a clotting screen. Assessment of respiratory and cardiovascular comorbidity is essential. The use of supplementary oxygen and both cardiac and oxygen saturation monitoring during the procedure are essential because of the high level of sedation that is often required.

The most common indication for therapeutic ERCP is the relief of biliary obstruction due to gallstone disease and benign or malignant biliary strictures. The preprocedural diagnosis can be confirmed by contrast injection, which will clearly differentiate the filling defects associated with gallstones and the luminal narrowing of a stricture. If there is likely to be a delay in relieving an obstructed system, percutaneous drainage may be required.

The cornerstone of gallstone retrieval is an adequate biliary sphincterotomy, which is normally performed over a well-positioned guidewire using a sphincterotome connected to an electrosurgical unit. Most gallstones less than 1 cm in diameter will pass spontaneously in the days and weeks following a sphincterotomy, but most endoscopists prefer to ensure duct clearance at the initial procedure to reduce the risk of impaction, cholangitis or pancreatitis. This can be achieved by trawling the duct using a balloon catheter or by extraction using a wire basket. If standard techniques fail, large or awkwardly placed stones can be crushed using mechanical lithotripsy. If adequate stone extraction cannot be achieved at the initial ERCP it is imperative to ensure biliary drainage with the placement of a removable plastic stent while alternative options are considered. These include surgery, endoscopically directed shockwaves under direct choledochoscopic vision (see below) and extracorporeal shockwave lithotripsy with subsequent ERCP to remove stone fragments.

Dilation of benign biliary strictures uses balloon catheters similar to those used in angioplasty inserted over a guidewire under fluoroscopic control. It is traditional to insert a temporary plastic stent to maintain drainage as several attempts at dilatation may be required. Self-expanding metal stents are most commonly used for the palliation of malignant biliary obstruction and are also normally inserted after a modest sphincterotomy. Correct stent placement can normally be confirmed by a flow of bile after release and by the presence of air in the biliary tree on follow-up plain abdominal radiographs. Stent malfunction, associated with recurrent or persistent biochemical cholestasis, may be due to poor initial stent position, stent migration, blockage with blood clot or debris or tumour ingrowth. A repeat procedure is required to assess the cause, which can usually be remedied by the insertion of a second stent through the original one.

In addition to the standard techniques discussed above, ERCP is also used for pancreatic disease and the assessment of biliary dysmotility (sphincter of Oddi dysfunction) using manometry in specialist centres. Indications include pancreatic stone extraction, the dilatation of pancreatic duct strictures and the transgastric drainage of pancreatic pseudocysts. To minimise the risks of subsequent pancreatitis, pancreatic sphincterotomy is most safely performed after the placement of a temporary pancreatic stent to prevent stasis within the pancreatic duct.

Visualisation and sampling of biliary lesions is becoming easier and more effective with the development of newer through-the-duodenoscope cholangioscopes that allow direct visualisation and instrumentation of the biliary and pancreatic ducts.

Complications associated with endoscopic retrograde cholangiopancreatography

The same risks associated with other endoscopic procedures also apply to patients undergoing ERCP, but risks may be increased because of the increased patient frailty and high sedation levels required. Complications specific to ERCP

Ruggero Oddi, 1845–1906, physiologist, Perugia, who later worked in Rome, Italy.

include duodenal perforation (1.3%)/haemorrhage (1.4%) after scope insertion or sphincterotomy, pancreatitis (4.3%) and sepsis (3–30%); the mortality rate approaches 1%. It is important to remember that postsphincterotomy complications may be retroperitoneal and, therefore, CT scanning is essential in patients with pain, tachycardia or hypotension postprocedure. Although normally mild, post-ERCP pancreatitis can be severe with extensive pancreatic necrosis and a significant mortality rate (*Table 15.5*). Many trials have assessed pharmacological strategies to reduce the incidence of pancreatitis. It is now recommended that, where there is no contraindication, all patients undergoing ERCP should be administered per-rectal indomethacin or diclofenac immediately before or after the procedure to reduce the risk of post-ERCP pancreatitis.

TABLE 15.5 Risk factors for post-ERCP pancreatitis.

Definite	Suspected SOD
	Young age
	Normal bilirubin
	Prior ERCP-related pancreatitis
	Difficult cannulation
	Pancreatic duct contrast injection
	Pancreatic sphincterotomy
	Balloon dilatation of biliary sphincter
Possible	Female sex
	Low volume of ERCPs performed
	Absent CBD stone

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; SOD, sphincter of Oddi dysfunction.

COLONOSCOPY

Early attempts at colonoscopy were hindered by poor technique and the limitations of the available instruments. The ability to steer an endoscope around the entire colon and into the terminal ileum was made possible by the development of fully flexible colonoscopes with greater than 90° angulation of the tip. Advances in bowel preparation have enhanced mucosal visualisation during the examination. Two key revelations about the practical performance of colonoscopy have allowed skilled operatives to achieve a greater than 95% caecal intubation rate and frequent ileal intubation with minimal discomfort using light sedation. The first is that continued inward pressure of the endoscope results in the formation of loops within the mobile sigmoid and transverse colon, decreasing angulation control at the tip and removing the beneficial effect of shaft torque to aid steering around acute bends. The second is that pulling back the scope regularly with appropriate torque to ensure a straight passage through the sigmoid colon and around the splenic flexure greatly aids the completion of right-sided examination. Targeted abdominal hand pressure to prevent loops in a mobile colon and regular patient position change to enhance mucosal views and remove residual bowel content are also important aids to successful colonoscopy. It is essential that caecal intubation is confirmed to avoid missing pathology by incorrectly assuming that the caecal pole has been reached. The landmarks may not be clear and, therefore, visualisation of the appendix orifice or preferably terminal ileal intubation is necessary to confirm a complete colonoscopy (**Figure 15.13**).

Mucosal biopsies may either be targeted to areas of abnormality or random to exclude microscopic colitis in a patient

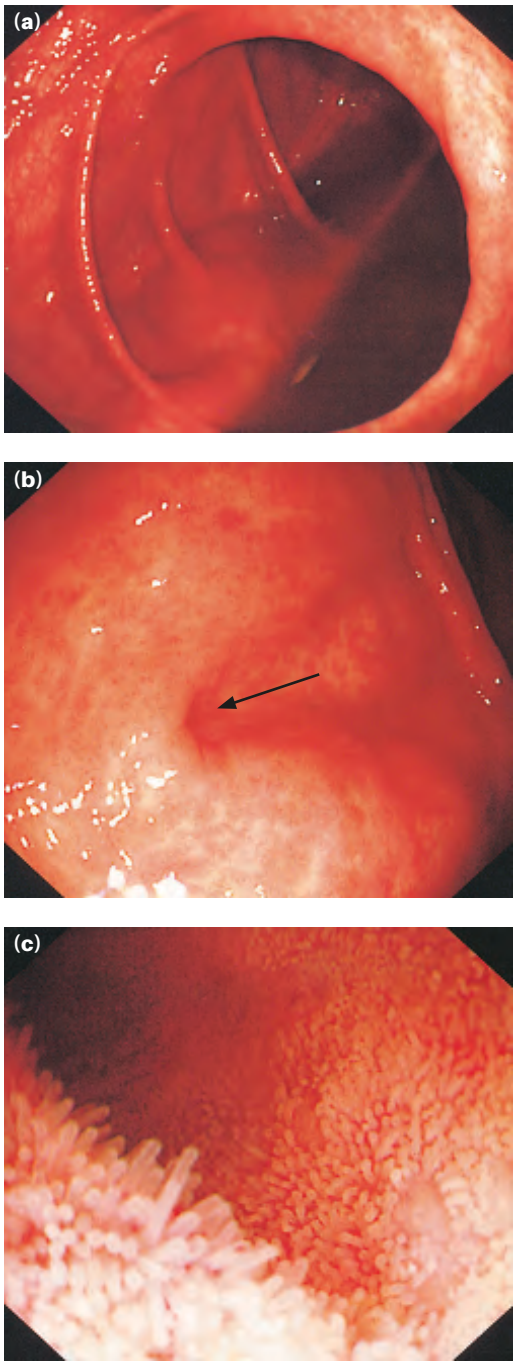

Figure 15.13 The caecal pole may not be easy to identify **(a)** and, therefore, the endoscopist should confirm complete colonoscopy by visualising the appendix orifice **(b)** (arrow) or preferably intubating the terminal ileum **(c)**, which demonstrates villi and Peyer's patches.

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

with chronic watery diarrhoea but a macroscopically normal mucosa. Despite the increasing sophistication of radiological techniques to assess the colon, such as CT colonography, the ability to biopsy areas of abnormality and resect polyps will ensure that colonoscopy remains the most appropriate investigation for the majority of patients. Several countries including the USA and the UK have recently introduced colorectal cancer (CRC) screening programmes in the asymptomatic population once they reach a predetermined age. The goal is to increase the number of early-stage CRCs detected and hence decrease mortality, as well as to identify and remove adenomatous polyps and prevent the onset of disease. Increased polyp detection rates are associated with a longer period of colonoscope withdrawal, optimal bowel preparation and retroversion of the colonoscope in the right colon to visualise both sides of colonic folds. Current research is assessing whether polyp detection rates are also increased by the use of devices such as a 'third eye' and an endocuff. There is ongoing debate about the relevant benefits of different screening modalities including colonoscopy, CT colonography, flexible sigmoidoscopy and biannual/one-off faecal occult blood testing with colonoscopy only in positive patients. Whichever modality is used, colonoscopy is essential to resect any polyps identified and biopsy unresectable lesions.

Summary box 15.8

Indications for colonoscopy

- Rectal bleeding with looser or more frequent stools +/– abdominal pain related to bowel actions
- Iron deficiency anaemia (after biochemical confirmation +/– negative coeliac serology): oesophagogastroduodenoscopy and colonoscopy together
- Right iliac fossa mass if ultrasound is suggestive of colonic origin
- Change in bowel habit associated with fever/elevated inflammatory response
- Chronic diarrhoea (>6 weeks) after sigmoidoscopy/rectal biopsy and negative coeliac serology
- Follow-up of colorectal cancer and polyps
- Screening of patients with a family history of colorectal cancer
- Assessment/removal of a lesion seen on radiological examination
- Assessment of ulcerative colitis/Crohn's extent and activity
- Surveillance of inflammatory bowel disease
- Surveillance of acromegaly/ureterosigmoidostomy

Therapeutic colonoscopy

The most common therapeutic procedure performed at colonoscopy is the resection of colonic polyps (**Figure 15.14**). Retrieved specimens can be assessed for risk factors for neoplastic progression and an appropriate surveillance strategy determined (http://www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/ccs_10.pdf). Small polyps up to 5 mm should be removed by cheese-wiring with a 'cold' snare. Hot biopsy is a technique in which the tip of a small pedunculated polyp is grasped between diathermy biopsy forceps and

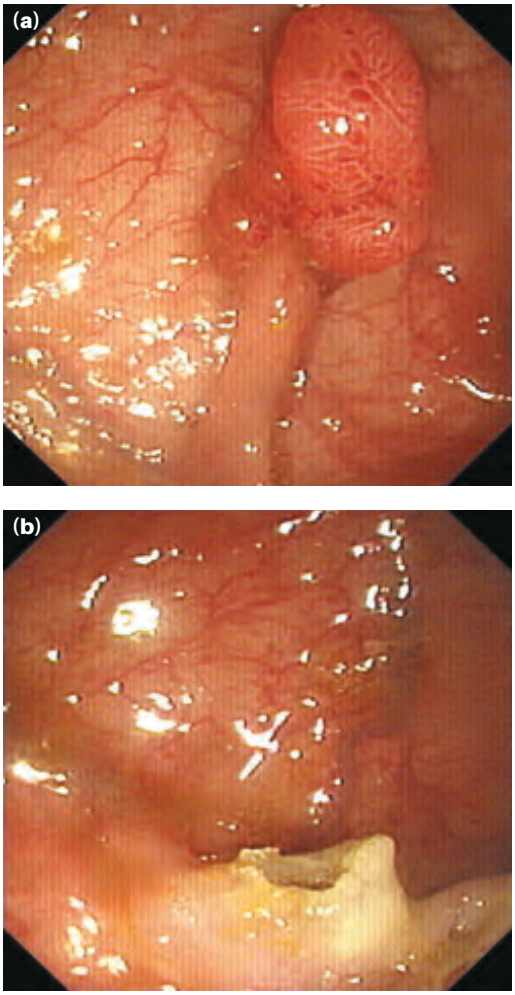

Figure 15.14 Colonoscopy is the most appropriate investigation to detect colonic polyps **(a)**, which can be removed by snare polypectomy during the same procedure leaving a clean polyp base **(b)**.

tented away from the bowel wall. A brief burst of monopolar current is used to coagulate the stalk, allowing the polyp to be removed. This is rarely performed in current practice due to an increased risk of immediate and delayed thermal damage to the bowel wall, particularly in the right colon. Larger polyps with a defined stalk can be resected using snare polypectomy with coagulating current either *en bloc* (French for 'in a block') or piecemeal depending on their size (**Figure 15.14**). Postpolypectomy bleeding can be prevented by the application of haemoclips or an endoloop to the polyp stalk. Sessile polyps extending over several centimetres can be removed by endoscopic mucosal resection, which involves lifting the polyp away from the muscularis propria with a submucosal injection of saline to prevent iatrogenic perforation (**Figure 15.15**). Any residual polyp is obliterated with APC. Care should be taken with all polypectomies in the right colon where the wall may only be 2–3 mm thick. Removal of large or extensive flat polyps should only be attempted by appropriately trained endoscopists. Endoscopic submucosal dissection (ESD) can be used to remove large flat lesions which are not amenable to EMR.

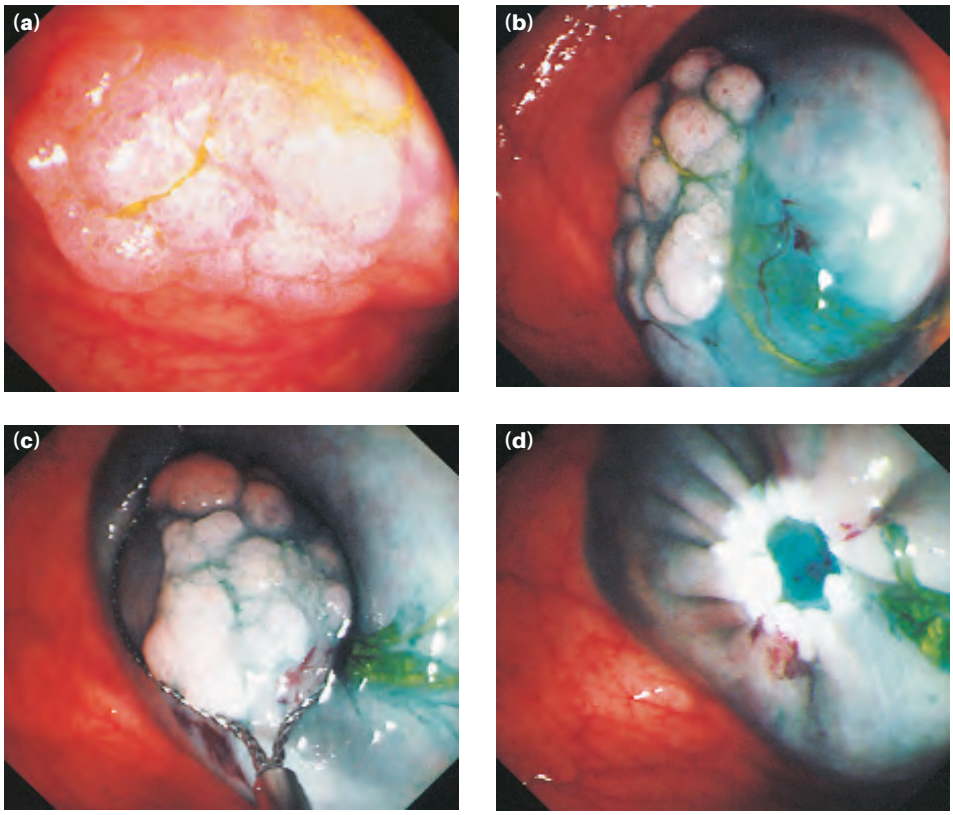

Figure 15.15 Large sessile polyps **(a)** can be removed by endoscopic mucosal resection. First the polyp is raised on a bed of injected saline containing dye **(b)**. This ensures that there is no submucosal invasion and protects from transmural perforation. A snare is closed around the polyp **(c)**, which is then resected leaving a clean excision base **(d)**.

APC and alternative thermal therapies such as heater probes are also used in the treatment of symptomatic angioectasias of the colon (**Figure 15.16**). Laser photocoagulation may be used to debulk colonic tumours not suitable for resection. As with benign oesophageal strictures, through-the-scope (TTS) balloons can be used to dilate short (less than 5 cm) colonic strictures. The dilatation of surgical anastomoses gives the most durable benefit as inflammatory strictures tend to recur even if intramucosal steroids are injected at the time of the dilatation. Finally, the colonoscopic placement of self-expanding metal stents may provide excellent palliation of inoperable malignant strictures (**Figure 15.17**) and may also play an invaluable role in decompressing an obstructed colon to allow planned as opposed to emergency surgery.

Figure 15.16 A large angioectasia of the colon. If this results in symptomatic anaemia, it should be obliterated with argon plasma coagulation.

Complications of colonoscopy

Complications during routine diagnostic colonoscopy by an experienced colonocopist are rare, although perforations have been reported as a result of excessive shaft tip pressure and with excessive air insufflation in severe diverticular disease.

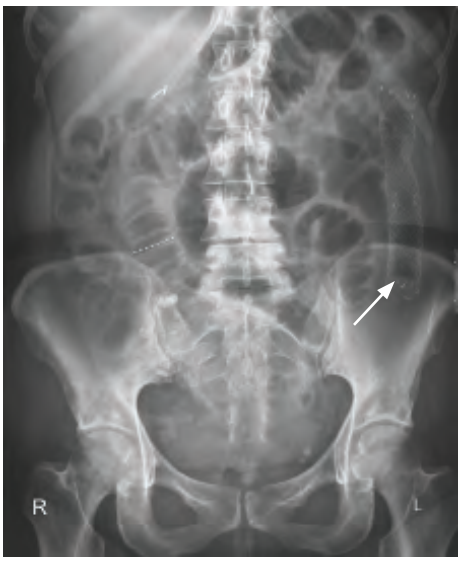

Figure 15.17 Malignant colonic obstruction can be palliated or temporarily relieved by insertion of a self-expanding metal stent (arrow).

Total colonoscopy is contraindicated in the presence of severe colitis; a limited unprepped examination and careful mucosal biopsy only should be performed. Polypectomy is associated with a well-documented rate of perforation (approximately 1%) and haemorrhage (1–2%). Immediate haemorrhage should be managed by re-snaring the polyp stalk where possible and applying tamponade for several minutes followed by careful coagulation if this is unsuccessful. Submucosal adrenaline injection and the deployment of haemoclips are alternatives if this is not possible. Delayed haemorrhage may occur 1–14 days postpolypectomy and can normally be managed by conservative observation. Transfusion may occasionally be required, but repeat colonoscopy is rarely necessary. If recognised at the time of polypectomy, small perforations should be closed using clips and the patient admitted for observation. Symptoms of abdominal pain and cardiovascular compromise after a polypectomy should alert one to the risk of delayed perforation. Patients should be kept nil by mouth and receive intravenous resuscitation and antibiotics. Prompt assessment with plain radiography and a CT scan will often distinguish between a frank perforation and a transmural burn with associated localised peritonitis (the postpolypectomy syndrome). Assessment by an experienced colorectal surgeon is essential, as surgery is often the most appropriate course of action.

ENDOSCOPIC ULTRASOUND

One key disadvantage of conventional endoscopy is that the views are limited to the mucosal surface and it is therefore not possible to diagnose submucosal or extraintestinal pathology. These limitations can be overcome using endoscopic ultrasound (EUS), which combines the traditional mucosal image with a separate ultrasound view that clearly depicts the intestinal layers and proximate extraintestinal structures. Its use has revolutionised the staging and management of upper gastrointestinal and hepatobiliary malignancy.

There are two main types of echoendoscope: the radial echoendoscope has a radially arranged ultrasound probe and a forward-viewing lens. This is used for diagnostic work such as local tumour staging in the oesophagus and stomach. The linear echoendoscope is a side-viewing scope with a working channel much like an ERCP scope, and a linearly arranged ultrasound probe. This conformation allows ultrasound assessment and ultrasound-guided sampling of tissues to be performed (**Figures 15.18 and 15.19**). It allows sampling of paraoesophageal and coeliac lymph nodes, sampling of pancreatic, biliary and other solid abdominal lesions and drainage of peripancreatic abscess or pseudocysts. Using TTS cystotomes it is possible to perform EUS cystgastrostomy and stent placement, and increasingly biliary interventional procedures are being performed with EUS assistance.

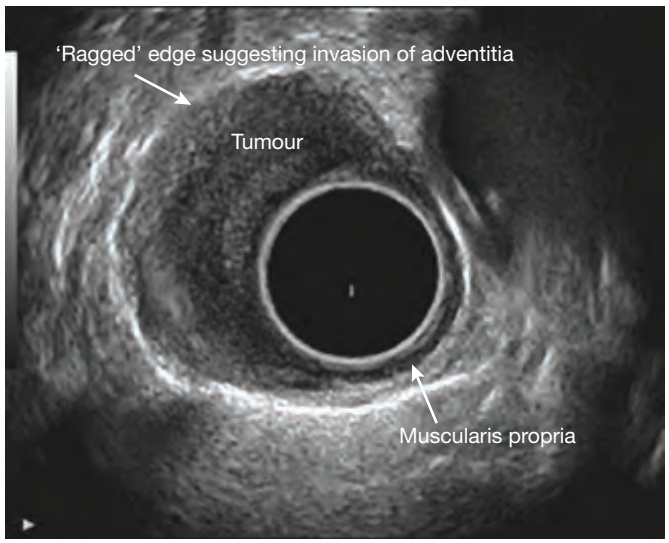

Figure 15.18 Endoscopic ultrasound image of an oesophageal tumour invading into the wall.

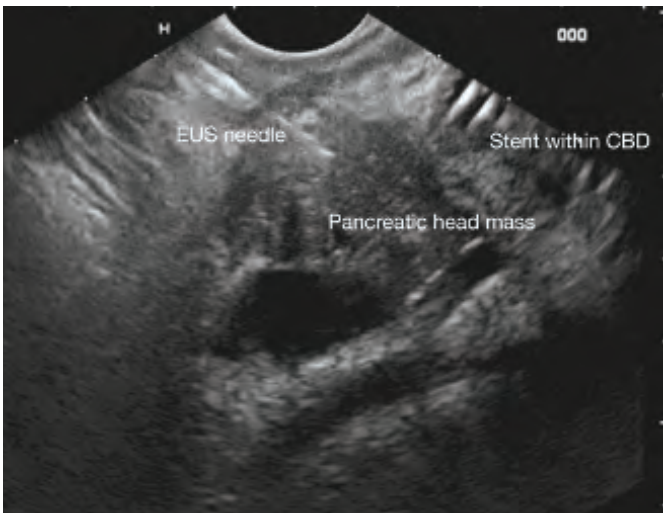

Figure 15.19 Endoscopic ultrasound-guided fine needle aspiration of a pancreatic head mass.

EUS requires dedicated training, both in scope manipulation and radiographic interpretation. Due to the width and lack of flexibility of the endo-ultrasound scope as well as the duration of complex therapeutic procedures, sedation is normally required, and some units perform tests using propofol-based anaesthesia. The main indications for endoscopic ultrasound are listed in *Table 15.6*. All patients undergoing therapeutic endoscopic ultrasound require a normal coagulation screen. Complications include over-sedation and oesophageal perforation during diagnostic procedures and haemorrhage/perforation during therapeutic procedures.

TABLE 15.6 Indications for endoscopic ultrasound.

Diagnostic:	Staging of oesophageal/gastric malignancy
	Staging of hepatobiliary malignancy
	Diagnosis of choledoccal microlithiasis
Therapeutic	Biopsy of paraoesophageal lymph nodes
	Biopsy of submucosal upper GI lesions
	Biopsy of pancreaticobiliary mass
	Biopsy of portal lymphadenopathy
	Biopsy of left adrenal and left liver masses
	Transgastric drainage of pancreatic pseudocyst
	Coeliac plexus block

IMPROVED ENDOSCOPIC IMAGING

Chromoendoscopy, narrow band imaging and high resolution magnification endoscopy

The ability to enhance lesion detection and achieve near-patient discrimination of pathology without the need for histology is a common theme of several active areas of endoscopic development. The goal is to allow accurate discrimination of dysplasia grade in areas of Barrett's oesophagus or quiescent ulcerative colitis and to aid polyp detection and the recognition of early gastric and colorectal cancer. The most widely available technique is chromoendoscopy, which involves the topical application of stains or pigments to improve tissue localisation, characterisation or diagnosis. Several agents have been described, which can broadly be categorised as absorptive (vital) stains such as methylene blue; contrast (reactive) stains, such as indigo carmine; and those used for tattooing, such as India ink. Acetic acid can be used to improve dysplasia detection in Barrett's oesophagus and Lugol's iodine can be useful in detecting early squamous cell carcinoma.

Narrow band imaging (NBI) relies on an optical filter technology that radically improves the visibility of capillaries, veins and other subtle tissue structures by optimising the absorbance and scattering characteristics of light. NBI uses two discrete bands of light: one blue at 415 nm and one green at 540 nm. Narrow band blue light displays superficial capillary networks, whereas green light displays subepithelial vessels; when combined they offer an extremely high contrast image of the tissue surface. Autofluorescence images can also be used to increase lesion discrimination. Finally, high-resolution magnifying endoscopy may be used alone or in combination with one of the above techniques to achieve near-cellular definition of the mucosa (**Figure 15.20**), and is of particular use in neoplasia surveillance. New directions for the future include the increased use of confocal endomicroscopy to achieve histological images at the time of the endoscopic procedure.

CONCLUSIONS

Over the last 30 years endoscopy has become an integral part of the diagnostic work-up of patients with gastrointestinal disease. Whereas advances in radiology may obviate the need for some diagnostic procedures (routine OGD and ERCP), the ability to take mucosal biopsies will ensure that it retains a vital role. Moreover, on-going advances in technology such as magnifying endoscopy and chromoendoscopy are able to give near-histological quality definition to allow near-patient diagnosis. There have also been major advances in the range of conditions that are amenable to endoscopic therapy; such therapy may have substantially lower associated morbidity rates than traditional surgical approaches. However, as the scope of procedures widens and the age range/comorbidities of the patients increases it is beholden to the endoscopist to ensure that he or she adheres to appropriate governance/consent and sedation practice to minimise complications.

Figure 15.20 Endoscopic diagnostic accuracy can be improved by novel endoscopic techniques. This duodenal adenoma can be seen with conventional white light **(a)** (arrow), but its full extent is more clearly delineated using narrow band imaging **(b)** or chromoendoscopy with indigo carmine **(c)**.

Chapter 16

Tissue and molecular diagnosis

LEARNING OBJECTIVES

To understand:

- The value and limitations of tissue diagnosis
- How tissue samples are processed
- The role of histology and cytology

To be aware of:

- The role of additional techniques used in clinical practice, including special stains, immunohistochemistry and molecular pathology
- The principles of microscopic diagnosis, including the features of neoplasia
- The importance of clinicopathological correlation
- Management issues

INTRODUCTION

In the past, tissue diagnosis was restricted to macroscopic examination of autopsy material and of a limited range of surgical specimens. In the nineteenth century, microscopic examination of human tissue from autopsies and surgical procedures was introduced, and its value was accepted eventually by physicians and surgeons. Tissue analysis is now an integral and routine element of clinical management. It is heavily dependent on microscopy and is usually the responsibility of a histopathologist, who is a medically qualified practitioner. The specialty variably known as Histopathology, Anatomic Pathology or Cellular Pathology, encompasses histopathology, cytopathology, autopsy work and molecular pathological tissue diagnosis.

Cellular pathology has changed considerably over the past few decades. There has been a steady increase in biopsy numbers, partly because of the widespread introduction of flexible endoscopy and also because of an ageing population with a higher risk of cancer. Screening programmes (breast, bowel and cervical) have had a major impact on volume and practice. New techniques have improved the quality and clinical value of histological assessment, while autopsies have steadily diminished in number. Adherence to national or international reporting standards, e.g. for cancer, is increasingly expected, as is participation by pathologists in multidisciplinary clinical management meetings. Tissue analysis has sometimes been replaced by newer less invasive methods, e.g. human papilloma virus (HPV) testing rather than cytological assessment of cervical smears for cervical cancer screening, while newer forms of radiology and imaging may be so informative that tissue analysis is not needed.

A modern cellular pathology department is usually located in a medium-sized or large hospital or in a purpose-built laboratory. Typically, more than 80% of specimens are from the gastrointestinal tract, gynaecological tract, urological system or skin. In line with clinical services, highly specialised work such as neuropathology is largely confined to major regional centres.

REASONS FOR ASSESSMENT OF TISSUE

There are several reasons for tissue analysis. These include diagnosis, staging of disease, prediction of clinical outcome, selection of therapy and audit. These reasons are often interrelated.

A new diagnosis may be made or a known diagnosis confirmed. Often, tissue analysis confirms or refines a suspected or suggested clinical diagnosis. There may be clues to a cause, e.g.

Summary box 16.1

Reasons for tissue analysis

- To make a new diagnosis
- To confirm a suspected or established clinical diagnosis
- To exclude additional diagnoses
- To assist with prognosis
- To stage tumours
- To help select therapy and plan management
- To assess response to treatment
- Audit

granulomas. Additional diagnoses, either expected or unexpected, may be made. For example, an appendix removed for appendicitis could contain an incidental carcinoid tumour, polyp or carcinoma, while biopsies from a patient with inflammatory bowel disease may be taken to confirm the diagnosis and to exclude dysplasia but might reveal additional findings, e.g. cytomegalovirus or lymphoma.

Tissue analysis also helps, increasingly, to determine or refine treatment and prognosis. For example, the assessment of a cancer resection specimen confirms the diagnosis but perhaps more importantly provides information about features such as tumour stage, vascular invasion and resection margin involvement, which in turn predict clinical outcome and help determine postoperative treatment. More recently, pathologists have been asked to assess the degree of tumour regression after neoadjuvant therapy. Increasingly, molecular pathological analysis of cancer tissue contributes to various aspects of management, including diagnostic categorisation, prognostic predictions and selection of targeted drug therapy.

Additionally, the pathologist's assessment of resection specimens helps surgeons and radiologists to audit their performance.

It is worth remembering that a tissue sample does not represent the entire patient. The interpretation of microscopic and molecular changes is enhanced considerably by correlation with the clinical picture and the macroscopic findings. Accordingly, a request form with adequate clinical details should accompany all specimens. Essential details include site of biopsy, date of birth, gender, medications, relevant risk factors, past medical and surgical history and details of neoadjuvant therapy in cancer cases.

TISSUE SPECIMENS

Routine tissue specimens received by a histopathology department include those intended for histopathological analysis and those for cytopathological assessment. These two areas may overlap.

Summary box 16.2

Common types of tissue sample

- Histology
  - Formalin-fixed tissue
    - Biopsy
      - Mucosal
      - Punch
      - Needle (core)
      - Curettings
      - Excision
    - Resection
  - Fresh tissue (usually for frozen section)
- Cytology
  - Cervical
  - Washings, brushings, scrapes
  - Fine-needle aspirate (FNA)
  - Fluids/sputum

Histology

Specimens for histology are arbitrarily classified as biopsies and resections. Biopsies are taken for diagnosis and assessment rather than treatment. A resection is usually done to remove a lesion (e.g. a tumour) or to manage a related problem (e.g. sleeve gastrectomy for obesity), but may also have other uses including diagnosis, staging, and determination of further management. Types of small biopsy include punch biopsy, needle core biopsy and mucosal biopsy. An excision biopsy is larger and serves as both a diagnostic biopsy and a limited resection.

All samples for routine histology are immediately placed in a fixative, usually formalin (10% formaldehyde), to preserve morphology. Ultrasound-guided and computed tomography (CT)-guided biopsies of focal and less accessible lesions have become more common and may pose challenges to the pathologist because of limited sample size.

Cytology

Cytological specimens can be obtained from many sites using a variety of approaches. Some are easy to obtain, e.g. urine and sputum, whereas others require more intervention. A conventional cervical smear is obtained by sampling the cervical transformation zone with a brush/broom. Bronchial aspirates, washings and brushings and gastrointestinal and biliary brushings sample a relatively wide area and may therefore be useful for the diagnosis of neoplasia.

Fine-needle aspiration (FNA) cytology may sample accessible sites such as the breast, thyroid and superficial lymph nodes, while FNA from deeper and less accessible structures, e.g. liver, pancreas, kidney and lung, is usually assisted by ultrasound or CT guidance. Ultrasound-guided transbronchial FNA may be used for mediastinal masses and transmucosal FNA for submucosal gastrointestinal lesions or perivisceral lesions. FNA cytology samples may be accompanied by a biopsy taken at the same procedure.

Fluids may be submitted directly to the laboratory for cytological assessment.

Fresh tissue

The most common indication for submission of a fresh tissue sample (i.e. without fixative) is rapid frozen section diagnosis, usually done intraoperatively. Other indications are microbiological assessment, electron microscopy, chemical analyses (e.g. quantification of iron) and some types of molecular pathological analysis. Before fixing a histology or cytology specimen, the operator should consider whether any of these investigations might be useful.

Risk management

Safety and risk management are priorities in the laboratory. Any risk of contamination by transmissible infection, e.g. hepatitis B virus, human immunodeficiency virus (HIV), must be minimised by the use of warning labels, especially when fresh tissue is being submitted. Formalin kills many micro-

organisms, but any risk of infection should still be notified. Also, formalin itself is toxic to the eyes and skin. Accordingly, leaking or faulty specimen containers should be discarded. Containers must be labelled with the patient's details to avoid errors of identity (Figure 16.1).

Figure 16.1 Sections on glass slides stained with haematoxylin and eosin (H&E). Each slide has a unique specimen identifying number (06S022081), a letter corresponding to the biopsy site (A1–F1) and a site label (e.g. DUOBX for duodenal biopsy).

SPECIMEN PROCESSING

Histology specimen

On arrival in the histopathology department, specimens are given a unique number and submitted for macroscopic assessment and sampling ('cut up'). The largest specimens are opened (e.g. bowel) or sliced (e.g. uterus) and left to fix in formalin for at least 1 day (Figure 16.2). When they are fixed and, accordingly, in a suitable condition for cutting and sampling, a text description of the specimen and any abnormality is made. Small specimens such as biopsies are processed in their entirety. Representative samples are taken from any specimen too large to be processed whole (Figure 16.3). This is traditionally done by a histopathologist, but increasingly may be done by specifically trained non-medical staff. In the UK, a local or national protocol for sampling is often followed. For example, samples from most types of cancer should include resection margins, tumour, lymph nodes, non-neoplastic tissue and any other abnormal areas. Coloured inks help to identify resection margins and surfaces as they are also visible under the microscope (Figure 16.4).

Specimens, or samples from specimens, are placed in plastic cassettes (Figure 16.5) and then embedded in paraffin wax while in the cassette to make a tissue block (Figure 16.6). Sections with a thickness of approximately 5 µm (microns) are cut from the block using a microtome (Figure 16.7). The sections are placed on a glass slide and stained with haematoxylin and eosin (H&E) (Figure 16.1). This work is done by expert trained staff, known in the UK as biomedical scientists (BMSs). High standards are necessary because a poorly cut section may have various artefacts, such as lines and folds, which impede accurate assessment. H&E as the first-line stain has stood the test of time, probably because it is inexpensive, safe, fast, reliable, familiar and informative.

The stained sections are examined with a microscope (Figure 16.8) and the histological features are correlated with the clinical details and the macroscopic description. After completion of any further studies, the pathologist writes a report that is usually entered onto a computer system.

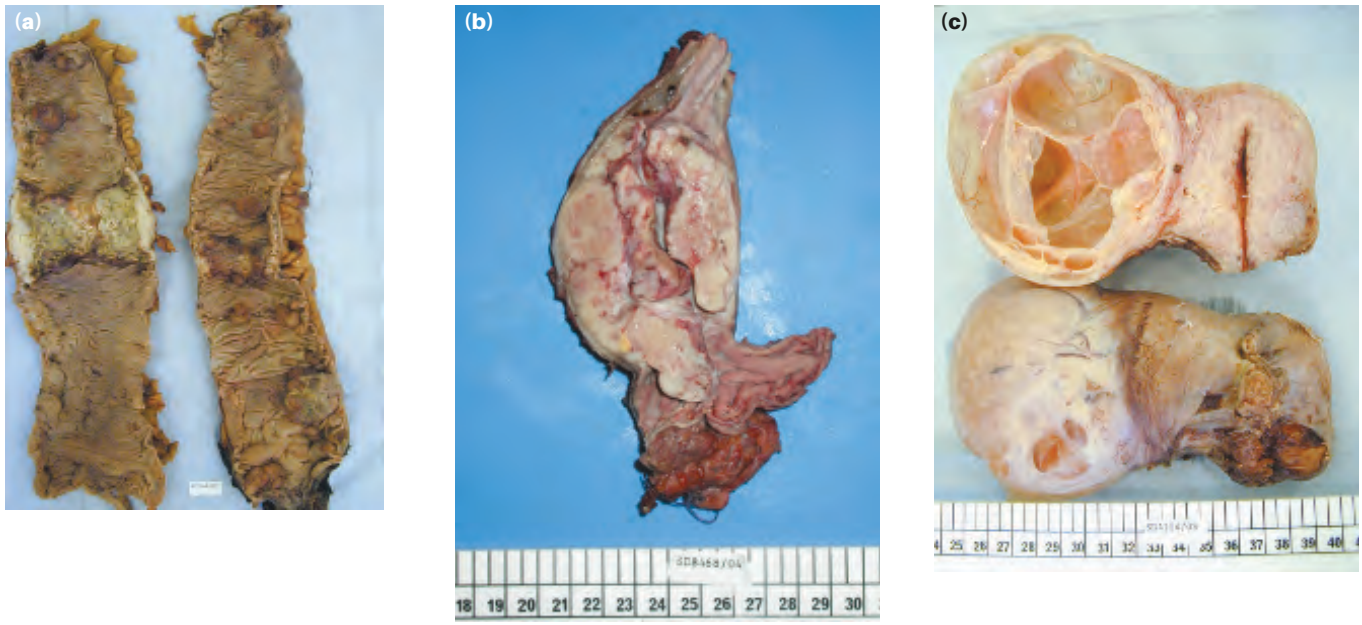

Figure 16.2 **(a)** A colon from a patient with familial adenomatous polyposis has been opened longitudinally to allow fixation. Multiple polyps and a carcinoma are seen. **(b)** An oesophagogastrectomy containing a distal oesophageal tumour has been opened and sliced to allow fixation. **(c)** A uterus and an adjacent cystic lesion have been bisected with a knife to allow fixation (all figures courtesy of Dr J Chin Aleong, Barts Health NHS Trust, London, UK).

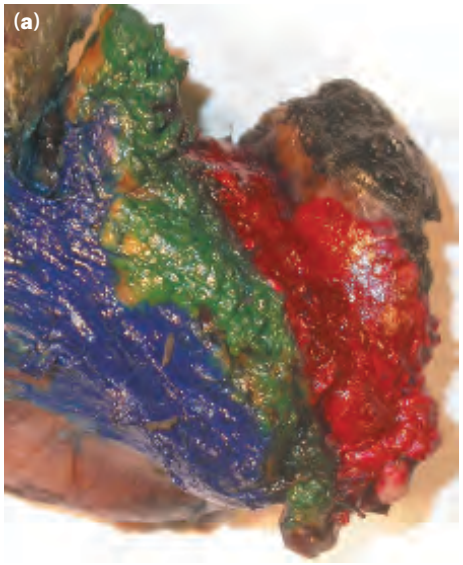
Figure 16.3 A scalpel is used to take a sample from a resection specimen.



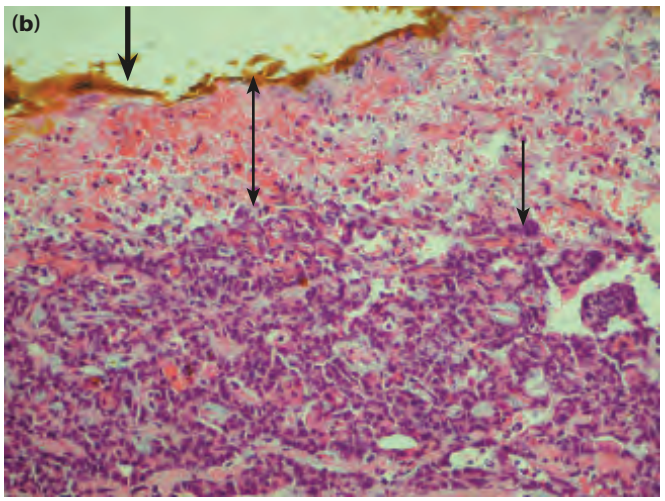


Figure 16.4 **(a)** An unopened pancreatoduodenectomy specimen (posterior view). Four inks of different colours have been painted onto various resection margins and external surfaces. **(b)** Yellow ink on the edge of a histology section (thick arrow). Tumour (thin arrow) lies close to the surface. The distance between the tumour and a surface or a resection margin can be measured (double-headed arrow).

Figure 16.5 A tissue sample from a resection specimen is placed in a cassette.

Figure 16.6 Paraffin wax blocks. Cassettes of different colours allow specimens to be organised into groups.

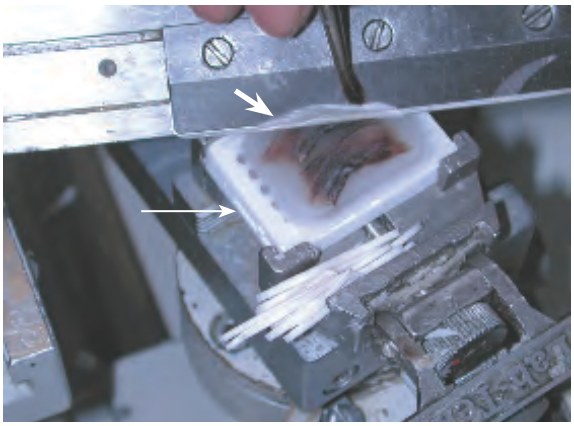

Figure 16.7 A section (thick arrow) being cut from a paraffin wax block (thin arrow) with a microtome.

Figure 16.8 A double-headed microscope allows a consultant histopathologist and a trainee to view a slide simultaneously.

Summary box 16.3

Histological processing: sequence of events

- Biopsy or resection specimen received
- Macroscopic (gross) description made
- Specimen sampled (unless small enough to submit in its entirety)
- Specimen or samples placed in cassette(s)
- Paraffin wax block(s) made
- 5-μm sections cut
- Sections put on glass slides
- Sections stained with H&E
- Histopathologist examines slides
- Histology compared with clinical and macroscopic findings
- Further studies if necessary
- Report entered onto computer system
- Report authorised or signed

Frozen section specimen

Frozen section diagnosis is useful when a very rapid answer is necessary for diagnosis or management. Surgeons are the main users of this service. A representative fresh tissue sample of the area of interest is supplied by the surgeon and frozen quickly in the pathology laboratory, and sections are cut and stained within several minutes. There are a few disadvantages: fresh tissue carries a higher risk of infection than fixed tissue; the quality of a frozen section slide is inferior to that of routinely processed material, reducing the accuracy and precision of diagnosis; small samples are required; certain types of tissue (e.g. fat) are difficult to deal with; and the process is time-consuming and disruptive for the histopathology department.

Cytology specimen

Many samples for cytology can be smeared immediately onto glass slides, fixed (usually in alcohol) or air dried and stained immediately or later. Several slides are usually produced, some of which are stained with a Papanicolaou (Pap) stain and some with another method such as May–Grünwald–Giemsa (MGG) or Romanowsky. Pap stain is regarded as the preferred stain for fixed specimens while MGG is better for air-dried material. Often the sample will be stained with both. Cervical smears are usually stained with a Pap stain only (**Figure 16.9**). There has been a move to liquid-based thin-layer technology for many samples, particularly cervical. For liquid-based cytology, the sampling device is usually washed in a liquid medium and the material obtained is then processed in the laboratory using purpose-built equipment.

Summary box 16.4

Frozen section: advantages and disadvantages

Advantages:

- Quick diagnosis

Disadvantages:

- Labour intensive
- Disruptive
- Risk of infection
- Poorer quality sections
- Small sample required
- Some tissue types difficult to process

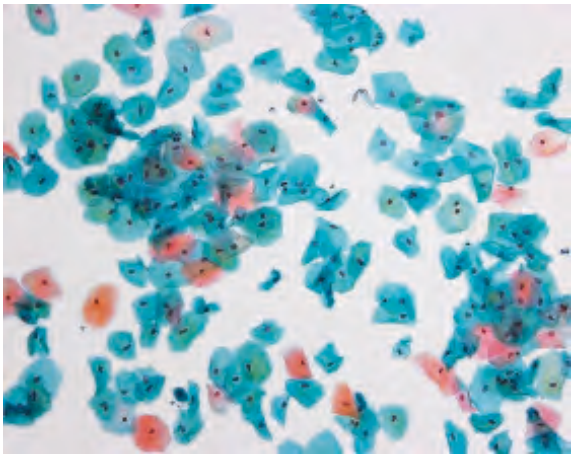

Figure 16.9 A cervical smear stained with a Papanicolaou stain. Numerous cells are present (courtesy of Professor MT Sheaff, Barts Health NHS Trust).

Storage

Resection specimens are generally stored for about 4–6 weeks. Tissue blocks are retained for as long as space permits, e.g. 30 years, while glass slides might be retained for a shorter time, e.g. 10 years. Fresh tissue can be frozen and stored. Stored tissue may be useful for future clinical review, teaching, audit or research. In many countries, the subsequent use of stored tissue for non-clinical purposes is now subject to legal constraints.

PRINCIPLES OF MICROSCOPIC DIAGNOSIS

Diagnosis of malignancy

Neoplasia is a broad term that includes benign and malignant tumours. Classification of a neoplasm or tumour as malignant

George Nicholas Papanicolaou, 1883–1962, Professor of Anatomy, Cornell University, New York, NY, USA, reported on the value of cervical smears in the diagnosis of carcinoma of the uterus in 1941.
Richard May, b.1863, physician, Münich, Germany.
Ludwig Grünwald, b.1863, otolaryngologist, Münich, Germany.
Gustav Giemsa, 1867–1948, bacteriologist who became Privatdozent in Chemotherapy, at The University of Hamburg, Hamburg, Germany.
Dmitri Leonidovich Romanowsky, 1861–1921, Professor of Medicine, St. Petersburg, Russia.

Summary box 16.5

Microscopic features of malignancy

- Metastasis
- Invasion
  - Of surrounding tissue
  - Vascular
  - Perineural
- Architectural abnormalities
- Necrosis
- Numerous mitotic figures
- Atypical mitotic figures
- Nuclear abnormalities
  - Pleomorphism
  - Enlargement
  - Hyperchromaticity
  - Chromatin clumping
- Nucleolar enlargement and multiplicity

(or as 'cancer') usually implies that it has the potential to behave aggressively. The main histological features of malignancy are metastasis, invasion, architectural changes and cytological features, but the criteria for a diagnosis of malignancy differ between anatomical sites and between tumour types.

Microscopic evidence of aggressive behaviour by the tumour is usually sufficient for a malignant label. For example, metastasis to another organ such as lymph nodes or liver is virtually always diagnostic of malignancy. Invasion of surrounding structures, perineural invasion (**Figure 16.10**) and vascular invasion (**Figure 16.11**) strongly suggest malignancy.

Other microscopic features that are typical of malignancy include derangement of the usual architecture, an increased number of mitotic figures, atypical mitoses and necrosis (tissue death) (**Figure 16.12**). Microscopic changes at the cellular level (cytological changes) include nuclear enlargement, an increased nuclear:cytoplasmic ratio, nuclear pleomorphism (variation in shape) and nuclear hyperchromasia (dark colour) (**Figure 16.13a**). Multiplicity, irregularity and enlargement of nucleoli may also be seen (**Figure 16.13b**).

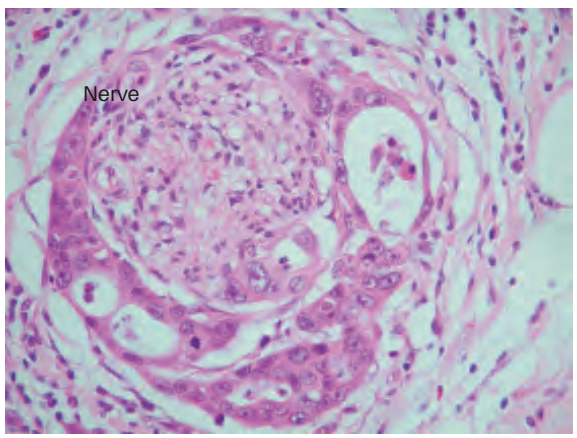

Figure 16.10 Perineural invasion. A nerve is almost completely surrounded by adenocarcinoma.

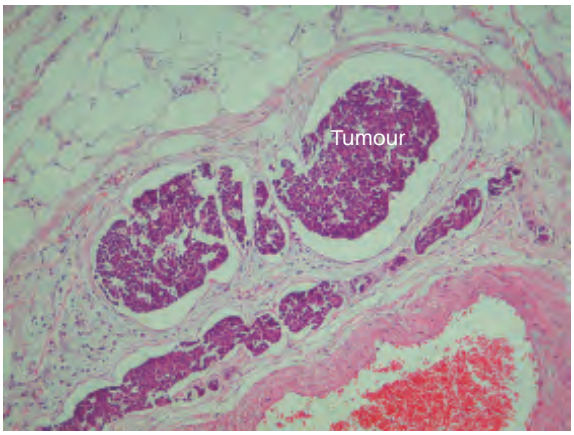

Figure 16.11 Vascular invasion. Aggregates of carcinoma cells are present within blood vessels. The tumour is poorly differentiated.

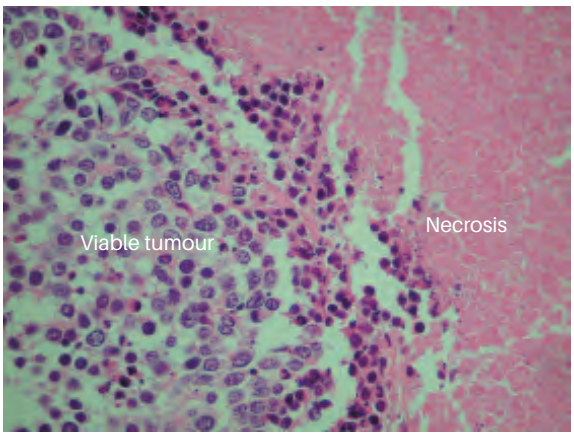

Figure 16.12 An area of necrosis in a poorly differentiated carcinoma.

The criteria for a histological diagnosis of malignancy are modified by the site and type of tissue. Carcinoma is the most common type of malignancy, and is typically diagnosed when epithelial cells invade beyond their normal boundaries. However, the categorisation of some types of non-epithelial proliferations (e.g. lymphoid, mesenchymal) as malignant may rely on cytological and architectural features rather than on invasiveness. In some cases, e.g. certain endocrine tumours, histological distinction between benign and malignant may be impossible. In other cases, e.g. gastrointestinal stromal tumours (GIST) and neuroendocrine tumours, there may be risk categories rather than benign and malignant designations. The risk categories are based on combinations of histological features that help predict the likelihood of aggressive behaviour.

Additional techniques such as immunohistochemistry and clonality studies may help to confirm neoplasia or malignancy (see below).

The term 'dysplasia' usually indicates that microscopic features of carcinoma, or similar to those of carcinoma, are present but that invasion has not occurred, e.g. cervical intraepithelial neoplasia (CIN), colorectal dysplasia (**Figure 16.14**).

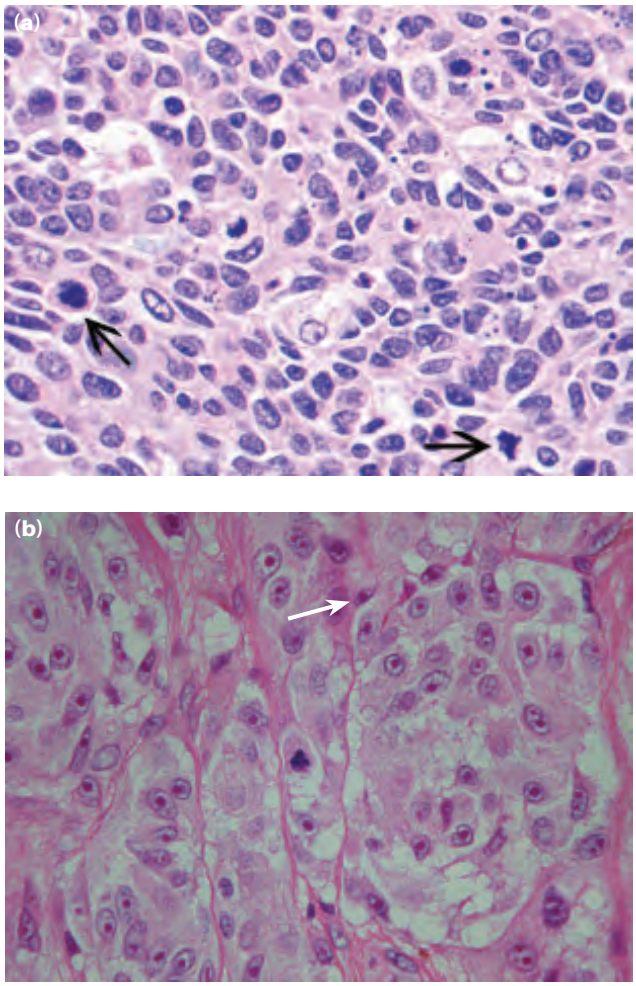

Figure 16.13 Cytological features of malignancy. **(a)** A high-grade neuroendocrine carcinoma showing nuclear pleomorphism (variation in shape) and variation in nuclear size. There are several mitotic figures (arrows). **(b)** A malignant melanoma showing nuclear pleomorphism and prominent nucleoli (arrow) (courtesy of Dr E Husain, Aberdeen Royal Infirmary, United Kingdom).

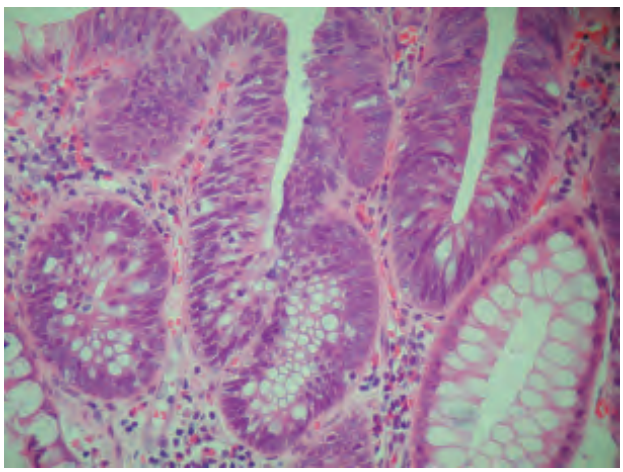

Figure 16.14 A colonic biopsy from a tubular adenoma with low-grade dysplasia. There is one non-dysplastic crypt (lower right corner). The remaining crypts show features of dysplasia, including nuclear stratification (multilayering) and nuclear hyperchromaticity (dark colour).

There are various causes of a false-positive diagnosis of malignancy. These include contamination of a specimen with tumour from elsewhere, interchanging of specimens and observer error. Several conditions can mimic malignancy histologically. For example, radiation effect on a mucosal layer can mimic malignancy, as can the histological changes in regenerating tissue adjacent to an ulcer. Additional studies may also be misleading, particularly if interpreted in isolation. The risk of interpretative error by the histopathologist is reduced by thorough training, regular updating, discussion of difficult cases with colleagues and avoidance of excessive workloads. The surgeon also helps to minimise such errors by supplying good clinical details, e.g. a history of radiotherapy.

A false-negative diagnosis, i.e. failure to diagnose malignancy when present, may reflect absence of tumour in the specimen or failure of the pathologist to recognise the changes as neoplastic.

Summary box 16.6

Causes of false-positive diagnoses of malignancy

- Interchanged samples
- Contamination
- Interpretative error
- Treatment-induced change
- Ulceration

Histological types of malignancy

A malignant tumour showing features of epithelial differentiation, and typically arising in an epithelial layer, is a carcinoma. Other important types of malignancy include malignant melanoma (melanocytes) **(Figure 16.13b)**, lymphoma (lymphoid cells) and sarcoma (mesenchymal cells). Further subclassification is usually possible. For example, a carcinoma can be classified as squamous cell carcinoma if it shows evidence of keratinisation **(Figure 16.15)**, adenocarcinoma if it shows evidence of glandular differentiation (in the form of tubule formation and/or mucin production) **(Figure 16.16)**, neuroendocrine carcinoma/small cell carcinoma **(Figure 16.13a)** (usually requiring immunohistochemical confirmation), clear cell carcinoma **(Figure 16.17)** or one of many other types.

Prognostic factors for malignant tumours

Tissue assessment is important for cancer prognosis. Stage is generally the most important prognostic factor for carcinomas. The commonly used and internationally accepted UICC (Union internationale contre le cancer)/AJCC (American Joint Committee on Cancer) staging schemes depend heavily on the histopathological TNM (**T**umour **N**ode **M**etastasis) category (pTNM), although the M category is usually evaluated clinically and the final stage is derived from a combination of clinical, imaging, pathological and other assessments. Degree of differentiation may also be prognostic and is usually determined microscopically. Well-differentiated tumours recapitulate some of the features of their non-neoplastic

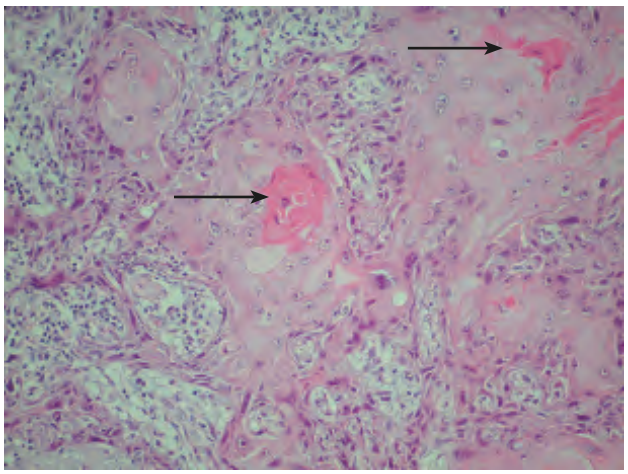

Figure 16.15 A well-differentiated squamous cell carcinoma. Irregular nests of squamous cells with foci of keratinisation (arrows).

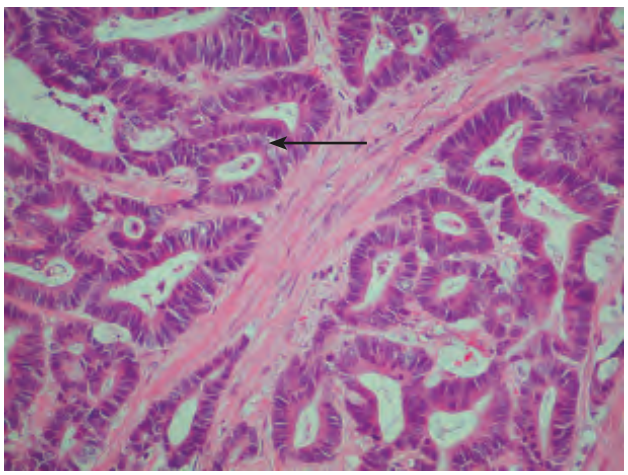

Figure 16.16 A well-differentiated adenocarcinoma. Gland formation (arrow) is obvious.

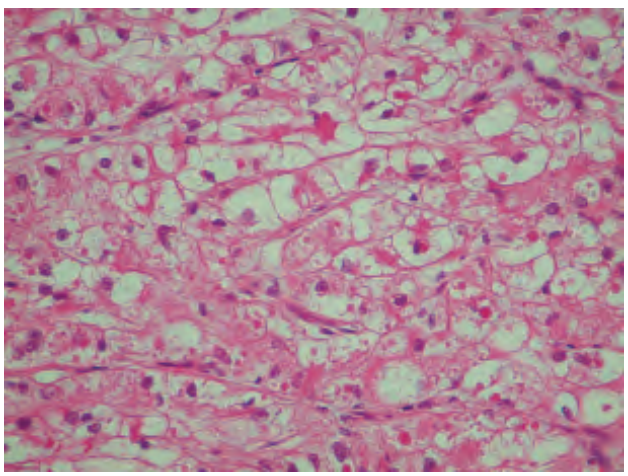

Figure 16.17 A metastatic clear cell carcinoma, composed of sheets of cells with clear cytoplasm. A tumour with this appearance is most likely to be of renal origin.

tissue counterparts **(Figures 16.15 and 16.16)**, whereas poorly differentiated tumours do not **(Figures 16.11 and 16.12)**. Other histological features associated with a worse prognosis include vascular invasion **(Figure 16.11)**, perineural invasion **(Figure 16.10)** and positive resection margins. The prognostic value of these factors differs between tumour types and sites.

Non-neoplastic and inflammatory conditions

Some of the commonest surgical specimens in the pathology laboratory are taken for the management of non-neoplastic disease. These include appendectomies for appendicitis, cholecystectomies for gallstone disease, hysterectomies for fibroids, partial gastrectomies for obesity, skin lesions such as sebaceous cysts and chippings from prostate glands with hyperplasia. All specimens are examined thoroughly in order to confirm the suspected clinical diagnosis and also to exclude other conditions that are not necessarily apparent to the surgeon, e.g. dysplastic and malignant lesions of the gallbladder, sarcomatous change within uterine fibroids or adenocarcinoma in prostatic chippings. Correlation with the clinical picture may be particularly important if a biopsy is taken specifically for non-neoplastic disease. For example, full clinical details are essential for meaningful interpretation of inflammatory bowel disease biopsies, inflammatory skin biopsies, renal biopsies and medical liver biopsies.

Microscopic features of inflammation

Acute inflammation is characterised by neutrophils (polymorphonuclear leucocytes) **(Figure 16.18)**, and chronic inflammation by lymphocytes and plasma cells. Other inflammatory cells include eosinophils **(Figure 16.19)**, mast cells and histiocytes. Granulomas (i.e. collections of epithelioid histiocytes) **(Figure 16.20)** raise the possibility of mycobacterial infection, fungal infection, sarcoid, Crohn's disease or a reaction to foreign material, among numerous possible causes. Eosinophils in large numbers may reflect parasitic infection or allergy. Interpretation depends heavily on the site and clinical setting.

Other terms

Other specific tissue abnormalities are also detectable by microscopy. Histopathologists may use specific terms for these changes. For example, hyperplasia means an increase in cell number while hypertrophy refers to an increase in cell size. Atrophy encompasses a reduction in cell number and/or cell size. Metaplasia describes the change from one mature cell type to another, e.g. columnar metaplasia in the oesophagus (known as Barrett's oesophagus) where squamous epithelium is

Norman Rupert Barrett, 1903–1979, surgeon, St Thomas's Hospital, London, UK.

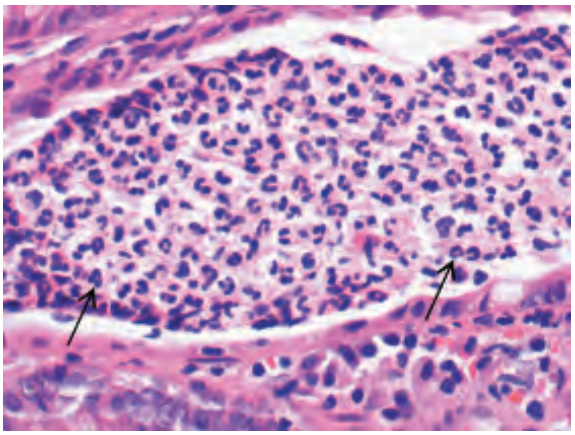

Figure 16.18 An acute inflammatory process characterised by numerous neutrophils. Note the typical multilobated nuclei in many cells (arrows).

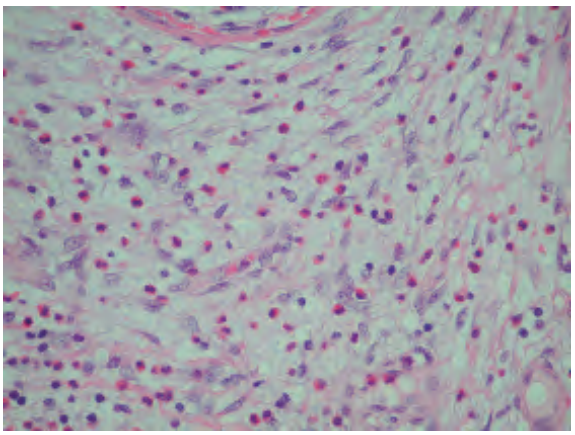

Figure 16.19 An inflammatory lesion in which eosinophils, characterised by bright red cytoplasm, are predominant.

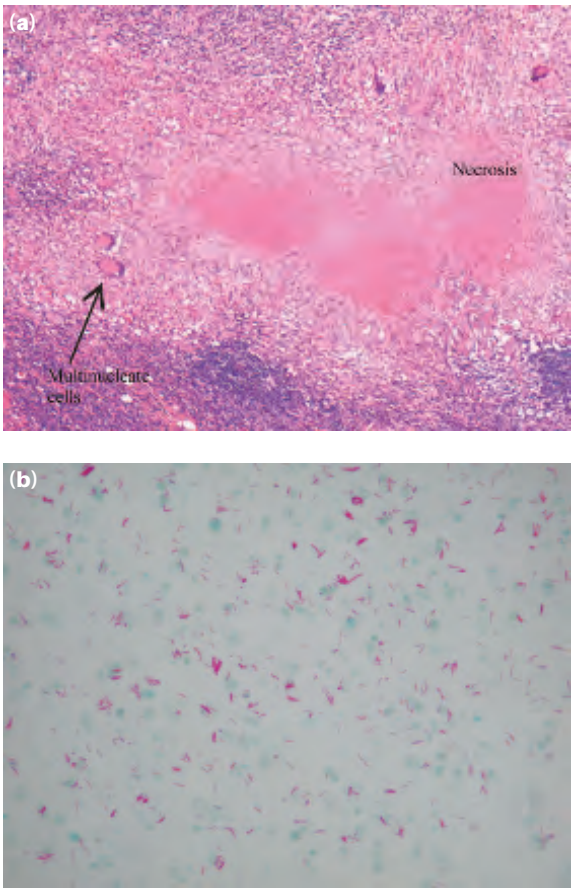

Figure 16.20 **(a)** A granuloma with necrosis, suggesting tuberculosis. Multinucleate giant cells of Langhan's type are also present (arrow). **(b)** A Ziehl–Neelsen stain (different case) shows numerous acid-fast bacilli.

replaced by gastric or intestinal type epithelium. Necrosis refers to cell or tissue death, typically as a result of external factors, and is often associated with cell swelling and inflammation. Apoptosis is a process of programmed cell death that occurs in normal cells as a result of internal signals, and typically causes cell shrinkage and nuclear chromatin condensation.

ASSESSMENT

Light microscopy

Most tissue assessment depends on conventional light microscopy. Microscopes have several lenses with various powers of magnification, typically ranging from ×20 to ×400 or more. A low-power lens allows a sample to be scanned and its overall architecture to be assessed, while a high-power lens allows a closer and more detailed view **(Figure 16.21)**. A teaching arm and a camera can be attached to most microscopes **(Figure 16.8).** Polarisation can be used to detect foreign material (e.g. sutures) or to assess a special stain (e.g. Congo red).

Histological assessment

In a histological preparation, the microscopic structure of the tissue is preserved, allowing direct visualisation of architecture. Accordingly, the pathologist can see not only the characteristics of the cells that form the tissue, but also the way in which these cells are related to one another and the way in which different tissue compartments are arranged.

Cytological assessment

A cytological preparation consists of a sample of cells. Architecture cannot be determined, because intact tissue is absent or sparse **(Figures 16.9 and 16.22)**. Therefore, assessment relies mainly on the characteristics of the cells themselves. Accordingly, it may be difficult to diagnose malignancy because many of the criteria, particularly invasiveness, cannot be assessed. However, cytology has several potential advantages over histology. A wider area may be sampled, and obtaining a specimen may be easier and less traumatic. Processing times are usually shorter and costs lower. Also, non-medical staff can be trained to report the cases, particularly cervical smears **(Figure 16.9)**.

Congo red is sodium diphenylbisazobisnaphthylamine sulphonate.

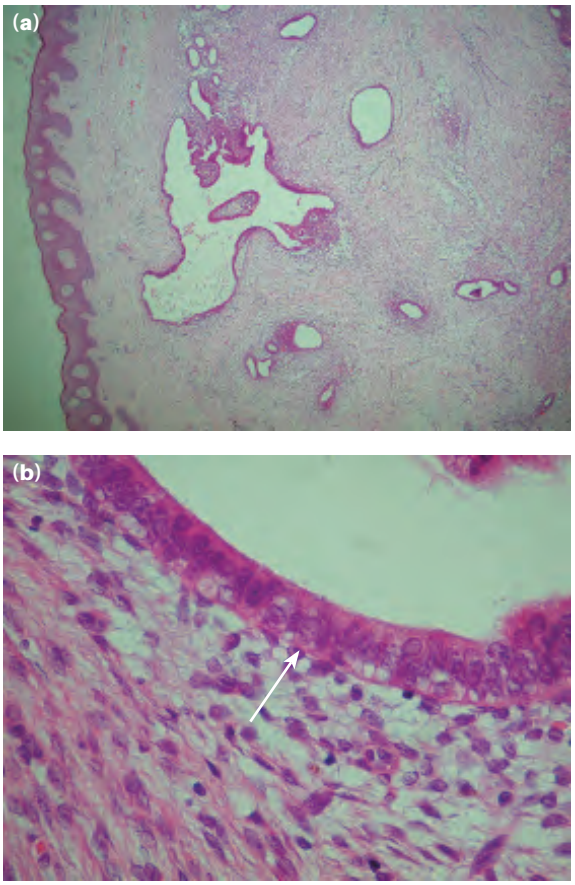

Figure 16.21 **(a)** Low-power view of an umbilical nodule. Glands are distributed irregularly through the tissue. **(b)** High-power view shows benign columnar epithelium lining the glands (arrow), favouring endometriosis over carcinoma.

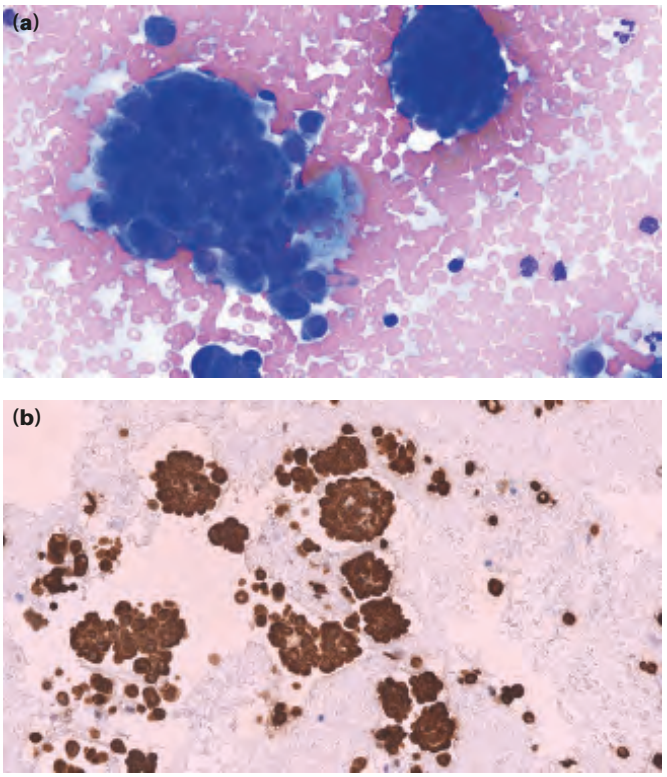

Figure 16.22 **(a)** A cytology preparation of a pleural effusion. Numerous cells with atypical features are present. **(b)** Immunohistochemistry shows positive staining for carcinoembryonic antigen (CEA), favouring carcinoma over mesothelioma

Summary box 16.7

Cytology compared with histology

Advantages:

- Wider area may be sampled
- Sampling may be less invasive
- Fast
- Cheap

Disadvantages:

- Cannot assess tissue architecture
- Less amenable to further studies

Screening

Screening programmes aim to detect and treat premalignant tissue changes, e.g. dysplasia, or early stage malignancy (rather than advanced disease). They may rely on cytology, histology or both. The largest is the cervical cancer programme, which currently uses cytology initially, with biopsy and histology follow-up if appropriate. The breast cancer screening programme may use cytology and/or histology, while the bowel cancer screening programme relies initially on a non-tissue-based test followed, if appropriate, by endoscopy and, where required, biopsy and histology. Screening for cancer in ulcerative colitis relies on endoscopic assessment and histology.

Specimen adequacy

There are several possible reasons for an inadequate specimen. The operator may fail to sample the intended organ or lesion, or may take too few samples to detect a heterogeneous abnormality. A sample from the centre of a necrotic or ulcerated lesion might include no viable tissue. Superficial biopsies from a carcinoma may fail to distinguish dysplasia (**Figure 16.14**) from invasive carcinoma. Cautery and crush artefact are sometimes severe enough to impede assessment.

Summary box 16.8

Reasons for an inadequate sample

Histology and cytology:

- Failure to sample the intended organ or lesion
- Sample too limited
- Non-viable tissue

Histology:

- Sample too superficial
- Cautery artefact
- Crush artefact

Deeper levels and extra blocks

The pathologist may request 'deeper levels', whereby the BMS cuts further into the paraffin block to obtain further sections. For example, deeper levels of a histologically atypical but non-invasive epithelial lesion might show foci of invasion, allowing carcinoma to be diagnosed. Extra blocks may be taken from a resection specimen if it has been sampled inadequately, e.g. if insufficient lymph nodes have been retrieved from a cancer case.

Summary box 16.9

Additional techniques

- Special stains
- Immunohistochemistry
- Electron microscopy
- Molecular pathology
- *In situ* hybridisation, including fluorescence *in situ* hybridisation (FISH)
- PCR-based techniques

FURTHER WORK

Further diagnostic work is performed on a significant minority of histology specimens, and includes special stains, immunohistochemistry and various molecular pathology techniques such as *in situ* hybridisation and polymerase chain reaction (PCR)-based methods. Electron microscopy is used less often. Some techniques can also be applied to cytology specimens (Figure 16.22).

Special stains

A 'special stain' is a stain that is not routine, i.e. not an H&E stain. Immunohistochemical stains are conventionally excluded from this category. Some special stains demonstrate normal substances in increased quantities or in abnormal locations. The periodic acid–Schiff (PAS) stain demonstrates both glycogen and mucin, whereas a diastase PAS (D-PAS) stain demonstrates mucin, e.g. in an adenocarcinoma. Perls Prussian blue stain demonstrates iron accumulation (Figure 16.23), e.g. in haemochromatosis. A reticulin stain helps to demonstrate fibrosis (Figure 16.24). Elastic stains also show fibrosis and can highlight blood vessels by outlining their elastic laminae. Special stains can also reveal the accumulation of abnormal substances, e.g. a Congo red stain for amyloid.

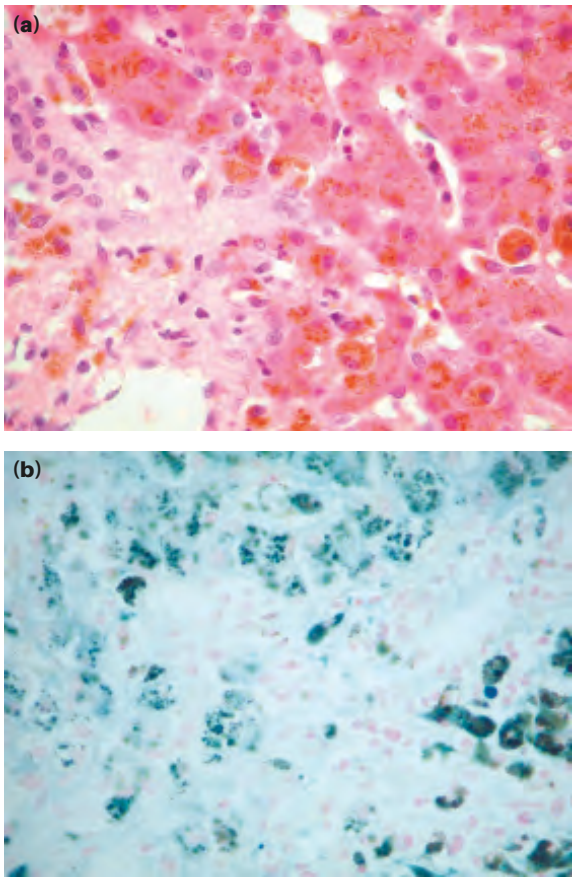

Figure 16.23 **(a)** Brown pigment in a biopsy. **(b)** A Perls stain is positive, indicating that the pigment is iron.

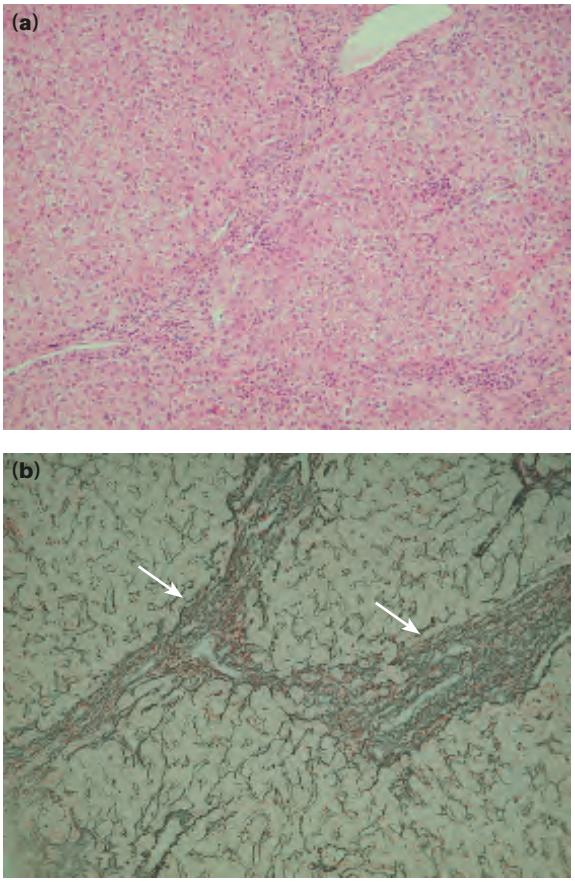

Figure 16.24 **(a)** A liver biopsy stained with haematoxylin and eosin (H&E) in which the severity of fibrosis cannot be determined. **(b)** A reticulin stain demonstrates fibrous bridges (arrows).

Hugo Schiff, 1834–1915, German biochemist who worked in Florence, Italy.
Max Perls, 1843–1881, pathologist, Giesen, Germany.

Summary box 16.10

Common special stains

- PAS: glycogen, fungi
- D-PAS: mucin
- Perls Prussian blue: iron
- Reticulin: reticulin fibres, fibrosis
- van Gieson: collagen
- Congo red: amyloid
- Ziehl–Neelsen: mycobacteria

Special stains are also useful for the diagnosis of infection. For example, a Ziehl–Neelsen stain demonstrates acid-fast bacilli, particularly mycobacteria, by staining them bright red in a blue background **(Figure 16.20)**. Mycobacteria cannot be seen on H&E slides. Other microorganisms that may be detectable on H&E but are easier to see with a special stain include fungi (PAS or Grocott stain), protozoa (Giemsa stain) and spirochaetes (Warthin–Starry stain).

Electron microscopy

Electron microscopy allows tissue to be visualised at very high magnification, e.g. ×1000 to ×500 000. It may help to decide the lineage of a non-neoplastic or neoplastic cell in difficult cases and may help to determine the nature of abnormal deposits, e.g. in renal disease. Unfortunately, it is time-consuming, labour intensive and expensive, and is now used very selectively.

Immunohistochemistry

Immunohistochemistry was introduced in the 1970s and has had a major impact on histopathological diagnosis. This technique detects a specific antigen using an antibody. The antibody is labelled with a dye and when bound to its target antigen is seen in the tissue section as a coloured stain, often brown **(Figure 16.25)**. This allows the presence, tissue distribution and cellular localisation of an antigen to be determined. It can also be used to quantify expression: for example, Ki67 is a cell cycle marker that allows a proliferative index to be calculated, which in turn has prognostic value for neuroendocrine tumours and other neoplasms. Immunohistochemistry can be applied to fixed and frozen tissue and to cytological preparations **(Figure 16.22b)**. It is specific, safe, quick and relatively inexpensive. However, false-positive results can result from non-specific staining or from cross-reaction with similar antigens. Over-reliance on immunohistochemistry by clinicians and pathologists should be avoided.

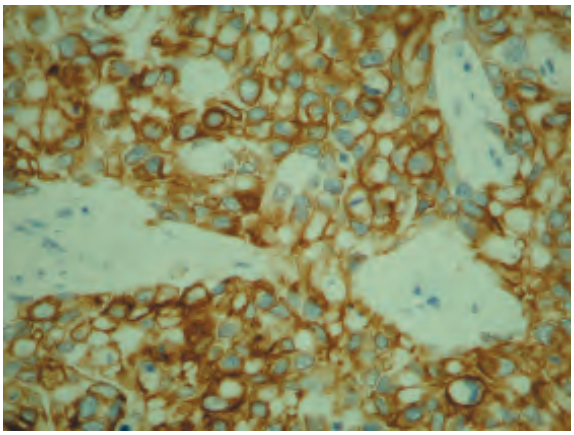

Figure 16.25 Diffuse immunohistochemical staining (brown) for a pancytokeratin marker in a malignancy, favouring carcinoma over other tumours.

Immunohistochemistry: tumour pathology

Immunohistochemistry has multiple applications in tumour pathology, including elucidation of site of origin and determination of cell type/direction of differentiation. Immunohistochemistry may also help to confirm neoplasia, determine the selection of treatment, refine prognostic predictions and screen for known underlying genetic changes.

Various immunohistochemical stains are used to detect cell type. Cytokeratins are expressed by epithelial cells. Cytokeratin positivity favours carcinoma **(Figure 16.25)** over

Summary box 16.11

Some immunohistochemical stains used for tumours

- Cell type/site of origin:
  - Epithelial (carcinoma): cytokeratins
  - Lymphoid (lymphoma): CD45, CD3, CD20
  - Melanocytic (melanoma): S100, HMB45, Melan A
  - Neuroendocrine: synaptophysin, chromogranin
  - Vascular: CD31
  - Myoid: desmin, actin
- Site of origin/cell type:
  - Prostate: prostate-specific antigen (PSA)
  - Lung: thyroid transcription factor-1 (TTF-1)
  - Thyroid: thyroglobulin
  - Colorectum: cytokeratin 20 (CK20), CDX2
  - Liver: HepPar
  - Gastrointestinal stromal tumour (GIST): CD117, DOG-1
- Prognosis and treatment:
  - Breast and gastric carcinomas: HER2
  - Neuroendocrine tumours: Ki67 labelling index
- Screening for mutations
  - Colorectal carcinoma: mismatch repair genes (MLH1, MSH2, MSH6, PMS2)

Ira Thompson van Gieson, 1866–1913, American neuropathologist, described this stain in 1889.
Franz Heinrich Paul Ziehl, 1859–1926, neurologist, Lübeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1894, pathologist, prosector, the Stadt-Krankenhaus, Dresden, Germany.
Aldred Scott Warthin, 1866–1931, Professor of Pathology, The University of Michigan, Ann Arbor, MI, USA.

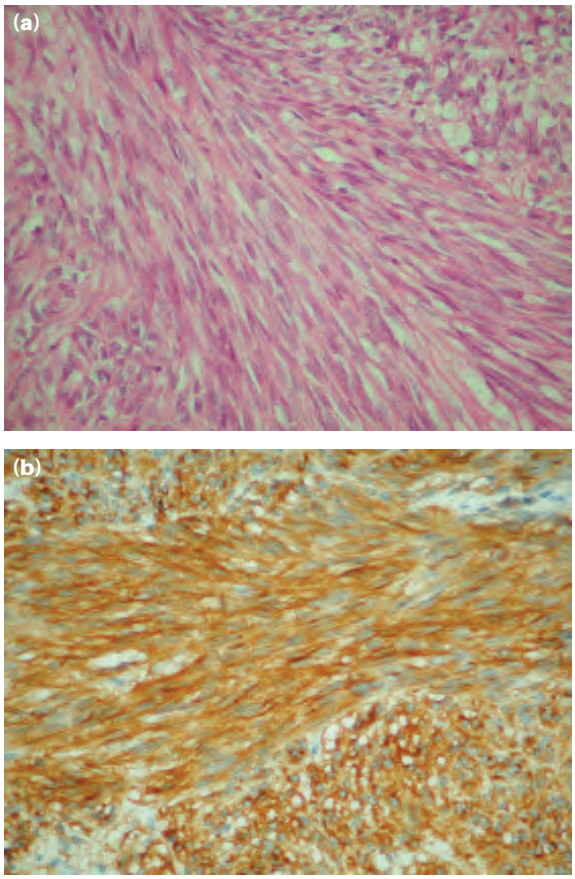

Figure 16.26 **(a)** A metastatic tumour composed of spindle cells. Gastrointestinal stromal tumour (GIST) was suspected. **(b)** Positive immunohistochemistry for CD117, confirming GIST.

other malignancies. Lymphoid markers include the panlymphoid marker CD45, the T-cell marker CD3 and the B-cell marker CD20. Markers of melanocytic differentiation include S100, MelanA and HMB45. Chromogranin, synaptophysin and CD56 stain neuroendocrine tumours such as carcinoid and small cell carcinoma. A gastrointestinal stromal tumour (GIST) typically expresses CD117 **(Figure 16.26)** and DOG-1. Endothelial cell markers include CD31, which may highlight vascular invasion or confirm a diagnosis of vascular neoplasia.

The site of origin of a metastatic tumour may be suggested by H&E appearances. For example, an adenocarcinoma has several possible sources. A clear cell carcinoma **(Figure 16.17)** is often of renal origin. Immunohistochemical stains may provide further information. Some are highly specific for an anatomical site, e.g. prostate-specific antigen (PSA) and thyroglobulin. Others are somewhat less specific, but still useful, e.g. thyroid transcription factor-1 (TTF-1), a marker of bronchogenic origin; HepPar, that suggests hepatocellular origin; and cytokeratin 20 and CDX2, typically expressed by colorectal carcinoma. Carcinoembryonic antigen (CEA) is seen in several types of carcinoma **(Figure 16.22b)**. However, some malignancies, especially poorly differentiated examples, do not conform to the typical patterns. Therefore, the clinical picture and imaging results should always be taken into account.

Less often, immunohistochemistry is used to help confirm malignancy. For example, kappa or lambda light chain restriction (expression of only one immunoglobulin light chain) in lymphoid proliferations suggests clonality and, in turn, neoplasia rather than a reactive process. Strong expression of p53 may support a diagnosis of dysplasia or neoplasia in specific settings.

Immunohistochemistry also plays a role in the selection of treatment and in predicting prognosis. For example, carcinomas of the breast are routinely assessed for oestrogen receptor (ER) and human epidermal growth factor receptor-2 (HER2) status, while lymphomas are typically subjected to a comprehensive panel of markers that help determine treatment and prognosis. Ki67 proliferative index is an important prognostic factor for neuroendocrine tumours and for some other neoplasms **(Figure 16.27)**.

Immunohistochemistry: infections and other applications

There are antibodies to many infective agents, including cytomegalovirus (CMV), Epstein–Barr virus (EBV), herpes simplex virus, human herpes virus 8 (HHV8), hepatitis B virus and *Helicobacter pylori*. Some of these organisms, e.g. *H. pylori* and CMV, can be seen or suspected on H&E slides, while others, e.g. EBV and HHV8, require immunohistochemistry or other techniques for their detection.

Immunohistochemistry can also be used to study immunoglobulin and complement expression (e.g. in lymphomas or renal biopsies); to assess the abnormal accumulation of various proteins such as alpha-1-antitrypsin (A1AT); to characterise amyloid; and to screen for mismatch repair gene mutations. As molecular pathological techniques progress, further immunohistochemical markers that detect specific

gene mutations are being developed and may become useful in clinical practice in the future.

DIAGNOSTIC MOLECULAR PATHOLOGY

The broad heading of diagnostic molecular pathology refers to multiple tests that assess molecules (proteins, ribonucleic acid [RNA] and deoxyribonucleic acid [DNA]) in tissue. The information that they provide may be useful for diagnosis, prognostic predictions, identifying patients with a hereditary cancer risk, determining treatment and identifying residual disease after treatment. Immunohistochemistry is conventionally excluded from this category.

Methods

In situ hybridisation

In situ hybridisation (ISH) uses a labelled oligonucleotide probe targeted at a specific sequence of RNA or DNA. It can be performed on fixed or fresh tissue sections, allowing the presence or absence of a particular sequence and its location to be seen *in situ*. Autoradiography, fluorescence microscopy or immunohistochemistry can be used for visualisation. Chromogenic *in situ* hybridisation (CISH) combines ISH and immunohistochemistry for the detection of DNA regions and it is widely and routinely used in pathology laboratories for the detection of HER2 amplifications. Viral genomes, e.g. EBV (**Figure 16.28**), CMV and human papillomavirus, can be detected using this approach. ISH plays an important role in the management of tumours (see below).

Polymerase chain reaction

The polymerase chain reaction (PCR) amplifies DNA, yielding millions of copies from a single copy of a selected target. RNA also may be amplified, using the technique of reverse transcriptase PCR (RT-PCR). PCR is fast and safe and can be performed on homogenised fresh or formalin-fixed tissue. PCR-based methods have many applications in oncology (see below), including mutational analysis (**Figures 16.29 and 16.30**), testing for clonality (**Figure 16.31**), detection of transcripts resulting from cytogenetic changes, detection of amplifications, demonstration of microsatellite instability and detection of gene hypermethylation. PCR-based methods can also be used to detect microorganisms.

Cytogenetics and FISH

Cytogenetics is the microscopic study of chromosomal changes in individual cells. Conventional cytogenetics is complemented, and is increasingly being replaced, by newer techniques including interphase cytogenetics and RT-PCR. Interphase cytogenetics relies mainly on FISH, although other forms of ISH may be used. Cytogenetic tests seek alterations such as gene amplification (e.g. HER2 in breast and upper gastrointestinal cancer; MDM2 in liposarcoma and atypical lipomas),

loss of segments of chromosomal material, loss of whole chromosomes (e.g. renal cell carcinoma) and translocations and fusion genes (e.g. haematological and soft tissue tumours).

Flow cytometry

Flow cytometry (FC) is a laser- or impedance-based technique used for cell counting, cell sorting, biomarker detection and protein engineering. Cells are suspended in a stream of fluid and passed by an electronic detection apparatus. It is useful for detecting antigens in haematological neoplasms, usually in blood samples, and for determining ploidy, i.e. the number of sets of chromosomes in the nucleus of a cell. Although traditional FC is of limited value for tissue analysis, new applications on image cytometric DNA analysis (ICDA) have been developed that allow detection of aneuploidy in tissue sections of gastrointestinal cancers.

Gene changes in tumours

In normal circumstances, the division and proliferation of cells is carefully controlled. For example, various growth factors influence division by binding to specific cell surface tyrosine kinase receptors resulting in the initiation of an intracellular cascade of changes. Damaged cells may undergo apoptosis, a carefully regulated process of programmed cell death.

Tumours occur as a consequence of uncontrolled cell proliferation. Abnormalities of numerous genes can affect cell proliferation and favour tumour development. The genes that are involved fall into two main categories. Those that stimulate cell proliferation are known as proto-oncogenes (often referred to as oncogenes), while those that inhibit proliferation are called tumour suppressor genes. Inappropriate activation of proto-oncogenes may accelerate cell proliferation, while inhibition of tumour suppressor genes may remove the controls that retard cell growth and division.

Several types of gene or nucleic acid abnormality can occur during tumorigenesis. Mutations are a very common type of abnormality. They are changes in the sequence of nucleic acids, usually DNA. Mutations can be either germline, i.e. inherited from a parent and accordingly present in every cell in the body; or somatic, i.e. acquired at some point during life and affecting only some cells in the body. Mutations are of several types. Point mutations are single nucleotide changes, where one base pair is replaced by another. Other types of mutation include deletions and insertions (indels). Examples of clinically relevant mutations include p53 tumour suppressor gene mutations, causing production of an abnormal p53 protein that lacks suppressor function; and mutation of the KIT gene, causing ligand-independent activation of a growth factor receptor.

Other abnormalities of genes include amplification, e.g. HER2, resulting in over-expression of the growth factor; translocations, e.g. t14:18 in follicular lymphoma that results in juxtaposition of the anti-apoptotic bcl-2 gene to a regulatory region of an immunoglobulin heavy chain gene, with subsequent bcl-2 overexpression; and loss of one of the two copies of a particular gene, or loss of heterozygosity.

Gene defects may ultimately interfere with the function of proteins involved in various regulatory processes, such as cell cycle control (e.g. p53); apoptosis (e.g. bcl-2); and signal transduction pathways. The latter can be affected by abnormalities of growth factor receptors or of intracellular components such as KRAS **(Figure 16.30)** and NRAS. DNA mismatch repair (MMR) genes can also be affected, causing instability of repeated sequences of DNA called microsatellites (known as microsatellite instability or MSI).

Epigenetic changes

Epigenetic factors are external to the gene and can switch it on or off. The latter is known as epigenetic silencing and can result from DNA methylation (addition of a methyl group to DNA with alteration of its structure), modifications of histones (components of chromatin) and RNA-associated silencing. Loss of methylation with gene activation can occur in tumours. Conversely, hypermethylation of tumour suppressor genes or of the mismatch repair gene MLH1 can reduce their activity, favouring malignancy. The importance and high frequency of epigenetic changes in tumours is increasingly being recognised.

Detection of mutations

There are two broadly related areas of clinical practice that rely on mutational analysis. Firstly, tumour tissue DNA can be analysed for mutations to improve diagnostic precision, enhance treatment plans and help predict clinical outcome. Secondly, a sample (usually blood) may be submitted for detection of germline mutations that are characteristic of an inherited disease. This is referred to as genetic testing and can be used to confirm non-neoplastic conditions, such as cystic fibrosis, or to diagnose a hereditary predisposition to cancer, e.g. Lynch syndrome (see below). Genetic testing may be offered to those who have a strong family history of cancer or whose clinical presentation suggests a family history of cancer, e.g. diagnosis before the age of 50.

Mutational analysis is based on PCR and requires extraction of DNA from tissue (or from other sources such as blood). It includes sequencing-based screening methods (e.g. Sanger sequencing, pyrosequencing) **(Figure 16.29)**, screening methods comparing mutated with normal DNA and targeted mutation detection methods.

Next-generation sequencing (NGS or NextGen) **(Figure 16.30)** has emerged relatively recently and has already changed cancer management profoundly. The term NGS encompasses several methods, each of which performs massively parallel sequencing, allowing millions of fragments of DNA to be examined simultaneously for mutations. It is quicker and potentially cheaper than older methods and is applicable to formalin-fixed tissue. Targeted NGS is capable of identifying multiple known and novel mutations and other variants in genes of interest in a single test. In addition, NGS is able to detect low-frequency alleles with higher sensitivity towards low-frequency mutations compared with traditional Sanger sequencing.

New powerful platforms have been developed recently, designed to detect simultaneously not only mutations but also copy number variants (CVN) and gene fusions in more than 100 genes involved in human oncogenesis with minimal nuclear acid (DNA and RNA) sample input (Oncomine cancer Panel).

NGS has several applications, including prediction of tumour response to therapy, prediction of clinical behaviour and, increasingly, diagnosis.

Adequate amounts of tumour DNA must be present in the tissue sample for these techniques to be successful. Many

- Monitoring disease burden

samples include both non-neoplastic tissue and tumour. If necessary, microdissection of the area of interest can be done using conventional techniques or laser-assisted approaches.

Molecular testing: examples of clinical settings

Lymphoma

The distinction between benign and malignant lymphoid proliferations relies initially on morphology, immunohistochemistry and the clinical setting, but is sometimes difficult. Clonal immunoglobulin heavy chain (IgH) gene rearrangements in B-cell proliferations and clonal T-cell receptor gene rearrangements in T-cell proliferations favour lymphoma over reactive proliferations, although clonality is not synonymous with malignancy. Clonality is typically detected using PCR-based methods **(Figure 16.31)**. Also, identification of characteristic cytogenetic abnormalities plays a very important role in diagnosis, classification and management of various lymphomas and other haematological neoplasms.

Soft tissue tumours

The diagnosis of many types of soft tissue tumour/sarcoma is assisted by molecular testing. Examples include Ewing's sarcoma, alveolar rhabdomyosarcoma and leiomyosarcoma. Characteristic cytogenetic changes are usually detected by FISH.

Gastrointestinal stromal tumour

Most GISTS have either a KIT gene mutation or a PDGFRA gene mutation, more often the former. Identification of known mutations helps confirm the diagnosis of GIST in difficult cases. Mutational profile may also help predict clinical outcome and response to chemotherapy (e.g. imatinib, a tyrosine kinase inhibitor).

Treatment of advanced colorectal carcinoma (CRC), lung cancer and malignant melanoma

An increasingly common reason for molecular testing is the prediction of response to drug therapy for advanced carcinomas and other malignancies ('theranostics'). In CRC, the anti-EGFR monoclonal antibodies cetuximab and panitumumab are used in combination with chemotherapy for metastatic disease. This drug is less likely to be effective if KRAS or NRAS mutations are present than if a tumour is 'wild-type' (i.e. has no RAS mutation). In lung cancer, response to the anti-EGFR tyrosine kinase inhibitor Gefitinib is confined to a minority of lesions and is predicted by specific EGFR mutations, while response to the anaplastic lymphoma kinase (ALK) inhibitor crizotinib is predicted by ALK gene rearrangement. In metastatic malignant melanoma, response to the BRAF kinase inhibitor vemurafenib is predicted by specific BRAF mutations.

HER2 gene amplification in breast and gastric cancer

The management of breast cancer, and more recently of untreated metastatic gastric adenocarcinoma, is influenced by the tumour's HER2 status. Patients whose tumours overexpress HER2 are offered treatment with the monoclonal antibody trastuzumab. Screening for HER2 overexpression relies on immunohistochemistry. Confirmation or exclusion of underlying gene amplification in equivocal cases depends on FISH testing or PCR.

Mismatch repair genes

CRC and endometrial carcinoma can harbour germline or sporadic abnormalities of mismatch repair (MMR) genes (MLH1, MSH2, MSH6 and PMS2). Lynch syndrome, characterised by germline MMR gene defects, predisposes to CRC and other tumours that may occur at a relatively young age. Immunohistochemistry is a common screening method for MMR mutations. Loss of immunohistochemical staining by neoplastic cells is a marker for a genetic defect and an indication for considering genetic testing of patients and their families for Lynch syndrome **(Figure 16.32)**. In addition, MMR gene defects in CRC predict lower recurrence rates, later recurrence, a better response to 5-FU-based chemotherapy and better survival rates.

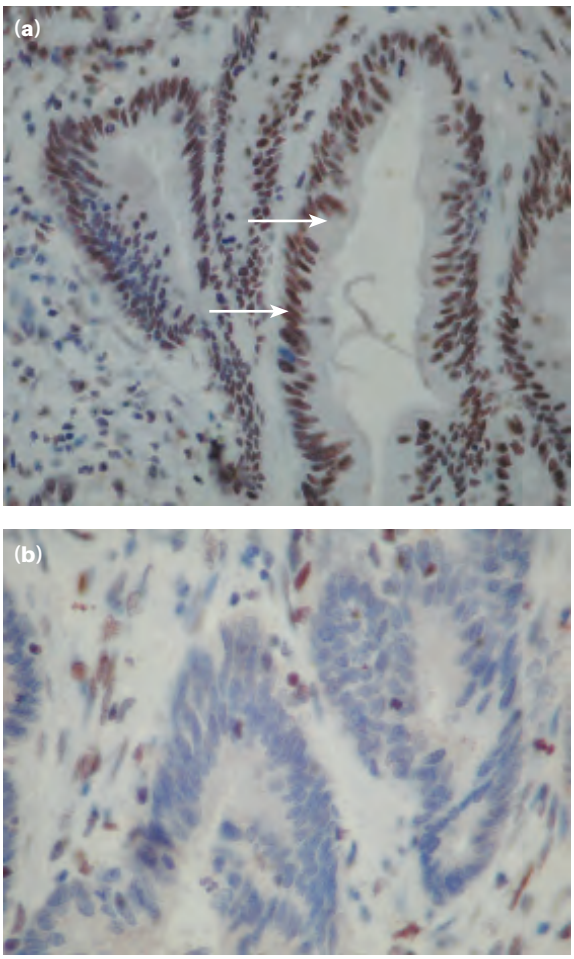

Figure 16.32 Immunohistochemical screening for mismatch repair gene mutations in a carcinoma. **(a)** Nuclear MLH1 expression is retained (arrows showing positively staining brown neoplastic nuclei). **(b)** In contrast, MSH2 expression is lost, suggesting a mismatch repair gene abnormality.

Staging and response to treatment

Tests can be used to confirm the presence or absence of a tumour at a particular anatomical site, thus refining staging. Similarly, they can help to assess the response to anti-cancer therapy. This has been particularly useful for haematological neoplasms such as myeloid leukaemias, where the presence of minimal residual disease can be detected by PCR-based methods.

Prognosis

Tests that help determine the selection of therapy for tumours may also have prognostic value, additional to that of established prognostic factors, e.g. BRAF in CRC. Some genetic changes have prognostic value in one type of tumour but not another, e.g. MMR gene defects are more predictive for CRC than for endometrial cancer. Of course, the outcome of many tumours now depends to some extent on their response to drug therapy, and accordingly a molecular test predicting response to therapy is at the same time prognostic. Packages of tests with additional prognostic value are also available, e.g. Oncotype DX, which analyses multiple genes in breast cancer tissue.

Cancer 'precision medicine'

This refers to the development of individualised cancer care plans, on the basis of molecular abnormalities. Germline and somatic mutations may be taken into consideration, so as to tailor treatments precisely and to target the cancer cells as effectively as possible. With the advent of NGS, analysis of a single sample of tumour tissue for multiple known and novel mutations that may predict treatment response is possible. In addition, mutations affecting as few as 5% of neoplastic cells can be detected. Other techniques may be used at the same time to detect abnormalities in the proteome (protein), transcriptome (mRNA), metabolome (metabolites) or epigenome, sometimes referred to as 'omics' assays. Such plans may, inevitably, be very complex.

Summary: diagnostic molecular pathology

Progress in molecular pathology is undoubtedly improving patient management. There is justifiable enthusiasm for the potential of emerging techniques. However, factors such as tumour heterogeneity, development of resistance to treatment and the genetic plasticity of many cancers could limit the development of precision medicine. Cost is also a consideration. Furthermore, the results of molecular studies should be interpreted not in isolation but with the clinical setting and basic tumour morphology in mind. For example, several types of tumour, including melanoma, CRC and papillary carcinoma of the thyroid, may have the same BRAF mutation, but the response to specific anti-BRAF therapy depends on the histology and the anatomical site. Similarly, the clinical implications of MMR gene defects in CRC and endometrial cancer are dissimilar. Finally, it is worth remembering that an H&E stained slide is inexpensive, easy to produce and a good summary of the genetic complexity of cells.

AUTOPSY

In the past, advances in medical knowledge were sometimes based on autopsy findings. Autopsies remain very useful for medical education and audit, as well as identifying the cause of death. In the UK there are two types of autopsy. The first is the coroner's postmortem, when the coroner decides that there is a need, or is obliged, to establish the cause of death. No consent from relatives is required. The second is the hospital autopsy, which requires relatives' consent. Valuable information may be revealed through both of these routes, especially in the unusual event of death following surgery.

FINAL COMMENTS

Analysis of tissue has played an increasingly important role in clinical management over the past few decades, and there has been rapid recent progress in the field of diagnostic molecular pathology. Pathologists need to work more closely with clinicians than ever before in order to optimise management, and to ensure that the value and limitations of tissue diagnosis and of new technologies are appreciated.

ACKNOWLEDGEMENTS

The author is very grateful to the following contributors: Professor MT Sheaff, for assistance with the sections of this chapter that discuss cytology and autopsy; Dr M Rodriguez-Justo, for reviewing and improving the section on diagnostic molecular pathology.

PART 3

Perioperative care

Chapter 17

Preoperative care including the high-risk surgical patient

Learning objectives

To be able to organise the preoperative care and the operating list

To understand preoperative preparation for surgery:

- Surgical, medical and anaesthetic aspects of assessment
- How to optimise the patient's condition
- How to identify and optimise the patient at higher risk
- Importance of critical care in management
- How to take consent
- How to organise an operating list

INTRODUCTION

The stress of major surgery can lead to increased oxygen demand by about 40%. Changes such as cytokine release-related inflammatory changes, endocrine responses, hypercoagulability and redistribution of fluid between compartments may last several postoperative days. The purpose of careful preoperative planning is to minimise the unwanted effects of these physiological changes.

Systematic history taking, examination and ordering of investigations at the preoperative clinic should include not only an assessment of functional reserve but also the formulation of advice on optimisation, to best cope with the anticipated operative stress. General practitioner (GP) records and hospital notes are useful sources of baseline information. GPs can help by monitoring chronic conditions, adjusting medications, and facilitating in weight reduction, exercise and the cessation of smoking.

A simple questionnaire, working within agreed guidelines, can identify high-risk patients undergoing high-risk surgery needing specific tests and optimisation (see later). Patients with severe comorbidities or undergoing high-risk surgery should be referred to specialists to quantify and to reduce perioperative risks. Risks of surgery, anaesthesia and the effects of comorbid conditions should be discussed so that the patient can make an informed decision. Patients should be given advice on 'nil by mouth' (NBM) and regular medication and premedication at the preoperative visit.

A plan for the operating list should be drawn-up and all those involved in making the list run smoothly should be informed. The World Health Organization (WHO) checklist, which is started just prior to induction of anaesthesia and continued during and after the surgery, aims to improve the safety of anaesthesia and surgery.

Summary box 17.1

Preoperative plan for the best patient outcomes

- Gather and record all relevant information
- Optimise patient condition
- Choose surgery that offers minimal risk and maximum benefit
- Anticipate and plan for adverse events
- Adequate hydration, nutrition and exercise are advised

PATIENT ASSESSMENT

Evidence suggests that correction of anaemia, better diabetes control, preoperative exercises and better nutrition leads to better patient outcomes and fewer postoperative complications. Based on population statistics, associated comorbidities and the type of surgery, one can estimate risks for an individual undergoing surgery and various tools and scores (see later) can be used as risk predictors.

History taking

Each organ system problem should be noted with dates, aetiology and treatment delivered (*Table 17.1*). Screening questions will reveal 'fitness' for surgery and anaesthesia. Patients with recent chest infections should be assessed for anaesthetic risks and postoperative surgical infection. Increasing severity of symptoms generally indicates worsening of the condition and possible need for a change in medication. Inability to achieve four metabolic equivalents, e.g. climbing a flight of stairs, increases cardiac risk after major surgery. Some factors leading to these findings may be amenable to treatment preoperatively such as anaemia, angina, palpitations or obesity.

The history of past surgery and anaesthesia can reveal the problems one may face during current hospitalisation (e.g. intra-abdominal adhesions for planned laparoscopic surgery, suxamethonium apnoea). The use of recreational drugs and alcohol consumption should be noted as they are known to be associated with adverse outcomes. Check for allergies and risk factors for deep vein thrombosis (DVT). Social history, ability to communicate and mobility are important in planning rehabilitation after surgery.

Summary box 17.2

Principles of history-taking

- Listen. What is the problem? (Open questions)
- Clarify. What does the patient expect? (Closed questions)
- Narrow. Differential diagnosis (Focused questions)
- Fitness. Comorbidities (Fixed questions)

TABLE 17.1 Key topics in past medical history.

Cardiovascular
- Ischaemic heart disease – angina, **myocardial infarction**
- **Hypertension**
- Heart failure
- Dysrhythmia
- Peripheral vascular disease
- Deep vein thrombosis and pulmonary embolism

Respiratory
- Chronic obstructive pulmonary disease
- Asthma
- Respiratory infections

Gastrointestinal
- Peptic ulcer disease and gastro-oesophageal reflux
- Liver disease

Genitourinary tract
- Urinary tract infection
- Renal dysfunction

Neurological
- Epilepsy
- Cerebrovascular accidents and transient ischaemic attacks
- Psychiatric disorders
- Cognitive function

Endocrine/metabolic
- Diabetes
- Thyroid dysfunction
- Phaeochromocytoma
- Porphyria

Locomotor system
- Osteoarthritis
- Inflammatory arthropathy such as rheumatoid arthritis

Other
- Human immunodeficiency virus
- Hepatitis
- Tuberculosis
- Malignancy
- Allergy

Previous surgery
- **Problems encountered**
- Family history of problems with anaesthesia

Entries in bold need to be recorded even when negative.

Examination

Patients should be treated with respect and dignity, receive a clear explanation of the examination undertaken and be kept as comfortable as possible (*Table 17.2*). A chaperone should be present, especially for intimate examinations. This is will often be part of a local guideline or policy.

In symptomatic patients one should look specifically for evidence of cardiac failure (raised jugular venous pressure (JVP), fine pulmonary crackles, gallop rhythm), peripheral vascular disease (loss of peripheral pulses, ulcerations) and valvular heart disease with characteristic murmurs (e.g. ejection systolic murmur in aortic stenosis, pansystolic murmur in tricuspid regurgitation and mid-diastolic murmur in mitral stenosis heard at respective areas on auscultation). When possible, the medical or surgical treatments for these conditions should be started and the patient stabilised before elective surgery. UK statistics show that patients with cardiac failure or cirrhosis even though on treatment have a high (8%) '30-day mortality' after major surgery.

The presence of a rapid respiratory rate, reduced air entry, crepitations and rhonchi may indicate respiratory problems. A history of dyspnoea along with examination findings of tachycardia, raised JVP, tricuspid regurgitation, hepatomegaly and oedematous feet will indicate severe respiratory disease with pulmonary hypertension and right ventricular failure.

Summary box 17.3

Examination

- General. Positive findings even if not related to the proposed procedure should be explored further
- Surgery related. Type and site of surgery, complications occurred due to underlying pathology
- Systemic. Comorbidities and extent of limitation of each organ function
- Specific. For example, suitability for positioning during surgery

TABLE 17.2 Medical examination.

General	Anaemia, jaundice, cyanosis, nutritional status, sources of infection (teeth, feet, leg ulcers)
Cardiovascular	Pulse, blood pressure, heart sounds, bruits, peripheral oedema
Respiratory	Respiratory rate and effort, chest expansion and percussion note, breath sounds, oxygen saturation
Gastrointestinal	Abdominal masses, ascites, bowel sounds, hernia, genitalia
Neurological	Consciousness level, cognitive function, sensation, muscle power, tone and reflexes
Airway assessment	

Examination specific to surgery

At preoperative assessment, the clinical findings, site, side, specific imaging or investigation findings related to the pathology for which the surgery is proposed should be noted. Suitability of the patient for the proposed surgical option and vice versa should also be assessed. For example, laparoscopic procedures are less invasive and are therefore preferred in most; however, not all patients can tolerate pneumoperitoneum and positioning.

The type of surgery along with patient comorbidities determine perioperative risks, for example perioperative mortality in major surgery such as that of open aortic aneurysm repair in the UK is 3% and that with endovascular repair is 1%.

Sources of potential bacteraemia can compromise surgical results especially if artificial material is implanted, such as in joint replacement surgery or arterial grafting. Check for and treat infections in the preoperative period, e.g. infected toes, pressure sores, teeth and urine; screen the patients for methicillin-resistant *Staphylococcus aureus* colonisation.

Investigations

The National Institute of Health and Care Excellence, UK (NICE) guidelines lay out the investigations needed for various categories of surgery.

Summary box 17.4

Investigations needed

- Type of surgery. Major surgery can lead to organ system dysfunction needing most investigations
- Patient. For example, sickle cell test for patients of Afro-Caribbean origin with family history of sickle cell disease
- Comorbidities. For example, peak flow rates for severe asthmatics

- Full blood count. A full blood count (FBC) is needed for major operations, in the elderly and in those with anaemia or pathology with ongoing blood loss and chronic disease. In case of suspicion or history of sickle crisis, a sickle cell test is needed in patients of Afro-Caribbean and Indian subcontinent origin.
- Urea and electrolytes. Urea and electrolytes (U&Es) are needed before all major operations, in most patients over 65 years of age especially with cardiovascular, renal and endocrine disease, or if significant blood loss is anticipated. It is also needed in those on medications that affect electrolyte levels, e.g. steroids, diuretics, digoxin, non-steroidal anti-inflammatory drugs, intravenous fluid or nutrition therapy and endocrine problems.
- Electrocardiography. Electrocardiography (ECG) is required for those patients over 65 years of age and symptomatic patients with a history of rheumatic fever, diabetes, cardiovascular, renal and cerebrovascular disease, with and without severe respiratory problems. It will also depend on if the surgery is minor/intermediate or major.
- Chest radiograph. Cost-effectiveness and risks of radiation exposure mean that chest radiographs should be restricted to specific patients, such as those with cardiac failure, severe chronic obstructive pulmonary disease (COPD), acute respiratory symptoms, pulmonary cancer, metastasis or effusions or those who are deemed to be at risk of active pulmonary tuberculosis.
- Clotting screen. If a patient has a history suggestive of a bleeding diathesis, liver disease, eclampsia, cholestasis or has a family history of bleeding disorder, or is on antithrombotic or anticoagulant agents then coagulation screening will be needed. However, the effects of antiplatelet agents, low molecular weight heparins and newer agents affecting factor Xa cannot be measured by routine laboratory tests.
- Urinalysis. Dipstick testing of urine should be performed on all patients to detect urinary infection, biliuria, glycosuria and inappropriate osmolality.
- β-Human chorionic gonadotrophin. Women of child-bearing age should be asked sensitively about their pregnancy status. If in doubt a laboratory test or a reliable pregnancy kit (low cost) can be used, after obtaining consent from the patient, to avoid danger of exposure to surgery and anaesthesia on the foetus.
- Blood glucose and HbA1c. Poor control of diabetes can lead to perioperative infection and slow recovery in patients with diabetes mellitus and endocrine problems. HbA1C indicates how well diabetes has been controlled over a longer duration. Early mobilisation, oral intake and return to routine medication should be the goals in management of diabetes.
- Arterial blood gases. A low-cost tool that can give quick and vital information in acute or chronic severe respiratory conditions, acid–base disturbances and conditions where there is changing milieu, e.g. immediately before kidney transplant.
- Liver function tests. These are indicated in patients with jaundice, known or suspected hepatitis, cirrhosis, malignancy or in patients with poor nutritional status.
- Other investigations. Specialist radiological views and recent imaging are sometimes required. If imaging is going to be needed during surgery, then this needs to be planned in advance.

SPECIFIC PREOPERATIVE PROBLEMS AND MANAGEMENT

Specific medical problems encountered during preoperative assessment should be corrected to the best possible level. Many patients with severe disease (see later) will need to be referred to specialists; the referral letter should include all the details including history, examination and investigation results.

Cardiovascular disease

Perioperative cardiovascular complications are frequent. Patients who can climb a flight of stairs without getting short of breath or chest pain or needing to stop are likely to

Summary box 17.5

Preoperative management of patients with systemic disease

- Capacity. Baseline organ function capacity should be assessed
- Optimisation. Medication, lifestyle changes, specialist referral will improve organ capacity
- Alternative. Minimally impacting procedure, appropriate postoperative care will improve outcomes
- Theatre preparations. Timing, teamwork, special instruments and equipment

tolerate a wide range of surgeries with an acceptable risk of perioperative cardiovascular morbidity and mortality. However, at preoperative assessment it is important to identify the patients who have a high perioperative risk of major adverse cardiovascular events (MACE) including myocardial infarction (MI), and make appropriate arrangements to reduce this risk. Patients at high risk are those with ischaemic heart disease (IHD), congestive cardiac failure (CCF), arrhythmias, severe peripheral vascular disease, cerebrovascular disease or significant renal impairment, especially if they are undergoing major intra-abdominal or intra-thoracic surgery.

In patients with ischaemic heart disease the cardiac and coronary reserve can be evaluated using a stress test (stress ECG, stress echocardiogram, myocardial scintigraphy). The tests have a high negative predictive value but a relatively low positive predictive value. If the test is negative, the patient is unlikely to have IHD; conversely, if it is positive the chances of the patient actually having IHD is not necessarily very high, but there is a need for further investigation such as coronary angiography. Recently, measurement of the fractional coronary flow reserve (FFR) during coronary angiography using a pressure wire, has made it possible to identify coronary lesions that have the largest impact on myocardial perfusion.

In patients with any suggestion of valvular heart disease or poor left ventricular function, an echocardiogram should be obtained. Pressure gradients across the valves, dimensions of the chambers and contractility can be determined using echocardiography; an ejection fraction of less than 30% is associated with poor patient outcomes.

Cardiopulmonary exercise testing provides a non-invasive assessment of combined pulmonary, cardiac and circulatory function.

The patient should be referred to a cardiologist if:

- A murmur is heard and the patient is symptomatic.
- The patient is known to have poor left ventricular function or cardiomegaly.
- Ischaemic changes can be seen on ECG even if the patient is not symptomatic (silent ischaemia, silent MIs are frequent).
- There is an abnormal rhythm on the ECG, for example tachy-/bradycardia or heart block.

Hypertension, ischaemic heart disease (IHD) and coronary stents

Prior to elective surgery blood pressure should be controlled to near 160/100 mmHg. If a new antihypertensive agent is introduced, a stabilisation period of at least 2 weeks should be allowed.

Patients with angina, that is not well controlled, should be investigated further by a cardiologist. The indications for coronary revascularisation in these patients before major surgery are the same as the medical indications. Pharmacological protection is indicated. Patients on β-blockers and on statins should be maintained on their medication. Initiating statins preoperatively should be considered. Most long-term cardiac medications should be continued over the perioperative period. Angiotensin-converting enzyme (ACE) inhibitors and receptor blockers are often omitted 24 hours prior to surgery and reintroduced gradually in the postoperative period.

After a proven myocardial infarction (**Figure 17.1**), elective surgery should be postponed for 3–6 months to reduce the risk of perioperative reinfarction. As primary percutaneous intervention is the treatment of choice for acute coronary syndromes, many patients receive stents and are on dual antiplatelet therapy for 12 months. If surgery is absolutely necessary within the period of dual antiplatelet therapy, the management strategy should be decided jointly by surgeon, cardiologist, anaesthetist and patient, as it is essential to consider the balance of risk of continuing antiplatelet agents (with the risk of increased bleeding) and stopping them (with the risk of stent thrombosis).

The risk of stent thrombosis with consequences of MI and death is reduced if elective surgery is delayed until after dual antiplatelet therapy is no longer needed (about 6 weeks after bare metal and 12 months after drug-eluting stent insertion, although with the newest drug-eluting stents 6 months dual antiplatelet therapy may be enough).

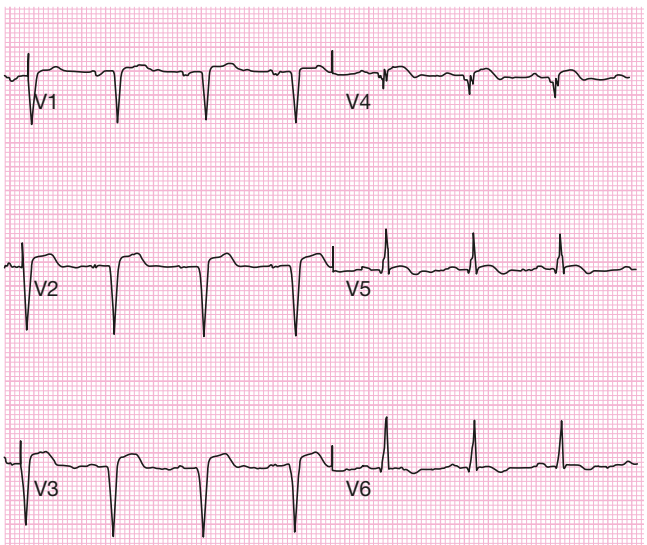

Figure 17.1 Preoperative electrocardiogram of a patient who complained of chest pain the previous day, showing recent transmural anterior myocardial infarction with Q waves and ST elevation.

If surgery cannot be postponed and the risk of significant perioperative bleeding is low, dual antiplatelet therapy can be continued during surgery. If the benefits of surgery can be negated by bleeding in closed cavities (spinal, intracranial, cardiac, posterior chamber of the eye and prostate surgery) clopidogrel or ticagrelor therapy may have to be stopped and, if possible, aspirin continued. However, a cardiology opinion should be sought.

Dysrhythmias

In patients with atrial fibrillation, β-blockers, digoxin or calcium channel blockers should be started preoperatively (or continued if the patient is already on such medication) in order to control rate and possibly rhythm. Cardiac output can increase by 15% if sinus rhythm is restored. Warfarin in patients with atrial fibrillation (AF) should be stopped 5 days preoperatively to achieve an international normalised ratio (INR) of 1.5 or less, which is safe for most surgery. The newer anticoagulants such as dabigatran (direct thrombin inhibitor) or rivaroxaban, apixaban and edoxaban (direct factor Xa inhibitors) do not have antagonists and must be stopped preoperatively, generally for 2–3 days in patients with normal renal function and longer when renal function is impaired. Alternative anticoagulation is not required in the perioperative period unless the risk of stroke is high (high CHA2DS2-VACs score). Bridging therapy with unfractionated heparin or low molecular weight heparin (LMWH) is recommended for patients with AF and a mechanical heart valve undergoing procedures that require interruption of warfarin. Decisions on bridging therapy should balance the risks of stroke and bleeding.

Implanted pacemakers and cardiac defibrillators

Checks and appropriate reprogramming should be done preoperatively by specialists. Monopolar diathermy activity during surgery may be sensed by the pacemaker as ventricular fibrillation. Therefore, cardioversion and overpace modes must be turned off (and switched on after surgery) or converted to 'ventricle paced, not sensed with no response to sensing' (VOO) mode. Bipolar diathermy should be made available at surgery.

Symptomatic heart blocks and asymptomatic second- (Mobitz II) and third-degree heart blocks, if discovered at preoperative assessment clinic, will need cardiology consultation and temporary or permanent pacemaker insertion.

Figures 17.2 and 17.3 illustrate ECGs from two cases requiring preoperative optimisation.

Valvular heart disease

While anaesthetic management is altered to achieve haemodynamic stability in moderate valvular diseases, the patients with severe aortic and mitral stenosis may benefit from valvuloplasty before elective non-cardiac surgery. Appropriate referral to anaesthetist and cardiologist should be made.

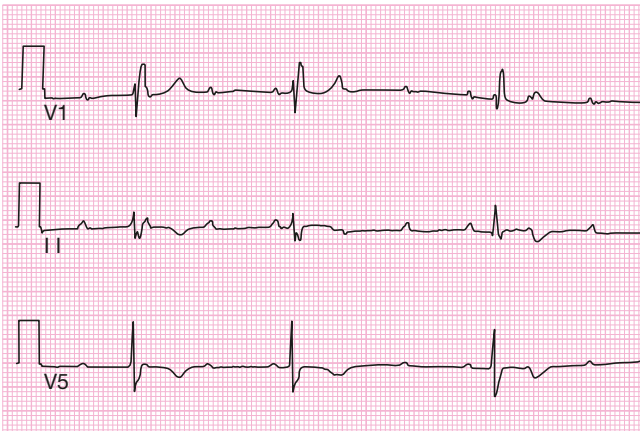

Figure 17.2 Routine preoperative electrocardiogram in an 83-year-old patient with no symptoms other than lethargy for the last 3 months. This shows complete heart block with dissociated P waves and QRS complexes, requiring preoperative pacing.

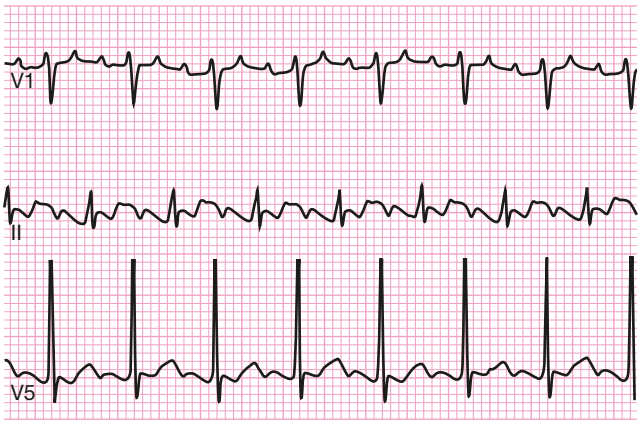

Figure 17.3 Atrial flutter.

In patients with mechanical heart valves, warfarin needs to be stopped for 5 days before surgery, and an infusion of unfractionated heparin started when the INR falls below 1.5. The activated partial thromboplastin time (APTT), should be monitored to keep it at 1.5 times normal and the infusion is then stopped 2 hours before surgery. Heparin and warfarin should be started in the postoperative period, and heparin is stopped when the full effect of warfarin takes effect. Thrombin inhibitors and factor Xa inhibitors are not licensed and should not be used in patients with mechanical valves.

Anaemia and blood transfusion

Patients found to be anaemic at preoperative assessment should be investigated for the cause of their anaemia. They should be treated with iron and vitamin supplements. Chronic anaemia is well tolerated in the perioperative period; however, if the patient is undergoing a major procedure preoperative transfusion may be considered. If excessive bleeding is expected, then a preoperative 'group and save' should be performed and an appropriate number of units of blood cross-matched.

Some patients may refuse blood transfusion, for example a Jehovah's witness. In such a case, during the consent process (see later) discussion should include which blood product and/or device system (e.g. cell salvage, reinfusion from drains) is acceptable. The discussion should extend to other areas, for example whether refusal of transfusion would apply in life-threatening situations. As in all consent processes, the discussion and outcome should be clearly documented (see Further reading; RCS 2016).

Respiratory disease

Postoperative respiratory complications, such as pneumonia, are a major cause of morbidity and mortality especially after major abdominal and thoracic surgery. A patient's current respiratory status should be compared with their 'normal state'. Make a note of the severity of the asthma and COPD, such as past hospital admissions for treatment of the condition, records of pulmonary function tests, use of oral steroids, home oxygen, non-invasive ventilation support and evidence of right heart failure.

A preoperative chest radiograph or scan is useful in a patient with known emphysematous bullae, pulmonary cancer, metastasis or effusions.

Patients on oral steroid treatment, oxygen therapy or who have a forced expiratory volume in the first second (FEV_1) less than 30% of predicted value (for age, weight and height), or $PaCO_2$ level of greater than 6kPa, have severe disease and are at risk of pneumonia and respiratory failure in the postoperative period.

Patients should continue to use their regular inhalers until the start of anaesthesia. Brittle asthmatics may also need extra steroid cover. Encourage the patients to be compliant with the medications, take a balanced diet and stop smoking. Information should be provided to indicate perioperative risks associated with smoking. Stopping smoking reduces carbon monoxide levels and offers the patient a better ability to clear sputum. Evidence suggests that preoperative inspiratory muscle training significantly improves respiratory (muscle) function in the early postoperative period, reducing the risk of pulmonary complications.

Regional anaesthetic techniques and less invasive surgical options should be considered in severe cases. Elective surgery should be postponed until acute exacerbations are treated.

The patient should be referred to a respiratory physician if:

- There is a severe disease or significant deterioration.
- Major surgery is planned in a patient with significant respiratory comorbidities.
- Right heart failure is present – dyspnoea, fatigue, tricuspid regurgitation, hepatomegaly and oedematous feet.
- The patient is young and has severe respiratory problems (indicates a rare condition).

Gastrointestinal disease

Nil by mouth and regular medications

Patients are advised not to take solids within 6 hours and clear fluids (isotonic drinks and water) within 2 hours before anaesthesia to avoid the risk of acid aspiration syndrome. These restrictions are further reduced in infants, as keeping hydrated reduces discomfort and is known to improve postoperative outcomes.

If the surgery is delayed, oral intake of clear fluids should be allowed until 2 hours before surgery or intravenous fluids should be started, especially in vulnerable groups of patients, e.g. children, the elderly and diabetics.

Patients can continue to take their specified routine medications with sips of water in the NBM period.

Regurgitation risk

Patients with hiatus hernia, obesity, pregnancy and diabetes are at high risk of pulmonary aspiration, even if they have been NBM before elective surgery. Clear antacids, H2-receptor blockers, e.g. ranitidine, or proton pump inhibitors, e.g. omeprazole, may be given at an appropriate time in the preoperative period.

Liver disease

In patients with liver disease, the cause of the disease needs to be known, as well as any evidence of clotting problems, renal involvement and encephalopathy. Elective surgery should be postponed until any acute episode has settled (e.g. cholangitis). The blood tests that need to be performed include liver function tests, coagulation, blood glucose and U&Es. The presence of ascites, oesophageal varices, hypoalbuminaemia and sodium and water retention should be noted, as all can influence the choice and outcome of anaesthesia and surgery.

Genitourinary disease

Renal disease

Underlying conditions leading to chronic renal failure such as diabetes mellitus, hypertension and ischaemic heart disease, should be stabilised before elective surgery. Appropriate measures should be taken to treat acidosis, hypocalcaemia and hyperkalaemia of greater than 6 mmol/L. Arrangements should be made to continue peritoneal or haemodialysis until a few hours before surgery. After the final dialysis before surgery, a blood sample should be sent for FBC and U&Es.

Chronic renal failure patients often suffer chronic microcytic anaemia that is well tolerated; therefore, preoperative blood transfusion is often not necessary.

Acute kidney injury can present with an acute surgical problem, for example bowel obstruction needing emergency surgery. In these patients, medical treatment should be started at the earliest opportunity and carried on through surgery and through into the critical care unit.

Urinary tract infection

Uncomplicated urinary infections are common in women, while outflow uropathy with chronically infected urine is common in men. These infections should be treated before embarking on elective surgery where infection carries dire consequences, e.g. joint replacement. For emergency procedures, antibiotics should be started and care taken to ensure that the patient maintains a good urine output before, during and after surgery.

Endocrine and metabolic disorders

Malnutrition

Body mass index (BMI) is weight in kilograms divided by height in metres squared. A BMI of less than 18.5 indicates nutritional impairment and a BMI below 15 is associated with significant hospital mortality. Nutritional support for a minimum of 2 weeks before surgery is required to have any impact on subsequent morbidity.

If a patient is unlikely to be able to eat for a significant period, arrangements should be made by the preoperative assessment team to start nutritional support in the immediate postoperative phase.

Obesity

Morbid obesity can be defined as BMI of more than 35 (other definitions exist) and is associated with increased risk of postoperative complications. Patients should be made aware of risks involved and advised on healthy eating and taking regular exercise.

Associated sleep apnoea can be predicted by using a clinical scoring system, the perioperative sleep apnoea prediction (P-SAP) score or sleep apnoea studies. There is evidence to suggest that patient outcomes improve with more than 6 weeks of use of a continuous positive airway pressure (CPAP) device preoperatively, and cholesterol reducing agents in the perioperative phase.

If possible surgery should be delayed until the patient is more active and has lost weight. If this fails, prophylactic measures need to be taken (such as preventative measures for acid aspiration and DVT) and associated risks need to be explained prior to the surgery.

Diabetes mellitus

Diabetes and associated cardiovascular and renal complications should be controlled to as near normal level as possible before embarking on elective surgery. Any history of hyper- and hypoglycaemic episodes, and hospital admissions, should be noted. HbA1c levels should be checked. For elective surgery, HBA1c of <69 mmol/mol is recommended. Lipid-lowering medication should be started in patients who are in a high-risk group for cardiovascular complications of diabetes.

Patients with diabetes should be first on the operating list and, if the operation is in the morning, advised to omit the morning dose of medication and breakfast. Though tight control of blood sugar is not needed, the patient's blood sugar levels should be checked 2 hourly. For those on the afternoon list, breakfast can be given with half their regular dose of intermediate-acting insulin (or full dose oral antidiabetic agents) and then managed with regular blood sugar checks as above. An intravenous insulin sliding scale should be started for insulin-dependent diabetes mellitus patients undergoing major surgery, or if blood sugar is difficult to control for other reasons.

Adrenocortical suppression

Patients receiving oral adrenocortical steroids should be asked about the dose and duration of the medication in view of supplementation with extra doses of steroids perioperatively, to avoid an Addisonian crisis.

Coagulation disorders

Thrombophilia

Patients with a strong family history or previous personal history of thrombosis should be identified (*Table 17.3*). They will need thromboprophylaxis in the perioperative period.

The progesterone-only contraceptive pill should be continued; however, the risks of continuing the combined pill (slight increase risk of significant thrombosis) should be weighed against the risks of an unplanned pregnancy. Consider stopping oestrogen-containing oral contraceptives or hormone replacement therapy 4 weeks before surgery (NICE guidance; see Further reading). The reader is advised to use an appropriate resource for precise formulation information and current guidance.

Patients with a low risk of thromboembolism can be given thromboembolism-deterrent stockings to wear during the perioperative period. High-risk patients with a history of recurrent DVT, pulmonary embolism and arterial thrombosis will be on warfarin. This should be stopped before surgery and replaced by low molecular weight heparin or factor Xa inhibitors. Local or national guidelines advise what type of DVT prophylaxis should be used for each type of surgery.

Neurological and psychiatric disorders

In patients with a history of stroke, pre-existing neurological deficit should be recorded. These patients may be on anti-

TABLE 17.3 Risk factors for thrombosis.

- Age >60 years
- Obesity BMI >30 kg/m^2
- Trauma or surgery (especially of the abdomen, pelvis and lower limbs), anaesthesia >90 minutes
- Reduced mobility for more than 3 days
- Pregnancy/puerperium
- Varicose veins with phlebitis
- Drugs, e.g. oestrogen contraceptive, HRT, smoking
- Known active cancer or on treatment, significant medical comorbidities, critical care admission
- Family/personal history of thrombosis, e.g. deficiencies in antithrombin III, protein S and C

Thomas Addison, 1795–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1849.

platelet agents or anticoagulants. If it is felt that the neurological and cardiovascular thrombotic risks are low, antiplatelet agents should be withdrawn (7 days for aspirin, 10 days for clopidogrel). If the thrombotic risks are perceived to be high and the patient is undergoing surgery with a high risk of bleeding, aspirin alone should be continued.

Anticonvulsants and anti-Parkinson medication is continued perioperatively to help early mobilisation of the patient.

Lithium should be stopped 24 hours prior to surgery; blood levels should be measured to exclude toxicity. The anaesthetist should be informed if patients are on psychiatric medications such as tricyclic antidepressants or monoamine oxidase inhibitors, as these may interact with anaesthetic drugs.

Musculoskeletal disorders

Rheumatoid arthritis can lead to an unstable cervical spine with the possibility of spinal cord injury during intubation. Therefore, flexion and extension lateral cervical spine radiographs should be obtained in symptomatic patients (**Figures 17.4 and 17.5**).

Assessment of the severity of renal, cardiac valvular and pericardial involvement as well as restrictive lung disease, should be carried out. Rheumatologists will advise on steroids and disease-modifying drugs so as to balance immunosuppression (chance of infections) against the need to stabilise the disease perioperatively (stopping disease modifying drugs can lead to flare-up of the disease).

In ankylosing spondylitis patients, in addition to the problems discussed above, techniques of spinal or epidural anaesthesia are often challenging. Patients with systemic lupus erythematosus may exhibit a hypercoagulable state along with airway difficulties.

With certain types of orthopaedic operations, such as joint replacement, antibiotic prophylaxis will be required, and will usually follow specific local or national guidelines.

Airway assessment

The ability to intubate the trachea and oxygenate the patient are basic and crucial skills of the anaesthetist. The ease or difficulty encountered when performing airway manoeuvres can be predicted by simple examination findings of full mouth opening (modified Mallampati class), jaw protrusion, neck movement and thyromental distance. The anaesthetist should look for loose teeth, obvious tumours, scars, infections, obesity, thickness of the neck, etc., which will indicate difficulty in visualising the airway. When more than one of the above tests are positive, the chances of experiencing difficulty in obtaining and securing the airway become greater. To obtain the modified Mallampati class, the anaesthetist sits in front of the patient who is asked to open their mouth and protrude the tongue (**Figure 17.6**). The higher the grade, the higher the risk in obtaining and securing an airway (*Table 17.4*).

Figure 17.4 Extension view of cervical spine in patient with rheumatoid arthritis.

Figure 17.5 Flexion view in the same patient as in Figure 17.4. Note the large increase in the atlantodens interval, implying significant instability at this level.

Preoperative assessment in emergency surgery

In urgent or emergency surgery the principles of preoperative assessment should be the same as in elective surgery, except that the opportunity to optimise the condition is limited by time constraints. Medical assessment and treatments should be started (e.g. as per Advanced Trauma Life Support guidelines) even if there is no time to complete them before the start of the surgical procedure. Some risks may be reduced but some may persist and, whenever possible, these need to be explained to the patient.

SR Mallampati published the original article suggesting that the size of the base of the tongue is an important factor determining the degree of difficulty of direct laryngoscopy in the *Canadian Anaesthetists' Society Journal* in 1985. The original Mallampati classifications was modified from a total of three to four classes by **GLT Sampsoon** and **JRB Young** after reviewing a series of obstetric and general surgical patients who had had difficult intubations.

Summary box 17.6

Preoperative assessment for emergency surgery

- Start. Similar principles to that for elective surgery
- Constraints. Time, facilities available
- Consent. May not be possible in life-saving emergencies
- Organisational efforts. For example, local/national algorithms for treatment of the patient with multiple injuries

ASSESSMENT OF THE HIGH-RISK PATIENT

Despite higher-risk patients presenting for surgery, the perioperative mortality has decreased significantly over the last half a century, especially in resource-rich countries. In a published systematic review in *The Lancet* (Bainbridge *et al.*, 2012), perioperative mortality has declined from 10 603 per million (95% CI: 10 423–10 784) in the 1970s to 1176 per million (1148–1205) in the 1990s–2000s ($p<0{\cdot}0001$). However, there remains a subgroup of patients who are at higher risk of morbidity and mortality after surgery. By identifying high-risk patients in the preoperative phase and planning their perioperative management, morbidity and mortality can be reduced.

Patients who have a predicted mortality ≥5% should be considered as 'high risk'. It is estimated that although the high-risk group accounts for less than 15% of all surgical procedures, they contribute to more than 80% of all perioperative deaths in UK.

What causes these patients to be at a high risk of death and complications after surgery? After surgery tissue destruction, blood loss, fluid shifts, changes in temperature, pain and anxiety result in increased demands for oxygen delivery to the tissues. This demand increases from an average of 110 mL/min/m^2 at rest to 170 mL/min/m^2 in the postoperative period. Most patients meet this increase in demand by increasing their cardiac output and tissue oxygen extraction. Patients who are unable to meet these demands, as a result of a limited cardiorespiratory reserve, are at a risk of oxygen debt.

Occult hypovolemia resulting from fluid shift or blood loss can further impair oxygen delivery. Splanchnic vasoconstriction to compensate for this may result in gut ischaemia. Those with coronary or cerebrovascular disease are also at a higher risk of myocardial ischaemia or stroke.

Factors contributing to risk

Risk is a complex interaction of multiple factors that can be classified into patient and surgical factors. Patient factors are listed in *Table 17.5*. The elderly, though not independently at higher risk, not only suffer more cardiac, pulmonary and renal disease but also require surgery four times as often as the rest of the population. Around 10% of the population over 65 have frailty with increasing incidence with age. Frailty is a distinctive state that is related to ageing. Multiple body systems lose their in-built reserves in the elderly.

The type of surgery contributes independently and is listed in *Table 17.6*. This risk increases if the surgery is performed as an emergency. Often, the underlying condition necessitating surgery itself may be associated with an increased risk of complications. For example, a patient with severe peripheral vascular disease resulting from heavy smoking, may need a femoral-popliteal bypass graft and can be expected also to have significant COPD and IHD.

Moreover, when mortality by type of surgery is adjusted for patient risk factors, the apparent hierarchy of surgical risk may change. The average mortality risk for an individual patient undergoing thoracic surgery, for example, is likely to be higher than the average risk for that same patient undergoing vascular surgery. Complications associated with the latter are nevertheless more frequent because vascular patients have greater medical risk factors (*Table 17.7*).

TABLE 17.5 Patient factors that predispose to high risk of morbidity and mortality.

Previous severe cardiorespiratory illness, e.g. acute myocardial infarction, COPD or stroke
Late stage vascular disease involving aorta
Age >70 years with limited physiological reserve in one or more vital organs
Extensive surgery for carcinoma
Acute abdominal catastrophe with haemodynamic instability (e.g. peritonitis)
Acute massive blood loss >8 units
Septicaemia
Positive blood culture or septic focus
Respiratory failure: PaO_2 <8 kPa or FiO_2 >0.4 or mechanical ventilation >48 h
Acute renal failure: urea >20 mmol or creatinine >260 mmol/L

(Based on clinical criteria used by Shoemaker and colleagues modified by Boyd.)

TABLE 17.6 Surgery specific estimates of risk

High risk (cardiac risk >5%)	Intermediate risk (cardiac risk 1–5%)	Low risk (cardiac risk <1%)

(From Eagle *et al*. *J Am Coll Cardiol* 2002; **39**(3): 542–53.)

TABLE 17.7 The effect of adjustment for patient factors on surgery-specific operative mortality.

Type of surgery	Unadjusted 30-day mortality (% (rank))	Adjusted 30-day mortality (%(rank))
Vascular	5.97 (1)	0.98 (5)
Thoracic	3.40 (2)	2.28 (1)
Abdominal	2.73 (3)	1.83 (2)
Cardiac	2.70 (4)	1.13 (4)
Neurosurgery	1.74 (5)	1.60 (3)
Orthopaedic	1.25 (6)	0.49 (7)
ENT	0.85 (7)	0.68 (6)
Urology	0.81 (8)	0.38 (8)
Gynaecology	0.13 (9)	0.17 (9)
Breast	0.07 (10)	0.08 (10)

(Modified from Noordzij *et al*. 2010.)

In summary, the typical high-risk patient is the elderly patient with coexisting conditions such as IHD and/or COPD undergoing major surgery. The risk will increase if the surgery is performed as an emergency.

Management of risk

The key to managing patients effectively is the identification and accurate quantification of the risk, and subsequent measures taken to minimise it.

Realistic estimates of risk are the cornerstone of informed patient consent and shared decision making. The patient and the surgeon may choose a less extensive or even a non-surgical option where risks of the definitive procedure are deemed to be too high or unacceptable. The Royal College of Surgeons (RCS) of England has recommended that the patients who are predicted to have greater than 5% mortality risk should have active consultant input in all stages of their management.

Surgical procedures in those with predicted mortality of >10% should be conducted under the direct supervision of consultant surgeon or anaesthetist, unless the consultants are satisfied with the seniority and competence of the staff managing these patients. Moreover, those with a mortality >10% should be managed in the critical care facility.

Depending on particular comorbidities, it may be possible for a patient's underlying conditions to be improved by optimising their medical therapy. Additional physiological optimisation may take the form of measures to minimise myocardial ischaemia or measures to improve oxygen delivery to the other major organs, depending on the prevailing risks.

Optimisation before surgery can be more effective in a critical care environment and patients may need to be admitted to a high dependency unit (HDU) or intensive therapy unit (ITU) preoperatively. The likelihood of the high-risk patient requiring postoperative critical care should be planned preoperatively and discussed with the duty critical care physician.

The identification of patients who will benefit the most from these interventions is important, not only for the improvement of outcomes but also the effective allocation of resources. As discussed above, emergency surgery is associated with higher risks because by its very nature there is less time and opportunity to organise these additional levels of care.

Summary box 17.7

A practical approach to the care for the high-risk patient

- Identify the high-risk patient
- Assess the level of risk
- Detailed preoperative assessment
- Adequate resusciatation
- Optimise medical management
- Investigation to define the underlying surgical problem
- Immediate and definitive treatment of underlying problems
- Consider admission to a critical care facility postoperatively

Identification of the high-risk patient

A number of scoring systems have been developed over the years with the aim of identifying high-risk patients (*Table 17.8*).

American Society of Anaesthesiologists system

The American Society of Anaesthesiologists (ASA) scoring system is widely used. Although not designed to be used as a risk prediction score, it has a quantitative association with the predicted percentage of postoperative mortality (*Table 17.9*). However, it does not account for age or nature of surgery and the term 'systemic disease' in ASA grading introduces an element of 'subjectivity'.

Metabolic equivalent

As discussed earlier, overall functional physical fitness can be judged by the ability to tolerate metabolic equivalent tasks (METs) (*Table 17.10*). One MET is equivalent to the oxygen consumption of an adult at rest (~3.5 mL/kg/min). Different tasks are assigned a number of METs. If the patient is able to perform >4 METs (e.g. climbing at least one flight of stairs) they are considered suitable candidates for major surgery. However, once again this depends on a subjective assessment of the ability of a patient and may be overestimated by them.

Objective indices based on weighted scores pertaining to surgery and comorbidity, have been created to stratify cardiac risk. Examples include the Goldman cardiac risk index and

TABLE 17.8 Surgical risk scores classified by outcome measures and need for intraoperative information.

	Scores predicting mortality	Scores predicting morbidity

TABLE 17.10 Metabolic equivalent of task (MET).

- 1 MET = 3.5 mL O_2/kg/min (oxygen consumption by 40-year-old,70 kg man at rest)
- 1 MET = eating and dressing
- 4 MET = climbing 2 flights of stairs
- 6 MET = short run
- >10 MET = able to participate in strenuous sport
- Patients who can exercise at 4 METS or above have lower risk of perioperative mortality

the revised cardiac risk index (RCRI) of Lee (*Table 17.11*). Although they can predict risk of cardiac complications, they are not designed to predict mortality.

POSSUM score

The POSSUM score (Physiologic and Operative Severity Score for the enUmeration of Mortality and Morbidity) and its modifications (P-POSSUM, CR-POSSUM) are used to predict all-cause mortality in postoperative critical care patients as well as non-cardiac morbidity.

TABLE 17.11 The revised cardiac risk index (RCRI) of Lee.

Risk factors	Risk of major cardiac complications (%)
History of ischaemic heart disease History of compensated or prior heart failure History of cerebrovascular disease Diabetes mellitus Renal insufficiency (creatinine >177 μmol/L) High-risk surgery	Number of factors 0 = 0.4 1 = 0.9 2 = 7.0 3+ = 11.0

ACS NSQIP score

The American College of Surgeons (ACS) National Surgical Quality Improvement Programme (NSQIP) surgical risk score estimates the chance of a complication or death after surgery for more than a thousand different surgical procedures. It compares the patient's risk with an average person's risk. It is a web based tool done preoperatively. The risk is calculated based on surgical procedure and 19 patient-specific preoperative risk factors.

Cardiopulmonary exercise testing

Cardiopulmonary exercise testing (CPET) can be used as a screening tool to identify high-risk patients. The oxygen (O_2) consumption and carbon dioxide (CO_2) production of the patient are measured while they undergo a 10 minute period of incrementally demanding exercise (usually on a cycle ergometer) up to their maximally tolerated level (**Figure 17.7**).

CPET is based on the principle that when a subject's delivery of O_2 to active tissues becomes inadequate, anaerobic metabolism begins; lactate is buffered by bicarbonate and the resulting CO_2 increases out of proportion to the escalation in physical difficulty and O_2 consumption. The 'anaerobic threshold' (AT) is the O_2 consumption in mL/kg/min above

Lee Goldman, b.1948, Dean of Health Sciences and Medicine, Columbia University, New York, NY, USA, since 2006. He developed his Index in 1977.
Thomas H Lee, Professor of Medicine, Harvard Medical School, Professor of Health Policy and Management, Harvard School of Public Health, Boston, MA, USA.

Figure 17.7 Cardiopulmonary exercise testing (CPET).

which this occurs. Peak oxygen consumption (VO_2) is also measured. They are the end product of a subject's combined respiratory, cardiac, vascular and musculoskeletal fitness, and subjects with either an AT above a somewhat arbitrary cut-off of 11 and a VO_2 below 15 mL/kg/min are at higher risk of morbidity and mortality after surgery.

When CPET is not available, a simple walk test, such as the 6-minute walk test (6MWT) and the incremental shuttle walk test (ISWT), can be used to assess the functional capacity of the patient. They depend on the patient's ability to walk for a fixed 6 minute period or at increasing speed over a flat surface.

Optimisation of the high-risk patient

As discussed above, all coexisting disease processes should be reviewed and optimised. Simple measures include stopping smoking (maximal benefit only seen if stopped for 8 weeks prior to surgery), reducing alcohol intake, losing weight, improving nutrition and/or haemoglobin levels.

In the high-risk group there may a need for more complex investigations, review of medication or even consideration of further surgery. Patients scheduled for abdominal aortic aneurysm (AAA) repair surgery for example, frequently require carotid duplex scans. If the scans reveal a significant blockage and a high risk of perioperative stroke, a carotid endarterectomy may be indicated prior to AAA repair.

All high-risk patients benefit from multidisciplinary team care and the involvement of experienced physicians in the perioperative period. The impact and management of the comorbidities that commonly contribute to risk are outlined below.

Ischaemic heart disease

Perioperative myocardial infarction (MI) is associated with a high mortality (15–25%). Ischaemia, and ultimately MI, occur when the supply of oxygen to the myocardium is exceeded by its demand. This situation can be precipitated by hypotension, tachycardia and procoagulant states (of which the inflammatory response to surgery is an example).

Preparation of these patients for surgery should aim to optimise myocardial oxygen supply and demand ratio and so minimise the risk of myocardial ischaemia developing. This work may involve further investigations or even the decision to postpone non-cardiac surgery for 3–6 months after an MI. Some patients may require preoperative revascularisation, using either a coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) with a stent or angioplasty.

Minimising myocardial ischaemia

Anaesthesia techniques that dampen the stress response to surgery (especially minimising pain) and provide a good degree of cardiac stability should be used. Anaesthesia should avoid tachycardia, systolic hypertension and diastolic hypotension, and may be facilitated by the use of invasive arterial blood pressure monitoring. Blood loss must be accurately monitored and haemoglobin maintained at a level suitable for the patient's cardiac risk factors. Perioperative use of β-blockers may be considered but this is controversial.

Troponin testing allows early diagnosis of perioperative MIs, but there are limited reperfusion options due to risk of bleeding from the surgical site. Admission to HDU should be considered for patients with IHD and supplemental oxygen therapy continued for 3–4 days.

Cardiac failure

Left ventricular failure is the end result of several conditions including IHD, hypertension, cardiomyopathies and valve dysfunction. Decompensated heart failure puts the patient at risk of multiorgan failure. Those with ejection fractions of less than 35%, and in whom the failure is undiagnosed or its severity underestimated, are at the highest risk. The patient's functional capacity needs to be assessed and surgery may have to be delayed for investigations such as an echocardiogram and/or for optimisation of medical therapy. Drugs used in chronic heart failure have significant implications for perioperative care, and β-blockers and probably ACE inhibitors (unless renal perfusion is to be significantly affected) should be continued. Anaesthesia should ensure minimal myocardial depression and change in afterload during surgery. Arrhythmias must be rapidly brought under control, particularly AF, and correcting any electrolyte imbalance is crucial in this respect. Invasive monitoring of trends in central venous and arterial pressure monitoring may help management, particularly when large fluid shifts are expected to occur.

Respiratory failure

Around 1.5% of patients develop lower respiratory tract infection after surgery with a 30-day mortality over 20%. Surgery, particularly open abdominal procedures under general anaesthesia, result in changes to respiratory physiology. The functional residual capacity of the lungs is reduced. This combined with the respiratory depressant effect of residual anaesthetic agents, the patient's limited mobility and pain from surgery causes atelectasis (failure of gas exchange due to alveolar collapse) and predisposes patients to postoperative

respiratory infection. Other complications including bronchospasm, pneumothorax and acute respiratory distress syndrome (ARDS) contribute as much to morbidity and length of hospital stay as cardiac complications. Respiratory failure defined as a PaO_2 <8 kPa in air, PaO_2/FiO_2 <40 kPa or inability to extubate a patient 48 hours after surgery, is by far the most significant of these and is associated with a mortality of 27–40%.

Again, as with cardiac risk management, it may be necessary to postpone surgery to allow medical optimisation or consider a non-operative option. Preoperatively, bronchodilator therapy will be required in those with reversible obstructive airway disease and steroids may need to be started or increased. Nutritional status should be optimised and albumin levels corrected. Physiotherapy for postural drainage, and deep breathing exercises or incentive spirometry should be considered for patients at increased risk of respiratory complications. General anaesthesia is associated with more respiratory complications and so regional techniques should be considered where possible in these patients. Hypoxemia and CO_2 retention leading to the need for reintubation is better avoided in those at risk, by delaying extubation until analgesia, hydration and acid–base status have been corrected. Patients may benefit from ITU admission and this needs planning. Application of non-invasive respiratory support (**Figure 17.8**) may allow certain patients to be extubated earlier.

Other comorbidities

Acute kidney injury, chronic kidney disease, diabetes, peripheral vascular disease and liver dysfunction are some of the medical conditions that contribute to risk and need to be optimised.

Sepsis

Sepsis needs urgent identification and treatment, as if not treated early it can lead to either a prolonged admission to a critical care unit or death. Early resuscitative measures in sepsis include administering broad spectrum antibiotics and treating hypotension, hypovolemia and elevated lactate levels with appropriate intravenous fluids. It is also important to deal with the source of sepsis as early as possible.

Minimising the impact of surgery in the high-risk patient

There are situations where the selection of one surgical technique over another may be significantly influenced by patient risk factors. Some procedures are not primarily high-risk but may become so in unsuitable patients. Laparoscopic surgery, for example, has come of age as a preferred technique for patients predisposed to postoperative respiratory complications, but its effect on cardiac physiology means the same may not apply to patients at risk of cardiac complications. The expanding demand and indications for minimal access surgery are now pushing the boundaries of intraoperative physiological tolerance. Robotic prostatectomy and some laparoscopic colorectal procedures require a pneumoperitoneum with steep Trendelenburg (head down) positioning for several hours (**Figure 17.9**). This can be associated with adverse cardiovascular and neurological complications, such as myocardial ischaemia and increased intracranial pressure in the high risk group. This risk may be minimised by attention to patient selection.

Role of critical care and outreach services

Optimal care in the high-risk group should be extended to include postoperative support, which for a majority of these patients means admission to a critical care bed. Reports from the National Confidential Enquiry into Surgical Deaths (NCEPOD) show that the majority of postoperative deaths

Figure 17.8 Non-invasive ventilation.

Figure 17.9 Robotic surgery.

Figure 17.10 A high-risk patient admitted to the intensive care unit postoperatively.

in the UK occur more than 5 days after surgery. Admission to a critical care unit allows for early intervention and a level of care that is difficult to deliver in the ward environment during this crucial period (**Figure 17.10**). The high-risk surgical population accounts for 80% of postoperative deaths but only about 15–30% of high-risk surgical patients are admitted to a critical care unit at any time following surgery. One study that compared surgical mortality in the UK and the USA found an observed mortality of 9.95 % in the UK as compared to 2.1% in USA. It is suggested that the difference may be related to the provision of critical care services, with 8.6 critical care beds per 100 000 population in the UK compared to 30.5 in the USA.

In the last decade, the role of critical care has been expanded to the concept of 'critical care without walls'. The intensive care outreach services (ICORS) grew from a recognition that there were many patients in the hospital who are at risk of being critically ill, and early identification of these patients using 'early warning scores' could allow for early intervention. The outreach team functions to bridge the gap between critical care unit and ward.

CONSENT

Consent should be both voluntary and informed. The process of consent has evolved over the years and in the UK, following a recent legal judgement, new guidance has been published (see Further reading; RCS). This describes the importance of supported decision-making concerning a treatment or operation. The guidance outlines the key principles of consent and how the discussion should:

- give the patient the information required to make a decision;
- be tailored to the individual patient;
- explain all reasonable treatment options;
- discuss all material* risks.

Furthermore, the guide explains that consent:

- should be written and recorded on a form;
- the key points of the discussion should be recorded in the case notes.

**Material risk: "whether, in the circumstances of the particular case, a reasonable person in the patient's position would be likely to attach significance to the risk, or the doctor is or should reasonably be aware that the particular patient would likely attach significance to it" (Source RCS 2016).*

Clearly in certain emergency situations, it may not be possible to follow all of the key principles. For consent to be given, the patient must have capacity, which includes the ability to understand the information provided, to retain and use the information to make a decision and to indicate what that decision is (see Further reading; RCS). The surgeon should presume the patient has capacity for consent (Mental Capacity Act, 2005) unless during the process it is demonstrated that this is not the case. Generally, children are presumed to have capacity at 16 and for those under that age, capacity can be assessed (GMC guidance, 2007).

The person obtaining consent must be appropriately experienced to do so.

Summary box 17.8

Consent

- Consent should be voluntary and informed
- Supported decision-making is considered good practice
- Explain all treatment options and material risks
- Capacity is needed for a patient to give their consent

ARRANGING THEATRE LIST

The date, place and time of operation should be matched with availability of personnel. Appropriate equipment and instruments should be made available. The operating list should be distributed as early as possible to all staff who are involved in making the list run smoothly (*Table 17.12*). If this is done electronically, familiarity with the computer system is required.

Prioritise patients, e.g. children and diabetic patients should be placed at the beginning of the list; life- and limb-threatening surgery should take priority; cancer patients need to be treated early.

TABLE 17.12 Perioperative teams.

- Ward, theatre and specialist nursing staff
- Anaesthetic and surgical teams
- Radiology, pathology involvement
- Rehabilitation and social care workers
- Specific personnel in individual cases

Chapter 18

Anaesthesia and pain relief

Learning objectives

To gain an understanding of:

- Techniques of anaesthesia and airway maintenance
- Methods of providing pain relief
- Local and regional anaesthesia techniques
- The management of chronic pain and pain from malignant disease

HISTORY

Anaesthesia, as we know it today, was first successfully demonstrated by William Morton, a local dentist, at the Massachusetts General Hospital Boston, USA on 16th October 1846 when he administered ether to Gilbert Abbot for operation on a vascular tumour on his neck. Earlier Horace Wells had successfully used nitrous oxide in 1844 for painless extraction of teeth.

Simpson at Edinburgh University overcame some of the technical difficulties of ether administration by introducing chloroform. The benefits of anaesthesia were then universally recognised and antagonism by religious leaders was countered when Queen Victoria accepted chloroform from John Snow during the birth of Prince Leopold in 1853.

KEY PRINCIPLES OF ANAESTHESIA

Optimum patient care is dependent on a collaborative approach from anaesthetic and surgical teams, together with the other perioperative care providers. The importance of multidisciplinary collaboration has been clearly demonstrated by national audits such as the *Confidential Enquiries in Perioperative Deaths (CEPOD)* and *Enquiries into Maternal Deaths UK*. These audits have led to changes in clinical and non-clinical practice to improve morbidity and mortality.

The use of a set of safety checklists in the operating theatre in the form of the *World Health Organisation's Surgical Safety Checklist* has shown a reduction in incidence of perioperative untoward events.

The role of the modern anaesthetist has evolved from just being responsible for the patient in the operating suite into a 'perioperative physician' who optimises the patient for surgery, assessing and minimising risk, cares for them during the operation, and then manages both pain and homeostasis in the postoperative period (*Table 18.1*).

TABLE 18.1 Key features of commonly used intravenous anaesthetic agents.

Propofol (di-isopropyl phenol) Smooth induction, better haemodynamic stability, blunting of autonomic reflexes and ability to use as a continuous infusion
Thiopentone (barbiturate) Rapid induction, myocardial depression. Reduced metabolic rate and lowering of intracranial pressure is useful in neurosurgical patients but drop in blood pressure can give detrimental effects
Etomidate (steroid derivative) Good haemodynamic stability, brief duration of action, but concern over adrenocortical depression
Ketamine (phencyclidine derivative) Preservation of blood pressure and respiratory reflexes together with excellent analgesia makes it an ideal choice for field anaesthesia. Emergence delirium is associated with administration of ketamine

Anaesthesia; the name was suggested by Oliver Wendell-Homes and first appeared in Bailey's English Dictionary in 1751.
Humphrey Davy, 1800, suggested that nitrous oxide inhalation might be used to relieve pain of surgical operations and named it 'laughing gas'.
Henry Edmund Gaskin Boyle in 1917 obtained his gas-oxygen machine which became the first 'Boyle apparatus'.
William Thomas Gren Morton, 1819–1868, dentist who practised in Boston, MA, USA.
Sir James Young Simpson, 1811–1870, Professor of Midwifery, Edinburgh, UK.
Alexandrina Victoria, Queen of the United Kingdom of Great Britain and Ireland, 1837–1901.
John Snow, 1813–1858, general practitioner, London, UK, was one of the pioneers of anaesthesia.
Prince Leopold, 1853–1884, who later became Duke of Albany, was the eighth of Queen Victoria's nine children, and her fourth son.

Summary box 18.1

Ground rules for anaesthesia

- Safe surgery is achieved by close teamwork between surgeon, anaesthetist and perioperative care providers
- Safety checklists make sure that things are not forgotten
- Risk assessments allow the best strategy to be chosen
- Anaesthetists are extending their care into the pre- and postoperative phase

PREPARATION FOR ANAESTHESIA

In the previous chapter, the preoperative preparation for anaesthesia was discussed in detail, and its importance is emphasised (Chapter 17). Moreover, a careful preassessment, multidisciplinary approach, standardised care pathway with a carefully chosen anaesthetic and analgesic technique form the cornerstone of 'enhanced recovery programmes' being introduced recently across the surgical specialities (see Chapter 20).

GENERAL ANAESTHESIA

General anaesthesia is commonly described as the triad of unconsciousness, analgesia and muscle relaxation.

Summary box 18.2

The general anaesthetic triad

- Amnesia: loss of awareness
- Analgesia: pain relief
- Muscle relaxation

Induction of general anaesthesia is most frequently done by intravenous agents. Propofol has replaced thiopentone as the most widely used induction agent and can be used for maintenance of anaesthesia. Other infrequently used intravenous agents include etomidate and ketamine. Newer agents based on benzodiazepine receptor agonists, etomidate derivatives and fospropofol are still in the experimental stage.

Inhalational induction using agents such as non-pungent sevoflurane is useful in children, needle-phobic adults and those in whom a difficult airway is anticipated. These patients will have a higher risk of developing airway obstruction (**Figure 18.1**).

Rapid sequence induction (RSI) using a predetermined dose of intravenous anaesthetic agent together with rapidly acting muscle relaxant is used in those with high risk of regurgitation in order to secure the airway quickly. Commonly needed in emergency surgery it is also a technique of choice in any non-emergency surgery in a patient with delayed emptying of stomach.

Total intravenous anaesthesia (TIVA) is becoming popular following the introduction of propofol and the ultra-short-acting opioid remifentanil. The lack of a cumulative effect, better haemodynamic stability, excellent recovery profile and concerns over environmental effects of inhalational agents have made TIVA an attractive choice. TIVA is routinely used in neurosurgery, airway laser surgery, during cardiopulmonary bypass and for day-case anaesthesia (**Figure 18.2**).

Figure 18.1 Anaesthetic machine.

Figure 18.2 Total intravenous anaesthesia pumps in use.

Summary box 18.3

Special terms in anaesthesia

- Rapid sequence induction (RSI) is a technique that allows the airway to be rapidly secured. It is used when there is a high risk of regurgitation that may lead to pulmonary aspiration
- Total intravenous anaesthesia (TIVA) is becoming increasingly popular

Maintenance of anaesthesia, on the other hand, can be done using continuous infusion of intravenous agent (propofol) or inhaled vapour such as isoflurane, sevoflurane or desflurane.

The use of nitrous oxide is declining despite its analgesic and weak anaesthetic properties due to concerns over postoperative nausea and vomiting. It also increases the size of the air bubble causing adverse effects, for example in eye, ear and abdominal surgery. Finally, it is possibly mutagenic and is a powerful greenhouse gas.

Management of airway during anaesthesia

Loss of muscle tone as a result of general anaesthesia means that the patient can no longer keep their airway open. Therefore, the patients need their airway maintained for them. The use of muscle relaxants will mean that they will also be unable to breathe for themselves and so will require artificial ventilation. Head tilt, chin lift and jaw thrust manoeuvres, along with adjuncts such as oropharyngeal airways, are used to facilitate bag-mask ventilation while induction agents exert full effect. Laryngeal mask airway or endotracheal tube are then inserted and the patient is allowed to breathe spontaneously or is ventilated during the procedure.

The addition of a cuff to the endotracheal tube facilitates positive pressure ventilation and protects the lungs from aspiration of regurgitated gastric contents.

Supraglottic airways

- **Laryngeal mask airway (LMA).** Developed by Dr Archie Brain in the UK, the original LMA is a first-generation supraglottic airway. The mask with an inflatable cuff is inserted via the mouth and produces a seal around the glottic opening, providing a very reliable means of maintaining the airway. Its placement is less irritating and less traumatic to a patient's airway than endotracheal intubation. The technique can be easily taught to non-anaesthetists and paramedics and can be used as an emergency airway management tool. Several varieties of first generation LMAs are available, including the classic LMA and the flexible LMA. Further advancement has led to the development of second-generation supraglottic devices such as the ProSeal LMA, the i-Gel and LMA Supreme (**Figure 18.3**). These devices usually have an in-built 'bite-block' and an oesophageal drain tube; they can be used for ventilation of the lungs at higher inflation pressures and are more suitable for patients with a higher body mass index. There are also modified versions of the LMA including the intubating LMA (ILMA) that allow a blind technique in aiding insertion of a tracheal tube in difficult conditions. There is increasing evidence that second-generation devices have a good safety and efficacy profile and should be replacing all first-generation devices.

Figure 18.3 The laryngeal mask airway. The laryngeal mask airway (left), i-Gel airway (centre) and reinforced laryngeal mask airway (right).

- **Difficult intubation.** Endotracheal intubation is feasible in most patients, but in a certain proportion of patients this may be difficult or impossible; if compounded by inability to ventilate the patient by bag-mask, consequences can be catastrophic hypoxia. Many devices have been developed to aid intubation if difficulty is anticipated and protocols created by specialised societies to deal with such situations. One specialised method for intubation in difficult situations is the use of the fibreoptic intubating bronchoscope facilitated by topical local anaesthetic in awake patients or using general anaesthesia. The anaesthetist places the endotracheal tube in the trachea by threading the tube over the bronchoscope, and so places the tube in the trachea under direct bronchoscopic vision. An awake intubation requires careful patient selection, as it may not be a suitable technique for all patient groups (**Figures 18.4, 18.5 and 18.6**).

Figure 18.4 The Macintosh laryngoscope with a standard blade (left) and McCoy's modification of the Macintosh blade (right).

Archibald Ian Jeremy Brain, formerly anaesthetist, The Royal Berkshire Hospital, Reading, UK.
Sir Robert Reynolds Macintosh, 1897–1989, Nuffield Professor of Anaesthetics, The University of Oxford, Oxford, UK. First Chair in anaesthesia in 1937. First Chair in anaesthesia in USA: **Ralph Waters**, Wisconsin, USA in 1933. First examination for the **Diploma in anaesthesia** was held in London in 1935.
Sir Ivan Whiteside Magill, 1888–1986, anaesthetist, The Westminster Hospital, London, UK. During the First World War Sir Ivan Magill and Stanley Rowbotham, while working with Harold Gillies (pioneer of plastic surgery), developed tracheal intubation. Sir Magill is also remembered for his laryngoscope, Magill attachment and laryngeal forceps.

Figure 18.5 Endotracheal devices. From left to right: an uncut orotracheal tube; reinforced orotracheal tube; oral version of a Ring, Adair and Elwyn (RAE) preformed tube; nasal version of an RAE preformed tube; tracheostomy tube.

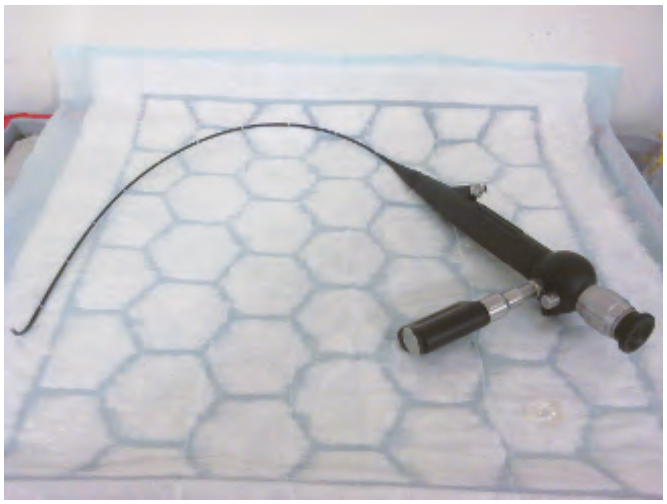

Figure 18.6 Fibreoptic intubating bronchoscope.

Double lumen tubes and endobronchial tubes are used in procedures such as thoracoscopic, pulmonary and oesophageal surgery to allow collapse of one lung (while ventilating the other) for ease of surgery. Their use is also essential to isolate the healthy lung in pyopneumothorax and in the case of a bronchopleural fistula.

Ventilating bronchoscopes and endobronchial catheters can be used to maintain oxygenation during laryngo-tracheal surgery or bronchoscopy by using intermittent jets of oxygen.

Summary box 18.4

Techniques for maintaining an airway

- Chin lift and jaw thrust: suitable for short term when no aid available
- Guedel airway: holds tongue forward but does not prevent aspiration
- Supraglottic device: easy insertion, reliable airway, allows ventilation
- Endotracheal intubation: secure and protected airway

Summary box 18.5

Complications of intubation

- Failed intubation
- Accidental bronchial intubation
- Trauma to teeth, pharynx, larynx
- Aspiration of gastric contents during intubation
- Disconnection, blockage, kinking of tube
- Delayed tracheal stenosis

Muscle relaxation and artificial ventilation

Pharmacological blockade of neuromuscular transmission provides relaxation of muscles allowing easy surgical access, but the patient requires artificial ventilation.

Neuromuscular blocking agents are broadly classified into depolarising and non-depolarising groups according to their mode of action.

Suxamethonium is the most commonly used depolarising agent. It binds to the nicotinic acetylcholine receptors, resulting in opening of the cation channel leading to depolarisation and rapid relaxation of muscles. Despite its adverse effects such as hyperkalaemia, muscle pain, anaphylaxis and potentially life-threatening malignant hyperthermia, suxamethonium is still widely used because of its quick onset and short duration of action. These properties are useful where rapid endotracheal intubation is necessary to protect the patient's airway or short-duration surgery is performed.

Non-depolarising muscle relaxants act by competitive blockade of postsynaptic receptors at the neuromuscular junction. They provide longer, predictable activity, but require careful monitoring, appropriate timing and reversal of their action by agents such as neostigmine and sugammadex at the end of the procedure. A peripheral nerve stimulator is routinely used to monitor the depth of neuromuscular block and also to confirm satisfactory recovery of muscle power prior to extubation (*Table 18.2*). With the increasing availability and evidence of the use of sugammadex, the non-depolarising muscle relaxant rocuronium is an alternative to suxamethonium in the 'rapid-sequence' induction, as it allows reversal of its actions with sugammadex in a rapid manner.

Ventilation during anaesthesia

Mechanical ventilation is required when the patient's spontaneous ventilation is inadequate or when the patient is not breathing because of the effects of the anaesthetic, analgesic agents or muscle relaxants.

In volume control ventilation, a preset volume is delivered by the machine irrespective of the airway pressure. The pressure generated will be in part dependent on the resistance and compliance of the airway. In laparoscopic surgery requiring the Trendelenburg position (the patient is positioned

The RAE tube takes its name from the initials of the surnames of the people who introduced it, Wallace Harold **Ring**, John **Adair** and Richard **Elwyn**.
Arthur Ernest Guedel, 1883–1956, Clinical Professor of Anaesthesiology, University of Southern California, Los Angeles, CA, USA.

TABLE 18.2 Properties of commonly used muscle relaxants.		
Suxamethonium	Quickest onset, very short duration, spontaneous recovery. Ideal for rapid intubation and for short procedures	Muscle pain, hyperkalaemia, prolonged apnoea and life-threatening malignant hyperthermia
Vecuronium	Long acting, minimal cardiovascular effect and less allergic reaction	Dependent on hepatic metabolism and renal clearance, hence caution if hepatic and renal impairment
Atracurium	Intermediate acting. Non-enzymatic Hoffmann degradation. Suitable in renal and hepatic failure	Histamine release and allergic reactions
Rocuronium	Rapid onset, intermediate action. Suitable for rapid intubation. Rapid reversal possible using sugammadex	Allergic reactions. Excreted unchanged via bile and urine

head down), and in morbidly obese patients and those with lung disease, this may result in excessive pressures being developed, which may lead to barotrauma (pneumothorax).

In pressure control mode, the ventilator generates flow until a preset pressure is reached. The actual tidal volume delivered is variable and depends on airway resistance, intra-abdominal pressure and the degree of relaxation.

Positive end expiratory pressure (PEEP) is often applied to help maintain functional residual capacity (FRC). This avoids lung collapse by opening collapsed alveoli, and maintains a greater area of gas exchange so reducing vascular shunting.

Summary box 18.6

Intermittent positive pressure ventilation

- Volume controlled, which ensures adequate gas entry but risks high pressure damage
- Pressure controlled, which avoids high pressure damage but risks inadequate ventilation
- Positive end expiratory pressure (PEEP) reduces alveolar collapse and reduces vascular shunting so improving perfusion

Monitoring and care during anaesthesia

A minimum basic monitoring of cardiovascular parameters is required during surgery. This includes:

- Vascular:
  - electrocardiogram (ECG);
  - blood pressure;
- Adequacy of ventilation:
  - inspired oxygen concentration;
  - oxygen saturation by pulse oximetry;
  - end tidal carbon dioxide concentration.

Monitors of temperature, ventilation parameters and delivery of anaesthetic agents are also routinely used, while measurement of urine output and central venous pressure are recommended for major surgery.

Anaesthesia for day case surgery

This is discussed in Chapter 21.

LOCAL ANAESTHESIA

Local anaesthetic drugs may be used to provide anaesthesia and analgesia as a sole agent or as adjuncts to general anaesthesia. Available techniques include topical anaesthesia, local infiltration, regional nerve blocks and central neuroaxial blocks (spinal and epidural anaesthesia) (*Table 18.3*).

TABLE 18.3 The common local anaesthetic drugs.		
Name	**Maximum dose**	**Comments**
Lignocaine	3 mg/kg (7 mg/kg with adrenaline)	Early onset, short acting, good sensory block
Bupivacaine	2 mg/kg	Long lasting, more cardiotoxic, must never be used intravenously
Prilocaine	6 mg/kg (9 mg/kg with adrenaline)	Least systemic toxicity, causes methaemoglobinaemia
Ropivacaine	3–4 mg/kg	Less cardiotoxic, greater sensory–motor separation
Levobupivaciane	2 mg /kg	Isomer of bupivacaine with fewer cardiotoxic properties

Local anaesthesia techniques can lead to complications that may be local, such as infection or haematoma, or systemic due to overdose or accidental intravascular injection. The systemic effects of local anaesthetic agents are dose dependent and manifest as cardiovascular (cardiac arrhythmia, cardiac arrest) or neurological (depressed consciousness, convulsions). Prilocaine overdose causes methaemoglobinaemia while bupivacaine overdose causes treatment-resistant ventricular arrhythmia and cardiac arrest.

The addition of adrenaline to local anaesthetic solutions hastens onset, prolongs duration of action and permits a higher upper dose limit. The use of adrenaline is contraindicated in patients with cardiovascular disease, those taking tricyclic and monoamine oxidase inhibitors and in end-arterial locations.

Appropriately skilled personnel, resuscitation equipment and oxygen should always be available with local anaesthetic use because of the potential risks of life-threatening complications.

Regional anaesthesia

Regional anaesthesia involves central neuroaxial or peripheral nerve or plexus blocks. It has a clear advantage where general anaesthesia carries a higher risk of morbidity and mortality, such as in patients with debilitating respiratory and cardiovascular disease and obstetric cases. It also provides excellent pain relief in the postoperative period, reducing the need for analgesics such as opioids.

As with general anaesthesia obtaining venous access, monitoring vital parameters should be performed during regional anaesthesia.

Localising nerves using anatomical landmarks and eliciting paraesthesia alone carries a high risk of nerve damage, intravascular injection and has lower success rate. The use of nerve stimulators to localise nerves improves success rate and reduces risks. Ultrasound-guided regional anaesthesia allows the visualisation of nerves and the spread of local anaesthetics, enabling the use of a smaller dose of local anaesthetic agents, with improved success rates and safety.

Summary box 18.7

Types of anaesthesia

- General anaesthesia may be more acceptable to the patients
- Regional anaesthesia has major advantages in obstetrics and patients with respiratory compromise
- Local blocks have been transformed by nerve stimulators and ultrasound guidance
- All require full resuscitation and monitoring equipment to be available

Common local anaesthesia techniques

Topical anaesthesia

- **EMLA (eutectic mixture of local anesthetics)**. This is a mixture of lignocaine and prilocaine for application to the skin for venepuncture in children.
- **Cocaine**. It may be called Mofatt's solution (with an added mixture of adrenaline and sodium bicarbonate) and used in nasal surgery for anaesthesia and vasoconstriction.
- **Lignocaine 2/4/10%**. Spray to anaesthetise the airway during awake fibreoptic intubation.

Nerve blocks

- Interscalene block for shoulder surgery produces excellent postoperative analgesia. Complications include phrenic nerve block, Horner's syndrome, as well as accidental intravascular and spinal injection.
- Axillary brachial plexus block can be used as the sole anaesthetic technique for upper limb surgery (Figure 18.7).
- Femoral and sciatic nerve blocks are often used for anaesthesia and analgesia for lower limb surgery.

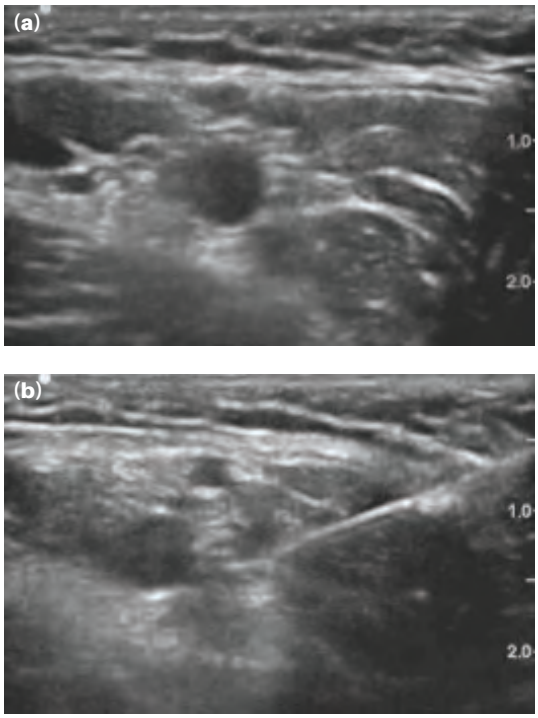

Figure 18.7 (a, b) Ultrasound scans of brachial plexus block.

TRANSVERSUS ABDOMINIS PLANE BLOCK

Transversus abdominis plane block (TAP) is growing rapidly in popularity. The technique has been shown to provide effective analgesia after a wide range of abdominal surgery. The T6–L1 segmental nerves enter the triangle of Petit just medial to the anterior axillary line. Injection of local anaesthetic into the fascial plane between the internal oblique and transversus abdominis muscles allows a block of all these nerves, and excellent anaesthesia of the anterior abdominal wall (Figure 18.8).

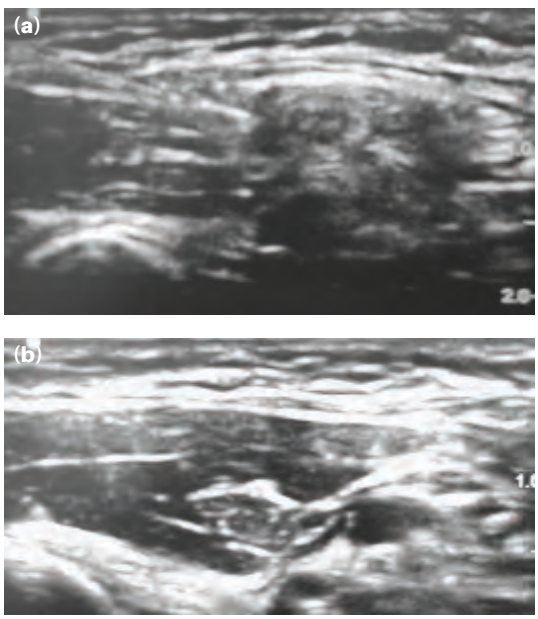

Figure 18.8 (a, b) Ultrasound scans of lateral abdominal wall and the spread of local anaesthetics.

INTRAVENOUS REGIONAL ANAESTHESIA (BIER'S BLOCK)

Bier's block produces excellent anaesthesia for short surgery, particularly for the upper limb (e.g. carpal tunnel release). Exsanguination using an Esmarch bandage, inflation of proximal cuff of the double tourniquet is followed by intravenous injection of prilocaine into the vein on the back of the hand that is being operated on. After 5–10 minutes the distal cuff of the tourniquet is inflated and then the proximal one deflated. Even if surgery is finished, the tourniquet should be left inflated until the local anaesthetic has bound to tissues (20 minutes), so that release of local anaesthetic into the systemic circulation does not occur. Lignocaine can be used with caution (consider safe dose and time of tourniquet inflation) but bupivacaine should never be used for Bier's block.

Spinal anaesthesia

Spinal anaesthesia alone, and in combination with general anaesthesia or sedation is used extensively for lower limb, obstetric and pelvic surgery. Injection of a 'single shot' local anaesthetic agent intrathecally produces intense and rapid block for surgery. Addition of opioids provides prolonged postoperative analgesia but carries the risk of late respiratory depression.

Autonomic sympathetic blockade produces hypotension, particularly if the level of block is above T10. Caution is needed in patients with hypovolemia and cardiovascular disease.

The incidence of dural puncture headache can be minimised by limiting the number of punctures and use of fine bore pencil tip needles designed to split rather than cut the dura.

Epidural anaesthesia

Epidural anaesthesia is slower in onset than spinal, but has the advantage of prolonged analgesia by multiple dosing or continuous infusion through a catheter placed in the epidural space. Being slower in onset, the resulting hypotension from sympathetic blockade can be better controlled and can reduce blood loss.

Continuous infusion (with a patient-controlled bolus) of weak local anaesthetic combined with opioids (such a fentanyl) is routinely used for postoperative analgesia. Placement of an epidural catheter in the high thoracic region provides excellent analgesia for a wide variety of upper abdominal and thoracic surgical operations, enabling early mobilisation and reducing respiratory complications.

Epidural anaesthesia is technically more difficult than spinal anaesthesia, with a higher failure rate and carries the risk of nerve damage, spinal injuries, accidental spinal injection of large volume of local anaesthetics and risk of infection and epidural haematoma (**Figure 18.9**).

Figure 18.9 Equipment for epidural/spinal anaesthesia.

Summary box 18.8

Local anaesthetics

- EMLA cream for children needing injections
- Regional and nerve blocks for limb surgery
- Spinal anaesthesia offers quick onset and short duration of anaesthesia
- Epidurals are more difficult but can then be topped-up postoperatively and used as continuous infusion

Chronic pain management

In surgical practice, the patient with chronic pain may present for treatment of the cause (e.g. pancreatitis, malignancy), or concomitant benign pathology. Acute pain after surgery may progress to chronic pain and is believed to be due to inadequate treatment of acute pain itself.

Chronic pain may be of several types:

- **Nociceptive pain** may result from musculoskeletal disorders or cancer activating cutaneous nociceptors (pain receptors). Prolonged ischaemic or inflammatory processes result in sensitisation of peripheral nociceptors and altered activity in the central nervous system, leading to exaggerated responses in the dorsal horn of the spinal cord. The widened area of hyperalgesia and increased sensitivity (allodynia) has been attributed to the increased transmission in the central nervous system.
- **Neuropathic (or neurogenic) pain** is dysfunction in peripheral or central nerves (excluding the 'physiological' pain due to noxious stimulation of the nerve terminals). It is classically of a 'burning', 'shooting' or 'stabbing' type and may be associated with allodynia, numbness and diminished thermal sensation. It is poorly responsive to opioids. Examples include trigeminal neuralgia, postherpetic and diabetic neuropathy. Monoaminergic, tricyclic inhibitors and anticonvulsant drugs are the mainstay of treatment.
- **Psychogenic pain** is associated with depressive illness; chronic pain and the illness may exacerbate each other.

August Karl Gustav Bier, 1861–1949, Professor of Surgery, Bonn (1903–1907) and Berlin, Germany (1907–1932).

Summary box 18.9

Types of pain

- Nociceptive pain arises from inflammation and ischaemia
- Neuropathic pain arises from a dysfunction in the central nervous system
- Psychogenic pain is modified by the mental state of the patient

Chronic pain control in benign disease

Surgical patients may present with chronic persistent pain (more than 3 months' duration) from a variety of disorders including postoperative neuropathic pain, chronic inflammatory disease, recurrent infection, degenerative bone or joint disease, nerve injury and sympathetic dystrophy. This may result from persistent excitation of the nociceptive pathways causing spontaneous firing of pain signals at N-methyl-D-aspartate receptors in the ascending pathways. This pain does not respond to opiates or neuroablative surgery and would merit neuropathic pain management.

Amputation of limbs may result in phantom limb pain; the likelihood is increased if the limb was painful before surgery. Continuous regional local anaesthetic blockade (epidural or brachial plexus) established before operation and continued postoperatively for a few days, is believed to effectively reduce the risk of phantom limb pain.

- **Local anaesthetic and steroid injections** can be effective around an inflamed nerve and they reduce the cycle of constant pain transmission with consequent muscle spasm. Transforaminal selective root blocks in the epidural space are used for the pain of nerve root irritation associated with or without minor disc prolapse, followed by active physiotherapy and rehabilitation to promote mobility.
- **Nerve stimulation procedures** such as acupuncture and transcutaneous nerve stimulation, increase the endorphin production in the central nervous system. Nerve decompression craniotomy rather than percutaneous coagulation of the ganglion is now performed for trigeminal neuralgia. Spinal cord stimulation by dorsal column stimulation is now a recognised and effective management of intractable neuropathic pain. This involves placement of electrodes in the posterior epidural space to allow dorsal column stimulation through an implantable pulse generator inserted in the body.

Summary box 18.10

Pain control in benign disease

- Bring pain under control before amputation to avoid phantom pain
- Local anaesthetic and steroid injected around a nerve may reduce muscle spasm
- Transcutaneous nerve stimulators (TNS) modifies pain by increasing endorphin production
- Trigeminal neuralgia responds to decompression of the nerve

Drugs in chronic non-malignant pain

Paracetamol and the non-steroidal anti-inflammatory drugs (NSAIDs) are the mainstay of musculoskeletal pain treatment. The tricyclic antidepressant drugs and anticonvulsant agents are often useful for the pain of nerve injury, although side effects can prove troublesome and reduce compliance. Both pregabalin and gabapentin reduce spontaneous neuronal activity by their action on the alpha-2-delta subunit of calcium channels, and are now used for managing neuropathic chronic pain. In more severe and debilitating non-malignant chronic pain, opioid analgesic drugs are used in slow release oral preparations of morphine and oxycodone, and transcutaneous patches delivering fentanyl and buprenorphine. Tapentadol with its dual action on opioid and noradrenaline selective reuptake inhibition pathways may provide relief in patients with pain of both neuropathic and nociceptive elements. Combinations of drugs often prove useful to achieve the optimum of efficacy with minimal side effects.

Treatment of pain dependent on sympathetic nervous system activity

Even minor trauma and surgery, (often of a limb) can provoke chronic burning pain, allodynia, trophic changes and resultant disuse due to excessive sympathetic adrenergic activity inducing vasconstriction and abnormal nociceptive transmission.

Management includes antineuropathic pain medications (pregabalin, gabapentin, amitriptyline) as part of multimodal analgesia with a multidisciplinary pain management approach including considerable input of psychological, targeted physiotherapy and counselling. Interventional treatment may include local anaesthetic injection of stellate ganglion for upper limb symptoms. Percutaneous chemical lumbar sympathectomy with local anaesthetic is used for relief of rest pain in advanced ischaemic disease of the legs.

Pain control in malignant disease

Pain is a common symptom associated with cancer, more so during the advanced stages. In intractable pain, the underlying principle of treatment is to encourage independence of the patient and an active life in spite of the symptom. The World Health Organisation's booklet advises use of a 'pain stepladder':

- First step. **Simple analgesics**: aspirin, paracetamol, non-steroidal anti-inflammatory agents, tricyclic drugs or anticonvulsant drugs.
- Second step. **Intermediate strength opioids**: codeine, tramadol or dextropropoxyphene.
- Third step. **Strong opioids**: morphine (pethidine has now been withdrawn).

Oral opiate analgesia is necessary when the less powerful analgesic agents no longer control pain on movement, or enable the patient to sleep. Fear that the patient may develop an addiction to opiates is usually not justified in malignant disease. It is also important to distinguish between the addiction and dependence; the former being a psychosocial

phenomenon while the latter is a pure physiological response to a given drug. Some patients experience 'breakthrough pain' (acute, excruciating and incapacitating), which occurs either spontaneously or in relation to a specific predictable or unpredictable trigger, experienced by patients who have relatively stable and adequately controlled background pain.

Oral morphine, often used for chronic pain, can be prescribed in short-acting liquid or tablet form and should be administered regularly every 4 hours until an adequate dose of drug has been titrated to control the pain over 24 hours. Once this is established, the daily dose can be divided into two separate administrations of enteric-coated, slow-release morphine tablets (MST morphine) every 12 hours. Additional short-acting opioids (morphine/fentanyl) can then be used to cover episodes of 'breakthrough pain'. Nausea treated using antiemetic agents does not usually persist, but constipation is frequently a persistent complication requiring regular prevention by laxatives.

Infusion of subcutaneous, intravenous, intrathecal or epidural opiate drugs

The infusion of opiate is necessary if a patient is unable to take oral drugs. Subcutaneous infusion of diamorphine is simple and effective to administer. Epidural infusions of diamorphine with an external pump can be used on mobile patients. Intrathecal infusions with pumps programmed by external computers are used; however, there is a possibility of developing infection with catastrophic effects. Intravenous narcotic agents may be reserved for acute crises, such as pathological fractures.

Neurolytic techniques in cancer pain

These should only be used if the life expectancy is limited and the diagnosis is certain. The useful procedures are:

- Subcostal phenol injection for a rib metastasis.
- Coeliac plexus neurolytic block with alcohol for pain of pancreatic, gastric or hepatic cancer.
- Intrathecal neurolytic injection of hyperbaric phenol.
- Percutaneous anterolateral cordotomy divides the spinothalamic ascending pain pathway. It is a highly effective technique in experienced hands, selectively eliminating pain and temperature sensation in a specific limited area.

Alternative strategies include:

- The development of antipituitary hormone drugs, such as tamoxifen and cyproterone, enables effective pharmacological therapy for the pain of widespread metastases instead of pituitary ablation surgery.
- Palliative radiotherapy can be most beneficial for the relief of pain in metastatic disease.
- Adjuvant drugs such as corticosteroids to reduce cerebral oedema or inflammation around a tumour may be useful in symptom control. Tricyclic antidepressants, anticonvulsants and flecainide are also used to reduce the pain of nerve injury.

In the management of chronic pain, a multidisciplinary approach by a team of medical and nursing staff working with psychologists, physiotherapists and occupational therapists can often achieve much more benefit than the use of powerful drugs. 'Pain Management Programmes' lay out a logical structure for this.

Summary box 18.11

Options for controlling severe pain in malignant disease

- Oral morphine using slow-release enteric-coated tablets
- Slow infusion of opiates subcutaneously, by epidural or intrathecally
- Neurolysis for patients with limited life expectancy
- Palliative hormone, radiotherapy, or steroids control pain from swelling

Chapter 19

Nutrition and fluid therapy

Learning objectives

To understand:

- The causes and consequences of malnutrition in the surgical patient
- Fluid and electrolyte requirements in the pre- and postoperative patient
- The nutritional requirements of surgical patients and the nutritional consequences of intestinal resection
- The different methods of providing nutritional support and their complications

INTRODUCTION

Malnutrition is common. It occurs in about 30% of surgical patients with gastrointestinal disease and in up to 60% of those in whom hospital stay has been prolonged because of postoperative complications. It is frequently unrecognised and consequently patients often do not receive appropriate support. There is a substantial body of evidence to show that patients who suffer starvation or have signs of malnutrition have a higher risk of complications and an increased risk of death in comparison with patients who have adequate nutritional reserves.

Long-standing protein–calorie malnutrition as seen in cachexia or general frailty is easy to recognise (Figure 19.1). Short-term undernutrition, although less easily recognised, frequently occurs in association with critical illness, major trauma, burns or surgery, and also impacts on patient recovery. The aim of nutritional support is to identify those patients at risk of malnutrition and to ensure that their nutritional requirements are met by the most appropriate route and in a way that minimises complications.

Figure 19.1 Severely malnourished patient with wasting of fat and muscle.

PHYSIOLOGY

Metabolic response to starvation

After a short fast, lasting 12 hours or less, most food from the last meal will have been absorbed. Plasma insulin levels fall and glucagon levels rise, which facilitates the conversion of liver glycogen (approximately 200 g) into glucose. The liver, therefore, becomes an organ of glucose production under fasting conditions. Many organs, including brain tissue, red and white blood cells and the renal medulla, can initially utilise only glucose for their metabolic needs. Additional stores of glycogen exist in muscle (500 g), but these cannot be utilised directly. Muscle glycogen is broken down (glycogenolysis) and converted to lactate, which is then exported to the liver where it is converted to glucose (Cori cycle). With increasing

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology and later Biochemistry, Washington University Medical School, St Louis, MI, USA and his wife Gerty Theresa Cori, 1896–1957, also Professor of Biochemistry at the Washington University Medical School. In 1947, the Coris were awarded a share of the Nobel Prize for Physiology or Medicine for their discovery of how glycogen is catalytically converted.

duration of fasting (>24 hours), glycogen stores are depleted and *de novo* glucose production from non-carbohydrate precursors (gluconeogenesis) takes place, predominantly in the liver. Most of this glucose is derived from the breakdown of amino acids, particularly glutamine and alanine as a result of catabolism of skeletal muscle (up to 75 g per day). This protein catabolism in simple starvation is readily reversed with the provision of exogenous glucose.

With more prolonged fasting, there is an increased reliance on fat oxidation to meet energy requirements. Increased breakdown of fat stores occurs, providing glycerol, which can be converted to glucose, and fatty acids, which can be used as a tissue fuel by almost all of the body's tissues. Hepatic production of ketones from fatty acids is facilitated by low insulin levels and, after 48–72 hours of fasting, the central nervous system may adapt to using ketone bodies as their primary fuel source. This conversion to a 'fat fuel economy' reduces the need for muscle breakdown by up to 55 g per day.

Another important adaptive response to starvation is a significant reduction in the resting energy expenditure, possibly mediated by a decline in the conversion of inactive thyroxine (T4) to active tri-iodothyronine (T3). Despite these adaptive responses, there remains an obligatory glucose requirement of about 200 g per day, even under conditions of prolonged fasting.

Summary box 19.1

Metabolic response to starvation

- Low plasma insulin
- High plasma glucagon
- Hepatic glycogenolysis
- Protein catabolism
- Hepatic gluconeogenesis
- Lipolysis: mobilisation of fat stores (increased fat oxidation) – overall decrease in protein and carbohydrate oxidation
- Adaptive ketogenesis
- Reduction in resting energy expenditure (from approximately 25–30 kcal/kg per day to 15–20 kcal/kg per day

Metabolic response to trauma and sepsis

This is described in full in Chapter 1 and summarised in *Summary box 19.2*.

From a nutritional point of view, two factors deserve emphasis. First, in contrast to simple starvation, patients with trauma have impaired formation of ketones, and the breakdown of protein to synthesise glucose (gluconeogenesis) cannot be entirely prevented by the administration of glucose. Second, although it is generally accepted that the metabolic response to trauma and sepsis is always associated with 'hypermetabolism' or hypercatabolism', these terms are ill defined and do not indicate the need for very high-energy intakes. There is no evidence to show that the provision of high-energy intake is associated with an amelioration of the catabolic process and it may indeed be harmful; there is mounting evidence for the benefits of permissive underfeeding in critically ill surgical patients.

Summary box 19.2

Metabolic response to trauma and sepsis

- Increased counter-regulatory hormones: adrenaline, noradrenaline, cortisol, glucagon and growth hormone
- Increased energy requirements (up to 40 kcal/kg per day)
- Increased nitrogen requirements
- Insulin resistance and glucose intolerance
- Preferential oxidation of lipids
- Increased gluconeogenesis and protein catabolism
- Loss of adaptive ketogenesis
- Fluid retention with associated hypoalbuminaemia

NUTRITIONAL ASSESSMENT

Laboratory techniques

There is no single biochemical measurement that reliably identifies malnutrition. Albumin is not a measure of nutritional status, particularly in the acute setting. Although a low serum albumin level (<30 g/L) is an indicator of poor prognosis, hypoalbuminaemia invariably occurs because of alterations in body fluid composition and because of increased capillary permeability related to ongoing sepsis. Malnutrition is associated with defective immune function, and measurement of lymphocyte count and skin testing for delayed hypersensitivity frequently reveal abnormalities in malnourished patients. Immunity is not, however, a precise or reliable indicator of nutritional status, nor is it a practical method in routine clinical practice.

Body weight and anthropometry

A simple method of assessing nutritional status is to estimate weight loss. Measured body weight is compared with ideal body weight obtained from tables or from the patient's usual or premorbid weight. Unintentional weight loss of more than 10% of a patient's weight in the preceding 6 months is a good prognostic indicator of poor outcome. Body weight is frequently corrected for height, allowing calculation of the body mass index (BMI, defined as body weight in kilograms divided by height in metres squared). A BMI of less than 18.5 indicates nutritional impairment and a BMI below 15 is associated with significant hospital mortality. Major changes in fluid balance, which are common in critically ill patients, may make body weight and BMI unreliable indicators of nutritional status.

Anthropometric techniques incorporating measurements of skinfold thicknesses and mid-arm circumference permit estimations of body fat and muscle mass, and these are indirect measures of energy and protein stores. These mea-

de novo is Latin for 'from the beginning'.

surements are, however, insufficiently accurate in individual patients to permit planning of nutritional support regimens. Similarly, use of bioelectrical impedence analysis (BIA) permits estimation of intra- and extracellular fluid volumes. These techniques are only useful if performed frequently on a sequential basis in individual patients; in this respect, trends are much more important than absolute impedance figures. All of these techniques are significantly impaired by the presence of oedema.

Clinical

The possibility of malnutrition should form part of the workup of all patients. A clinical assessment of nutritional status involves a focused history and physical examination, an assessment of risk of malabsorption or inadequate dietary intake and selected laboratory tests aimed at detecting specific nutrient deficiencies. This is termed 'subjective global assessment' and encompasses historical, symptomatic and physical parameters. Recently, the British Association of Parenteral and Enteral Nutrition introduced a malnutrition universal screening tool (MUST), which is a five-step screening tool to identify adults who are malnourished or at risk of undernutrition (Figure 19.2).

FLUID AND ELECTROLYTES

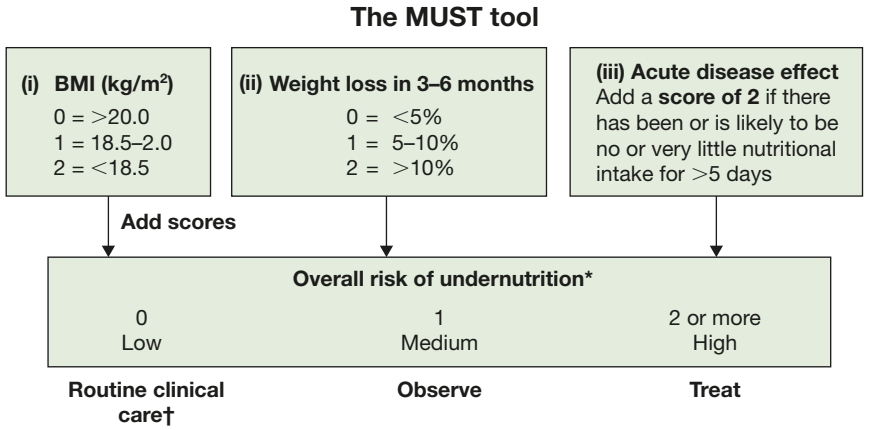
Fluid intake is derived from both exogenous (consumed liquids) and endogenous (released during oxidation of solid foodstuffs) fluids. The average daily water balance of a healthy adult is shown in *Table 19.1*.

TABLE 19.1 Average daily water balance of a healthy adult in a temperate climate (70 kg).

Output	Volume (mL)	Intake	Volume (mL)
Urine	1500	Water from beverage	200
Insensible losses	900	Water from food	1000
Faeces	100	Water from oxidation	300

Fluid losses occur by four routes:

1 **Lungs**. About 400 mL of water is lost in expired air each 24 hours. This is increased in dry atmospheres or in patients with a tracheostomy, emphasising the importance of humidification of inspired air.



Repeat screening
Hospital – every week
Care homes – every month
Community – every year for special groups, e.g. those >75 years

Hospital – document dietary and fluid intake for 3 days
Care homes (as for hospital)
Community – repeat screening, e.g. from <1 month to >6 months (with dietary advice if necessary)

Hospital – refer to dietician or implement local policies. Generally food first followed by food fortification and supplements
Care homes (as for hospital)
Community (as for hospital)

***If height, weight or weight loss cannot be established**, use documented or recalled values (if considered reliable). When measured or recalled height cannot be obtained, use knee height as a surrogate measure.
If neither can be calculated, obtain an overall impression of malnutrition risk (low, medium, high) using the following:
(i) Clinical impression (very thin, thin, average, overweight);
(iia) Clothes and/or jewellery have become loose fitting;
(iib) History of decreased food intake, loss of appetite or dysphagia up to 3–6 months;
(iic) Disease (underlying cause) and psychosocial/physical disabilities likely to cause weight loss.

† Involves treatment of underlying condition, and help with food choice and eating when necessary (also applies to other categories).

Figure 19.2 The malnutrition universal screening tool (MUST) for adults (adapted from Elia M (ed.). *The MUST Report. Development and use of the 'malnutrition universal screening tool' (MUST) for adults*. A report by the Malnutrition Advisory Group of the British Association for Parenteral and Enteral Nutrition. Report No. 152, 2003, ISBN 1 899467 70X).

Marinos Elia, contemporary, Head of the Adult Clinical Nutrition Group, The Medical Research Council, Cambridge, UK.

2 **Skin**. In a temperate climate, skin (i.e. sweat) losses are between 600 and 1000 mL/day.
3 **Faeces**. Between 60 and 150 mL of water are lost daily in patients with normal bowel function.
4 **Urine**. The normal urine output is approximately 1500 mL/day and, provided that the kidneys are healthy, the specific gravity of urine bears a direct relationship to volume. A minimum urine output of 400 mL/day is required to excrete the end products of protein metabolism.

Maintenance fluid requirements are calculated approximately from an estimation of insensible and obligatory losses. Various formulae are available for calculating fluid replacement based on a patient's weight or surface area. For example, 30–40 mL/kg gives an estimate of daily requirements.

The following are the approximate daily requirements of some electrolytes in adults:

- sodium: 50–90 mM/day;
- potassium: 50 mM/day;
- calcium: 5 mM/day;
- magnesium: 1 mM/day.

The nature and type of fluid replacement therapy will be determined by individual patient needs. The composition of some commonly used solutions is shown in *Table 19.2*.

Note that Hartmann's solution also contains lactate 29 mmol/L. Dextrose solutions are also commonly employed. These provide water replacement without any electrolytes and with modest calorie supplements (1 litre of 5% dextrose contains 400 kcal). A typical daily maintenance fluid regimen would consist of a combination of 5% dextrose with either Hartmann's or normal saline to a volume of 2 litres.

There has been much controversy in the literature regarding the respective merits of crystalloid versus colloid replacement. There is no consensus on this topic and the usual advice is to replace like with like. If the haematocrit is below 21%, blood transfusion may be required. There is increasing recognition, however, that albumin infusions are of little value.

In addition to maintenance requirements, 'replacement' fluids are required to correct pre-existing deficiencies and 'supplemental' fluids are required to compensate for anticipated additional intestinal or other losses. The nature and volumes of these fluids are determined by:

- A careful assessment of the patient including pulse, blood pressure and central venous pressure, if available. Clinical examination to assess hydration status (peripheries, skin turgor, urine output and specific gravity of urine), urine and serum electrolytes and haematocrit.
- Estimation of losses already incurred and their nature: for example, vomiting, ileus, diarrhoea, excessive sweating or fluid losses from burns or other serious inflammatory conditions.
- Estimation of supplemental fluids likely to be required in view of anticipated future losses from drains, fistulae, nasogastric tubes or abnormal urine or faecal losses.
- When an estimate of the volumes required has been made, the appropriate replacement fluid can be determined from a consideration of the electrolyte composition of gastrointestinal secretions. Most intestinal losses are adequately replaced with normal saline containing supplemental potassium *(Table 19.3)*.

TABLE 19.3 Composition of gastrointestinal secretions (mmol/L).

	Na	K	Cl	HCO_3
Saliva	10	25	10	30
Stomach	50	15	110	–
Duodenum	140	5	100	–
Ileum	140	5	100	30
Pancreas	140	5	75	115
Bile	140	5	100	35

NUTRITIONAL REQUIREMENTS

Total enteral or parenteral nutrition necessitates the provision of the macronutrients, carbohydrate, fat and protein, together with vitamins, trace elements, electrolytes and water. When planning a feeding regime, the patient should be weighed and an assessment made of daily energy and protein requirements. Standard tables are available to permit these calculations.

Daily needs may change depending on the patient's condition. Overfeeding is the most common cause of complications, regardless of whether nutrition is provided enterally or parenterally. It is essential to monitor daily intake to provide an assessment of tolerance. In addition, regular biochemical monitoring is mandatory *(Table 19.4)*.

TABLE 19.2 Composition of crystalloid and colloid solutions (mmol/L).

Solution	Na	K	Ca	Cl	Lactate	Colloid
Hartmann's	131	5	2	111	29	
Normal saline (0.9% NaCl)	154			154		
Dextrose saline (4% dextrose in 0.18% saline)	30	30				
Gelofusine	150	150				Gelatin 4%
Haemacel	145	5.1	<1	145		Polygelin 75 g/L
Hetastarch						Hydroxyethyl starch 6%

Alexis Frank Hartmann, 1898–1964, paediatrician, St Louis, MO, USA.

TABLE 19.4 Monitoring feeding regimes.

Daily	Body weight Fluid balance Full blood count, urea and electrolytes Blood glucose Electrolyte content and volume of urine and/or urine and intestinal losses Temperature
Weekly (or more frequently if clinically indicated)	Urine and plasma osmolality Calcium, magnesium, zinc and phosphate Plasma proteins including albumin Liver function tests including clotting factors Thiamine Acid–base status Triglycerides
Fortnightly	Serum vitamin B12 Folate Iron Lactate Trace elements (zinc, copper, manganese)

Macronutrient requirements

Energy

The total energy requirement of a stable patient with a normal or moderately increased need is approximately 20–30 kcal/kg per day. Very few patients require energy intakes in excess of 2000 kcal/day. Thus, in the majority of hospitalised patients in whom energy demands from activity are minimal, total energy requirements are approximately 1300–1800 kcal/day.

Carbohydrate

There is an obligatory glucose requirement to meet the needs of the central nervous system and certain haematopoietic cells, which is equivalent to about 2 g/kg per day. In addition, there is a physiological maximum to the amount of glucose that can be oxidised, which is approximately 4 mg/kg per minute (equivalent to about 1500 kcal/day in a 70-kg person), with the nonoxidised glucose being primarily converted to fat. However, optimal utilisation of energy during nutritional support is ensured by avoiding the infusion of glucose at rates approximating physiological maximums. Plasma glucose levels provide an indication of tolerance. Avoid hyperglycaemia. Provide energy as mixtures of glucose and fat. Glucose is the preferred carbohydrate source.

Fat

Dietary fat is composed of triglycerides of predominantly four long-chain fatty acids. There are two saturated fatty acids (palmitic (C16) and stearic (C18)) and two unsaturated fatty acids (oleic (C18 with one double bond) and linoleic (C18 with two double bonds)). In addition, smaller amounts of linolenic acid (C18 with three double bonds) and medium-chain fatty acids (C6–C10) are contained in the diet.

The unsaturated fatty acids, linoleic and linolenic acid, are considered essential because they cannot be synthesised *in vivo* from non-dietary sources. Both soybean and sunflower oil emulsions are rich sources of linoleic acid and provision of only 1 litre of emulsion per week avoids deficiency. Soybean emulsions contain approximately 7% alpha-linolenic acid (an omega-3 fatty acid). The provision of fat as a soybean oil-based emulsion on a regular basis will obviate the risk of essential fatty acid deficiency.

Safe and non-toxic fat emulsions based upon long-chain triglycerides (LCTs) have been commercially available for over 30 years. These emulsions provide a calorically dense product (9 kcal/g) and are now routinely used to supplement the provision of non-protein calories during parenteral nutrition. Energy during parenteral nutrition should be given as a mixture of fat together with glucose. There is no evidence to suggest that any particular ratio of glucose to fat is optimal, as long as under all conditions the basal requirements for glucose (100–200 g/day) and essential fatty acids (100–200 g/week) are met. This 'dual energy' supply minimises metabolic complications during parenteral nutrition, reduces fluid retention, enhances substrate utilisation (particularly in the septic patient) and is associated with reduced carbon dioxide production.

Concerns have been expressed about the possible immunosuppressive effects of LCT emulsions. These are more likely to occur if the recommended infusion rates (0.15 g/kg per hour) are exceeded. Nonetheless, these concerns have prompted the development of newer emulsions based upon medium-chain triglycerides, omega-3 fatty acids and, most recently, structured triglycerides, which combine long and medium-chain triglycerides in the same emulsion. The evidence of clinical benefit for these emulsions compared with conventional LCTs is tenuous, particularly if infusion rates are appropriate and hypertriglyceridaemia is avoided.

Protein

The basic requirement for nitrogen in patients without pre-existing malnutrition and without metabolic stress is 0.10–0.15 g/kg per day. In hypermetabolic patients the nitrogen requirements increase to 0.20–0.25 g/kg per day. Although there may be a minority of patients in whom the requirements are higher, such as after acute weight loss when the objective of therapy is longterm repletion of lean body mass, there is little evidence that the provision of nitrogen in excess of 14 g/day is beneficial.

Vitamins, minerals and trace elements

Whatever the method of feeding, these are all essential components of nutritional regimes. The water-soluble vitamins B and C act as coenzymes in collagen formation and wound healing. Postoperatively, the vitamin C requirement increases to 60–80 mg/day. Supplemental vitamin B12 is often indicated in patients who have undergone intestinal resection or gastric surgery and in those with a history of alcohol dependence. Absorption of the fat-soluble vitamins A, D, E and K is reduced in steatorrhoea and the absence of bile.

Sodium, potassium and phosphate are all subject to significant losses, particularly in patients with diarrhoeal illness.

in vivo is Latin for 'in a living thing'.

Their levels need daily monitoring and appropriate replacement.

Trace elements may also act as cofactors for metabolic processes. Normally, trace element requirements are met by the delivery of food to the gut and so patients on long-term parenteral nutrition are at particular risk of depletion. Magnesium, zinc and iron levels may all be decreased as part of the inflammatory response. Supplementation is necessary to optimise utilisation of amino acids and to avoid refeeding syndrome.

FLUID AND NUTRITIONAL CONSEQUENCES OF INTESTINAL RESECTION

Up to 50% of the small intestine can be surgically removed or bypassed without permanent deleterious effects. With extensive resection (<150 cm of remaining small intestine), metabolic and nutritional consequences arise, resulting in the disease entity known as short bowel syndrome. The clinical presentation of patients with short bowel syndrome is dependent upon the site and extent of intestinal resection.

Small bowel motility

Small bowel motility is three times slower in the ileum than in the jejunum. In addition, the ileocaecal valve may slow transit. The adult small bowel receives 5–6 litres of endogenous secretions and 2–3 litres of exogenous fluids per day. Most of this is reabsorbed in the small bowel. In the jejunum, the cellular junctions are leaky and jejunal contents are always isotonic. Fluid absorption in this region of bowel is inefficient compared with the ileum. It has been estimated that the efficiency of water absorption is 44% and 70% of the ingested load in the jejunum and ileum, respectively. The corresponding figures for sodium are 13% and 72%, respectively. It can be seen, therefore, that the ileum is critical in the conservation of fluid and electrolytes.

Ileum

The ileum is the only site of absorption of vitamin B12 and bile salts. Bile salts are essential for the absorption of fats and fat-soluble vitamins. The enterohepatic circulation of bile salts is critical to maintain the bile salt pool. Following resection of the ileum, the loss of bile salts increases and is not met by an increase in synthesis. Depletion of the bile salt pool results in fat malabsorption. In addition, loss of bile salts into the colon affects colonic mucosa, causing a reduction in salt and water absorption, which increases stool losses.

Colon

Transit times in the colon vary between 24 and 150 hours. The efficiency of water and salt absorption in the colon exceeds 90%. Another important colonic function is the fermentation of carbohydrates to produce short-chain fatty acids. These have two important functions: first, they enhance water and salt absorption from the colon and, second, they are trophic to the colonocyte.

Effects of resection

Resection of proximal jejunum results in no significant alterations in fluid and electrolyte levels as the ileum and colon can adapt to absorb the increased fluid and electrolyte load. Absorption of nutrients occurs throughout the small bowel, and resection of jejunum alone results in the ileum taking over this lost function. In this situation, there is no malabsorption.

Resection of ileum results in a significant enhancement of gastric motility and acceleration of intestinal transit. Following ileal resection, the colon receives a much larger volume of fluid and electrolytes and it also receives bile salts, which reduce its ability to absorb salt and water, resulting in diarrhoea. Even the loss of 100 cm of ileum may cause steatorrhoea, which can necessitate the administration of oral cholestyramine to bind bile salts. With larger resections (>100 cm) dietary fat restriction may be necessary. Regular parenteral vitamin B12 is required.

The most challenging patients are those with short bowel syndrome who have had in excess of 200 cm of small bowel resected together with colectomy. These patients will usually have a jejunostomy. They are conveniently divided into two groups termed ‘net absorbers’ and ‘net secretors’. Absorbers characteristically have more than 100 cm of residual jejunum and they absorb more water and sodium from the diet than passes through the stomach. These patients can be managed without supplementary parenteral fluids.

Secretors usually have less than 100 cm of residual jejunum and lose more water and sodium from their stoma than they take by mouth. These patients require supplements. Their usual daily jejunostomy output may exceed 4 litres per 24 hours. The sodium content of jejunostomy losses or other high-output fistulae is about 90 mmol/L. Jejunal mucosa is leaky and rapid sodium fluxes occur across it. If water or any solution with a sodium concentration of less than 90 mmol/L is consumed, there is a net efflux of sodium from the plasma into the bowel lumen. It is therefore inappropriate to encourage patients with high-output jejunostomies (secretors) to drink large amounts of oral hypotonic solutions. Treatment begins with restricting the total amount of hypotonic fluids (water, tea, juices, etc.) consumed to less than 1 litre a day. Patients should be encouraged to take glucose and saline replacement solutions, which have a sodium concentration of at least 90 mmol/L. The World Health Organization (WHO) cholera solution has a sodium concentration of 90 mmol/L and is commonly used.

Complications of short bowel syndrome include peptic ulceration related to gastric hypersecretion, cholelithiasis because of interruption of the enterohepatic cycle of bile salts and hyperoxaluria as a result of the increased absorption of oxalate in the colon predisposing to renal stones. Some patients with short bowel syndrome develop a syndrome of slurred speech, ataxia and altered affect. The cause of this syndrome is fermentation of malabsorbed carbohydrates in the colon to d-lactate and absorption of this metabolite. Treatment necessitates the use of a low carbohydrate diet.

Anti-secretory drugs reduce the amount of fluid secreted from the stomach, liver and pancreas. These include H2-receptor antagonists, proton pump inhibitors and the somatostatin analogue octreotide. Octreotide also reduces gastrointestinal motility, while proton pump inhibitors lower gastric pH sufficiently to decrease the need for neutralisation of acid in the duodenum and proximal jejunum. This results in significant lowering of high jejunostomy outputs and dosage should be titrated against stoma effluent pH for optimal results. Anti-motility drugs include loperamide and codeine phosphate, which also decrease water and sodium output from the stoma by about 20%.

ARTIFICIAL NUTRITIONAL SUPPORT

The indications for nutritional support are simple. Any patient who has sustained 5 days of inadequate intake or who is anticipated to have no or inadequate intake for this period should be considered for nutritional support. The periods may be less in patients with pre-existing malnutrition. This concept is important because it emphasises that the provision of nutritional support is not specific to certain conditions or diseases. Although patients with Crohn's disease or pancreatitis, or those who have undergone gastrointestinal resections, may frequently require nutritional support, it is the fact that they have had inadequate intakes for defined periods that is the indication rather than the specific disease process.

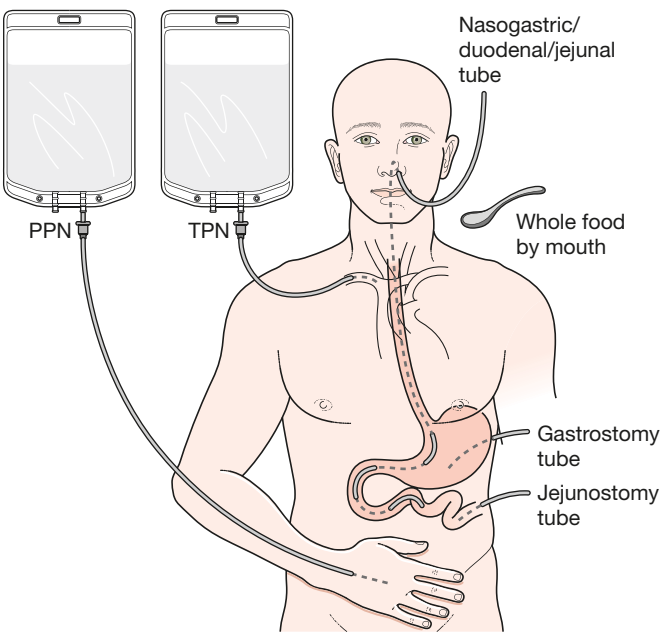


Figure 19.3 Techniques used for adjuvant nutritional support. PPN, partial parenteral nutrition; TPN, total parenteral nutrition. Redrawn with permission from Rick Tharp, rxkinetics.com.

Enteral nutrition

The term 'enteral feeding' means delivery of nutrients into the gastrointestinal tract. The alimentary tract should be used whenever possible. This can be achieved with normal food, oral supplements (sip feeding) or with a variety of tube-feeding techniques delivering food into the stomach, duodenum or jejunum.

A variety of nutrient formulations are available for enteral feeding. These vary with respect to energy content, osmolarity, fat and nitrogen content and nutrient complexity; most contain up to 1–2 kcal/mL and up to 0.6 g/mL of protein. Polymeric feeds contain intact protein and hence require digestion, whereas monomeric/elemental feeds contain nitrogen in the form of either free amino acids or, in some cases, peptides. These are less palatable and are used much less frequently than in previous years. Newer feeding formulations are available that include glutamine and fibre to optimise intestinal nutrition, or immunonutrients such as arginine and fish oils, but these are expensive and their use is controversial.

Sip feeding

Commercially available supplementary sip feeds are used in patients who can drink but whose appetites are impaired or in whom adequate intakes cannot be maintained with *ad libitum* intakes. These feeds typically provide 200 kcal and 2 g of nitrogen per 200 mL carton. There is good evidence to demonstrate that these sip-feeding techniques are associated with a significant overall increase in calorie and nitrogen intakes without detriment to spontaneous nutrition. The evidence that these techniques improve patient outcomes is less convincing.

Tube-feeding techniques

Enteral nutrition can be achieved using conventional nasogastric tubes (Ryle's), fine-bore feeding tubes inserted into the stomach, surgical or percutaneous endoscopic gastrostomy (PEG) or, finally, postpyloric feeding utilising nasojejunal tubes or various types of jejunostomy (**Figure 19.3**). The choice of method will be determined by local circumstances and preference in many patients. Whichever method is adopted, it is important that tube feeding is supervised by an experienced dietician who will calculate the patient's requirements and aim to achieve these within 2–3 days of the instigation of feeds. Conventionally, 20–30 mL are administered per hour initially, gradually increasing to goal rates within 48–72 hours. In most units, feeding is discontinued for 4–5 hours overnight to allow gastric pH to return to normal. There is some evidence that this might reduce the incidence of nosocomial pneumonia and aspiration. There is good evidence to confirm that feeding protocols optimise the tolerance of enteral nutrition. In these, aspirates are performed on a regular basis and if they exceed 200 mL in any 2-hour

ad libitum is Latin for 'freely or as much as you wish'.
John Alfred Ryle, 1889–1950, Regius Professor of Medicine, Cambridge University and later Professor of Social Medicine, Oxford University, Oxford, UK, introduced the Ryle's tube in 1921.

period, then feeding is temporarily discontinued or the rate of feed administration is diminished.

Tube blockage is common. All tubes should be flushed with water at least twice daily. If a buildup of solidified diet occurs, instillation into the tube of agents such as chymotrypsin may salvage a partially obstructed tube. Guidewires should not be used to clear blockages as these may perforate the tube and cause contiguous damage.

Nasogastric tubes are appropriate in a majority of patients. If feeding is maintained for more than a week or so, a fine-bore feeding tube is preferable and is likely to cause fewer gastric and oesophageal erosions. These are usually made from soft polyurethane or silicone elastomer and have an internal diameter of <3 mm.

Fine-bore tube insertion

The patient should be semi-recumbent. The introducer wire is lubricated and inserted into the fine-bore tube (**Figure 19.4**). The tube is passed through the nose and into the stomach via the nasopharynx and oesophagus. The wire is withdrawn and the tube is taped to the patient. There is a small risk of malposition into a bronchus or of causing pneumothorax. The position of the tube should be checked using plain abdominal radiography (**Figure 19.5**). Confirmation of position by pH testing is possible but limited by the difficulty of obtaining a fluid aspirate with narrow lumen tubes.

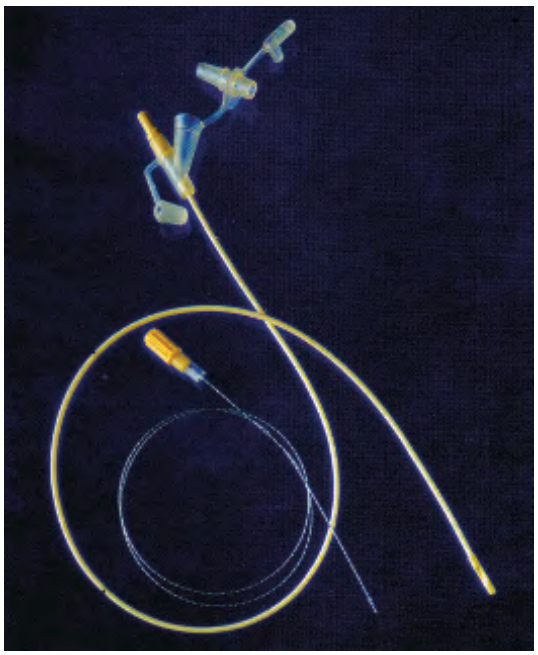

Figure 19.4 A fine-bore feeding tube with its guidewire.

Gastrostomy

The placement of a tube through the abdominal wall directly into the stomach is termed 'gastrostomy'. Historically, these were created surgically at the time of laparotomy. Today, the majority are performed by percutaneous insertion under endoscopic control using local anaesthesia, known as PEG (percutaneous endoscopic gastrostomy) tubes (**Figure 19.6**).

Figure 19.5 Radiograph of a tube similar to that in Figure 19.4 inserted beyond the duodenojejunal flexure.

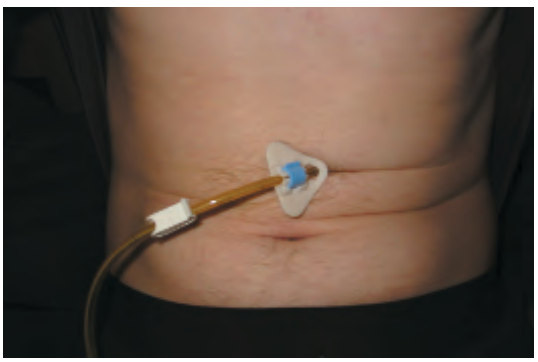

Figure 19.6 Percutaneous endoscopic gastrostomy tube.

Two methods of PEG are commonly used. The first is called the 'direct-stab' technique in which the endoscope is passed and the stomach filled with air. The endoscopist then watches a cannula entering the stomach having been inserted directly through the anterior abdominal wall. A guidewire is then passed through the cannula into the stomach. A gastrostomy tube (commercially available) may then be introduced into the stomach through a 'peel away' sheath. The alternative technique is the transoral or push-through technique, whereby a guidewire or suture is brought out of the stomach by the endoscope after transabdominal percutaneous insertion and is either attached to a gastrostomy tube or the tube is pushed over a guidewire. The abdominal end of the wire

is then pulled, advancing the gastrostomy tube through the oesophagus and into the stomach. Continued pulling abuts it up against the abdominal wall.

If patients require enteral nutrition for prolonged periods (4–6 weeks), then PEG is preferable to an indwelling nasogastric tube; this minimises the traumatic complications related to indwelling tubes. PEG does have procedure-specific complications, although these are uncommon. Necrotising fasciitis and intra-abdominal wall abscesses have been recorded. Sepsis around the PEG site is more common and may necessitate systemic antibiotics or repositioning. A persistent gastric fistula can occur on removal of a PEG if it has been in place for prolonged periods and epithelialisation of the tract has occurred. This necessitates surgical closure.

Jejunostomy

In recent years, the use of jejunal feeding has become increasingly popular. This can be achieved using nasojejunal tubes or by placement of needle jejunostomy at the time of laparotomy. Some authorities advocate the use of jejunostomies on the basis that postpyloric feeding may be associated with a reduction in aspiration or enhanced tolerance of enteral nutrition. In particular, there are many advocates of jejunostomies in patients with severe pancreatitis, in whom a degree of gastric outlet obstruction may be present, related to the oedematous head of pancreas. In most patients it is appropriate to commence with conventional nasogastric feeding and progress to postpyloric feeding if the former is unsuccessful.

Nasojejunal tubes often necessitate the use of fluoroscopy or endoscopy to achieve placement, which may delay commencement of feeding. Surgical jejunostomies, even using commercially available needle-insertion techniques, do involve creating a defect in the jejunum, which can leak or be associated with tube displacement; both of these complications result in peritonitis.

Complications

Most complications of enteral nutrition can be avoided with careful attention to detail and appropriate infusion rates. Patients should be nursed semi-recumbent to reduce the possibility of aspiration. Complications can be divided into those resulting from intubation of the gastrointestinal tract and those related to nutrient delivery. The former are more frequent with more invasive means of gaining access to the intestinal tract (see above under Enteral nutrition). The latter include diarrhoea, bloating and vomiting. Diarrhoea occurs in more than 30% of patients receiving enteral nutrition and is particularly common in the critically ill. Up to 60% of patients in intensive care units may fail to receive their targeted intakes. There is no evidence that the incidence of diarrhoea and bloating is reduced by the use of half-strength feeds. It is important to introduce normal feeds at a reduced rate according to patient tolerance. Metabolic complications associated with excessive feeding are uncommon in enterally fed patients. There have been reports of nosocomial enteric infections associated with contamination of feeds, which should be kept in sealed containers at 4°C and discarded once opened. In all patients, it is essential to monitor intakes accurately as target intakes are often not achieved with enteral nutrition.

The complications of enteral nutrition are summarised in *Summary box 19.3*.

Summary box 19.3

Complications of enteral nutrition

- Tube-related
  - Malposition
  - Displacement
  - Blockage
  - Breakage/leakage
  - Local complications (e.g. erosion of skin/mucosa)
- Gastrointestinal
  - Diarrhoea
  - Bloating, nausea, vomiting
  - Abdominal cramps
  - Aspiration
  - Constipation
- Metabolic/biochemical
  - Electrolyte disorders
  - Vitamin, mineral, trace element deficiencies
  - Drug interactions
- Infective
  - Exogenous (handling contamination)
  - Endogenous (patient)

Parenteral nutrition

Total parenteral nutrition (TPN) is defined as the provision of all nutritional requirements by means of the intravenous route and without the use of the gastrointestinal tract.

Parenteral nutrition is indicated when energy and protein needs cannot be met by the enteral administration of these substrates. The most frequent clinical indications relate to those patients who have undergone massive resection of the small intestine, who have intestinal fistula or who have prolonged intestinal failure for other reasons.

Route of delivery: peripheral or central venous access

TPN can be administered either by a catheter inserted in the central vein or via a peripheral line. In the early days of parenteral nutrition, the only energy source available was hypertonic glucose, which, being hypertonic, had to be given into a central vein to avoid thrombophlebitis. In the second half of the last century, there were a number of important developments that have influenced the administration of parenteral nutrition. These include the identification of safe and non-toxic fat emulsions that are isotonic; pharmaceutical developments that permit carbohydrates, fats and amino acids to be mixed in single containers; and a recognition that the provision of

energy during parenteral nutrition should be a mixture of glucose and fat and that energy requirements are rarely in excess of 2000 kcal/day (25–30 kcal/kg per day). These changes enabled the development of peripheral parenteral nutrition.

Peripheral

Peripheral feeding is appropriate for short-term feeding of up to 2 weeks. Access can be achieved either by means of a dedicated catheter inserted into a peripheral vein and manoeuvred into the central venous system (peripherally inserted central venous catheter (PICC) line) or by using a conventional short cannula in the wrist veins. The former method has the advantage of minimising inconvenience to the patient and clinician. PICC lines have a mean duration of survival of 7 days. The disadvantage is that when thrombophlebitis occurs, the vein is irrevocably destroyed. In the alternative approach, intravenous nutrients are administered through a short cannula in wrist veins, infusing the patient's nutritional requirements on a cyclical basis over 12 hours. The cannula is then removed and resited in the contralateral arm. Peripheral parenteral nutrition has the advantage that it avoids the complications associated with central venous administration, but suffers the disadvantage that it is limited by the development of thrombophlebitis (**Figure 19.7**). Peripheral feeding is not indicated if patients already have an indwelling central venous line or in those in whom long-term feeding is anticipated.

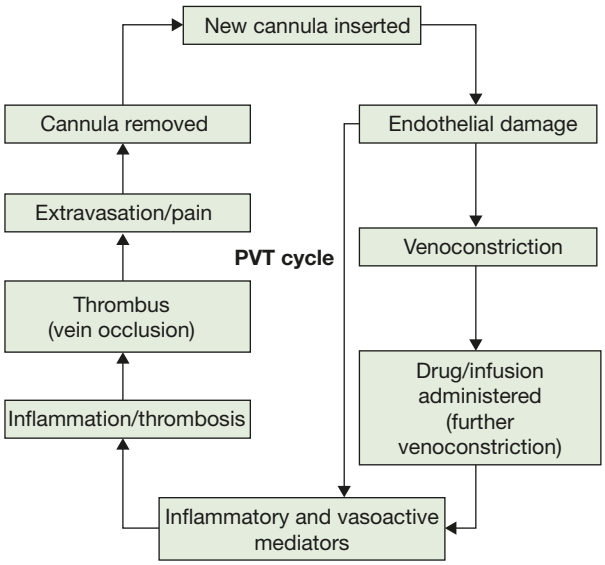

Figure 19.7 Cycle of causes of peripheral vein thrombophlebitis (PVT) (after Payne-James J, Grimble G, Silk D (eds). *Artificial nutrition support in clinical practice*, 2nd edn. London, Greenwich Medical Media, 2001).

Central

When the central venous route is chosen, the catheter can be inserted via the subclavian or internal or external jugular vein. There is good evidence to show that the safest means of establishing central venous access is by insertion of lines under ultrasound guidance; however, this will not be practicable for all cases. Most intensive care physicians and anaesthetists favour cannulation of internal or external jugular veins as these vessels are easily accessible. They suffer the disadvantage that the exit site is situated inconveniently on the side of the neck, where repeated movements result in disruption of the dressing with the attendant risk of sepsis. The infraclavicular subclavian approach is more suitable for feeding as the catheter then lies flat on the chest wall, which optimises nursing care (**Figure 19.8**).

Figure 19.8 Infraclavicular subclavian line.

For longer-term parenteral nutrition, Hickman lines are preferable. These are often inserted by a radiologist with fluoroscopic guidance or ultrasound. They incorporate a small cuff, which sits at the exit site of a subcutaneous tunnel. This is thought to minimise the possibility of line dislodgement and reduce the possibility of line sepsis. Whichever technique is employed, a postinsertion chest x-ray is essential before feeding is commenced to confirm the absence of pneumothorax and that the catheter tip lies in the distal superior vena cava, to minimise the risk of central venous or cardiac thrombosis. Multilumen catheters can be used for the administration of TPN; one port should be employed for that sole purpose and strict protocols of aseptic care employed.

An alternative technique for central intravenous access allows the PICC technique under ultrasound guidance to cannulate the cephalic vein in the arm, which facilitates passage of a catheter into the bracheocephalic vein or superior vena cava. This has many advantages as it minimises the risks of insertion and ensures distance between the site of skin entry and the tip of the catheter. Thrombophlebitis, however, can occur.

Complications of parenteral nutrition

The commencement of TPN may precipitate or accentuate underlying nutrient deficiency by encouraging anabolism.

John Jason Payne-James, contemporary forensic physician and medical writer, Leigh-on-Sea, Essex, UK.
Robert O Hickman, b.1929, formerly paediatric nephrologist, Seattle Childrens' Hospital, Seattle, WA, USA.

Common metabolic complications include fluid overload, hyperglycaemia, abnormalities of liver function and vitamin deficiencies. Fluid overload can be avoided by daily weighing of the patient. A weight change of >1 kg/day normally indicates fluid retention. Hyperglycaemia is common because of insulin resistance in critically ill patients. Even modest rates of glucose administration may be associated with hyperglycaemia. Hyperglycaemic patients undergoing surgery are known to run a substantially higher risk of infectious complications.

Abnormalities of liver enzymes are common in patients who are receiving TPN. Although the precise mechanisms are unclear, intrahepatic cholestasis may occur and hepatic steatosis and hepatomegaly have been reported. Reducing the fat content or infusion of fat-free TPN may be required. If liver enzymes continue to deteriorate, TPN should be temporarily discontinued. In addition, overfeeding is a major factor in hepatic and other metabolic complications associated with TPN. Supplemental parenteral glutamine during parental nutrition should be considered, particularly in the critically ill patient.

Catheter-related sepsis occurs in 3–14% of patients. It may occur at the time of line insertion or afterwards by migration of skin bacteria along the external catheter surface. Some studies suggest that manoeuvring of the catheter hub due to frequent manipulation is a common cause. Contamination of the infusate is rare. Seeding on the catheter at the time of bacteraemia from a remote source may also cause catheter infection.

Diagnosis of catheter-related sepsis requires that the same organism is grown from the catheter tip as is recovered from blood and that the clinical features of infection resolve on removal of the catheter. Traditional methods of confirming line sepsis have necessitated removal of the line with subsequent bacteriological assessment. An alternative approach is to use an endoluminal brush passed down the catheter and withdrawn into a polythene sheath. The brush tip is cultured at the same time as performing blood cultures. Catheter sepsis is confirmed if identical organisms are cultured from brush and blood. A second alternative is to culture blood withdrawn through the catheter and compare this with peripheral blood cultures. If the colony count from the catheter sample is five or more times higher than that from peripheral blood, then line sepsis is probable.

Some of the complications of TPN may not be a direct result of the provision of nutrients by the intravenous route, but rather a consequence of the absence of luminal nutrients. This may cause a shift in the mucosa-associated intestinal microbiome, an increased mucosal proinflammatory state and the loss of epithelial barrier function leading to bacterial translocation of enteric organisms. The gut origin of sepsis, mediated by bacterial translocation, may be significant in critical illness and multiorgan failure.

The complications of parenteral nutrition are summarised in *Summary box 19.4*.

Summary box 19.4

Complications of parenteral nutrition

- Related to nutrient deficiency
  - Hypoglycaemia/hypocalcaemia/ hypophosphataemia/ hypomagnesaemia (refeeding syndrome)
  - Chronic deficiency syndromes (essential fatty acids, zinc, mineral and trace elements)
- Related to overfeeding
  - Excess glucose: hyperglycaemia, hyperosmolar dehydration, hepatic steatosis, hypercapnia, increased sympathetic activity, fluid retention, electrolyte abnormalities
  - Excess fat: hypercholesterolaemia and formation of lipoprotein X, hypertriglyceridaemia, hypersensitivity reactions
  - Excess amino acids: hyperchloraemic metabolic acidosis, hypercalcaemia, aminoacidaemia, uraemia
- Related to sepsis
  - Catheter-related sepsis
  - Possible increased predisposition to systemic sepsis
- Related to line
  - On insertion: pneumothorax, damage to adjacent artery, air embolism, thoracic duct damage, cardiac perforation or tamponade, pleural effusion, hydromediastinum
  - Long-term use: occlusion, venous thrombosis

Refeeding syndrome

This syndrome is characterised by severe fluid and electrolyte shifts in malnourished patients undergoing refeeding. It can occur with either enteral or parenteral nutrition, but is more common with the latter. It results in hypophosphataemia, hypocalcaemia and hypomagnesaemia. These electrolyte disorders can result in altered myocardial function, arrhythmias, deteriorating respiratory function, liver dysfunction, seizures, confusion, coma, tetany and death. Patients at risk include those with alcohol dependency, those suffering severe malnutrition, anorexics and those who have undergone prolonged periods of fasting. Treatment involves matching intakes with requirements and assiduously avoiding overfeeding. Calorie delivery should be increased slowly and vitamins administered regularly. Hypophosphataemia and hypomagnesaemia require treatment.

Nutrition support teams

Multidisciplinary nutrition teams ensure cost-effective and safe nutritional support, irrespective of how this is administered. The incidence of catheter-related sepsis is significantly reduced.

SUMMARY

Fluid therapy and nutritional support are fundamental to good surgical practice. Accurate fluid administration demands an understanding of maintenance requirements and an appreciation of the consequences of surgical disease on fluid losses. This requires knowledge of the consequences of surgical intervention and, in particular, intestinal resection. Malnutrition is common in hospital patients. All patients who have sustained or who are likely to sustain 5 days of

inadequate oral intake should be considered for nutritional support. This may be dietetic advice alone, sip feeding or enteral or parenteral nutrition. These are not mutually exclusive. The success or otherwise of nutritional support should be determined by tolerance to nutrients provided and nutritional end points, such as weight. It is unrealistic to expect nutritional support to alter the natural history of disease. It is imperative that nutrition-related morbidity is kept to a minimum. This necessitates the appropriate selection of feeding method, careful assessment of fluid, energy and protein requirements, which are regularly monitored, and the avoidance of overfeeding.

Chapter 20

Postoperative care

Learning objectives

To understand:

- What is required to deliver immediate postoperative care
- What are the common postoperative problems seen in the immediate postoperative period
- How to predict and prevent common postoperative complications
- How to recognise and treat common postoperative complications
- The principles of enhanced recovery
- A system for discharging patients

INTRODUCTION

The aim of postoperative care is to provide the patient with as quick, painless and safe a recovery from surgery as possible. This requires the appropriate knowledge and skills to manage medical, as well as surgical, postoperative problems.

Standards of postanaesthesia care in the immediate postoperative period

Both the American Society of Anaesthesiologists (ASA) and Association of Anaesthetists of Great Britain and Ireland (AAGBI) have set standards for the provision of immediate postoperative care of patients who have undergone a procedure requiring a general anaesthetic or central neuraxial blockade. In brief, they both specify that care should be undertaken in a dedicated postanaesthetic care unit (PACU) with staff trained in the management of patients in the immediate postoperative care period. Standards for equipment (including resuscitation, difficult airway and monitoring), drugs and schedules of measurement of patient vital signs are described, as well as the discharge criteria each patient must satisfy prior to transfer out.

Immediate postoperative care

In many settings around the world, the process starts with a 'sign out' as part of the World Health Organization check list. The theatre team should then formally hand over the care of the patient to the PACU staff. The information provided should include the patient's name, age, the surgical procedure, existing medical problems, allergies, the anaesthetic and analgesics given, fluid replacement, blood loss, urine output, any surgical and anaesthetic problems encountered or expected and a plan for the management of pain and nausea or vomiting.

Postoperative observations

The patient's vital signs (including pulse, blood pressure and pulse oximetry reading), level of consciousness, pain and hydration status are monitored in the recovery room and supportive treatment is given. In recent years, patient observations have been collated in recording systems designed to provide an early warning of clinical deterioration (**Figure 20.1**).

Surgery-specific observations such as Doppler flow for a free flap, regular neurological evaluation and laboratory tests, such as blood gas analysis, should also be performed when necessary.

The patient can be discharged from PACU when they fulfil the following criteria:

- Patient is fully conscious.
- Respiration and oxygenation are satisfactory.
- Patient is normothermic, not in pain and not nauseous.
- Cardiovascular parameters are stable.
- Oxygen, fluids and analgesics have been prescribed.
- There are no concerns related to the surgical procedure.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

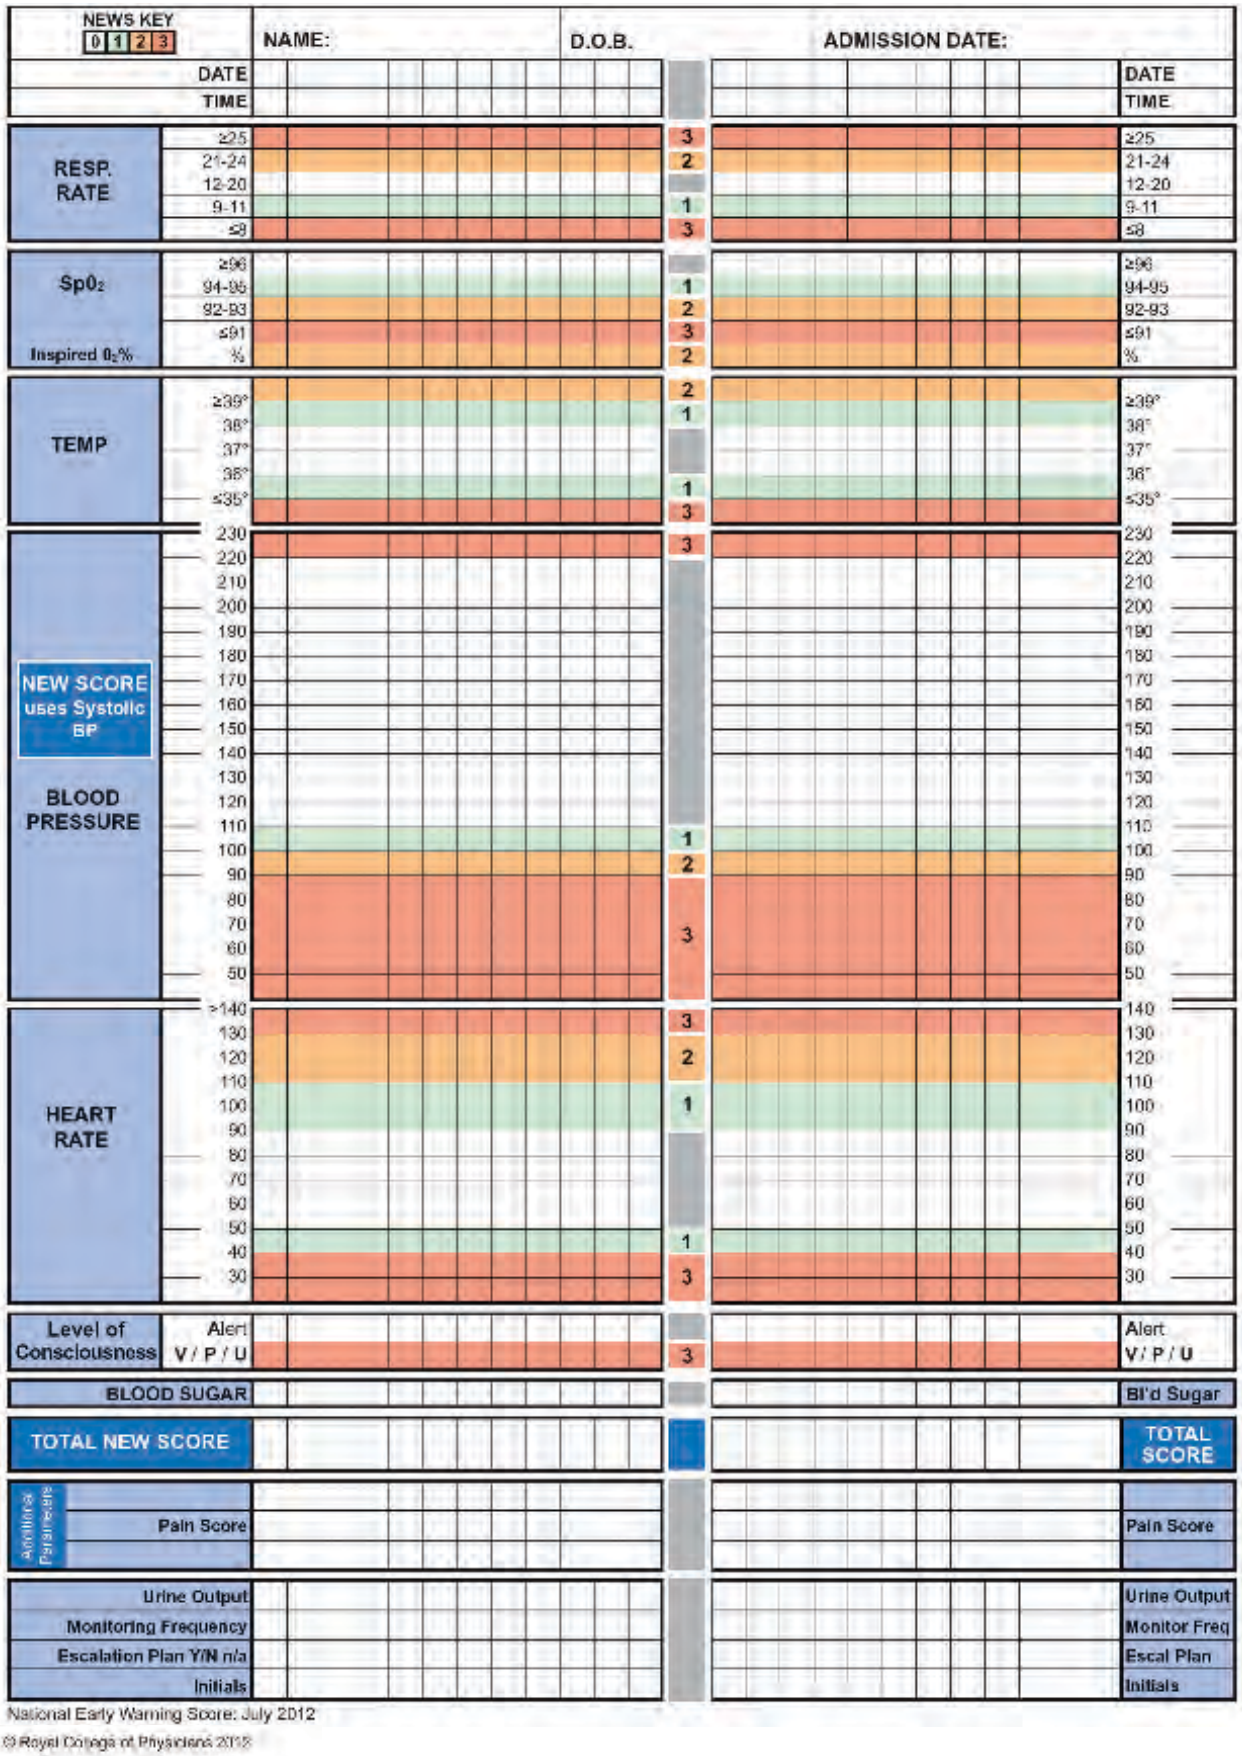

Figure 20.1 An example of an early warning system using patient observations; the National Early Warning System from the Royal College of Physicians.

Summary box 20.1

Postoperative period

- All anaesthetised patients should be recovered in a dedicated PACU
- All vital parameters should be monitored and documented according to local protocols
- Treat pain and nausea/vomiting
- Observe for complications

SYSTEM-SPECIFIC POSTOPERATIVE COMPLICATIONS

Postoperative complications are an important cause of morbidity, mortality, extended hospital stay and increased costs. Most patients at increased risk of developing postoperative complications can be identified prior to surgery at the preoperative assessment clinic using a variety of scoring systems (for example the American College of Surgeons National Surgical Quality Improvement Programme risk stratification for perioperative myocardial infarction and cardiac arrest (NSQiP) surgical risk calculator, see Chapter 17). Early identification of risk allows for targeted, appropriate, anticipatory and supportive medical care, which will reduce both the incidence and severity of such complications when they occur.

Classification of postoperative complications

There are three common approaches for the classification of postoperative complications of surgery:

1 Linked to time after surgery:
   - immediate (within 6 h of procedure);
   - early (6–72 h);
   - late (>72 h).
2 Generic and surgery specific.
3 Clavian-Dindo: this system relates to surgical complications only and is used to objectively and reproducibly measure the impact of the surgical complication on the outcome of the procedure. It is included here for completeness and will be discussed no further.

Respiratory system

Early detection of respiratory complications is facilitated by periodic assessment of airway patency, respiratory rate and routine oxygen saturation measurement, performed during emergence and recovery as described earlier.

Immediate respiratory complications

AIRWAY

Upper airway obstruction is one of the commonest immediate postoperative complications and can be due to laryngospasm, persisting relaxation of airway muscles, soft tissue oedema, haematoma, vocal cord dysfunction or foreign body. Vigilance and early intervention are necessary to prevent harm to the patient. Most interventions are simple and involve manual support of the jaw or insertion of an oral or nasal airway.

RESPIRATION

The residual effects of anaesthetic drugs (neuromuscular blockers, anaesthetic agents, opioids) can contribute to reduced or impaired adequacy of ventilation postoperatively. Continuous pulse oximetry and respiratory rate evaluation can identify respiratory compromise and consequent hypoxia early. Supplemental oxygen should be given to all patients in PACU until adequate respiration and oxygenation are restored.

HYPOXAEMIA

This may occur, in addition to the situations already described above, as a consequence of acute pulmonary oedema (fluid overload, cardiac failure, postobstructive), bronchospasm, pneumothorax (**Figure 20.2**), aspiration and, rarely, pulmonary embolism (**Figure 20.3**). *De novo* pneumonia is very

Figure 20.2 Radiograph showing a right tension pneumothorax with tracheal deviation to the left (courtesy of Professor Stephen Eustace, Dublin).

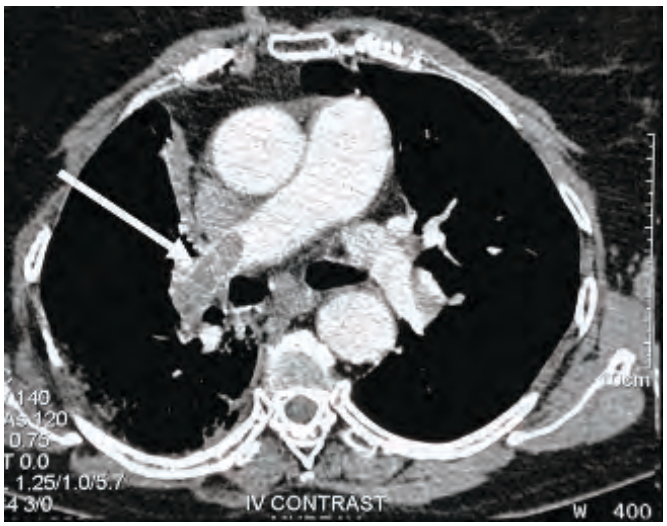

Figure 20.3 Computed tomography (CT) scan showing pulmonary artery blood embolism (arrow) (courtesy of Professor Stephen Eustace, Dublin).

unusual in the immediate postoperative period. Hypoxaemia develops most quickly in patients with obstructive sleep apnoea, lung disease and obesity, who should therefore be closely observed.

Patients with hypoxaemia should be treated urgently. If the patient is breathing spontaneously, oxygen should be administered at 15 L/min using a non-rebreathing mask. A head tilt, chin lift or jaw thrust should relieve obstruction related to reduced muscle tone. Suctioning of any blood or secretions and insertion of an oropharyngeal airway may be needed. Early anaesthetic intervention may be required.

SURGERY-SPECIFIC

Vocal cord palsy (as a consequence of recurrent laryngeal nerve injury), neck haematoma and post-tonsillectomy bleeding are recognised and life-threatening complications of head and neck surgery, which need immediate medical attention for safe resolution.

Early and late respiratory complications

Early and late postoperative pulmonary complications are a significant cause of postoperative morbidity and mortality (figures vary between 5% and 70%). Complications include fever (due to microatelectasis), cough, dyspnoea, bronchospasm, hypercapnoea, atelectasis (**Figure 20.4**), pneumonia (**Figure 20.5**), pleural effusion, pneumothorax and respiratory failure. The risk of each varies with the patient and the type of surgery being performed. Thoracic or abdominal surgery carries the highest risk. The majority of patients at risk (obese, smokers, chronic lung disease, obstructive sleep apnoea, poor nutritional status) can be identified preoperatively, facilitating the development of strategies that will reduce the impact of surgery on the individual patient.

Figure 20.4 Radiograph showing right upper lobe atelectasis (courtesy of Professor Stephen Eustace, Dublin).

Figure 20-.5 Radiograph showing classical *Staphylococcus aureus* pneumonia (courtesy of Professor Stephen Eustace, Dublin).

Summary box 20.2

Respiratory complications

- Respiratory complications can occur either immediately or a few days later on the ward
- Obesity, smoking, chronic lung disease, poor nutritional status and obstructive sleep apnoea predispose to a higher risk of respiratory complications
- Early intervention and multidisciplinary involvement can prevent life-threatening respiratory complications

Cardiovascular system

Cardiovascular complications are the leading cause of death within 30 days after non-cardiac surgery. Recent trials, reported in the *New England Journal of Medicine*, have identified ways to improve safety and therefore outcome (see Further reading).

Routine pulse, blood pressure, and electrocardiographic (ECG) monitoring detect cardiovascular complications, reduce adverse outcomes and should be recorded during emergence from, and recovery after, anaesthesia. There are certain categories of patient and procedure for which routine cardiovascular monitoring may be required for upwards of 24 hours, usually in a PACU or high-dependency unit.

Immediate cardiovascular complications

HYPOTENSION

In the immediate postoperative period this is associated with adverse outcomes. Multivariable analysis from the POISE-2 trial showed that clinically important hypotension was an

independent predictor of the subsequent risk of myocardial infarction (see Further reading).

Hypotension may be due to hypovolaemia, myocardial impairment or vasodilatation from subarachnoid and epidural anaesthesia. Other causes of hypotension such as surgical bleeding, sepsis, arrhythmias, tension pneumothorax, pulmonary embolism, pericardial tamponade and anaphylaxis should also be considered in the differential diagnosis.

Treatment should be aimed at the cause. Postoperative hypotension leading to end-organ dysfunction, (e.g. decreased urine output <0.5 mL/kg/h, decreased level of consciousness, myocardial ischaemia, capillary refill >2 seconds) needs immediate management with fluid and may require the use of vasopressors and inotropes.

HYPERTENSION

Hypertension is also common. It may be due to pain, agitation, anxiety, bladder spasm secondary to urinary catheterisation or pre-existing poorly-controlled hypertension. Consequences include bleeding from vascular suture lines, cerebrovascular haemorrhage and myocardial ischaemia or infarction.

MYOCARDIAL ISCHAEMIA

Patients with a history of cardiovascular disease or with known cardiac risk factors undergoing major surgery are at risk of major adverse cardiac events. This risk can be predicted preoperatively using the ACS National Surgical Quality Improvement Programme (NSQIP) risk stratification for perioperative myocardial infarction and cardiac arrest (MICA). Symptoms can include retrosternal pain radiating into the neck, jaw or arms, nausea, dyspnoea or syncope, but many events in the perioperative period are silent.

ECG changes can include ST-elevation in two continuous leads, new left bundle branch block or an arrhythmia. In the case of a non-ST segment MI, only a rise in serial troponin levels will clarify the diagnosis. Cardiologists should be involved early and may start coronary reperfusion therapy in the form of primary percutaneous coronary intervention or thrombolysis. These should be discussed with the surgical team due to the risk of bleeding after major surgery.

ARRHYTHMIAS

When they occur in the postoperative period, arrhythmias can cause hypotension, myocardial ischaemia and cardiac arrest. Treatment should be guided by the Resuscitation Council periarrest guidelines.

Tachycardia (sinus or supraventricular) may occur due to anxiety, pain, myocardial ischaemia or infarction, hypovolaemia, sepsis or hypoxia in the postoperative period. Consideration should be given to correction of the underlying causes and rate controlled with β-blockers, amiodarone or cardioversion, depending on the state of the patient.

Sinus bradycardia may be normal in athletes but it may also be associated with hypoxia, preoperative β-blockers, digoxin and increased intracranial pressure. Pharmacological options include glycopyrrolate or atropine intravenously.

STROKE

Stroke is a recognised complication of carotid endarterectomy surgery both early (secondary to emboli) and later (secondary to cerebral hyperperfusion syndrome). It is also a recognised consequence of both hypotension and hypertension. Thrombolysis may be indicated but the neurology and surgical teams must discuss together the risks and benefits of such a treatment plan.

Early and late cardiovascular complications

Major postoperative cardiac complications account for at least one-third of postoperative deaths, resulting in substantial rates of complications, prolonged length of stay and increased medical costs.

MI, congestive heart failure, arrhythmias and stroke need to be identified and treated early. Recent studies advocate shared postoperative care of patients at high risk, in order that the signs of deterioration may be identified early and treated (see Further reading).

Summary box 20.3

Cardiovascular complications

- Hypotension and hypertension in the postoperative period can be multifactorial and result in serious morbidity
- Arrhythmias can be prevented and corrected by treating hypotension and electrolyte imbalance
- Arrhythmias, myocardial ischaemia/infarction and stroke will need management with the help of cardiologists and neurologists

Renal and urinary system

Acute kidney injury

About one-quarter of cases of hospital-acquired renal failure occur in the perioperative period and are associated with high mortality, especially after cardiac and major vascular surgery. Patients with known chronic renal disease, diabetes, liver failure, peripheral vascular disease and cardiac failure are at high risk (*Table 20.1*).

According to national guidance (National Institute for Health and Care Excellence, NICE) based on several definitions, acute kidney injury can be detected by the following criteria (see Further reading):

- a rise in serum creatinine of 26 μmol/L or greater within 48 hours;

TABLE 20.1 Common causes of acute kidney injury.

Prerenal	Hypotension Hypovolaemia
Renal	Nephrotoxic drugs (gentamicin, diuretics, non-steroidal anti-inflammatory drugs) Surgery involving renal vessels Myoglobinuria Sepsis
Postrenal	Ureteric injury Blocked urethral catheter

- a ≥50% rise in serum creatinine known or presumed to have occurred within the past 7 days;
- a fall in urine output to less than 0.5 mL/kg/h for more than 6 hours in adults and more than 8 hours in children and young people;
- a ≥25% fall in estimated glomerular filtration rate in children and young people within the past 7 days.

Urinary retention

Inability to void after surgery is common with pelvic and perineal operations, or after procedures performed under spinal anaesthesia. Pain, hypovolaemia, problems with access to urinals and bed pans and a lack of privacy on wards may contribute to the problem of urine retention. The diagnosis of retention may be confirmed by clinical examination and by using ultrasound imaging. Catheterisation should be performed prophylactically when an operation is expected to last 3 hours or longer, or when large volumes of fluid are administered.

Urinary infection

Urinary infection is one of the most commonly acquired infections in the postoperative period. Patients may present with dysuria and/or pyrexia. Immunocompromised patients, diabetics and those patients with a history of urinary retention are known to be at higher risk. Treatment involves adequate hydration, proper bladder drainage and antibiotics depending on the sensitivity of the microorganisms.

Summary box 20.4

Renal and urinary complications

- Postoperative renal failure is associated with high mortality
- Prophylactic measures to prevent renal failure should be taken in high-risk cases
- Urinary retention and infection are common problems postoperatively

Central nervous system

Postoperative delirium

With an increasingly frail and elderly population presenting for elective surgery, the incidence of postoperative delirium (POD) is increasing. POD is frequently recognised late and has significant postoperative sequelae.

POD can occur during recovery from anaesthesia or a few days after surgery. The overall incidence of POD is 5–50%. It occurs more frequently in the elderly orthopaedic patient and those undergoing emergency surgical procedures. Delirium is associated with increased all-cause morbidity, mortality and discharge to a nursing home. There are two types of delirium – hyperactive (restlessness, incoherent speech, agitation, hallucinations) and hypoactive (withdrawn, poorly responsive to the environment, depressed). Preoperative risk factors for POD include pre-existing cognitive impairment, dementia, frailty, Parkinson's disease, severe illness, renal impairment and depression. Precipitating factors include surgery, intraoperative administration of narcotics and benzodiazepines, change of medications, electrolyte and fluid abnormalities, constipation, catheterisation and an unfamiliar environment (*Table 20.2*).

Correcting any reversible cause, involving relatives or friends whom the patient knows and pain control can all contribute to reducing the impact and duration of delirium. As a last option, haloperidol may be given in titrated doses according to local protocols.

TABLE 20.2 Causes of delirium.

Renal	Renal failure/uraemia Hyponatraemia and electrolyte disorders Urinary tract infection Urinary retention
Respiratory	Hypoxia, e.g. chest infection Atelectasis
Cardiovascular	Pulmonary embolism Dehydration Septic shock Myocardial infarction Chronic heart failure Arrhythmia
Drugs	Opiates including heroin Hypnotics Cocaine Alcohol withdrawal Hypoglycaemia
Neurological	Epilepsy Encephalopathy Head injury Cerebrovascular accident
Idiopathic (rare)	Hypothyroidism Hyperthyroidism Addison's disease

Stroke – has been discussed above.

Seizures – are uncommon except in those patients with known poorly-controlled epilepsy. They may occur as a complication of neurosurgery.

GENERAL POSTOPERATIVE COMPLICATIONS

Bleeding

Postoperative haemorrhage is most common in the immediate postoperative period. It may be caused by an arterial or venous leak, but also by a generalised ooze or a coagulopathy. Slow bleeds may go undetected for hours and then the patient suddenly decompensates. All patients must have their vital signs (pulse rate, blood pressure, oximetry, central venous pressure, if available, and urine output) monitored regularly. Dressings and drains should be inspected regularly in the first 24 hours after surgery. If haemorrhage is suspected, blood samples should be taken for a full blood count, coagulation profile and cross match. A large bore intravenous cannula should be sited

Thomas Addison, 1795–1860, physician, Guy's Hospital. London, UK, described the effects of disease of the suprarenal capsules in 1849.

and fluid resuscitation commenced. If the source of bleeding is in doubt and the patient is stable, an ultrasound or computed tomography (CT) scan may be required to determine the nature of the bleed (most commonly if a haematoma is suspected in the days following surgery). If the patient's cardiovascular system is unstable or compromised in any way (for example neck haematoma or bleeding tonsil) they should be taken back to the operating theatre immediately.

The treatment of haemorrhage is both to stop the bleeding and supportive. Supportive treatment includes oxygen and fluid resuscitation. It may require correction of coagulopathy. All patients will require close observation. Blood transfusion carries risks (acute haemolytic transfusion reaction, sensitisation, fluid overload, hyperkalaemia, transfusion-related lung injury and transmission of blood-borne infection). There is much published about what is the right transfusion trigger and how to balance the need for adequate tissue perfusion and the risks of transfusion. The decision about when to transfuse should be based on the individual patient; in general, however, the accepted transfusion trigger is 75 g/L except in the presence of known or suspected coronary artery disease when a higher trigger is acceptable.

All hospitals should have a 'major haemorrhage protocol' in place. The consultant surgeon, anaesthetist and haematologist should all be involved early on in the care of unstable patients.

Summary box 20.5

Postoperative bleeding

- All hospitals should have a major haemorrhage protocol in place
- Need to transfuse blood in absence of continued bleeding in patients with haemoglobin >75 g/L should be weighed against the risks

Deep vein thrombosis

Deep vein thrombosis (DVT) is a well-known and, when complicated by pulmonary embolus, potentially fatal complication of surgery (*Table 20.3*). All hospitals must have a process for screening all surgical patients to identify those at risk and for implementing prophylactic measures. There is international agreement on risk and therapeutic options. Methods of prevention are guided by the risk score and include the use of compression stockings, calf pumps and pharmacological agents, such as low molecular weight heparin.

The symptoms and signs of DVT include calf pain, swelling, warmth, redness and engorged veins. However, most will show no physical signs. On palpation the muscle may be tender and there may be a positive Homans' sign (calf pain on dorsiflexion of the foot), but this test is neither sensitive nor specific.

Duplex Doppler ultrasound and venography can be used to assess flow and the presence of a thrombosis. Other investigations include D-dimer. If a significant DVT is found (one that extends above the knee), treatment with parenteral anticoagulation initially, followed by longer-term warfarin or new oral anticoagulant (refer to national guidance, e.g. NICE; see Further reading). In some patients with a large DVT, a caval filter may be required to decrease the possibility of pulmonary embolism.

TABLE 20.3 Stratification surgical procedure and the associated risk of deep vein thrombosis.

Low
• Maxillofacial surgery
• Neurosurgery
• Cardiothoracic surgery
Medium
• Inguinal hernia repair
• Abdominal surgery
• Gynaecological surgery
• Urological surgery
High
• Pelvic elective and trauma surgery
• Total knee and hip replacement

Pulmonary embolus

Pulmonary embolism (PE) is not usually an immediate complication, but can present in the early postoperative period. Thrombus can arise from DVT in the legs/pelvis, venae cavae or the right atrium. Signs and symptoms depend on the size of the embolus and may range from dyspnoea, cough, and pleuritic chest pain to sudden cardiovascular collapse. Diagnosis of PE begins with history (including risk factors and recent surgery) and physical examination (which may include signs of DVT). Investigations may include, depending on the presentation, ECG, chest radiograph, blood tests (arterial blood gas and d-dimer) and radiological tests (usually CT pulmonary angiography). If the presentation includes cardiovascular collapse, resuscitation will be needed. Thrombolysis can be considered with massive PE causing cardiovascular collapse, but this should include senior clinical opinion and would generally follow appropriate guidelines. The patient may need inotropes and admission to the intensive care unit. In less severe cases of PE, supportive measures include oxygen therapy and analgesia. After initial resuscitation, the patient will need anticoagulation, initially parenteral anticoagulation, followed by long-term oral anticoagulation (refer to national guidance, e.g. NICE; see Further reading). A vena cava filter may be needed if anticoagulation is not possible or if the patient has an embolism while anticoagulated (see Further reading).

Fever

About 40% of patients develop pyrexia after major surgery; however, in most cases no cause is found. The inflammatory response to surgical trauma may manifest itself as fever, and so pyrexia does not necessarily imply sepsis. However, in all patients with a pyrexia, a focus of infection should be sought.

John Homans, 1877–1954, Professor of Clinical Surgery, Harvard Medical School, Boston, MA, USA.

The causes of a raised temperature postoperatively include:

- atelectasis of the lung;
- superficial and deep wound infection;
- chest infection, urinary tract infection and thrombophlebitis;
- wound infection, anastomotic leakage, intracavitary collections and abscesses.

The possible causes of pyrexia of a non-infective origin include:

- DVT;
- transfusion reactions;
- wound haematomas;
- atelectasis;
- drug reactions.

Patients with a persistent pyrexia need a thorough review. Relevant investigations include full blood count, urine culture, sputum microscopy and blood cultures.

Summary box 20.6

Fever

- A very common problem postoperatively
- Consider infection in the lung, urine and wound

Wound dehiscence

Wound dehiscence is disruption of any or all of the layers in a wound. Dehiscence may occur in up to 3% of abdominal wounds and is very distressing to the patient.

Wound dehiscence most commonly occurs from the fifth to the eighth postoperative day when the strength of the wound is at its weakest. It may herald an underlying abscess and usually presents with a serosanguinous discharge. The patient may have felt a popping sensation during straining or coughing. Most patients will need to return to the operating theatre for resuturing. In some patients it may be appropriate to leave the wound open and treat with dressings or vacuum-assisted closure (VAC) pumps.

Summary box 20.7

Risk factors in wound dehiscence

General

- Malnourishment
- Diabetes
- Obesity
- Renal failure
- Jaundice
- Sepsis
- Cancer
- Treatment with steroids

Local

- Inadequate or poor closure of wound
- Poor local wound healing, e.g. because of infection, haematoma or seroma
- Increased intra-abdominal pressure, e.g. in postoperative patients suffering from chronic obstructive airway disease, during excessive coughing

Pressure sores

Patients undergoing surgery for a prolonged period of time are vulnerable to the development of a pressure sore or to worsening of a pre-existing sore. Careful positioning and padding of the patient is standard practice intraoperatively to reduce risk. Pressure sores occur as a result of friction or persisting pressure on soft tissues. They particularly affect the pressure points of a recumbent patient, including the sacrum, greater trochanter and heels. Risk factors are poor nutritional status, dehydration and lack of mobility and nerve block anaesthesia technique. Early mobilisation prevents pressure sores. High-risk patients may be nursed on an air mattress, which automatically relieves the pressure areas.

Summary box 20.8

Preventing pressure sores

- Recognise patients at risk
- Address nutritional status
- Keep patients mobile or regularly turned if bed-bound

SURGERY-SPECIFIC COMPLICATIONS

Abdominal surgery

The abdomen should be examined daily for excessive distension, tenderness or drainage from wounds or drain sites. In certain operations, such as those for intestinal obstruction, oesophageal and gastric procedures, a nasogastric tube may be required. It is of particular value in those patients suffering from ileus or a marked level of altered consciousness, who are therefore liable to aspirate.

Paralytic ileus

Paralytic ileus may present with nausea, vomiting, loss of appetite, bowel distension and absence of flatus or bowel movements. Following laparotomy, gastrointestinal motility temporarily decreases. Treatment is usually supportive, with maintenance of adequate hydration and electrolyte levels. However, intestinal complications may present as prolonged ileus and so should be actively sought and treated.

Return of function of the intestine occurs in the following order: small bowel, large bowel and then stomach. This pattern allows the passage of faeces despite continuing lack of stomach emptying and, therefore, vomiting may continue even when the lower bowel has already started functioning normally.

Localised infection

An abscess may present with persistent abdominal pain, focal tenderness and a spiking fever. The patient may have a prolonged ileus. If the abscess is deep-seated these symptoms may be absent. The patient will have a neutrophilic leucocytosis and may have positive blood cultures. An ultrasound or CT scan of the abdomen should identify any suspicious collection

and will identify a subphrenic abscess, which can otherwise be difficult to find.

Summary box 20.9

The main complications after abdominal surgery

- Paralytic ileus
- Bleeding or abscess
- Anastomotic leakage

Orthopaedic surgery

Neurovascular supply to the extremity

Patients who have undergone extremity surgery, for example open reduction and internal fixation of a fracture, require regular neurovascular observations, both in recovery and on the ward (this will usually follow a local or national guideline). Moreover, if a tourniquet has been used, the restoration of the distal neurovascular supply should be established. Careful documentation of findings before and after surgery will allow comparison. Concern about the neurovascular status requires urgent and experienced surgical review and further management. Circumferential casts can be split and dressings cut down to skin.

Compartment syndrome

Raised pressure in an osseofascial compartment can prevent adequate tissue perfusion and present after surgery. Patients with compartment syndrome complain of pain out of proportion to that expected, pain that is increasing and pain on passive stretching of the muscles in the affected compartment. Other symptoms that relate to pressure on nerves (paralysis, paraesthesia) and blood vessels (pallor and pulselesness) occur late. When suspected, prompt senior input is required. In terms of initial management, circumferential casts can be split, dressings cut down to skin and the limb elevated. Further management will require experienced judgement and may include compartment pressure monitoring and/or fasciotomies. Compartment syndrome is considered more extensively in Chapter 28.

Summary box 20.10

Compartment syndrome symptoms and signs

- Pain out of proportion to that expected
- Pain that is increasing
- Pain on passive stretching of the muscles in the affected compartment
- Paralysis, paraesthesia, pallor and pulselessness generally occur late

Neck surgery

Patients having neck surgery, e.g. thyroid surgery, must be observed for accumulation of blood in the wound, which may cause rapid asphyxia. Another potential complication is damage to the recurrent laryngeal nerve, which can produce voice change.

Thoracic surgery

Careful fluid management is important in patients undergoing a lobectomy or pneumonectomy as they are susceptible to fluid overload in the first 24–48 hours postoperatively. Chest drains require regular review. If the fluid in a chest drain swings then the drain has been correctly inserted into the pleural cavity. If the chest drain continues to bubble then a bronchopleural fistula probably exists. A haemothorax or pleural effusion will reveal itself as a prolonged loss of blood or fluid, respectively, into the drain. Cardiac patients require continuous ECG monitoring postoperatively.

Neurosurgery

Postoperatively the patient should be kept under close observation. A rise in intracranial pressure may be signalled by a deterioration in the state of consciousness, as well as by neurological signs. Some patients may have an intracranial monitoring device to allow for more sensitive monitoring.

Vascular surgery

The patency of grafts and anastomoses, for example femoropopliteal bypasses and abdominal aneurysmal, needs to be checked by regular clinical assessment of the limbs and by Doppler ultrasound in the postoperative phase.

Plastic surgery

The viability of flaps is crucial and the perfusion needs to be monitored regularly. The blood supply may be compromised by position, dressings or collection of fluids or blood beneath the flap.

Urology

Catheter patency must be checked regularly following urological surgery. In patients who have undergone transurethral resection of the prostate (TURP), continuous bladder irrigation may be used. More generalised complications can occur, for example transurethral resection syndrome, and are discussed further in the appropriate section.

GENERAL POSTOPERATIVE PROBLEMS AND MANAGEMENT

When considering postoperative problems, the importance of pain control and fluid management should be appreciated, and the reader is directed to Chapters 18 and 19.

Nausea and vomiting

Postoperative nausea and vomiting (PONV) are unpleasant for patients, can delay recovery and prolong length of stay.

They can lead to more serious complications including aspiration pneumonia, precipitation of bleeding and dehiscence of wounds by dislodging the clots and bursting suture lines. In neurosurgical patients PONV may precipitate raised intracranial pressure with disastrous effects.

Risk factors for PONV include female gender, non-smoking, and a history of PONV, motion sickness or migraine. Use of volatile anaesthetic agents, opioids and nitrous oxide add to the risk. Duration and type of surgery also affect the incidence of PONV.

The risk of PONV can be estimated by using validated risk scores such as the Apfel (*Table 20.4*) or Koivuranta scores and appropriate preoperative strategies applied to high-risk individuals.

Treatment of PONV includes adequate treatment of pain, anxiety, hypotension and dehydration. Antiemetics can be administered both prophylactically and for treatment. A multimodal pharmacological approach, using drugs that work at different sites, such as HT3 receptor antagonists (e.g. ondansetron), steroids (e.g. dexamethasone), phenothiazines (e.g. prochlorperazine) and antihistamines (e.g. cyclizine), is the most effective.

TABLE 20.4 Apfel score to predict postoperative nausea and vomiting (PONV).

Characteristics	Points
Female sex	1
History of motion sickness or PONV	1
Non-smoker	1
Postoperative opioid treatment is planned	1
Total:	____

Score	Probability of PONV (%)
0	10
1	21
2	39
3	61
4	78

Hypothermia and shivering

Anaesthesia induces loss of thermoregulatory control. Exposure of skin and organs to a cold operating environment, antiseptic skin preparation (that cools by evaporation), and the infusion of cold intravenous fluids all lead to hypothermia. This in turn can lead to shivering, with imbalance of oxygen supply and demand (risking cardiac morbidity), a hypocoagulable state and immune function impairment, with the possibility of wound infection, dehiscence and anastomotic breakdown. It is now expected that temperature is monitored intraoperatively and the incidence of postoperative hypothermia has decreased significantly as a consequence. Active warming devices should be used to treat hypothermia as appropriate.

Drains

Drains are used to prevent accumulation of blood, serosanguinous or purulent fluid or to allow the early diagnosis of a leaking surgical anastomosis. In clean surgery, such as joint replacement, blood collected in drains can be transfused back into the patient provided that an adequate volume is collected rapidly and that a specifically-designed drain and filter system is used.

The use of surgical drains has decreased in recent years as the evidence for their benefits has been questioned. Complications of drains include trauma to surrounding tissues and infection. The quantity and character of drain fluid can be used to identify an abdominal complication such as fluid leakage (e.g. bile or pancreatic fluid) or bleeding.

Drains should be removed as soon as possible and certainly once the drainage has stopped or become less than 25 mL/day.

Wound care

Within hours of the wound being surgically closed, the dead space fills up with an inflammatory exudate. Within 48 hours of closure a layer of epidermal cells from the wound edge bridges the gap. Consequently, sterile dressings applied in theatre should not be removed before this time.

Wounds should be inspected only if there is a concern about their condition or the dressing needs changing. Inspection of the wound should be performed under sterile conditions. If the wound looks inflamed, a wound swab can be taken and sent for microbiological examination, but this can be unreliable. Infected wounds and haematomata may need treatment with antibiotics or even wound washout. If a surgical procedure is performed it gives an opportunity to collect samples for bacteriology (before any antibiotics, if the patient's general condition allows), to excise dead tissue and to control any bleeding. Depending on location, the wound may require packing if it is contaminated or if non-viable tissue remains. The dressing should then be changed regularly until the wound is clean.

Skin sutures or clips are usually removed between 6 and 10 days after surgery. The period can be shorter in wounds on the face or neck, and are left longer if the incision has been closed under tension. Wound healing is delayed in patients who are malnourished, or have vitamin A and C deficiency. Steroids also inhibit the adequate healing of wounds as they inhibit protein synthesis and fibroblast proliferation. Poorly-controlled diabetes delays wound healing and increases the risk of infection at the surgical site.

ENHANCED RECOVERY

Enhanced recovery is an approach to the perioperative care of patients undergoing surgery. It is designed to speed clinical recovery of the patient and reduce both the cost and the length of stay of the patient in the hospital. It is achieved by optimising the health of the patient before surgery through prehabilitation and then delivering evidence-based best care in the perioperative period.

Postoperative strategies advocated by enhanced recovery protocols include:

- Early planned physiotherapy and mobilisation.
- Early oral hydration and nourishment.
- Opioid-sparing analgesia regimens that include the use of regional blocks, regular non-steroidal anti-inflammatory drugs and paracetamol.
- Discharge planning is started before the patient is admitted to hospital and involves support from stoma care nurses, physiotherapists and other community care workers.

Early mobilisation is encouraged to reduce the risks of DVT, urinary retention, atelectasis, pressure sores and faecal impaction. Telephone follow-up is carried out to make sure that the patient is recovering well.

DISCHARGE OF PATIENTS

Patients discharged home need a 'discharge letter' detailing the postoperative plan. The discharge letter should include details of the final diagnosis, the treatment and any complications that may have occurred. There should be advice for referring the patient back to hospital and indications for readmission if specific problems do occur. The general practitioner (GP) should be informed of the subsequent care plan, including follow-up, physiotherapy and other support needed. Pathology results should be included if available, and the basis of these in the subsequent care plan should be described along with the prognosis if appropriate.

Summary box 20.11

Discharge letter

Diagnosis
Treatment
Laboratory results
Complications
Discharge plan
Support needed
Follow-up

Follow-up in clinic

Patients should only be reviewed in clinic when a key decision on management needs to be made. The findings and the care plan agreed with the patient at the clinic appointment should be included in a letter to the patient's GP, as well as in a clear entry in the notes or electronic patient record. This should include advice on how to recognise the onset of complications and what to do if there is concern. Patients should be discharged from clinic as soon as their GP or they themselves, can manage their care.

Chapter 21

Day case surgery

Learning objectives

To understand:

- The concept of the day surgery pathway
- The importance of patient selection and preoperative assessment
- Basic principles of anaesthesia for day surgery
- The spectrum of surgical procedures suitable for day surgery
- Postoperative management and discharge arrangements

DAY SURGERY

The delivery of a surgical procedure on a day case basis offers advantages in providing significant benefits for both patient and healthcare providers. The removal of an overnight stay causes less disruption to the patient's domestic and social situation, and provides significant financial savings to the hospital. In resource-rich countries, day surgery is now an integral component of healthcare delivery, while in resource-poor countries, day surgery is increasing in popularity due to patient preference and healthcare reorganisation.

Day surgery is defined as the admission and discharge of a patient for a specific procedure within the 12-hour working day. Where a patient requires an overnight admission, then the term '23 hour stay' should be used.

Day surgery is a patient pathway, not a surgical procedure, and extends from first patient contact to final discharge (Figure 21.1). Success in day surgery requires each component of the pathway to be safe and efficient and to be performed in sequence. Unplanned overnight admissions are minimised by ensuring that:

- the patient is informed and fit for the procedure;
- the procedure itself is achievable as a day case;
- the procedure is scheduled early on the operating list to allow safe recovery and discharge; and
- the home environment can support a postoperative ambulatory patient.

Summary box 21.1

Definition of terms used in ambulatory surgery

- Outpatient surgery: not admitted to a ward facility
- Procedure room surgery: surgery not requiring full sterile theatre facilities
- Day or same-day surgery: admitted and discharged within the 12-hour day
- Overnight stay: 23-hour admission with early morning discharge
- Short-stay surgery: admission of up to 72 hours

MODELS OF CARE

Office-based care

This model, common in North America and Europe, where diagnostics and ambulatory interventions are performed in

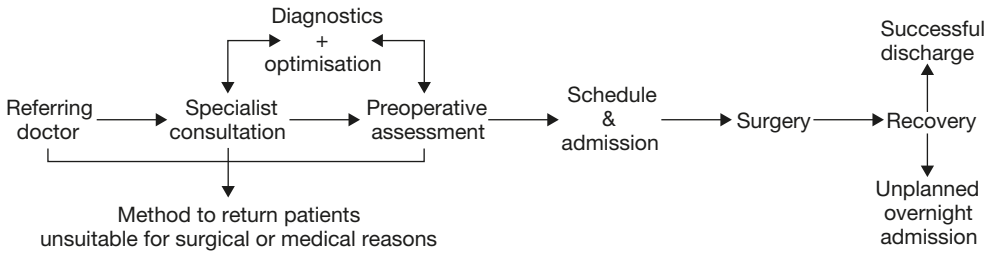

Figure 21.1 Elective day surgery pathway.

James H Nicoll, 1864–1921, paediatric surgeon, Glasgow, Scotland, specialised in pyloric stenosis and spina bifida and pioneered the 'Glasgow dispensary', where his work earned him the title of 'father of Day Surgery'. He was made Legion of Honour France.

consultation premises, allows patients ready access to 'high street' care. The downside is that the practice is usually limited to procedures under local anaesthesia, with or without conscious sedation. The use of general anaesthesia is limited, as this requires additional equipment and personnel, and raises safety issues in an isolated facility.

Stand-alone day surgery facilities

Where day case procedures are performed in isolated facilities, either on a remote site, or in the campus of the parent hospital, the workload is free from interference by emergency admissions. The spectrum of procedures performed is, by necessity, limited to those under local or regional anaesthesia or minor to intermediate procedures under general anaesthesia, to avoid unplanned overnight admissions and the requirement to transfer the patient to the parent hospital, which may be some distance away.

Self-contained integrated day surgery facilities

Though structurally part of a hospital, self-contained units have their own reception, ward, theatre and recovery areas and are functionally separate from the main hospital and potential disruption by emergency admissions. The back-up facilities of the main hospital are readily available if required, so these units can undertake a full spectrum of day surgery procedures. The growing demand for day surgery can lead to capacity issues and there may be duplication of costly capital equipment where procedures are performed on both a day case and inpatient basis.

Integrated day and short-stay surgery facilities

This type of unit allows complete flexibility in the delivery of day and short-stay surgery, with the ability to embark on more challenging day surgery procedures or consider day surgery on less fit patients. The availability of overnight beds has its downside: the preassessment team may convert fewer patients from overnight stay to day surgery by adopting the easy option of keeping the more challenging patient in overnight. Moreover, the availability of beds rather than day surgery recovery trolleys, puts these ambulatory beds at risk from emergency admissions.

While dedicated day surgery facilities are welcome, regardless of model, they are not mandatory for the successful delivery of the day surgery pathway. Success *does* require a dedicated day ward facility, where the staff can concentrate on the timely recovery and discharge of the day case patient. In mixed wards of day cases and inpatients, nursing and medical staff naturally prioritise the care of the less fit patient, and it may be easier to keep the day case patient overnight, rather than ensuring an optimum discharge process.

SELECTION CRITERIA

Medical criteria

Age

There is no upper age limit. The physiological health of the patient is a superior determinant of day surgery success.

Summary box 21.2

Selection criteria for day surgery

- Medical: use physiological rather than chronological age
  - ASA status over 2 requires careful review
  - Provided that the BMI is under 40, this alone is not a contraindication
- Social: a responsible adult carer must be available for the first
  - 24 hours, for the elderly and patients at risk of covert bleeding
  - home conditions need to be suitable
  - ability to contact hospital in an emergency
- Surgical: operations up to 2 hours
  - recognised day surgery procedures
  - ability to eat and drink within a reasonable timescale

Comorbidity

Day surgery units traditionally use the American Society of Anaesthesiologists (ASA) Classification, which is a crude evaluation of chronic health (*Table 21.1*). Stand-alone units often confine their criteria to ASA 1 and 2 patients, while ASA 3 patients are more suitable for hospital-integrated units. Patients with significant respiratory or cardiovascular disease should be reviewed by an anaesthetist before being accepted for day surgery (see Chapter 17). Many patients who are fit but hypertensive are incorrectly excluded from day surgery. There is no evidence to support cancellation when blood pressure is below 180/110 mmHg.

Diabetes

The incidence of diabetes is increasing worldwide. Patients with well-controlled Type 1 and Type 2 diabetes are good candidates for the well-managed day surgery pathway. Control can be assessed by measuring their HBA1c, with a level of below 8.5% indicating good control. Diabetes is associated with potentially severe comorbidities, such as renal disease,

TABLE 21.1 The American Society of Anaesthesiologists (ASA) Physical Status Classification (American Society of Anaesthesiologists 1963).

ASA 1	A normal healthy patient
ASA 2	A patient with mild systemic disease
ASA 3	A patient with severe systemic disease
ASA 4	A patient with severe systemic disease that is a constant threat to life
ASA 5	A moribund patient who is not expected to survive without the operation

autonomic neuropathy and cardiovascular disease, and so these patients must be assessed carefully preoperatively and managed by an experienced team. It is important to have protocols for the care of diabetic patients that have been agreed with the local diabetic team and to involve them in the care of more complex patients. Success depends on ensuring these patients return to normal eating and drinking and managing their own diabetes as quickly as possible in the postoperative period.

Traditional care, with placing the patient first on the list and providing them with instructions on management of their medication preoperatively, works well. Those on morning lists can simply miss their morning dose of oral hypoglycaemic medication or insulin, though they must be instructed to bring their medications with them and to manage any hypoglycaemia as they would normally. Those on afternoon lists and those patients who are on more complex therapy, such as continuous subcutaneous infusions, can still be managed with input from the anaesthetic or diabetic team.

Epilepsy

A diagnosis of epilepsy does not contraindicate day surgery. Patients who have well-controlled epilepsy should be managed as normal patients, though it is important to ensure that their regular medication is not omitted in the preoperative period. Patients who are on medication but remain poorly controlled need careful review and discussion with their medical and anaesthetic teams. However, if they have suitable home support and the proposed surgery does not put them at risk, then they too are suitable for day surgery.

Obesity

The body mass index (BMI) is calculated as weight in kilograms divided by the square of height in metres (kg/m^2) and obesity is defined as a BMI >30 (**Figure 21.2**). Traditional guidelines are conservative about obesity due to fears of intra- and postoperative complications. Although there is an increased incidence of non-serious respiratory complications intraoperatively and in the immediate postoperative recovery

Figure 21.2 Body mass index calculator.

Adolphe Quetelet, 1796–1874, Belgian mathematician, astronomer and statistician, the pioneer in establishing the criteria of obesity that became known as the Quetelet Index. In 1972 Ancel Keys (1904–2004), an American scientist from the University of Minnesota and an expert on human nutrition, public health and epidemiology, named it the body mass index.

period, the course of these patients is otherwise uneventful. They should however, be managed by experienced medical and nursing staff. Hypertension, congestive cardiac failure and sleep apnoea are all more common in patients with morbid obesity, but in selected and optimised patients, a BMI up to 40 for surface procedures and 38 for laparoscopic procedures are acceptable and achievable in advanced units. Patients established on nasal positive airway pressure for obstructive sleep apnoea can be managed successfully.

Anticoagulants

Patients are generally on oral anticoagulants due to atrial fibrillation, previous thromboembolism or because they have a metal heart valve. It is therefore important to review these patients carefully before deciding to discontinue their anticoagulant for their operation. When it is felt that surgery will require its discontinuation, this should be discussed with their cardiologist and the risks involved explained to the patient.

Social criteria

Safe and comfortable discharge home requires the patient to be accompanied by a responsible and physically able adult. A journey time to home of 1 hour or less is advocated, but the comfort of the journey rather than the time involved is more relevant. Home circumstances require appropriate toilet facilities and the means of contacting the hospital should complications occur.

Surgical criteria

Patients undergoing procedures up to 2 hours in duration can safely undergo day surgery with modern anaesthetic techniques. The degree of surgical trauma is an important determinant of success, with entry to abdominal and thoracic cavities confined to minimal access techniques. Whatever the procedure, the main requirement is that there is suitable control of pain and the ability to drink and eat in a reasonable timescale. With day surgery now applicable to more major and prolonged procedures, patients should undergo a venous thromboembolism risk assessment and have prophylaxis provided if required.

PREOPERATIVE ASSESSMENT

The evaluation and optimisation of a patient's fitness for surgery is known as preoperative assessment (see Chapter 17) and is best performed by a specialist nursing team with support from an anaesthetist with an interest in day surgery. All elective surgical patients should be initially regarded as suitable for day surgery until proved otherwise. The assessment should be performed early in the pathway to allow time to optimise health problems before surgery The consultation consists of a basic health screen to include the measurement of BMI, blood pressure and an assessment of past medical history with current medication recorded. Appropriate investigations are performed to ensure the patient is fit for surgery. The patient and/or their carer should be given verbal and written information regarding admission, operation and discharge.

Summary box 21.3

Preoperative assessment

- On all day surgery patients
- Early in the patient pathway
- By a specialist nursing team with anaesthetic support

PERIOPERATIVE MANAGEMENT

Scheduling

With dedicated day surgery lists, major procedures should be scheduled early on morning lists to allow maximum recovery time. When the list is in the afternoon, the allocation of local or regional anaesthetic cases later in the day helps reduce unplanned overnight admissions. When mixed lists of day and inpatient cases are planned, then day cases are scheduled first. The mixing of day and complex inpatient cases is not advisable. The complex case may be inappropriately delayed if the day case is scheduled first and, conversely, if the day case patient is scheduled later, there is a risk of cancellation or unplanned overnight admission for the day case.

Anaesthesia and analgesia

Successful day surgery anaesthesia requires a multimodal approach to analgesia, while ensuring patients are given optimal dosages of anaesthetic agent (see Chapter 18). The agents used matter less than the skill of the person providing anaesthesia.

Multimodal analgesia starts in the preoperative period and unless contraindicated, patients should receive full oral doses of paracetamol and a non-steroidal anti-inflammatory drug, such as ibuprofen. Intraoperative anaesthesia can be maintained by any of the traditional inhalational agents. Total intravenous anaesthesia (TIVA) techniques using propofol are also popular and offer the advantage of reduced postoperative nausea and vomiting (PONV). The use of intraoperative analgesia will depend on the procedure being performed. When available, the anaesthetist should use short-acting opioids (fentanyl, alfentanil). Careful use of these agents can minimise the incidence of PONV. Where the choice is limited to morphine, this should be used in small doses (<0.1 mg/kg) to minimise sedation and PONV. Wherever possible, a long-acting local anaesthetic agent such as bupivacaine should be injected into wounds by the surgeon.

Pain levels should be routinely assessed in the postoperative recovery area. Further doses of paracetamol, fentanyl or low doses of morphine can be used to ensure that patients are comfortable prior to return to the ward.

Postoperative complications

The range of postoperative complications is no different from inpatient surgery. However, the fact that the patient is discharged home within a few hours of surgery requires proactive monitoring in the immediate postoperative period.

Summary box 21.4

Optimal analgesia and anaesthesia

- Multimodal analgesia with paracetamol and NSAIDs (if not contraindicated) should be given preoperatively
- Use long-acting local anaesthetic infiltration of the surgical wound
- Careful dosing of inhalational or intravenous agents should be used to maintain anaesthesia
- Avoid long-acting opiates such as morphine, to reduce the incidence of sedation and PONV

Reactionary haemorrhage is uncommon but requires careful consideration following tonsillectomy and laparoscopic procedures. Reactionary haemorrhage following tonsillectomy occurs within the first 6 hours and these patients should be monitored for this period. The danger in laparoscopic surgery is covert haemorrhage, especially in young fit patients who can lose over 15% of their blood volume before showing any cardiovascular signs of hypovolaemia (tachycardia and hypotension). These patients require a high index of suspicion as the first signs can often be as subtle as slow recovery and mobilisation or uncontrolled abdominal pain. When problems do occur, there should be clear escalation policies to ensure the patient is reviewed by the surgical team as soon as possible. Nausea and vomiting is not uncommon and should be managed actively to maximise successful discharge (**Figure 21.3**).

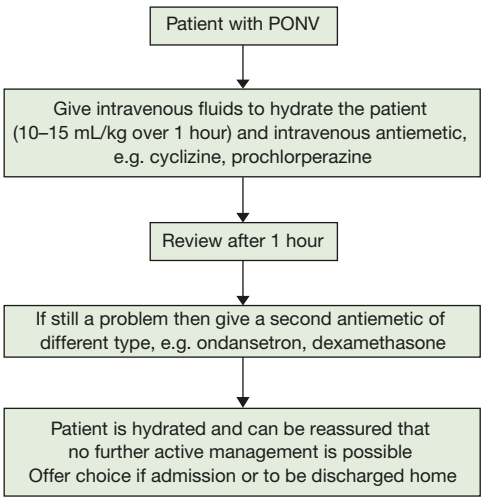

Figure 21.3 Active management of postoperative nausea and vomiting (PONV).

Summary box 21.5

Surgical haemorrhage

- Reactionary: occurs 4–6 hours after surgery and is caused by ligature slippage, clot displacement or cessation of vasospasm after mobilisation or coughing
- Secondary: occurs more than 24 hours after surgery and is due to infection eroding a vessel

ELECTIVE DAY SURGERY

For some surgical specialties, over 90% of their elective workload can be achieved in day surgery. As a result, teaching and training now routinely occurs on day surgery lists but requires structure and close supervision. As the spectrum of procedures has increased and become more challenging, many surgeons have increased their involvement in day surgery. This is important because safe and efficient day surgery demands the competence and skill of an experienced surgeon. Some surgeons have concerns regarding patient safety after discharge. The risk of postoperative haemorrhage occurring once the patient has returned home is often stated as a major reason to keep the patient in hospital overnight, especially where the abdominal or thoracic cavities have been entered. Reactionary haemorrhage commonly occurs in the first 4–6 hours after surgery, but the patient is unlikely to have been discharged home within this time period. It may be caused by slippage of a ligature or displacement of blood clot, precipitated by a rise in blood pressure, coughing or increased mobility. Postoperative monitoring of vital signs should alert the recovery team to any underlying bleed. Secondary haemorrhage is defined as occurring at least 24 hours after surgery but usually presents several days later, as it is due to postoperative infection. Thus, even if the patient had stayed overnight, these postoperative bleeds are still likely to occur once the patient has returned home.

Good surgical technique requires minimal tissue traction or tension and good haemostasis. In day surgery these attributes are even more important. The number and variety of surgical procedures performed on a day case basis is increasing year on year. Volume procedures in general surgery where the British Association of Day Surgery considers at least 40% of procedures can be performed on a day case basis, are shown in *Table 21.2*.

TABLE 21.2 Volume procedures where 40% or more should be performed on a day case basis.

Abdominal	Excisional/treatment of anal lesions, haemorrhoidectomy, primary and recurrent inguinal/femoral herniae, laparoscopic cholecystectomy, laparoscopic fundoplication, pilonidal sinus surgery
Breast	Excision/biopsy breast lesion, sentinel node excision
Genitourinary	Laser prostatectomy, orchidectomy, circumcision, excision of hydrocoele/varicocoele/epididymis
Orthopaedic	Dupuytren's fasciectomy, carpal tunnel release, therapeutic arthroscopy of knee or shoulder, bunion operations, removal of metalwork
Vascular	Varicose vein procedures, thoracoscopic sympathectomy

British Association of Day Surgery 2012.

Summary box 21.6

Successful day surgery requirements

- Minimal access techniques
- Good haemostasis
- Avoidance of unnecessary tissue handling or tension

TABLE 21.3 Common procedures suitable for the emergency day surgery pathway.

Arthroscopy
Biopsy (temporal, lymph node)
Evacuation retained products of conception
Irreducible or strangulated hernia (inguinal, femoral, paraumbilical)
Incision and drainage of abscess (axillary, groin, neck, perianal, pilonidal)
K-wiring (finger or wrist)
Laparoscopic appendicectomy
Laparoscopic ovarian cystectomy
Reduction and internal fixation
Tendon repair

EMERGENCY DAY SURGERY

Many emergency surgical procedures are minor and non-life threatening, and traditionally have been considered low priority for surgical intervention. The prioritisation of more urgent cases to restricted emergency theatre slots may result in extensive delays for minor cases, with unnecessary bed stays and preoperative starvation. Many of these cases, such as incision and drainage of abscesses, can be safely discharged home after their initial evaluation in the emergency department. They are provided with adequate analgesia and scheduled to return to the hospital at an appointed time the following day, suitably starved for their operation. This allows same-day discharge for minor emergency procedures.

If performed early in the day, the surgery rather than the pathway, may be defined as 'day case'. Some patients may, by chance, achieve a true day case pathway with admission, operation and discharge in the same day, provided they are admitted early in the day, there is no diagnostic delay and a theatre slot is available. Others may only achieve day case surgery, but not a day case pathway, if there has been diagnostic or clinical delay on admission (**Figure 21.4**). Common procedures suitable for the emergency day surgery pathways are shown in *Table 21.3*.

The success of an emergency day surgery pathway is dependent on the identification of unallocated theatre slots. These may be planned where there is reasonable predictability of emergency cases or may arise on elective lists, either day case or inpatient, due to patient cancellations. Emergency facilities may also be underutilised when there are delays in getting the more seriously ill patient to surgery. There is therefore an opportunity, providing staff are available, to utilise the empty theatre for a minor case before bringing the optimised sick patient to operation. This allows the ambulatory patient to be discharged on the day of surgery, provided discharge protocols are in place. This balance between clinical and managerial priority can be difficult to achieve without surgical experience, but forethought can permit a positive outcome for the quality of emergency patient care and the managerial requirement to shorten duration of stay.

When designing an emergency day surgery pathway, traditional day surgery selection criteria are ignored, with clinical judgement used to determine whether patients are appropriate for day surgery. The only absolute contraindications are systemic sepsis, unstable diabetes, major comorbidities and if parenteral, rather than oral, analgesia is required.

DISCHARGE

The assessment of when a patient is fit for discharge is best performed by trained day surgery nurses using strict discharge criteria (*Table 21.4*). While postoperative review by the surgical team is encouraged, the discharge should not be delayed by failure of their timely attendance. A suitable supply of analgesics for the management of pain should be provided. Paracetamol, NSAIDs and codeine form the basis of the drugs available in many countries.

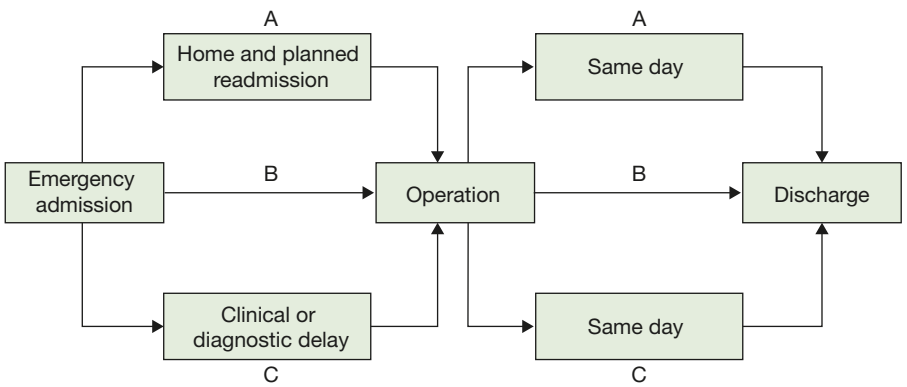

Figure 21.4 Emergency day surgery pathways. A, Planned preoperative discharge home with imminent return for day surgery. B, 'True' emergency day surgery with the entire pathway of admission, surgery and discharge on the same day. C, Preoperative delay, but surgery and discharge on a day case basis.

TABLE 21.4 Discharge criteria.

Vital signs stable for at least 1 hour
Correct orientation as to time, place and person
Adequate pain control with supply of oral analgesia
Understands how to use oral analgesia supplied
Ability to dress and walk where appropriate
Minimal nausea, vomiting or dizziness
Has taken oral fluids
Minimal bleeding or wound drainage
Has passed urine (if appropriate)
Has a responsible adult to take them home
Written and verbal instructions given about postoperative care
Knows when to come back for follow-up (if appropriate)
Emergency contact number supplied

PART 4

Trauma

Chapter 22

Introduction to trauma

Learning objectives

- Become familiar with the timeline concept in trauma management
- Understand how to assess a trauma problem
- Learn how to respond to a trauma problem
- Understand how to select early total care and damage control surgical strategies

DEFINITION OF TRAUMA

Trauma originates from the Greek word meaning 'wound'. It implies that a physical force exerted on a person has led to a physical injury. External energy forms and forces that can lead to injury include chemical, thermal, ionising radiation and, most frequently, those of mechanical origin. The degree and severity of trauma sustained can vary substantially and depend upon the magnitude of force exerted.

Major trauma denotes injuries to more than one body region and organ system. In the next group of chapters, trauma will be examined from a variety of viewpoints, interconnected to different specialties. In this section we will examine the facets that bind the whole topic together.

THE MAGNITUDE OF THE PROBLEM

Trauma remains the most common cause of death and disability in children and young adults in the resource-rich countries. Globally, approximately 10 000 people die daily as a result of an injury. Road traffic accidents (RTA), falls and intentional violence have been identified as the major vectors of traumatic injury. It is notable that the major burden of injury is increasingly occurring in middle- and low-income countries as they industrialise and adopt motorised transportation.

In terms of the annual incidence and trends over time there is variation from country to country. Information is usually obtained from national statistics organisations that use the International Classification of Disease, a system that can be limited in providing accurate descriptions of injury severity. However, the Abbreviated Injury Scale (AIS) dictionary consists of a greater level of detail (including more than 2000 injury codes) and assigns to every injury a severity score between 1 (mild) and 6 (maximum). This can be summated into the so called Injury Severity Score (ISS), providing an image of the anatomical severity of injury suffered by the individual patient. Major trauma is defined as an ISS greater than 15, which can be written as >15. The majority of hospital admissions with injury have low ISS values, ranging between the values 4 and 8, and are secondary to single isolated limb fractures and isolated mild head injury. Overall, major trauma affects approximately 15% of all injured patients.

The total number of casualties from RTA alone reported to the police in Great Britain during 2015 was 186 189, which was around 4% lower when compared with 2014. Of these, 21 657 people were seriously injured, among whom 1730 lost their lives, representing a 3% decrease compared with 2014. Across Europe, according to the data presented by the European Transport Safety Council's Performance Index (PIN) report, it appears that fatalities rose in the majority of countries. Of the 32 countries covered, 21 had an increase in the number of fatalities in 2015, ten had a decrease, and one remained unchanged. Since countries do not use the same definition of serious injury, international comparisons are based on road deaths per million inhabitants **(Figure 22.1)**. The United Kingdom as a whole had 27.7 deaths per million inhabitants in 2015. The only European countries with a better rate than this in 2015 were Sweden with 26.6, Malta with 25.6 and Norway with 22.6. The UK and Sweden have been consistently at the head of this table for a number of years.

A large proportion of the severely injured survivors experience long-term or permanent disability as a result of their injuries. Almost 30% of them are no longer able to return to their previous occupation and a great deal of time is lost from work. These individuals end up having profound changes in their lifestyle, with long-term pain and suffering. It should be emphasised that an injury not only affects the injured person but also affects everyone who is involved in the injured person's life. The impact of the modern epidemic of road traffic

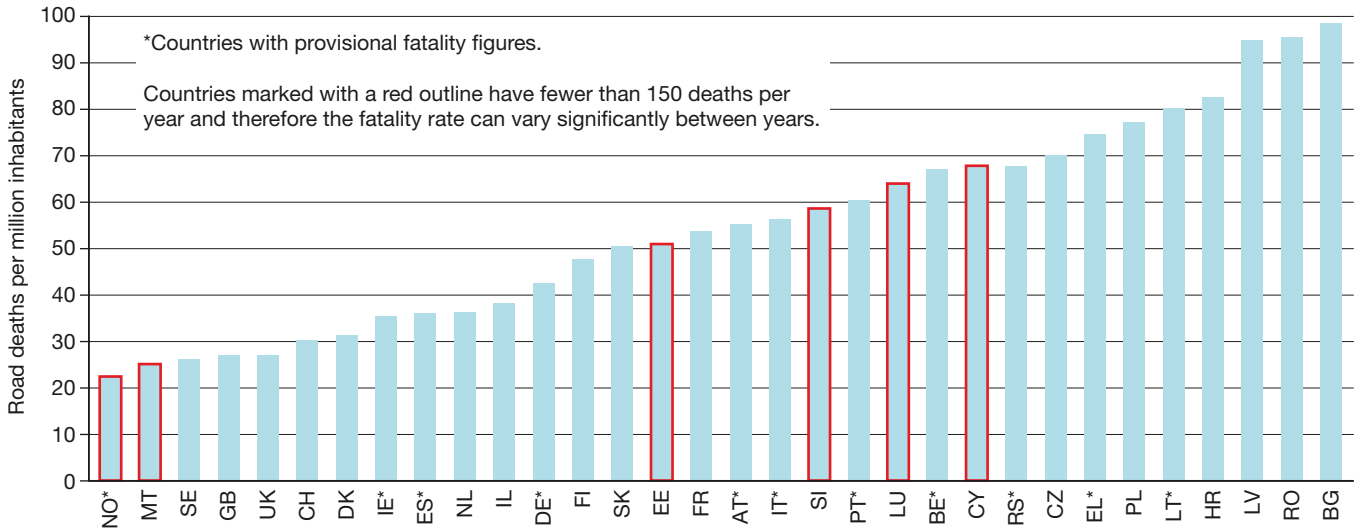

Figure 22.1 Number of road deaths per million inhabitants.

accidents on the universal epidemic of violent injury cannot be overstated. The annual direct medical cost of injuries treated in hospitals and additional care facilities is estimated to be £3.7 billion. Moreover, additional costs, due to loss of earnings, loss of productivity and quality of life damage, increase the total sum significantly.

While young patients are involved in road traffic accidents characterised by high energy transfer, older patients may sustain injuries from falls (low energy transfer). The most common group to be admitted to hospital in the UK are older patients who have sustained a 'fragility' fracture. Approximately 65 000 to 70 000 patients are admitted annually with proximal femoral fractures, among whom 30% over the age of 65 will die within a year of the incident. Most of the rest will end up having diminished independence and functional capacity. It is therefore no surprise that this particular cohort of patients, which will increase in the coming years owing to the anticipated increase in life expectancy, is thought to represent a huge burden on healthcare services and society in general.

In general terms, the vast majority of injuries sustained are not limb threatening or life threatening. They are straightforward and most patients are expected to recover fully and return to their preinjury status. Nonetheless, the challenge remains to appreciate and diagnose the injuries at an early stage, with an awareness of important features that may influence the outcome.

For instance, we must be vigilant not to miss non-accidental injury (NAI) in children (see Chapter 39) and injuries in other age groups related to an underlying disease process rather than the injury itself, for example pathological fractures. Of note, it has been shown that in 66% of cases when children die as a result of abuse, there has been some previous interaction with a health professional or social services but the seriousness of the situation was not fully appreciated.

Summary box 22.1

Trauma: the magnitude of the problem

- The vast majority of injuries are not life or limb threatening
- Severe trauma continues to be a major cause of death in young patients
- Older patients with fragility fractures pose an additional burden to the healthcare system
- Look for important features of injuries that could influence the outcome

THE MANAGEMENT OF TRAUMA

From the moment that injury is sustained, every aspect of decision making and management is essential in terms of the survival of the victim. Our initial assessment and concepts of management have specific objectives and are usually based on knowledge acquired over a long period of time in practice. A better understanding of the physiological processes underpinning the host responses to an acute threat to our homeostatic mechanisms, together with protocols formulated to allow clinicians to use standardised measures and to speak a common language, have revolutionised the way we manage patients. All of the above help to reduce delays, particularly when under pressure to make a decision. However, it remains crucial to understand the reasoning as to why we are carrying them out.

In trauma, as in other acute conditions, the patient is particularly reliant upon the clinician. A patient with a chronic condition is familiar with the nature of their problem and the way in which it is progressing. The surgeon may offer a remedy and the patient may consider the potential benefits and choose appropriately whether to accept it. The injured patient does not know what will happen without treatment and so relies on their surgeon to inform them of both the natural history and the potential benefits of any intervention. The implication is that as surgeons we have a duty to be aware of both.

The significance of time in the outcome

Injury can occur in the blink of an eye. In the seconds prior to the application of the external injury force or vector, the patient is at their normal baseline, which can be called time zero. All subsequent events, including the acute physiological response to injury, the body's internal mechanisms to maintain homeostasis (to compensate for the sequelae of trauma), the healing processes and the actions instigated by health professionals, are associated with a 'timeline'. Being familiar with the 'timeline principle', one should be aware that there is a critical time window in which we can intervene for a positive treatment outcome, before the loss of compensatory mechanisms. Moreover, the timeline allows evaluation of any progress made from time zero to other important events and to reflect on whether a specific course of action could have been performed better.

Overall, interventions can be distinguished as emergency (life saving), acute (restoring haemodynamic stability) and delayed or semielective, focusing on the treatment of post-fracture fixation complications (non-union, infection and malunion from the orthopaedic trauma point of view).

It is essential to appreciate that the physiological crisis initiated in the immediate aftermath of trauma will continue to evolve and the risk of mortality is substantial unless the correct and timely interventions are performed. For instance, conditions such as airway obstruction, tension haemothorax and haemopericardium can progress very rapidly if left untreated and should be given priority in terms of our initial medical response to the injured patient. Thus, the seriousness and the immediate impact of a specific clinical condition should be prioritised and treated in a systematic approach (what kills first should be managed first). This concept of the hierarchy of medical responses can only be applied and become effective when we are in a position to diagnose early the underlying clinical conditions (**Figure 22.2**).

The ATLS (Advanced Trauma Life Support) system delineates an order of priorities set by ABCD; that is, **a**irway, **b**reathing, **c**irculation and **d**isability (neurology). This hierarchy of priorities is instituted upon the 'time dependence' principle. The clinician should bear in mind that a successful management plan is dependent on, first, the time needed to evaluate and diagnose the nature of the problem and, second, the time taken to respond effectively to the condition discovered (**Figure 22.3**).

Evaluating and diagnosing a condition can be challenging, as the initial clinical signs may be non-specific. The clinical condition will continue to evolve as the time progresses, but by the time the diagnosis has been made it may be too late to prevent mortality. Taking into consideration the mechanism of the accident and promptly requesting special investigations, for example computed tomography (CT), the underlying diagnosis can be made punctually, thus allowing intervention in a timely fashion.

A patient presenting following a road traffic accident with a scalp laceration and a reduced Glasgow Coma Scale (GCS) score of 13/15 represents an example of such a scenario, where a drop in the GCS could be related to a head injury or to the presence of shock and hypoxia. An injury to the brain can deteriorate with the development of an expanding haematoma, which can be diagnosed with a head CT prior to the presentation of clinical signs. Surgical decompression can be organised speedily, reducing the risk of morbidity and mortality. In this situation, if the time taken to make the diagnosis was prolonged and the clinical signs had presented prior to treatment intervention, it may be too late to prevent the death of the patient (**Figure 22.4**). This clinical case scenario demonstrates the principle that we need to introduce a treatment response even before we have made the definitive diagnosis if we want to save the patient's life. It is clear, therefore, that the 'timeline concept' is critical in the safe management of trauma patients.

Reducing the diagnosis time and response time of our interventions is dependent not only on the clinical staff but also on the availability of resources. Recently, the 24/7 availability of the trauma team and the designation of regional hospitals to operate as Level I Trauma Centres, with the availability of all disciplines and appropriate equipment on site, has provided the necessary foundation for the development of a unified trauma care system in England. Indeed, the first reports published on its effectiveness in saving lives have been very positive.

The 'timeline concept' that has been discussed in the management of patients with multiple trauma can be applied

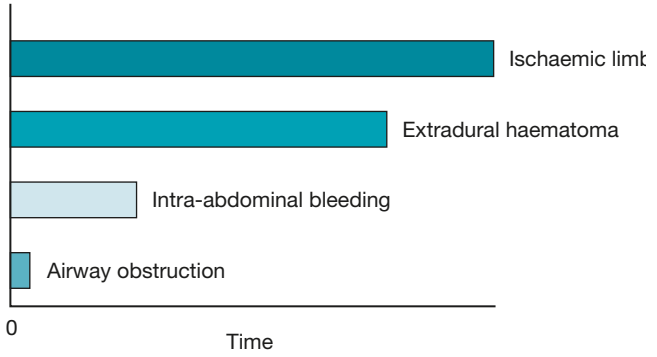

Figure 22.2 Estimated time from incident to death or irretrievable damage for various conditions.

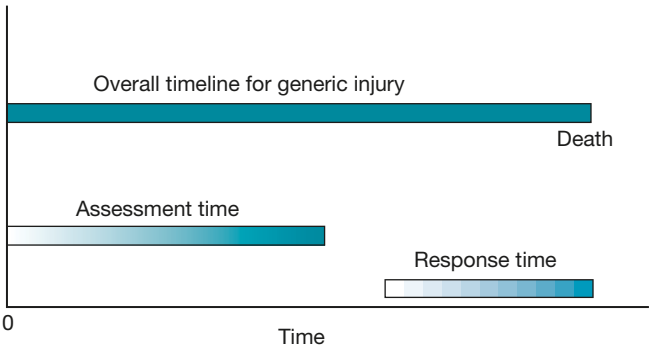

Figure 22.3 Diagrammatic representation of the relationship between assessment and response times. In this example, there is time to assess and respond effectively before death.

Summary box 22.2

The importance of time

- The 'timeline concept' is an essential component of trauma management
- Assessment should be completed within a set time
- The time to respond is limited
- Both assessment and response should take place in the time window prior to irreversible damage or death

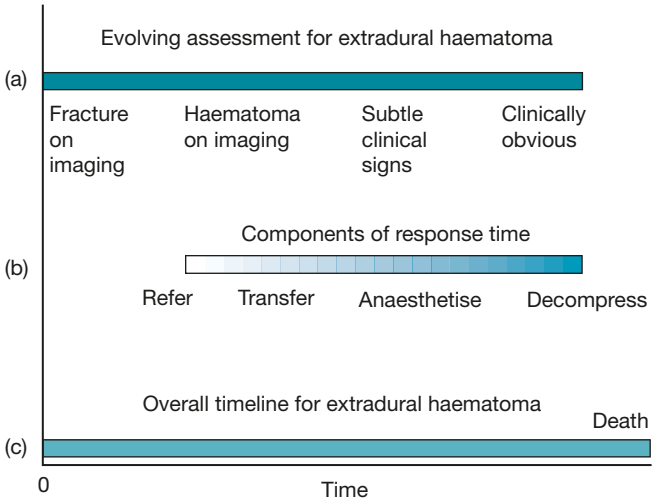

Figure 22.4 Diagrammatic representation of the relationship between assessment and response times for extradural haematoma: **(a)** the stages of assessment, **(b)** the components of the response and **(c)** the overall time from incident to death. It can be seen that relying on obvious clinical signs gives insufficient time to respond effectively.

to patients with isolated injuries. The key issue, irrespective of the type of patient managed, with or without multiple injuries, is to reduce unnecessary delays in making the diagnosis and initiating appropriate treatment. Such a global approach would save lives, minimise morbidity and would make the healthcare system more efficient in terms of resource utilisation, as well as cost-effectiveness.

Finally, it should not be forgotten that all clinical conditions are characterised by a dynamic process. This implies that our observations and analysis of the situation can change rapidly and to an extent that interventions would have to be modified accordingly. Ongoing evaluation of the patient is therefore essential in order to identify and respond to the changes noted in a timely fashion (as previously discussed). The initial primary survey, applied according to the ATLS protocol in trauma patients, should be followed by secondary and tertiary clinical assessment, even after the acute phase of treatment has been completed successfully. Ongoing monitoring of vital organ activity, ordering of the necessary biochemical and radiological investigations and recording of all the findings in a single place can allow easier evaluation and identification of trends over time to facilitate prompt intervention. Such a strategy may reduce the risk of having undiagnosed injuries and delays in their treatment. A number of studies have been published reporting on missed injuries and making some recommendations on how to avoid this.

The timeline following an injury is continuous, and the accumulated documentation may become voluminous, complex and confusing. It is helpful periodically to make the effort to stand back and summarise the situation. The UK National Institute for Health and Care Excellence (NICE), in their recent Trauma Guidelines, recognise this and advise that a plain language summary of the situation directed at the patient's family doctor, but intelligible and available to the patient or carers, should be available within 24 hours.

ASSESSMENT AND RESPONSE

The assessment of trauma

The initial assessment of the trauma patient, besides the clinical examination, should include analysis of the interactions between the patient, the mechanism of injury and the extent of the injury sustained. Being able to synthesise the inter-relationships among these parameters is essential to addressing the pressures of the 'timeline concept' previously discussed. The associations among these three factors are usually very clear, but can be hidden.

For instance, a 50-year-old male restrained passenger in a car involved in a head-on collision with another vehicle may sustain rib fractures, a sternal fracture, thoracic spine fracture and possibly cardiac contusion. Abdominal injuries could also be suspected but, overall, the clinician, knowing the mechanism, can proceed quickly in making the diagnosis and initiating treatment. However, in cases where no association can be synthesised (between the mechanism of the accident, the patient's condition and the clinical signs observed) the reasons behind this 'picture' should be sought, for example the reported mechanism may have been underestimated. We will now analyse how the clinician can make best use of the information available.

Summary box 22.3

The assessment of trauma

- Include the information formula: mechanism + patient = injury
- Look for both obvious and less obvious features
- Identify more reasons when the above formula does not make sense

Mechanisms

Mechanisms may be blunt, penetrating or even of a combined nature (*Table 22.1*). Blunt trauma can be categorised as direct or indirect, and continues to be the most common mechanism. In a direct mechanism, the damage is localised to the site of injury. In contrast, in an indirect mechanism the damage occurs at a distant site after transmission of the force

TABLE 22.1 Examples of patterns of injury.

Mechanism	Obvious features	Covert injuries
Left-sided impact from road traffic accident	Lateral compression of the pelvis	Splenic rupture
	Left-sided pneumothorax	Extradural haematoma
Flexion distraction (lap belt)	Chance fracture of the lumbar spine	Duodenal rupture
	Dislocated knee	Popliteal artery disruption
	Head injury	Cervical spine fracture
Electrocution	Burn on hand and collapse	Posterior dislocation of the shoulder
Dashboard impact	Knee wound	Posterior dislocation of the hip

Figure 22.5 The injury force in a car accident can be transmitted from the dashboard, to the knee and then to the hip, which is the site of injury.

exerted. For example, a direct kick to the medial aspect of the mid-shaft of the tibia in a footballer by an opponent will induce an isolated tibial fracture. Such an injury represents a direct mechanism with bruising and ecchymosis at the area of the force exertion. On the other hand, a fall from a height of 1 metre with a twisting moment as the foot hits the ground can lead to a spiral fracture of the distal tibia. In this situation, the vector of the force was transmitted through the body's tissues to a location some distance away from its original point of application. In this case, other injuries should also be looked for, such as a fibular fracture or even an ipsilateral tibial plateau fracture, around the knee joint area. Similarly, a motor vehicle crash associated with direct trauma of the knee joint of the driver on the dashboard of the car could induce a fracture dislocation of the acetabulum and hip joint (transmission of force from the knee joint to the hip socket – an indirect blunt mechanism) (**Figure 22.5**).

The 'timeline concept' previously discussed may or may not be urgent, depending on the location and type of injury sustained. For instance, a minimally displaced tibial fracture that a footballer has sustained can be treated satisfactorily for some time after the moment of injury but, in contrast, a fracture of the acetabulum with a hip dislocation (as described above) represents an emergency owing to the potential development of neurovascular complications (damage to sciatic nerve; avascular necrosis of the femoral head). Therefore, the clinician's decision-making process should take into account both the peculiarities of the type of injury sustained and the anatomical location involved.

Moreover, it should be appreciated that the conduction of energy in an indirect mechanism, which is transferred via the soft tissues or fluid, can be difficult both to understand and to diagnose (accurately and promptly). For example, the rise in pressure secondary to a lower abdominal force could be passed to the vascular tree (aorta), leading to unexpected haemorrhage and death. All in all, one can argue that the effects of direct mechanisms are easier to comprehend than those of indirect ones.

Penetrating mechanisms can be divided into those caused by sharp objects and those induced by firearms (see Chapter 30). With regard to injuries caused by sharp objects, it is necessary to take into account the length of the sharp object, its surface area and the size of the entry point. The sharp object, for example a pair of scissors, will cause damage to the underlying tissues that it contacts (skin, subcutaneous fat, fascia, etc.). Local examination will confirm the extent of the injury and the need for wound exploration. Being familiar with the relevant anatomy of the area involved allows assessment of the peripheral nerve function, and tendon and muscle integrity. Here again the 'timeline concept' of prompt assessment and response (treatment) can be crucial in cases where there is vascular injury, a compartment syndrome due to internal bleeding or even joint penetration that could lead to septic arthritis. Knowledge of the anatomical structures at risk is essential to making the right decision in a timely fashion. This is particularly critical for penetrating wounds over the torso (see Chapter 27), because it is not always easy to establish the track that the sharp object has followed. In this context, it should not be forgotten that the abdominal structures extend higher than anticipated, and as high as the level of the fifth rib in expiration.

Summary box 22.4

Sharp object injuries

- Think about the length of the sharp object involved
- Knowledge of the local anatomy is essential
- Remember that abdominal structures at risk of injury extend high into the chest

Firearms induce penetrating injuries, which are more difficult to comprehend than incisional injuries caused by sharp objects. For instance, a high velocity projectile (bullet) causes extensive damage to the tissues as it travels, inducing lateral acceleration far from the point of impact, and producing either a permanent or a temporary cavity (see Chapter 30). The importance of the temporary cavity is that it lasts only for milliseconds and usually is not evident during the clinical examination. It is important to be aware that this temporary cavity usually extends far from the boundaries of the apparent injury **(Figure 22.6)**. Awareness of this phenomenon will ensure that the surgeon carries out sufficient exploration and wound excision.

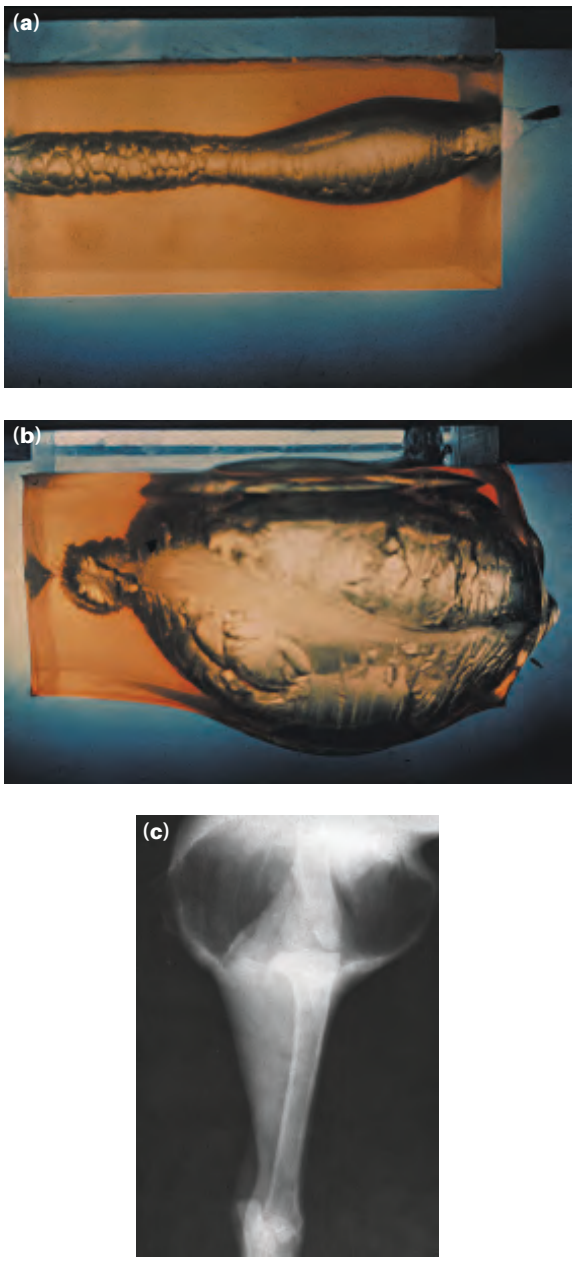

Figure 22.6 A projectile passing through a gelatin block: **(a)** low energy transfer; **(b)** high energy transfer; **(c)** the effect of high energy transfer on tissues (courtesy of Professor J Ryan).

Summary box 22.5

Firearm injuries

- High velocity bullets induce permanent and temporary cavitation
- Temporary cavitation can contain foreign material
- Low velocity bullets induce similar damage to knives

Patient factors

All patients possess a unique profile and medical history and so will react and respond differently to a given traumatic incident. Children and adults of different ages will sustain different injuries as a result of the same mechanism. For instance, a car hitting a pedestrian will induce different injuries in an adult, compared with a child **(Figure 22.7)**. It is important to consider the other aspects of the patient's history. Past medical history, medication and allergy risk will direct not only the clinical assessment but also the treatment.

Obvious injuries

Some injuries are very obvious and can be identified before details of the mechanism or patient are known. One can take advantage of this, as the presence of an obvious injury can inform and lead to the identification of another which is less obvious. Obvious injuries are usually visible externally. It is therefore no surprise that at the end of the ABCD protocol there is also an E, referring to exposure and the need to look for other signs of injury. Bruising to the scrotum of a motorcyclist following a collision with a car suggests a pelvic fracture. Contusion over the greater trochanter of the proximal femur in an older patient experiencing difficulty with straight leg raise points to a neck of femur fracture. Finger-shaped bruises on a child's arms or thighs suggest NAI. The presence of a seat belt mark on the lower abdomen of a patient involved in a car crash and who has substantial abdominal pain points to damage inside the abdomen. Thus, exposure of the trauma patient should be routine practice in order to avoid missing the 'obvious'.

Hidden factors

MECHANISMS

When analysis of the relationship of the formula 'mechanism + patient = injury' does not seem to add up, then the hidden information may be contained in the mechanism. Occasionally, it is observed that there has been a deliberate attempt to misinform. While the majority of alert and orientated patients tell the truth, others, in order to protect themselves or others, may fabricate a mechanism. This may mislead the clinician and lead them to look for the wrong pattern of injuries. For instance, a young patient with a calcaneal fracture may report that this was the result of a fall into a hole in the road, when in fact it had occurred during a burglary, following a fall from a height of 10 metres. This can delay the accurate diagnosis of the specific injury and may prevent the diagnosis of other important injuries, such as a lumbar spine fracture. Although the patient should be given the chance to tell their

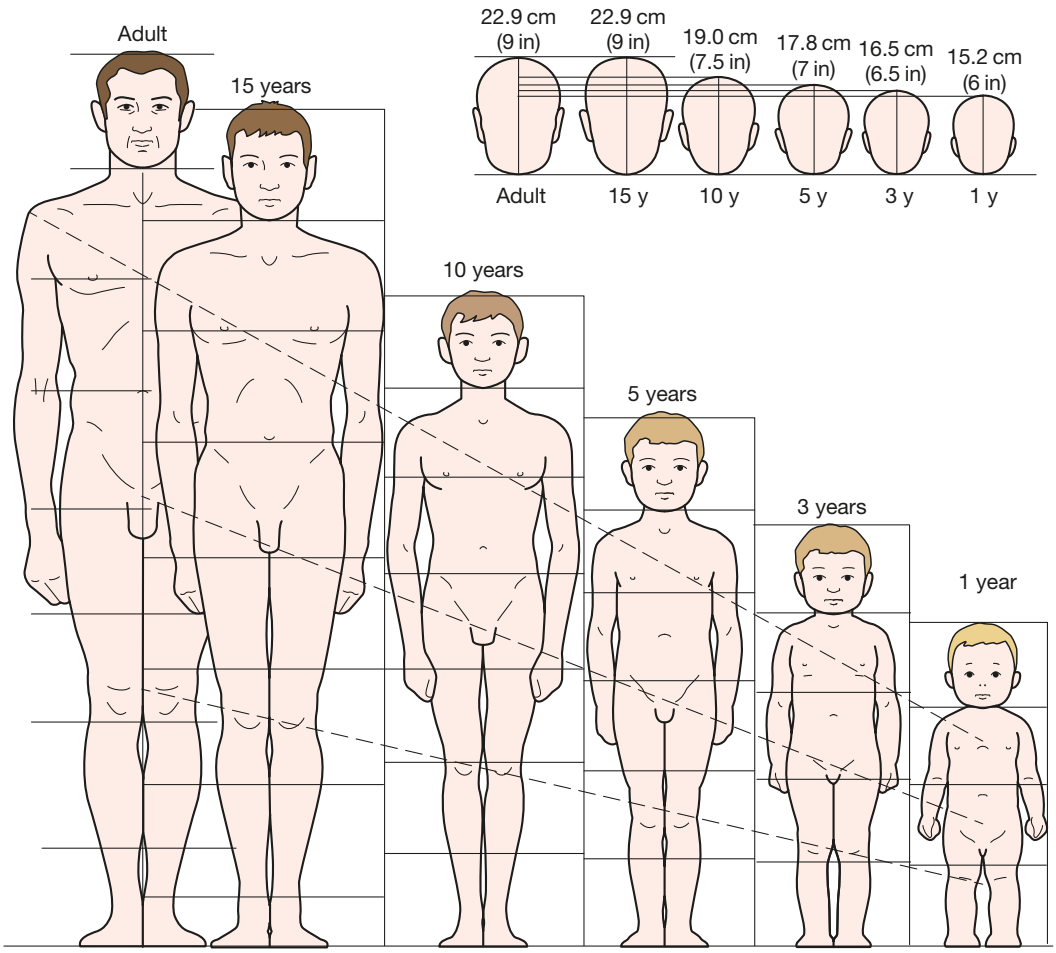

Figure 22.7 Body proportions at various ages and anatomical location of injuries when hit by a car.

story, it should not always be believed, particularly if there are inconsistencies.

A hidden mechanism can also arise when the patient is unable to give their history of events, for instance patients who are unconscious. The physically and mentally vulnerable include older patients, perhaps with dementia, and very young children. The difficulty or inability to report the injury is compounded by the fact that it might relate to criminal activity (e.g. NAI). Parameters that should alert the clinician and raise suspicion of NAI include:

- external signs of injuries not consistent with the mechanism reported;
- long bone fractures in a preambulatory child;
- inconsistent or changing history;
- aggressive or unusual behaviour of carers at interview;
- posterior rib injuries.

It must be emphasised that the clinician, in addition to diagnosis and treatment, must also protect the patient from further harm. This is of paramount importance when dealing with vulnerable individuals (children and the elderly). If the early signs of abuse are ignored or not taken seriously, it may not be possible to prevent later episodes, where serious harm may occur. While NAI is a serious issue to address, mechanisms are usually in place and can be followed by passing on the problem to the appropriate team and professionals (see Chapter 39).

Another important issue is the fact that any obvious injuries may provide important evidence regarding the mechanism, which may be important to a criminal investigation. We must endeavour, without compromising treatment, not to affect such evidence by our medical actions and bear in mind that forensic evidence may be needed for a conviction at a later stage. Furthermore, the importance is made more apparent if we consider that the victim of an attack may subsequently be a murder victim.

Summary box 22.6

Hidden mechanisms

- The vast majority of conscious patients will tell the truth
- Patients involved in criminal activity may not tell the truth
- Fear of abuse may prevent vulnerable patients from telling the truth
- Clinicians have the responsibility to take action when NAI is suspected

PATIENTS

In circumstances where the injury and mechanism are inconsistent, one should consider the possibility that the patient may have an unknown pre-existing condition. For example, an apparently healthy middle-aged woman who bends to lift a box and sustains a fracture at the thoracolumbar junction of her spine may have pathological weakness of the vertebral bone, such as advanced osteoporosis. Treatment should not be confined to the local injury, but should extend to appropriate investigation and treatment of the underlying fragility of the skeleton, thus reducing the risk of further fracture. Similarly, fractures may be secondary to an undiagnosed or poorly controlled medical condition. For example, a patient presenting with a scalp laceration and a wrist fracture may have fallen as a result of a transient ischaemic attack (a hidden patient factor). In this situation, it is essential to include a medical secondary survey to identify the real cause of the injuries sustained and prevent further trauma.

INJURIES

When analysis of the formula 'mechanism + patient = injury' has failed to identify hidden injury, there are two other approaches:

1 the look everywhere approach;
2 the focused exclusion approach.

Look everywhere approach. This represents the secondary and tertiary elements of the ATLS system and involves a detailed secondary survey, from top to bottom and at different time points: soon after the initial treatment phase when measures relating to saving the patient's life have been completed, the day after injury, e.g. during a ward round, or several days after injury, e.g. when the patient first wakes up in the intensive care environment. The implementation of whole body CT (WBCT) (scanning the whole body) in all major trauma centres has allowed the clinical team to pick up injuries early. Such injuries would have been missed in the past when reliance was made on the initial radiographs of the chest, pelvis and cervical spine. The threshold for using more WBCT has been lowered substantially. There is no doubt that WBCT scan algorithms have been shown to accelerate diagnostic work-up, but their effect on survival is controversial. Moreover, concerns have been voiced about the overexposure of patients to radiation with the increasing and often uncritical use of this type of scan. The effective radiation dose to all organs from a single full-body CT is 12–16 millisieverts (mSv). Survivors of the atomic bomb whose radiation dose ranged 5–100 mSv had a statistically significant increase in the risk of solid cancers. Overall, the risks associated with one scan are relatively modest, approximately 1 in 1250, or 0.08%. However, it has been reported that widespread liberal CT use is responsible for 1.5–2.0% of all cancers in the USA. Of interest, WBCT equates to 76 chest x-rays or 6 months of background radiation. It has been suggested that it should be requested wisely and that developing a triaging protocol can minimise the critisim of its overuse.

Focused exclusion approach. This is based on the knowledge that some specific injuries are missed on a remarkably regular basis. Such injury patterns include metatarsal and metacarpal fractures, scaphoid fractures, perilunate dislocations and posterior shoulder dislocations. When such injuries are suspected, a detailed focused history, clinical examination and appropriate investigations should be carried out to either confirm or exclude them.

Summary box 22.7

Trauma assessment

- Knowledge of timelines for important diagnoses is essential
- Initial assessment should focus on what kills first
- Screen high-risk patients before clinical signs become apparent, as it may be too late to intervene once signs develop

THE RESPONSE TO TRAUMA

Completion of the initial assessment according to the formula (patient + mechanism = injury) should provide the necessary information to formulate and execute a 'response' (treatment). During this stage of care, the response to injury will continue to evolve and decompensation may occur unexpectedly. Vigilance is required throughout management to identify the potential exhaustion of reserve mechanisms.

The patient's response to injury

From the time of the accident, a cascade of physiological responses will be upregulated to maintain survival. All such responses are part of homeostatic mechanisms that alter with the time elapsed following injury. The timing and nature of interventions should be altered accordingly. Important patient responses that require prompt attention, in order to avoid a subsequent negative impact on the patient's haemodynamic condition, include the body temperature, oxygenation and organ perfusion. A decline in body temperature is a frequent finding after injury and may be due to exposure, blood loss and inactivity. Measures should be taken not only to prevent further reduction in temperature but also to restore it. Covering the patient with appropriate blankets during transportation, resuscitation and in the theatre environment will minimise the risk of hypothermia, coagulation disturbances and ongoing bleeding.

Patient oxygenation can be optimised with the administration of inspired oxygen or ventilation if needed.

Blood loss can give rise to an altered level of consciousness, low blood pressure, reduced perfusion of the extremities (skin discolouration) and tachycardia. By way of response, endogenous clotting factors are activated to stop the bleeding and to maintain adequate circulatory volume. A further consideration is that traumatised lung parenchyma cannot tolerate surplus fluid. Therefore, the latest resuscitation guidelines advocate a reduction in crystalloid administration and the

early transfusion of blood products. Furthermore, there is a need to quickly identify and stop the source of bleeding.

Another important part of the response to injury is the activation of the immune–inflammatory system. Acute phase mediators are released systemically, stimulating cellular elements (polymorphonuclear leukocytes) to interact with the endothelium. Under certain circumstances, extravasation of leukocytes may take place, with possible autodestruction. Clinical decisions should aim to minimise the risk of an exaggerated immune–inflammatory reaction. Surgical procedures, which can act as a second hit, where injury is considered the first hit, should be carefully timed and selected.

The medical response to injury

Initial management

Where resources are available, a patient found to have sustained serious injuries at the scene of the accident will lead the paramedics to activate 'the trauma team on call', allowing personnel to await the patient's arrival in the resuscitation room. The team leader, according to the ATLS protocol, will assign trained nurses and doctors to specific tasks. Protective clothing, such as gloves and lead aprons, is required to protect the personnel from fluids and radiation exposure. Following the ATLS protocol should be a routine process, involving experienced team members and ideally avoiding careless delays, which may compromise the response time. Potential problems can be predicted. The involvement of different disciplines in assessing and planning treatment of injuries in different body areas may lead to issues around priority, which can lead to confusion and uncertainty: 'Who should go first?' 'What investigation should be next?' It is the role of the team leader to ensure that this is avoided and that decisions which may be critical for the patient's wellbeing are executed smoothly.

In situations where the system operates according to locally developed protocols, someone should have the responsibility of overruling the protocol if this would be to the best interest of the patient, in order to keep the process rolling.

Following common pathways to manage patients can save time and reduce errors. The management of hip fractures in older age groups has improved in the UK with the regulated and monitored involvement of surgeons, geriatricians and anaesthetists. However, early labelling can also be misleading and troublesome. For instance, an older female patient with multiple medical problems might, after falling down a step, sustain an ankle fracture and be given the label 'ankle fracture'. Once the label is given the 'pathway' is set and she may be placed in a plaster of Paris back slab and be admitted for fixation under the care of someone who thinks primarily about mechanical matters. The so-called 'accidental benign falls' may be associated with more severe pathology and injuries. Furthermore, a patient may fall as a result of a medical condition (e.g. a mini stroke) and, in addition to an ankle fracture, may sustain other injuries including fractures of the pubic ramus and ribs. The wrong label may disguise the seriousness of the injuries sustained and the fact that the patient's condition may rapidly deteriorate, putting their life at risk. The first person in the diagnostic chain has disproportionate responsibility. Early labelling after inappropriate assessment can be incorrect and direct the patient to the wrong care pathway. In general terms, all patients, and particularly vulnerable patients, should undergo physiological triage to reduce the risk of being wrongly assigned.

Beyond the first hour

Following the initial assessment and management according to the ATLS protocol, and when the end points of resuscitation have been accomplished, further interventions are necessary in a patient with multiple injuries. The presence of an open book pelvic fracture, a lumbar spine fracture, a femoral fracture, a liver laceration and a tarsometatarsal dislocation are examples of outstanding injuries waiting treatment. The timing of the initiation of fixation, the type of fixation to use and the priority of various injuries have been points of discussion for some years.

The original work by Bone *et al.* in the 1980s, demonstrating the benefits of early fracture fixation of all injuries, led to the acceptance and wide application of the so called 'early total care' (ETC) philosophy. This practice became the gold standard of treatment for patients with multiple injuries. However, in some specific patient groups, for example those with severe chest and/or head injuries or those in an extreme physiological state (with ongoing bleeding from different sources such as abdomen, pelvis and chest), it was observed that the ETC concept led to early complications and mortality.

Knowledge acquired at the molecular level related to the immune–inflammatory response to injury and the concepts of the phenomena of the first hit (the impact exerted on the homeostatic mechanisms as a result of the original trauma sustained) and the second hit (the additional physiological stress induced by surgical procedures) led to the acceptance and implementation of the so call 'damage control orthopaedics' (DCO) philosophy, which is called damage control surgery (DCS) in more generalised settings (see later chapters). The stages of DCO are:

- resuscitation;
- haemorrhage control;
- decompression;
- decontamination;
- fracture splintage.

In the DCO concept, initially any long bone fractures and the pelvis are temporarily stabilised with the use of external fixators. Definitive stabilisation of the fractures (conversion of the external fixators to intramedullary (IM) nailing for the femur and plating of the pelvis) would take place usually 4 days later, when the physiological state of the patient has been stabilised. In contrast, a patient with similar injuries who has stable physiology throughout would be managed with IM nailing of the femoral fracture and plating of the pelvis within the first 24–36 hours: the ETC approach. The two strategies of fracture fixation, the ETC and DCS, are currently practised on the basis of some specific criteria. The vast majority of polytrauma patients are suitable for ETC (80–90%). Specific criteria are shown in *Table 22.2*.

TABLE 22.2 Criteria for damage control surgery (DCS) and early total care (ETC).

Criteria for DCS	Criteria for ETC
Hypothermia: <34°C	Stable haemodynamics
Acidosis: pH <7.2	No need for vasoactive/ inotropic stimulation
Serum lactate >5 mmol/L	No hypoxaemia, no hypercapnia
Coagulopathy	Serum lactate <2 mmol/L
Blood pressure <70 mmHg	Normal coagulation
Transfusion approaching 15 units	Normothermia
Injury severity score >36	Urinary output >1 mL/kg/hour

It is important for the clinician to appreciate that the physiology of the patient can change rapidly. Patients with a high injury severity score, the so called 'patient at risk' can decompensate quickly. Ongoing evaluation of the patient is therefore paramount to allow the clinician to choose the right strategy for the right patient. ETC and DCS should complement, rather than compete with, each other. The decision regarding 'who should go first, what is to be fixed first and with what type of implant' is, most of the time, straightforward. Nonetheless, the clinician should always be prepared for the unexpected and have a bail out solution ready to be implemented.

Consequently, a plan should always be made available to the trauma team to inform them about the details of treatment, particularly in the operating room environment. The plan can be recorded on a whiteboard with clear guidance on the alternative pathway to be implemented should the patient's condition deteriorate. Ongoing monitoring of such parameters as core temperature, lactate, base excess, coagulation, etc. will give knowledge of the patient's condition at any time point during care. Appropriate decisions can then be taken to ensure that the safety of the patient has not been compromised. For instance, if the ETC concept has been applied and a polytrauma patient with a head injury and chest trauma is on the operating table, waiting to have a femoral fracture stabilised with IM nailing, and their condition deteriorates the ETC plan can be changed to DCO (an external fixator can be applied quickly to stabilise the femoral fracture temporarily). This allows prompt transfer of the patient to the intensive care unit (ICU) where resuscitation can continue within a safe environment with ongoing monitoring of vital organ function (lungs and brain).

When injuries involve the input of different disciplines in terms of surgical intervention, for instance a general surgeon for a liver laceration, a neurosurgeon for an intracranial haematoma, an orthopaedic surgeon for a pelvic and femoral fracture and a maxillofacial surgeon for a depressed orbital fracture, the most important intervention should go first. Clearly, communication and prioritisation among the team members is essential. As each procedure nears its completion, communication with the anaesthetist will allow a decision as to whether it is safe to go on to the next procedure. Not infrequently, and assuming that it is technically possible, two teams can work simultaneously to significantly shorten the time the patient will spend in the operating theatre environment and allow subsequent prompt transfer to the ICU for optimisation and ongoing monitoring.

LOCAL PROTOCOLS AND GUIDELINES

While the ATLS protocol has become the standard of care for the initial management of patients with multiple injuries, other protocols and guidelines have also been developed to allow the treatment of patients in a more standardised way. It is not uncommon for each trauma centre to develop its own local guidelines, although national guidelines may also exist. Regional guidelines may refer to smaller areas of practice, such as antibiotic prophylaxis for open fractures, mass transfusion, pharmacotherapy for coagulation disturbances, steroids for spinal cord injuries, clearance of the cervical spine and angiographic embolisation of pelvic fractures. These protocols can facilitate quicker decision making, eliminating delays and benefiting the patient. They also protect the clinician and care provider with regard to medicolegal issues. An example referring to angiographic embolisation of pelvic fractures is shown in Figure 22.8.

Local policies focusing on the creation of single charts facilitating daily input of patients' vital signs and biochemical results are useful in allowing sequential observation of the results, which can demonstrate important trends. These trends can be useful in identifying early a clinical condition which can be treated within the timeline frame concept and prior to the establishment of irreversible damage to the affected organ, at which point any form of intervention will be meaningless. For instance, the clinical evolution of respiratory insufficiency in an individual without pre-existing lung disease secondary to pulmonary embolism is easier to identify by evaluating the trend in the oxygen saturation of inspired oxygen.

Planning an individual operation

Operative procedures in a polytrauma patient struggling for survival are critical in the acute phase. Their outcome can

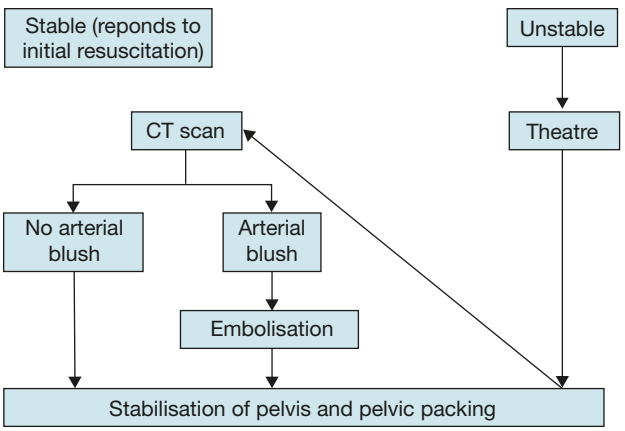

Figure 22.8 Pelvic fracture: angiography protocol.

Summary box 22.8

The response to trauma

- Rationalise patient management with development of protocols and guidelines
- Avoid unnecessary delays
- Observe trends and identify promptly evolving conditions

affect morbidity and mortality. For this reason, it is **essential** to get it right the first time. It is therefore also essential that there is adequate study of the problem to be solved, followed by the appropriate planning and execution. Analysing the fracture pattern, and deciding about patient positioning, the surgical approach to be used to get adequate access to the bone for reduction, the type of implant to be used, the correct positioning of the implant, the soft tissue handling and the type of rehabilitation, are just some of the parameters for consideration.

The surgeon should answer questions such as: Is it the optimum time to carry out the procedure? Am I the most appropriate person to carry out the procedure? Have I made a contingency plan should the procedure become difficult to complete? What is my plan A, B, or C so I am able to successfully finish the procedure? Recording all the important issues on a piece of paper, or suitable alternative, will ensure that no parameter of importance will be left out of the planning. In order that the procedure runs smoothly in theatre, documentation of the plan can be made on the white board. Such a practice will allow every member of the surgical team to be aware of the potential issues to be addressed and the plan of action that has been decided. The appropriate surgical equipment for plans A, B and C can be clearly identified and kept in close proximity to the operating theatre. The above strategy will eliminate unnecessary detail and ensure that there will be no surprises, for instance required equipment found to be unavailable.

The response to the mechanism of injury (injury prevention)

Not infrequently, patients are seen who have been injured at the same geographical area with the same mechanism. A possible scenario is that, over a period of a few weeks, several patients are noted to present with a fall of 2–3 metres, in the same location, from a particular bridge. Further investigation might establish that the bridge is easy to access, perhaps because of damage to safety measures. With appropriate steps the damage can be rectified and the access to the bridge limited, preventing further harm. In this example, the surgeon is involved in both the treatment and the prevention of injury. Therefore, when a mechanism of injury becomes more frequent and is associated with serious life-threatening trauma, it is essential to take steps either to eliminate the mechanism or to lessen the consequences.

The issue of injury prevention is not only an important consideration for clinicians but also for other stakeholders, for example politicians (developing appropriate legislation relevant to road safety), manufacturers (optimising the safety of cars) and the construction industry. This accounts for the improvements in safety that can be achieved.

Summary box 22.9

Planning an individual operation

- Adequate preoperative planning is essential to eliminate unnecessary delays
- Document the plan to ensure no important parameter is left out
- A whiteboard can be used to demonstrate the order of plan execution and act as a means of communication with the staff

Summary box 22.10

Response to the mechanism of injury

- Be alert to identify frequent patterns of injury
- Many stakeholders, including clinicians, should engage in injury prevention
- Legislation and education are essential

The response to patient factors

Injuries presenting with increased frequency in an individual patient require special attention. Older patients, perhaps with multiple medical problems, can represent such a vulnerable group. The reduced bone mineral density making their skeletons 'fragile' is associated with an increased risk of fracture. Hip fractures, wrist fractures, spinal fractures and pelvic fractures are just some of the many results following minimal trauma. The risk of fracture is increased with the presence of comorbidities such as visual impairment, parkinsonism or transient ischaemic heart attacks. Consequently, knowing the parameters associated with a particular group of patients, attempts can be made to reduce the number of patients requiring treatment. For instance, prescription of bone protection therapy and addressing early the medical comorbidities (e.g. cataract surgery) may help to reduce the number and severity of injuries sustained. Development of specific guidelines and protocols can facilitate the much needed implementation of unified measures allowing easy patient access and treatment.

Summary box 22.11

Response to patient factors

- Older patients may be vulnerable to injury, owing to poor bone stock and other comorbidities
- Bone protection treatment is essential
- Development of local and national guidelines to respond to patient factors is desirable

CONCLUSION

Trauma can affect all patient age groups. The severity of injury depends on the type and nature of the mechanical force applied. The formula 'patient + mechanism = injury' should be kept in mind when dealing with trauma patients. There is a connection among the three components of the formula, all of which should fit together in a coherent way. When no relationship can be made, examine for pre-existing pathology and hidden injuries, or consider whether the history given by the patient is at fault (including deliberate attempts to mislead).

Be aware of the timeline concept because there is a minimum response time to initiate and complete treatment in order to deal with a specific condition successfully.

Early assessment and management of patients with multiple injuries is carried our using the ATLS protocol and other guidelines developed either locally or at a national level. Subsequent treatment for definitive stabilisation can be personalised by one of two of the existing fracture fixation strategies, ETC or DCO. Specific criteria can assist the clinician to make the right decision for the right patient. Different groups of patients, such as older patients and children, have different demands and should be managed accordingly. While we, as clinicians, are focusing on treating the injury sustained, we have other responsibilities including our active involvement in preventive measures. Preventive measures should be commissioned when particular mechanisms can be identified as being common or important causes of injury.

Summary box 22.12

Conclusion

- Look for hidden injuries
- Remember the timeline concept
- Specific criteria will decide the fixation strategy: ETC or DCO

Chapter 23

Early assessment and management of severe trauma

Learning objectives

- How to identify and assess the severely injured patient
- Early treatment goals for multiply injured patients
- Understand the role of permissive hypotension, tranexamic acid and massive transfusion protocols
- Understand the principles of damage control surgery (DCS) versus early total care (ETC)

IDENTIFICATION OF SEVERE TRAUMA

The severely injured patient, with multiple injuries to different body systems, poses unique diagnostic and treatment challenges. The early assessment and management of severe trauma begins in the prehospital environment. Many of these patients will be easily identified at the scene of injury and forewarning the receiving hospital allows the activation of the trauma team to prepare for the patient's arrival. Key information in the pre-alert includes basic demographic information (age and gender), mechanism of injury, injuries identified and vital signs, including respiratory rate, pulse, blood pressure and Glasgow Coma Scale (GCS).

Patients that are identified prehospital as sustaining, or at high risk of sustaining, severe multisystem trauma should generate trauma team activation in the receiving hospital. It should be noted that not all patients with severe multisystem trauma are immediately obvious. An elderly patient falling down a few steps can easily sustain a hip fracture, multiple rib fractures and a small subdural haemorrhage. At first glance the patient can appear well, but their injury severity score (ISS) and potential mortality could easily exceed those of the younger patient with multiple open long bone fractures. Both patients are critically injured and should be managed with the same principles in mind.

ROLE OF THE TRAUMA TEAM

All hospitals managing severe trauma should have a dedicated trauma team, who are available immediately to attend and manage patients presenting with severe trauma. The composition of the team will depend on local policies but it will invariably involve doctors from the emergency department, anaesthetics and/or critical care, orthopaedics and general surgery. Increasingly, radiology and haematology doctors are contributing to the trauma team, as part of the patient's initial assessment and management. Hospitals managing large volumes of cases of severe multisystem trauma are recognising the need for an enhanced trauma team activation for the most severely injured patients – the so called 'code-red trauma call'. Patients identified prehospital as being haemodynamically unstable or with acute airway compromise may initiate 'code-red', triggering the automatic attendance of the most senior clinicians from each discipline prior to the patient's arrival and prehospital activation of massive transfusion protocols.

The role of the trauma team is to apply the principles of Advanced Trauma Life Support (ATLS) to rapidly identify and treat life-threatening injuries during the primary survey. The principle advantage of a trauma team is that this activity can occur concurrently instead of sequentially; while the anaesthetist may be assessing and managing the patient's airway, another team member can be assessing and managing the patient's breathing, etc. The importance of the trauma team leader cannot be overemphasised: they brief and prepare the team, coordinate these sequential activities, manage time, interpret findings and plan the next move. Increasing recognition of the importance of this role has led to the development of postgraduate training courses designed to teach both the technical and non-technical skills required. Generally, the trauma team leader and most senior clinicians should be standing back from the patient, looking at the bigger picture, in order to anticipate the next key decisions.

Summary box 23.1

The role of the trauma team

- Allows the simultaneous and efficient application of ATLS principles to rapidly identify and treat life-threatening pathologies
- Should be led by the most senior clinician
- The most senior clinicians from each specialty should attend 'code red trauma calls'
- The team leader should be trying constantly to anticipate the next move

PRIMARY SURVEY

The primary survey aims to identify and manage the most immediately life-threatening pathologies first and follows **cABCDE**.

c: Exsanguinating external haemorrhage

Experience from war zones over the past 20 years has shown that exsanguinating external haemorrhage from massive arterial bleeding needs to be controlled even before the airway is managed (see Chapter 30). Most of these injuries are due to gunshot wounds or blasts and are mainly seen in military practice. However, they are encountered in civilian practice. Bleeding must be controlled immediately by the application of packs and pressure directly onto the bleeding wound and artery. Haemostatic dressings that contain agents that augment local coagulation are now available. Failure to control bleeding in the limb by direct pressure should be followed by the application of a tourniquet proximal to the wound. In the field, simple tourniquets can be improvised if pneumatic tourniquets are not available. It is vital to appreciate that once a tourniquet is applied the limb becomes ischaemic – the time for which the tourniquet is applied must be recorded on the patient and the patient requires **urgent** surgical control of the bleeding in order to reperfuse the limb.

A: Airway with cervical spine control

All trauma patients should have their cervical spine immobilised and protected throughout. An immediate assessment of the patient's airway is made. A compromised airway requires a stepwise progression, first clearing the airway by suctioning secretions or blood, followed by simple airway manoeuvres such as a jaw thrust, chin lift and insertion of an oropharyngeal or nasopharyngeal airway. Advanced airway manoeuvres necessitate the insertion of a cuffed endotracheal tube. This may require an anaesthetic with rapid sequence induction or a surgical airway. Emergency intubation of the severely injured trauma patient is a difficult and demanding skill – standardised and rehearsed procedures should be in place for failure to intubate (**Figure 23.1**). Equipment and expertise for achieving a surgical airway must be readily available.

Figure 23.1 Unrestrained driver with severe craniofacial injury (courtesy of Johannesburg Hospital Trauma Unit).

B: Breathing and ventilation

All patients should receive high-flow oxygen. Life-threatening chest pathology such as tension pneumothorax, massive haemothorax and flail segment should be diagnosed and managed immediately. Equipment and expertise for rapid insertion of intercostal chest drains should be available.

C: Circulation and haemorrhage

All patients require adequate intravenous access with at least two large-bore intravenous (IV) cannulae. Equipment and expertise for insertion of central or intraosseous venous access should be available where peripheral access is not easily obtainable. Blood should be taken for cross-match and laboratory assessment, including haemoglobin and venous lactate. An assessment of the haemodynamic status should be made to identify shocked patients: the skin may be pale, cool and sweaty, the pulse rate raised to over 100 per minute and the blood pressure low. A pelvic binder should be applied to all haemodynamically unstable patients following blunt trauma and not removed until after a pelvic fracture has been excluded. Hypotensive trauma patients are treated as hypovolaemic until proven otherwise. The priority is now simultaneous fluid resuscitation and identification of the source of the haemorrhage.

Permissive hypotension, massive transfusion protocols and tranexamic acid

The initial aim of resuscitation is to maintain the blood supply to the vital organs: the brain, heart and kidneys. For a short time, this can be achieved with a target systolic blood pressure of 70–90 mmHg, although a higher pressure of >90 mmHg should be the target if a head injury is suspected. Small boluses of IV fluids (e.g. 250 mL of O negative blood, or normal saline if blood is not immediately available) should be administered to achieve this target, which should result in a palpable radial pulse. Excessive intravenous crystalloid or colloid solutions should be avoided because they cause haemodilution, increase coagulopathy and increase the risk of adult respiratory distress syndrome (ARDS). However, the key to this approach of permissive hypotension is that it is time limited. The primary source of haemorrhage must be identified and controlled as soon as possible.

Severely injured hypovolaemic patients should be resuscitated with blood and blood products, not crystalloid/colloid fluids. These must be warmed. All hospitals managing severe trauma should have a massive transfusion protocol which aims to provide blood and blood products in a ratio of 1 packed red cells:1 fresh frozen plasma:1 platelets.

TRANEXAMIC ACID

Tranexamic acid is an antifibrinolytic drug that reduces the risk of mortality from bleeding in both blunt and penetrating trauma. One gram is given intravenously over 10 minutes, followed by a further 1 g dose over 8 hours. Tranexamic acid should be given to all trauma patients suspected to have significant haemorrhage, including those with a systolic blood pressure of <110 mmHg or a pulse of over 110 per minute. It needs to be administered within 3 hours of injury and in the UK it is normally given by paramedics in the prehospital environment.

Summary box 23.2

Severe hypovolaemia

- Tranexamic acid reduces mortality after trauma
- All traumatised patients with signs of shock should receive tranexamic acid as soon as possible after injury
- All trauma centres should have an established massive transfusion protocol
- Severely hypovolaemic trauma patients should be resuscitated using blood and blood products
- The only role for crystalloids in the initial management of severely hypovolaemic patients is for the administration of small quantities to maintain blood pressure while waiting for blood products to arrive

Identification and management of haemorrhage

The sites of major haemorrhage in trauma patients are the chest, abdomen, pelvis, long bones and external haemorrhage (**Figure 23.2**). Blunt trauma patients frequently have multiple sources of haemorrhage. Clinical examination and investigations should aim rapidly to confirm or exclude significant bleeding from each of these sites. Computed tomography (CT) from the head to pelvis with IV contrast, the so called 'whole body CT' (WBCT) is the gold standard investigation in patients with signs or symptoms of multiple injury or deranged physiology, but note that WBCT should not be performed on the basis of the mechanism of injury alone (see Further reading). There is no role for scanning selective body systems in the severely injured trauma patient. Wherever possible, WBCT should be performed as soon as possible during the patient's resuscitation. A provisional 'hot report' can be issued within minutes to identify immediate life-threatening pathology to the trauma team. A more detailed definitive report should be available within 30–60 minutes.

Traditionally, chest and pelvis radiographs have been obtained early in the assessment of patients with polytrauma but these investigations are increasingly omitted in favour of obtaining a rapid CT scan, as described above. Most trauma centres now have rapid access to CT scanners located within, or immediately adjacent to, the resuscitation area. This has allowed haemodynamically unstable patients to have a WBCT with resuscitation by the trauma team continuing simultaneously during CT. Identifying which patients are too haemodynamically unstable to scan safely is a difficult decision for the trauma team leader and will be influenced by local factors and facilities.

Some patients will be so haemodynamically unstable on arrival that they need immediate surgical control of their haemorrhage before a CT scan. The most likely sources are abdominal or pelvic bleeding. An immediate chest radiograph will exclude catastrophic intrathoracic haemorrhage. An immediate pelvic radiograph is essential but should not delay transfer to the operating room. A focused abdominal sonography for trauma (FAST) scan (if immediately available) may also be useful in this scenario to locate the major source of haemorrhage. All patients undergoing immediate laparotomy in the operating room should have a pelvic binder applied **and not removed**. A correctly positioned pelvic binder at the level of the greater trochanters does not obstruct trauma laparotomy. These patients will invariably require a WBCT scan after surgical control of haemorrhage has been achieved.

Summary box 23.3

'Whole body CT' (WBCT)

- WBCT from the head to pelvis with IV contrast is the gold standard investigation of the severely injured adult blunt trauma patient
- There is no role for selective scanning of body systems in these patients
- WBCT scan is a time-critical investigation and should be obtained as early as possible in resuscitation of the severely injured patient
- Any patient undergoing immediate trauma laparotomy after blunt trauma without a WBCT scan should have a pelvic binder applied and not removed until a pelvic fracture is excluded. Such patients should have an immediate pelvic radiograph either in the emergency department, or as they arrive in the operating room

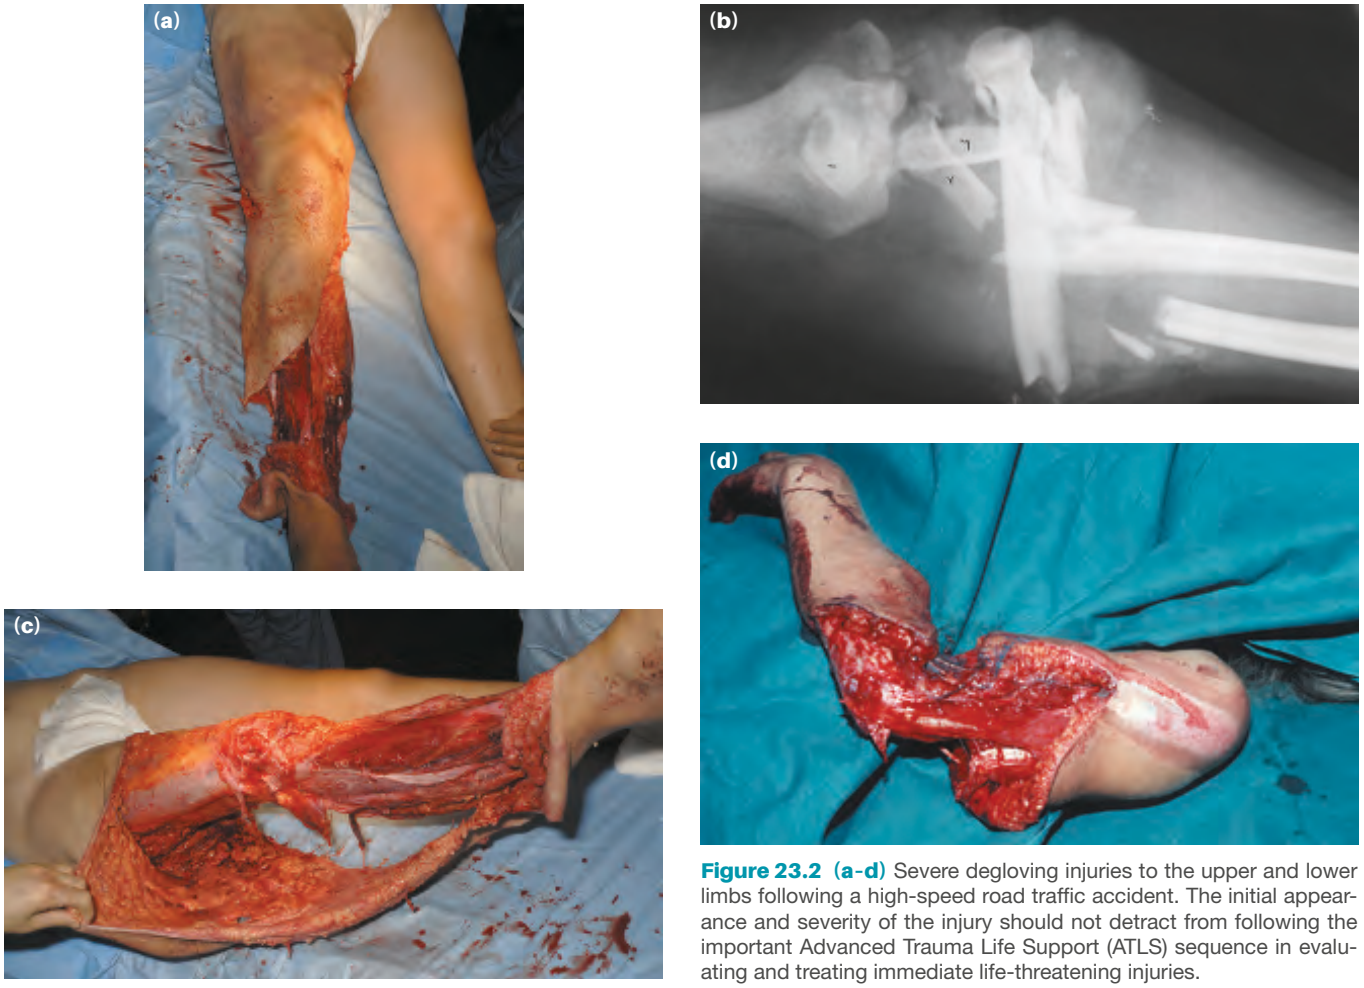

Figure 23.2 (a-d) Severe degloving injuries to the upper and lower limbs following a high-speed road traffic accident. The initial appearance and severity of the injury should not detract from following the important Advanced Trauma Life Support (ATLS) sequence in evaluating and treating immediate life-threatening injuries.

D: Disability and E: Exposure

On admission, the GCS score should be calculated (*Table 23.1*), the pupils assessed for size and reaction to light and the patient observed to determine whether they are moving all four limbs. The core temperature must be recorded. Patients are managed with cervical spine protection (cervical collar and blocks) and protection of the thoracolumbar spine using standard log roll techniques until a spinal injury has been excluded. Early WBCT scan will rapidly identify the majority of intracranial and spinal pathology.

The patient must be adequately exposed to allow a thorough and systematic clinical examination during the secondary survey but they must be kept warm. Trauma patients are frequently hypothermic and this will further increase coagulopathy. Every effort should be made to maintain normal temperature by minimising unnecessary exposure of the patient, and by using warmed blankets and trolleys and warmed fluids during resuscitation.

Log-rolling patients with severe pelvic fractures may harm the patient by disturbing established blot clots. Log-rolling should not occur until a pelvic fracture has been radiographically excluded. If patients need to be moved during their primary survey, such as when moving on to the CT scanning gantry, a 20° roll with inline spinal stabilisation should be used. Modern 'Scoop Stretchers' mean that there is no requirement to roll any patient more than 20° until a pelvic fracture has been excluded.

TABLE 23.1 Glasgow Coma Scale

Best eye response (E)	Best verbal response (V)	Best motor response (M)
4 Eyes opening spontaneously	**5** Oriented	**6** Obeys commands
3 Eye opening to speech	**4** Confused	**5** Localises to pain
2 Eye opening in response to pain	**3** Inappropriates words	**4** Withdraws from pain
1 No eye opening	**2** Incomprehensible sounds	**3** Flexion in response to pain
	1 None	**2** Extension to pain
		1 No motor response

Formal log-rolling of the blunt trauma patient to examine the back during the primary survey adds minimal useful clinical information, delays the WBCT scan and may cause harm to a patient with a pelvic fracture. It should be deferred until after the primary survey, with the exception of patients with penetrating trauma, where it is important to identify the presence of a posterior torso wound.

Mechanical testing of the pelvis in the emergency room ('springing the pelvis') adds no useful clinical examination and will disrupt any blot clot that has formed around a pelvic fracture. It should never be performed – a pelvic fracture should always be diagnosed radiographically.

Summary box 23.4

The cABCDE of trauma care

- c – Control of massive external haemorrhage
- A – Airway with cervical spine protection
- B – Breathing and ventilation
- C – Circulation and haemorrhage control: apply a pelvic binder and do not remove until a pelvic fracture is excluded
- D – Disability (neurological status)
- E – Exposure (assess for other injuries)

SECONDARY SURVEY

All severely injured patients require a detailed top to toe examination after life-threatening injuries have been identified and managed during the primary survey. Patients may be intubated and unresponsive at this point, limiting the accuracy of clinical examination. Such patients should have a 'tertiary survey' when extubated and alert, to identify any missed 'minor' injuries such as a scaphoid fracture in the wrist or a rotator cuff tear in the shoulder. These injuries have the potential to cause significant long-term disability. It is essential that the findings of the primary, secondary and tertiary surveys are clearly recorded in the patient case notes.

DAMAGE CONTROL SURGERY VERSUS EARLY TOTAL CARE

As discussed in Chapter 22, the concept of damage control surgery (DCS) was developed because severely traumatised patients with impaired physiology have poor outcomes after lengthy and complex surgical reconstructive procedures performed shortly after their trauma. Prolonged procedures result in additional trauma and further immune and physiological derangement; the 'triad of death', a cycle of acidosis, coagulopathy and hypothermia, may develop and result in multiorgan failure and death.

Consequently, surgical interventions in the trauma patient with physiological abnormality are limited to rapid life- and limb-saving procedures: control of haemorrhage, decompression of cavities (e.g. craniotomy), revascularisation of ischaemic organs and limbs and removal of contamination. This damage control approach aims to rapidly achieve these objectives and then move the patient to a critical care environment and continue with resuscitation.

Subsequent definitive reconstructive procedures are deferred until the patient is adequately resuscitated and physiologically optimised. DCS in the abdomen is limited to packing and control of haemorrhage, debridement and resection of devitalised tissue and removal of contamination by foreign bodies or faeces. Damage control orthopaedic surgery is limited to debridement of severe open fractures, rapid temporary splintage or stabilisation of long bone fractures and decompression of limb compartment syndrome where required.

Revascularisation of a limb following arterial injury may be appropriate for isolated injuries but in the patient with severe multiple system trauma it may increase the threat to life and therefore amputation may be the better option. Such patients are then transferred to critical care for further resuscitation and physiological stabilisation before definitive surgical procedures can be planned.

The majority of trauma patients respond well to resuscitation and are not physiologically compromised after appropriate resuscitation. A number of physiological indices are used to evaluate the response to resuscitation, including a pulse rate less than 100 per minute, normal blood pressure and respiratory rate, as well as urine output >30 mL per hour. The patient should not have hypothermia (temperature <35°C) nor evidence of acidosis on arterial blood gases and should have a normal coagulation screen.

Lactate levels are also a good indicator of tissue perfusion and should rapidly return to normal. In this situation, it is usually safe for the surgeon to proceed with definitive repair or reconstruction of injured organs.

For musculoskeletal injuries, early total care allows definitive fixation of all unstable long bone, spinal and pelvic fractures within 36 hours of injury. This facilitates nursing care, allows early mobilisation of the patient and reduces pulmonary complications and length of stay on intensive care.

If a sequence of fracture fixations is required, at the conclusion of each procedure the surgeon and anaesthetist should determine whether the patient's physiological status has been maintained sufficiently to allow the next procedure, or whether the patient should return to critical care for a further period of resuscitation.

Summary box 23.5

Early total care versus damage control surgery

- Early total care describes the definitive management of a patient's injuries within 36 hours of injury after a period of initial resuscitation
- Damage control surgery describes simultaneous resuscitation with early rapid life- and limb-saving surgery. Time-consuming definitive surgery is deferred until the patient's physiological status allows
- An early total care approach can be changed to a damage control approach if the patient's physiology deteriorates during definitive surgery

Venous lactate

Venous lactate is a useful marker of resuscitation and physiological state. A normal lactate (<2 mmol/L) is a sign that the patient is probably resuscitated and suitable for early total care. An elevated lactate (>3 mmol/L) suggests the patient is under-resuscitated and should either have a period of further resuscitation, or DCS if surgery is urgent. If a patient's lactate is 2–3 mmol/L then the trend (upwards or downwards) should be noted and the other physiological markers considered, to determine whether the patient is suitable for definitive surgical procedures.

The identification of patients suitable for ETC versus DCS should be made by senior surgeons and anaesthetists/critical care doctors. This may be an easy decision, for example the haemodynamically unstable patient with intra-abdominal bleeding will always undergo rapid damage control laparotomy. In other cases a careful review of the patient's physiology and coagulation state will be required.

Summary box 23.6

Venous lactate is an essential marker of resuscitation

- <2 mmol/L – Early total care
- 2–3 mmol/L – Look at the trend (increasing or decreasing)
- >3 mmol/L – May be under-resuscitated; should either have further resuscitation or damage control surgery (DCS) if surgery is urgent
- >5 mmol/L – DCS (see Chapters 22 and 27)

SUMMARY

The early assessment and management of trauma patients should follow established ATLS principles.

A WBCT scan, from the head to the pelvis, with IV contrast is the gold standard investigation for major trauma patients and should be performed early and whenever possible.

Warmed blood and blood products in a 1:1:1 ratio should be used with tranexamic acid in the early resuscitation of haemodynamically unstable trauma patients.

Trauma patients requiring surgery should have an early decision made whether a damage control or ETC approach is required. Surgical procedures in physiologically compromised patients should be limited to those required to save the life and/or limb of the patient, while simultaneous resuscitation is continued.

Chapter 24

Traumatic brain injury

Learning objectives

To understand:

- The physiology of cerebral blood flow and the pathophysiology of raised intracranial pressure
- The classification and assessment of head injury
- Management and sequelae of minor and mild traumatic brain injury
- Medical and surgical management of moderate and severe traumatic brain injury

INTRODUCTION

Head injury accounts for 3–4% of emergency department attendances, with around 1500 cases per 100 000 population per year in the UK. Annual mortality attributable to head injury is estimated at 9 per 100 000, and it remains the leading cause of death and disability from childhood to early middle age, with an estimated 2% of the US population suffering long-term disability as a result of head injury. Road traffic accidents are the leading cause of head injury, being responsible for up to 50% of cases. Other common mechanisms of injury include falls and assault. There is significant geographical variation, for example firearms are the third leading cause in the US.

Significant traumatic brain injury can be considered a combination of the primary injury sustained on impact, and secondary injury developing in the following hours and days. Understanding the importance of intracranial pressure and related parameters is key to minimising secondary injury and improving outcomes.

INTRACRANIAL PRESSURE

Intracranial pressure and cerebral blood flow

The brain depends on continuous perfusion for oxygen and glucose delivery, and hence survival. Normal cerebral blood flow (CBF) is about 55 mL per minute for every 100 grams of brain tissue. Ischaemia results when this rate drops below 20 mL per minute, and even lower levels will result in infarction unless promptly corrected.

Flow depends on cerebral perfusion pressure (CPP), the difference between mean arterial pressure (MAP) and intracranial pressure (ICP).

Summary box 24.1

Intracranial pressure (ICP)

- A continuous supply of oxygenated blood is essential for brain survival
- Raised ICP can compromise cerebral perfusion, resulting in a cycle of secondary brain injury and swelling

CPP (75–105 mmHg) = **MAP** (90–110 mmHg) – **ICP** (5–15 mmHg)

Typical normal values are given in parentheses. In fact, in the normal brain, variations in vascular tone maintain a constant CBF across a range of MAP between 50 and 150 mmHg (or higher in the setting of chronic hypertension), and a corresponding range of CPP, the process of cerebral autoregulation.

The Monro Kellie doctrine and herniation syndromes

Alexander Monro observed in 1783 that the cranium is a 'rigid box' containing a 'nearly incompressible brain'. Any expansion in the contents, especially haematoma and brain swelling, may be initially accommodated by exclusion of fluid components, venous blood and cerebrospinal fluid (CSF). Further expansion is associated with an exponential rise in ICP (**Figure 24.1**)

Uncontrolled increases in ICP result in cerebral herniation (**Figure 24.2**). Typically, herniation of the uncus of the temporal lobe over the tentorium results in pupil abnormalities (see *Pupils* below), usually occurring first on the side of any expanding haematoma. Cerebellar tonsillar herniation through the foramen magnum compresses medullary vasomotor and respiratory centres, classically producing **Cushing's**

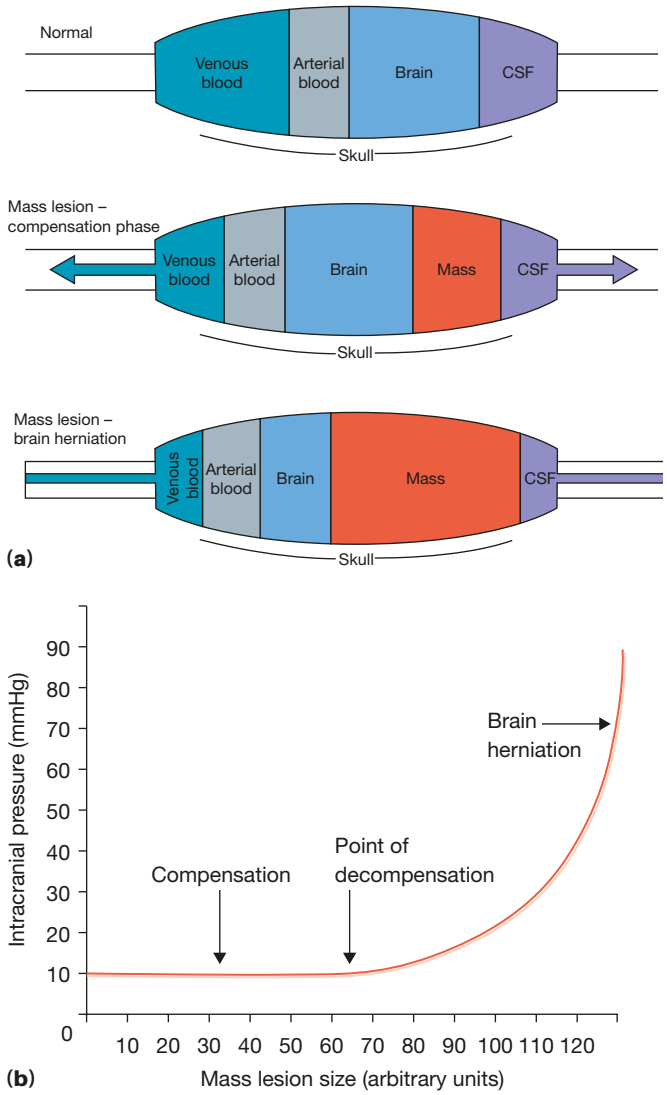

Figure 24.1 The Monro Kellie doctrine accounts for the ability of the intracranial compartment to accommodate expanding mass lesions, primarily by excluding venous blood and cerebrospinal fluid (CSF), and the rapid rise in pressure associated with exhaustion of this compensation.

triad – hypertension, bradycardia and irregular respiration. The patient is then said to be 'coning', and brainstem death will result without immediate intervention.

CLASSIFICATION OF HEAD INJURY

Severity of head injury is classified according to the postresuscitation Glasgow Coma Scale (GCS) (*Table 24.1*), as it is the GCS score, and in particular the motor score (see *Table 24.4*), that is the best predictor of neurological outcome. In broad terms, significantly obtunded patients have moderate injuries and comatose patients have severe injuries; alcohol and drug effects often complicate the classification.

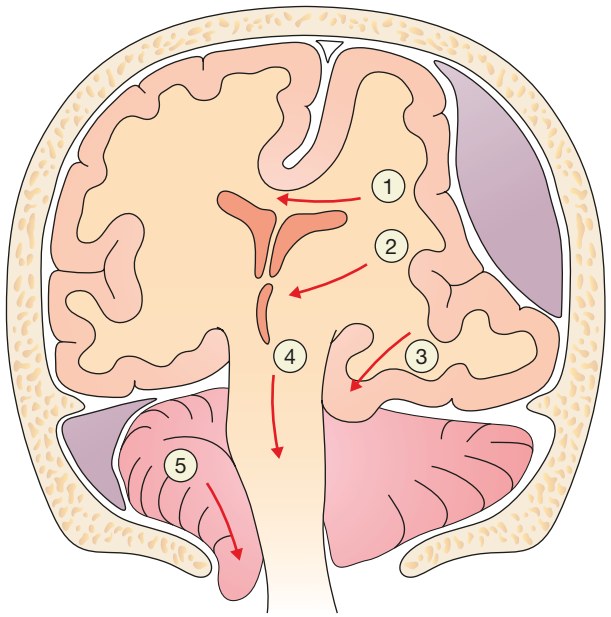

Figure 24.2 Brain herniation. Herniation of the cingulate gyrus under the falx cerebri is termed subfalcine herniation (1). (2) Midline shift is evident. (3) Uncal herniation: the temporal lobe is herniating over the tentorium cerebelli where it can compress the third nerve. (4) Central herniation and (5) tonsillar herniation result in brainstem compromise, manifesting as Cushing's triad.

TABLE 24.1 Head injury classification using the Glasgow Coma Scale (GCS) score.

Minor head injury	GCS 15 with no loss of consciousness (LOC)
Mild head injury	GCS 14 or 15 with LOC
Moderate head injury	GCS 9–13
Severe head injury	GCS 3–8

MINOR AND MILD HEAD INJURY

After exclusion of associated cervical spine injury, the major concern for these patients is to avoid discharge during the 'lucid interval' that may precede delayed deterioration due to an expanding intracranial haematoma. In general, patients with isolated head injuries and without ongoing deficits can safely be discharged from the emergency department, provided they meet suitable criteria, for instance those provided by the UK National Institute for Heath and Care Excellence (*Table 24.2*).

Summary box 24.2

Minor and mild head injury

- Decisions on imaging and discharge are best made guided by published criteria
- In preverbal children and other vulnerable groups, non-accidental injury must be considered
- Amnesia, confusion, headaches and somnolence are typical features of concussion

TABLE 24.2 National Institute for Health and Care Excellence discharge criteria in minor and mild head injury.

- GCS 15/15 with no focal deficits
- Normal CT brain if indicated (see below)
- Patient not under the influence of alcohol or drugs
- Patient accompanied by a responsible adult
- Verbal and written head injury advice: seek medical attention if:
  - Persistent/worsening headache despite analgesia
  - Persistent vomiting
  - Drowsiness
  - Visual disturbance
  - Limb weakness or numbness

CT, computed tomography; GCS, Glasgow Coma Scale.

TABLE 24.3 National Institute for Health and Care Excellence guidelines for computed tomography (CT) in head injury.

Indications for CT imaging within 1 hour
GCS <13 at any point
GCS <15 at 2 hours
Focal neurological deficit
Suspected open, depressed or basal skull fracture
More than one episode of vomiting
Post-traumatic seizure
Indications for CT imaging within 8 hours
Age >65 years
Coagulopathy (e.g. aspirin, warfarin or rivaroxaban use)
Dangerous mechanism of injury (e.g. fall from a height, road traffic accident)
Retrograde amnesia >30 minutes

Patients who do not meet all the discharge criteria will need admission for a further period of observation, and/or brain imaging. Early computed tomography (CT) imaging is desirable in patients with a persistent reduced conscious level, focal deficits, suspected fractures or risk factors for intracranial bleed (*Table 24.3*). Significant clinical or radiological abnormalities should be discussed with the neurosurgical service. Many of these patients will struggle with features of concussion for a period after their injury, with headaches and somnolence typical. Follow-up by a head injury specialist nurse or equivalent is therefore desirable.

Non-accidental injury

Head injury in children and vulnerable adults may be due to abuse. Significant findings include delayed presentation, injuries of disparate age, retinal haemorrhages, bilateral chronic subdural haematomas, multiple skull fractures and neurological injury without external signs of trauma.

Concussion, second impact syndrome and postconcussive syndrome

Concussion is defined as alteration of consciousness as a result of closed head injury, but is generally used in describing mild head injury without imaging abnormalities; loss of consciousness (LOC) at the time of injury is not a prerequisite. Key features include confusion and amnesia. The patient may be lethargic, easily distractable, forgetful, slow to interact or emotionally labile. Gait disturbance and incoordination may be seen. It is claimed that while symptomatic following a head injury, patients may be especially vulnerable to repeat impacts. It is proposed that in the context of disordered cerebral autoregulation, a second minor injury may trigger a form of malignant cerebral oedema refractory to treatment. Although the existence of the syndrome is disputed, and it is certainly rare, it should be considered in advice to individuals engaged in sports or activities carrying a risk of further injury: symptomatic players should not return to play.

Postconcussive syndrome is a loosely defined constellation of symptoms, persisting for a prolonged period after injury, and exacerbated in some patients by the potential for secondary gain (compensation). Patients may report somatic features such as headache, dizziness and disorders of hearing and vision. They may also suffer a variety of neurocognitive and neuropsychological disturbances, including difficulty with concentration and recall, insomnia, emotional lability, fatigue, depression and personality change.

MODERATE AND SEVERE TRAUMATIC BRAIN INJURY

Resuscitation and evaluation

Resuscitation is performed according to Advanced Trauma and Life Support (ATLS) guidelines, beginning with management of the airway and cervical spine control, and proceeding to assess and manage breathing and circulation. History obtained in parallel is key to shaping ongoing management.

History

Mechanism

In moderate and severe traumatic brain injury (TBI), history must be obtained from witnesses and paramedics. High-energy mechanisms of injury, including fall from a height or high-speed road traffic accident (RTA), will require careful clinical and radiological exclusion of associated multisystem

Summary box 24.3

History

Bystanders and paramedics may give vital information on the:

- preinjury state (fits, alcohol, chest pain)
- mechanism and energy involved in the injury (speed of vehicles, height fallen)
- conscious state and haemodynamic stability of the patient after the accident
- length of time taken for extrication

Check the medication history especially anticoagulants and antiplatelet agents

and spinal injury (see Chapter 25). In the case of RTAs in particular, extraction time and evidence of hypoxia or haemodynamic instability at the scene is important information to obtain from the paramedics. Falls and crashes are often caused by a primary medical problem such as myocardial infarction, hypoglycaemia or subarachnoid haemorrhage, with implications for management.

Neurological progression

A specific check should be made for any loss of consciousness at the time of injury, and its duration. The GCS and pupil responses at the scene and on arrival in the emergency department should be obtained and documented. They should also be checked regularly thereafter; deterioration in GCS is an important index of developing, and potentially reversible, secondary injury. It is also useful to assess the extent of amnesia, retrograde (events prior to the injury) and anterograde (events afterwards). If the patient was intubated at the scene of the accident it is valuable to know whether the patient was moving all four limbs before this.

Past medical history

Details of the patient's medical background should be obtained, including allergies and normal medications. Of particular note here, are antiplatelet agents, potentially requiring platelet transfusion especially if surgery is required, and anticoagulants, which may need reversal.

Examination: primary survey

ATLS guidelines address a fundamental priority, ensuring uninterrupted perfusion of the brain with oxygenated blood. This is especially important after a head injury given the disturbance to intracranial autoregulation and the sensitivity of the primary injured brain tissue to further insult. Bleeding from scalp lacerations may require management as part of the primary survey, as the blood loss can be substantial and ongoing. Check the responsiveness of the pupils, conscious level and for any gross focal neurological deficits. Blood glucose level should also be measured as early as possible as hypoglycaemia is very dangerous and easily reversible.

Summary box 24.4

Primary survey

- Ensure adequate oxygenation and circulation
- Exclude hypoglycaemia
- Check pupil size and response and Glasgow Coma Scale score as soon as possible
- Check for focal neurological deficits before intubation, if possible

Pupils

The pupil size should be recorded in millimetres, and reactivity documented as present, sluggish or absent. Uncal herniation **(Figure 24.2)** can compress the third nerve, compromising the parasympathetic supply to the pupil. Unopposed sympathetic activity produces a sluggish enlarged pupil, progressing to fixed and dilated under continued compression. Established pupil changes may reflect pathology anywhere in the eye or the reflex loop made up by the optic nerve, the oculomotor nerve and the brainstem. Direct ocular trauma or nerve injury in association with a skull base fracture can cause mydriasis (dilated pupil) present from the time of injury. Pre-existing discrepancy in pupil size (anisocoria), as a result of Holmes–Adie pupil or cataracts for example, may also complicate assessment.

Glasgow Coma Scale score

The GCS is the sum of scores on three components as detailed in *Table 24.4*. The breakdown of the GCS into eye opening, verbal and motor components should always be recorded and used when communicating the status to other doctors. Remember that the score represents the best performance elicited, so a patient flexing in response to a painful stimulus on the left and localising on the right scores 'M5'. A sternal or supraorbital rub, or trapezius squeeze represents an appropriate painful stimulus.

Neurological deficit

Gross focal neurological deficits, such as paraplegia, may be evident at the primary survey, and an assessment to exclude such deficit should be carried out, especially if the patient is to

TABLE 24.4 Glasgow Coma Scale score for head injury.

Eyes open	Spontaneously	4
	To verbal command	3

Sir Gordon Morgon Holmes, 1876–1965, physician, The National Hospital for Nervous Diseases, Queen's Square, London, UK.
William John Adie, 1886–1935, physician, The National Hospital for Nervous Diseases, Queen's Square, London, UK.

be intubated so that subsequent examination will be impossible. Detailed neurological examination is included in the secondary survey.

Examination: secondary survey

A full secondary survey will be required. Particular attention must be paid to head, neck and spine.

Head

Examination of the head should include inspection and palpation of the scalp for evidence of subgaleal haematoma and scalp lacerations, which may bleed profusely, and potentially overlie fractures. Examine the face for evidence of fractures, especially to the orbital rim, zygoma and maxilla. Clinical evidence of a skull base fracture may include Battle's sign (**Figure 24.3**), and 'racoon' or 'panda' eyes (bilateral periorbital bruising). Haemotympanum, or overt bleeding from the ear if the tympanic membrane has ruptured, and CSF rhinnorrhoea or otorrhoea are also highly suggestive of a fracture of the base of the skull.

A complete examination of the cranial nerves will reveal, for example, facial or vestibulo-cochlear nerve damage associated with skull base fracture. Midbrain or brainstem dysfunction may produce gaze paresis (inability of eye to look across beyond the midline), dysconjugate gaze (inability of the eyes to work together) or roving eye movements. Inspect the conjunctiva and cornea of the eyes, and the retina using an ophthalmoscope, looking for hyphaema (blood in the anterior chamber of the eye), papilloedema or retinal detachment. Blood in the mouth may be due to tongue-biting at seizure. The GCS and pupil status, assessed as part of the primary survey, require re-evaluation at the secondary survey and regularly thereafter.

Figure 24.3 Battle's sign. A skull base fracture may be associated with bruising over the mastoid process.

Neck and spine

Studies have demonstrated an incidence of cervical fracture of up to 10% in association with moderate and severe TBI. Cervical spine injury must be presumed in the context of head injury until actively excluded. In a high-energy mechanism such as RTA or fall from a height, thoracic and lumbar spine injuries must also be excluded. Plain radiographs can be of limited value in excluding significant cervical spine injury. Even CT imaging does not exclude the possibility of significant ligamentous injury. Therefore, whenever feasible, these patients should be managed in a hard collar until the neck can be cleared clinically.

A peripheral nerve examination with documentation of limb tone, power, reflexes and sensation needs to be performed early to identify spinal pathology. This is especially important in patients who may subsequently be intubated and ventilated, when this assessment will no longer be possible. Obtunded patients should move all four limbs in response to an appropriate painful stimulus.

The patient will need to be log-rolled to palpate for thoracic or lumbar deformity, and any cervical collar should be removed at this stage to allow palpation of the cervical spine, before it is replaced. If there is associated spinal injury, a thoracic sensory level is much more easily established by sensory examination on the back. A per rectal examination is also performed at log-roll, assessing for anal tone, sensation in the awake patient and anal wink (sphincter seen to contract in response to a pinprick stimulus). Priapism is a strong predictor of severe cord injury even in intubated patients.

Summary box 24.5

Secondary survey

- Battle's sign, periorbital bruising and blood in ears/nose/mouth may point to base of skull fracture
- Cervical spine fractures are common and must be actively excluded
- Log-roll to check whole spine for steps and tenderness, and for per rectum exam

Surgical management

Fractures: skull vault

Closed linear fractures of the skull vault are managed conservatively. Open or comminuted fractures should be considered for debridement and prophylactic antibiotic therapy.

William Henry Battle, 1855–1936, surgeon, St Thomas's Hospital, London, UK.
A racoon is a small mammal native to North and Central America that has a pale face with dark rings round its eyes.

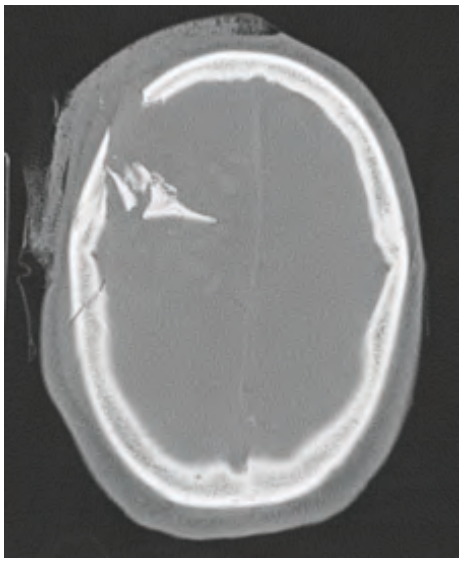

Figure 24.4 A right frontal comminuted depressed skull fracture, with a linear undisplaced fracture of the right parietal bone visible posteriorly.

Depressed skull fractures involve inward displacement of a bone fragment by at least the thickness of the skull (Figures 24.4 and 24.5). They occur when small objects hit the skull at high velocity. They are usually compound (open) fractures, and are associated with a high incidence of infection, neurological deficit and late-onset epilepsy. These fractures require exploration and elevation, especially where intracranial air is present pointing to a breach in the dura mater. Fractures that involve the air sinuses should generally be managed as open fractures, using broad spectrum antibiotics with or without exploration.

Fractures: skull base

Clinical signs of skull base fracture include bleeding or CSF leak from the ears (otorrhoea) or nose (rhinnorrhea), and bruising behind the ear (Figure 24.3) or around the eyes. Skull base fractures may be complicated by pituitary dysfunction, arterial dissection or cranial nerve deficits, with anosmia, facial palsy or hearing loss typical. CSF leak will generally resolve spontaneously but persistent leak can result in meningitis so repair may be required. Blind nasogastric tube placement is contraindicated in these patients.

Extradural haematoma

Extradural haematoma (Figure 24.6) is a neurosurgical emergency. It results from rupture of an artery, vein or venous sinus, in association with a skull fracture. The classical injury is a fracture to the thin squamous temporal bone, with associated damage to the middle meningeal artery. Transient loss of consciousness is typical, and the patient may then present in the subsequent lucid interval with headache but without any neurological deficit. As the haematoma expands, compensation is exhausted (see Monro Kellie doctrine above), with rapid deterioration. There is contralateral hemiparesis, reduced conscious level and ipsilateral pupillary dilatation, the cardinal signs of brain compression and herniation.

Although this classical presentation occurs in only one-third of cases, it emphasises the potential for rapid avoidable

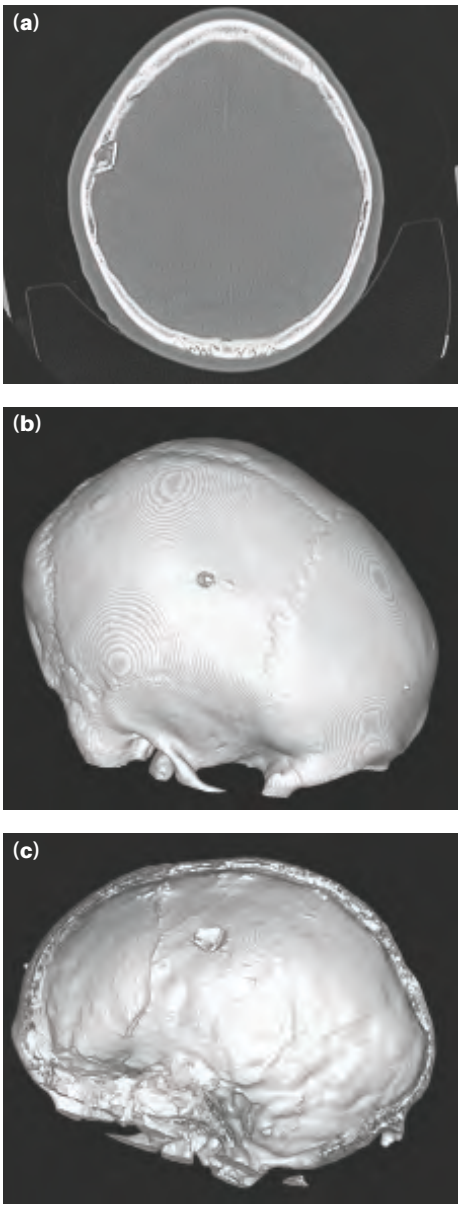

Figure 24.5 A small depressed skull fracture of the parietal bone visible on axial bone windows **(a)**, visualised on bone vault reconstructions **(b)** and with an underlying breach of dura **(c)**.

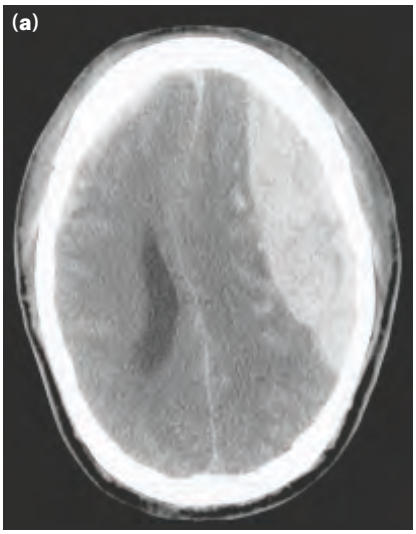
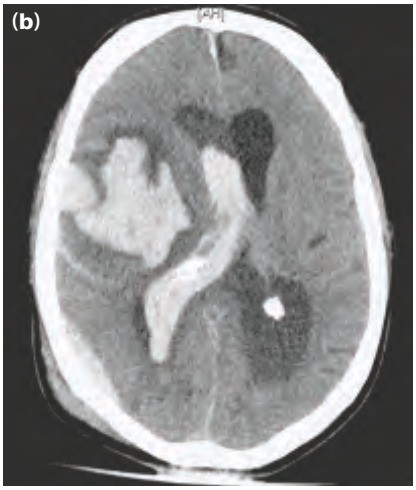
Summary box 24.6

Extradural haemorrhage

- Can follow relatively minor trauma with brief loss of consciousness
- Followed by a lucid interval and then sudden deterioration
- Lentiform lesion on computed tomography
- Require immediate transfer to a neurosurgical unit for decision on evacuation





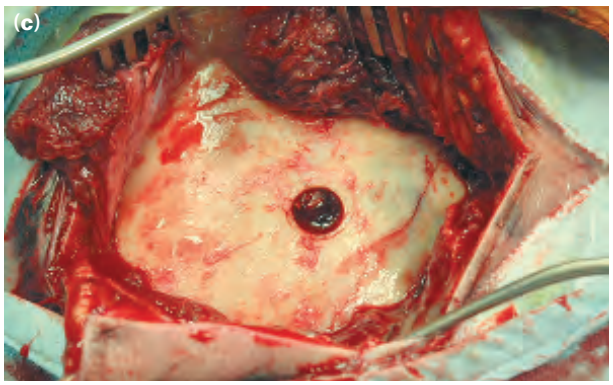


Figure 24.6 **(a)** A large left extradural haematoma (note the biconvex shape) exerts mass effect; a smaller right acute subdural haematoma is also evident. **(b)** Right frontal intracerebral haematoma extending into the lateral ventricle is evident. There is a small right posterior extradural haematoma and traumatic subarachnoid bleeding in the sulci of the right hemisphere. **(c)** A surgical temporal bone exposure showing a linear skull fracture with underlying extradural haematoma visible through a burr hole.

secondary brain injury in patients with minimal primary injury.

On CT, extradural haematomas appear as a lentiform (lens-shaped or biconvex) hyperdense lesion between skull and brain, constrained by the adherence of the dura to the skull. Mass effect may be evident, with compression of surrounding brain and midline shift. Areas of mixed density suggest active bleeding. A skull fracture will usually be evident. Extradural haematoma mandates urgent transfer to the most accessible neurosurgical facility, for immediate evacuation in deteriorating or comatose patients or those with large bleeds, and for close observation with serial imaging in other cases. The prognosis for promptly evacuated extradural haematoma, without associated primary brain injury, is excellent.

Acute subdural haematoma

Acute subdural haematoma **(Figure 24.7a)** is encountered in two broadly distinct contexts. Firstly, high-energy injury mechanisms can result in the rupture of cortical surface vessels with significant associated primary brain injury. This results in expanding haematoma with rapid deterioration and

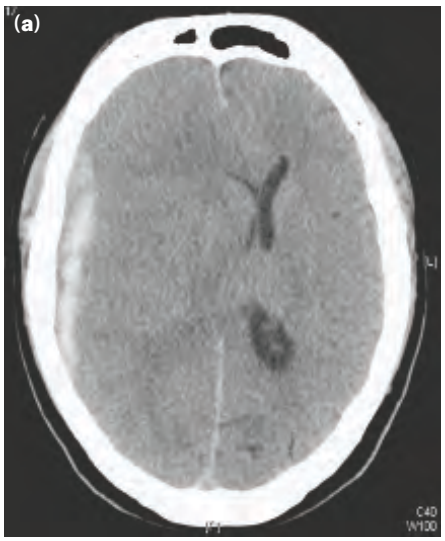

Figure 24.7 **(a)** Right-sided acute subdural haematoma (hyperdense). The substantial midline shift reflects brain swelling as well as bleeding; this is a high-energy injury. **(b)** Bilateral chronic subdural haematomas: the left is mixed density, the hypodense material representing old blood and the higher density indicating more recent bleeding, probably loculated so requiring a craniotomy to evacuate. The bleed on the right is isodense, indicating intermediate age.

developing signs of raised ICP, reminiscent of extradural haematoma without the lucid interval. These collections require prompt evacuation, typically by craniotomy or craniectomy.

In a second group of patients, older and often anticoagulated, a lower-energy injury leads to venous bleeding around the brain. Depending on the total volume of bleeding, the resulting haematoma may present early as acute subdural haematoma, after delay and osmotic expansion as chronic subdural haematoma or may even remain clinically silent. This latter group may present much later with a further 'acute-on-chronic' subdural haematoma. On diagnosis, clotting function should be corrected wherever possible. Bleeds of significant size, with significant associated midline shift or with deteriorating neurology, require urgent evacuation. Smaller bleeds in neurologically stable patients may be managed conservatively, at least initially: liquefaction of the clot over 7–10 days after the bleed may allow for a much less invasive evacuation through burr holes.

Summary box 24.7

Acute subdural haemorrhage

- High-energy injury, or elderly/anticoagulated
- Generally requires urgent evacuation by craniotomy/craniectomy

Since the dura is not adherent to the brain as it is to the skull, subdural blood is free to expand across the brain surface giving a diffuse concave appearance.

Chronic subdural haematoma

Chronic subdural haematoma **(Figure 24.7b)** is a common cause of acute neurological deterioration in the elderly. Cerebral atrophy in this age group results in stretching of cortical–dural bridging veins, which are then vulnerable to rupture. The resulting haematoma can expand over days or weeks by osmosis, ultimately producing symptoms of raised ICP or focal deficits. There is usually a history of recent injury, but especially in the context of antiplatelet or anticoagulant medication even apparently trivial impacts may be responsible.

Summary box 24.8

Chronic subdural haemorrhage

- Common in the elderly especially those on anticoagulants
- Clinical deficits result from osmotic expansion of a degrading clot over days/weeks
- Diffuse hypodense lesion on computed tomography
- Burr hole drainage is usually preferred.

On presentation, it is important to exclude coexisting electrolyte disturbance and infections, which may contribute to clinical impairment. Imaging reveals diffuse hypodensity overlying the brain surface. Recent bleeding may be isodense or hyperdense, and mixed density can indicate an acute-on-chronic subdural haematoma.

Anticoagulation should be reversed, either by administration of vitamin K, or urgently by transfusion of recombinant clotting factors in patients who have deteriorated acutely. Conservative management, sometimes with administration of corticosteroids, can be considered for small bleeds without symptoms or with headache alone. For the majority, drainage is performed using burr holes. Urgency is dictated by the clinical condition of the patient and imaging evidence of mass effect. If clinically stable, a delay of 7–10 days may be considered to allow platelet function to normalise after withdrawal of aspirin/clopidogrel.

Traumatic subarachnoid haemorrhage

Trauma is the commonest cause of subarachnoid haemorrhage **(Figures 24.6b, 24.8)**, and this is managed conservatively. It is not usually associated with significant vasospasm, which characterises aneurysmal subarachnoid haemorrhage (see later). The possibility of spontaneous subarachnoid haemorrhage leading to collapse and so causing a head injury needs to be borne in mind, and formal or CT angiography may be required to exclude this.

Summary box 24.9

Specific head injuries

- Traumatic vs. primary subarachnoid haemorrhage is an important distinction
- Cerebral contusions arise adjacent to rough bone surfaces
- Diffuse axonal injury results from extreme accelerations of the skull contents
- Arterial dissection is associated with fractures of the skull base

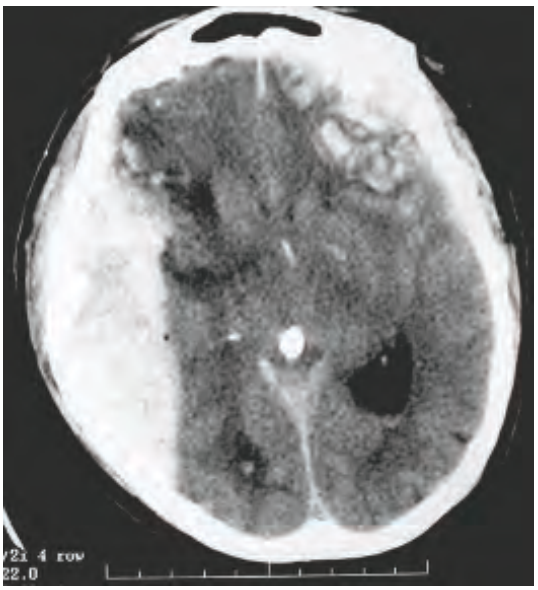

Figure 24.8 A large right extradural haematoma is evident. There are widespread cerebral contusions most prominent in the left frontal lobe. There is traumatic subarachnoid blood in the third and lateral ventricles.

Cerebral contusions

Contusions are common and are found predominantly where brain is in contact with the irregularly ridged inside of the skull, i.e. at the inferior frontal lobes and temporal poles. 'Coup contre-coup' contusions are brain injury at the site of impact and where the brain is struck by the inside of the skull on the far side, as the skull and brain accelerate and then decelerate out of synchrony with each other. Contusions appear heterogenous on CT, reflecting their composition of injured brain matter interspersed with acute blood (**Figure 24.8**). Contusions rarely require surgical intervention, but may warrant delayed evacuation to reduce mass effect.

Diffuse axonal injury

This is a form of primary brain injury, seen in high-energy accidents, and which usually renders the patient comatose. It is strictly a pathological diagnosis made at postmortem, but haemorrhagic foci in the corpus callosum and dorsolateral rostral brainstem on CT may be suggestive, although the CT often appears normal.

Arterial dissection

Cerebral arterial dissection occurs spontaneously or in the context of trauma. In the hours after significant trauma, dissection of the carotid extracranially, or at the skull base in association with fractures, is most common. It presents with headache, neck pain and focal ischaemic deficits, due to occlusion by mural haematoma, thrombus and thromboembolism. Intracranial dissection often affects the vertebral artery and may result in subarachnoid bleeding.

Medical management

From initial resuscitation, through surgical intervention and into the subsequent phase of intensive care management, medical management strategies aim to minimise secondary brain injury, through avoidance of hypoxia and hypotension and control of ICP. Unchecked, secondary injury leads to a further cycle of deterioration (**Figures 24.2 and 24.9**).

Summary box 24.10

Medical management of head injury

- First-line ICP control involves optimising sedation, ventilation and serum sodium levels
- Paralysis and external ventricular CSF drainage are important adjuncts
- There is little evidence for benefit with therapeutic hypothermia, barbiturate coma or decompressive craniectomy
- Check pituitary function, consider seizure prophylaxis, commence enteral nutrition within 72 hours

The role of neurosurgical centres

Early discussion of patients and imaging with the regional neurosurgical service is advisable. UK trauma audit and research network data show higher mortality in patients with severe TBI managed in non-neurosurgical centres, and this is reflected in NICE guidelines, which recommend early transfer irrespective of the need for surgery.

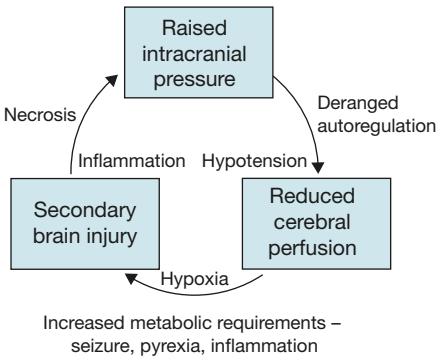

Figure 24.9 Brain swelling and mass lesions contribute to a raised intracranial pressure, which compromises perfusion, leading to secondary brain injury and further swelling.

Control of intracranial pressure

Intubation and ventilation is required early in the management of severe brain injury for airway control. It is often required in moderate brain injury to facilitate the safe management and transfer of unstable and frequently agitated patients and in order to control ICP. UK trauma audit and research network data indicate that severe TBI survival is better in a neurosurgical centre, irrespective of the need for surgery. Where there is evidence of raised ICP, for example pupil changes, a bolus of mannitol may be administered to control pressure temporarily while scanning and transferring the patient.

Management of the intubated patient, following evacuation of any focal haematomas, is guided by ICP monitoring using a bolt ICP monitor, or else an external ventricular drain inserted into the lateral ventricle, which can also contribute to ICP control by permitting CSF drainage. A sustained rise of ICP over 20–25 mmHg above normal is associated with a poor outcome, and maintenance of a cerebral perfusion pressure of at least 60 mmHg is important in preventing secondary injury.

ICP can be controlled by simple measures including raising the head of the bed and loosening the collar to improve venous drainage. Seizures and pyrexia should be actively controlled. Medical management titrated to ICP includes escalating doses of sedatives, analgesics and ultimately muscle relaxants. Target ventilatory and circulatory parameters are set out in *Table 24.5*.

Where these measures fail, neurointensivists may seek to control brain swelling using mannitol or hypertonic saline infusions. Where autoregulation is preserved, inducing high cerebral perfusion pressure may reduce ICP through vasoconstriction. A range of further interventions are effective in controlling ICP, but evidence for long-term outcome benefit is limited or absent. These include induction of therapeutic hypothermia or thiopentone coma and surgical decompressive craniectomy.

TABLE 24.5 Key parameters to maintain in head-injured patients in neurointensive care.

pCO_2 = 4.5–5.0 kPa
pO_2>11 kPa
MAP = 80–90 mmHg
ICP <20 mmHg
CPP >60 mmHg
[Na^+] >140 mmol/L
[K^+] >4 mmol/L

Pituitary dysfunction

Electrolyte imbalance is common in TBI, and contributes to brain swelling and to causing seizures. Diverse mechanisms are involved. Cerebral salt wasting, a poorly understood form of excretory dysregulation in association with brain insult, leads to volume depletion and hyponatraemia. The syndrome of inappropriate antidiuretic hormone (SIADH) leads to a water retention and hyponatraemia in the context of pituitary damage. This is of particular concern in head injury since low serum osmotic pressure can contribute to brain swelling, so hypotonic fluids are avoided in this setting. Conversely, ADH secretion may be compromised in the context of trauma, producing diabetes insipidus resulting in hypernatraemia.

All aspects of pituitary function may be compromised in the setting of TBI. Routine screening of pituitary hormone levels and liaison with endocrinology is an important aspect of optimal medical management. Note that routine, rather than directed, administration of corticosteroids in severe head injury is associated with increased mortality and is not recommended.

Seizures

Seizures may occur early (within 7 days) or late. The cumulative probability is between 2% (mild TBI) and 60% (severe TBI with exacerbating features). Risk factors include injury severity, especially the presence of intracerebral haemorrhage, and depressed skull fractures and tears of the dura. Antiepileptics, typically phenytoin, are administered prophylactically to patients at high risk of seizures.

Nutrition

Enteral nutrition is preferred to intravenous parenteral nutrition on grounds of cost and associated complications, and should be commenced within 72 hours of injury. Prokinetics (e.g. metaclopramide, erythromycin) can be administered to promote absorption.

Outcomes and sequelae

The long-term sequelae of moderate and severe traumatic brain injury include headache, memory and cognitive impairments, contributing to the postconcussive syndrome described above. Rehabilitation represents a complex and prolonged multidisciplinary challenge. The Glasgow outcome score is used to quantify the degree of recovery achieved after head injury, especially for research purposes, and is detailed in *Table 24.6*. Good recovery implies independence and potential to return to work rather than a full return to previous capacity.

TABLE 24.6 Glasgow outcome score (GOS).

Good recovery	5
Moderate disability	4
Severe disability	3
Persistent vegetative state	2
Dead	1

Chapter 25

Neck and spine

Learning objectives

To be familiar with:

- The accurate assessment of spinal trauma
- The basic management of spinal trauma and the major pitfalls
- The pathophysiology and types of spinal cord injury
- The prognosis of spinal cord injury, factors affecting functional outcome and common associated complications

ANATOMY OF THE SPINE AND SPINAL CORD

Spinal column anatomy

The vertebral column is composed of a series of motion segments (Figure 25.1). A motion segment consists of two adjacent vertebrae, their intervertebral disc and ligamentous restraints (Figure 25.2).

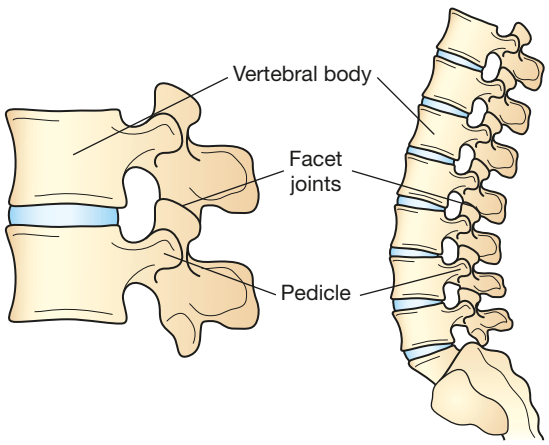

Figure 25.1 The spinal motion segment.

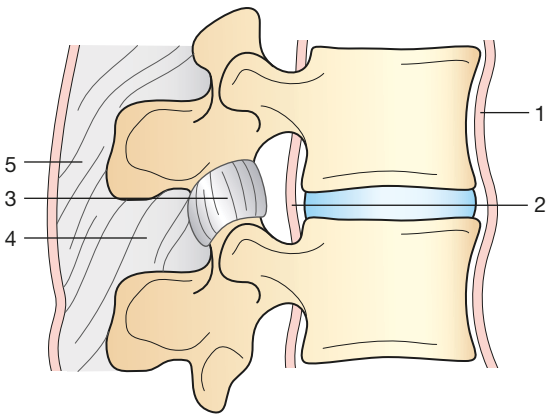

Figure 25.2 Ligamentous spinal restraints. (1) Anterior longitudinal ligament, (2) intervertebral disc and posterior longitudinal ligament, (3) facet joint capsule, (4) interspinous ligament, (5) supraspinous ligament.

Regional variations

Upper cervical spine anatomy is designed to facilitate motion (Figure 25.3), and stability here is dependent on ligamentous restraints (Figure 25.4). Vertebral anatomy from C3 to C7 is similar. The cervicothoracic (Figure 25.5) and thoracolumbar junctions (Figure 25.6) are transitional zones where the

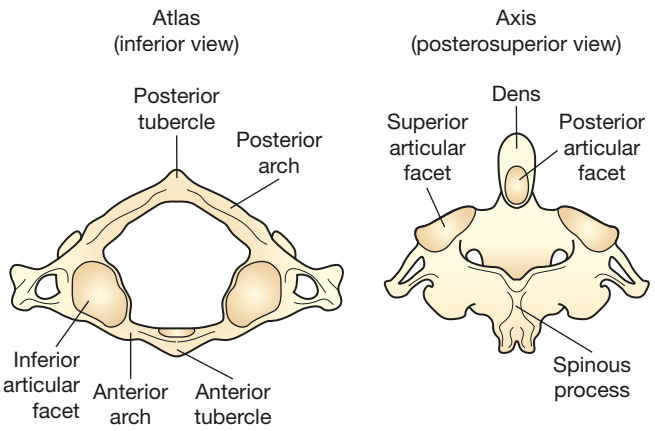

Figure 25.3 Atlantoaxial bony anatomy.

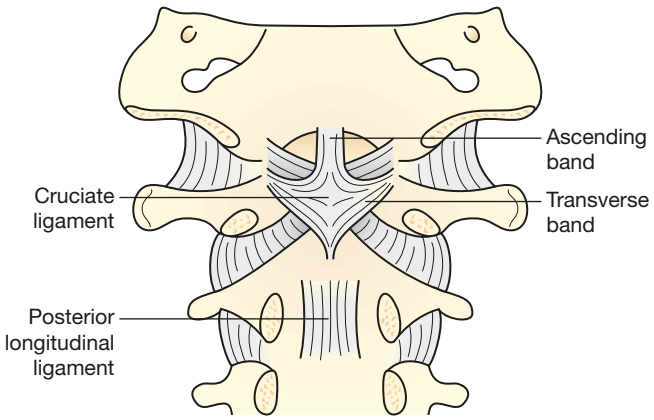

Figure 25.4 Atlantoaxial ligaments.

Figure 25.5 Cervicothoracic facet subluxation (arrow) (easily missed with inadequate x-rays).

spine changes from a mobile section (cervical and lumbar) to a more fixed one (thoracic). These two areas are common sites of injury.

Spinal stability

Spinal stability is the ability of the spine to withstand physiological loads with acceptable pain, avoiding progressive deformity or neurological deficit. The spinal column can be

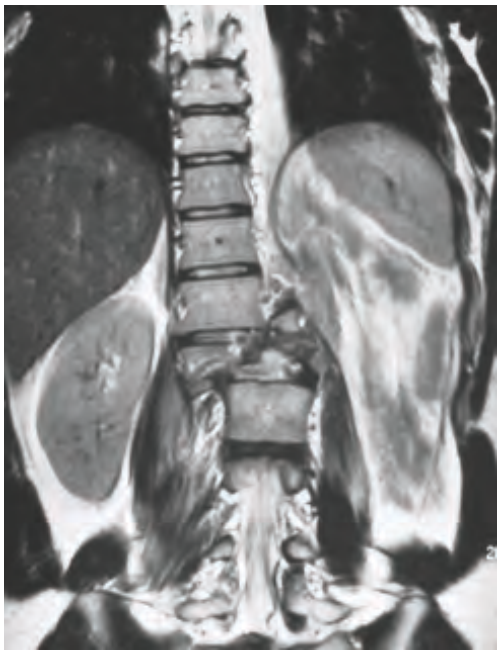

Figure 25.6 Coronal T2-weighted magnetic resonance image demonstrating a fracture dislocation at the thoracolumbar junction.

divided into three columns: anterior, middle and posterior (Figure 25.7) If two or more columns of the spine are injured the spine is considered unstable. The AO classifications (Magerl and AO Spine Subaxial Classification System) are based on the mechanism of injury and used to assess spinal stability.

Summary box 25.1

Spinal column anatomy

- Upper cervical spine stability is dependent on ligamentous restraints
- The cervicothoracic and thoracolumbar junctions are common sites of injury

Spinal neuroanatomy

The spinal cord extends from the foramen magnum to the L1/L2 level, where it ends as the conus medullaris in adults (lower in children) (Figure 25.8). Below this level lies the cauda equina. Figure 25.9 illustrates a cross-section of the spinal

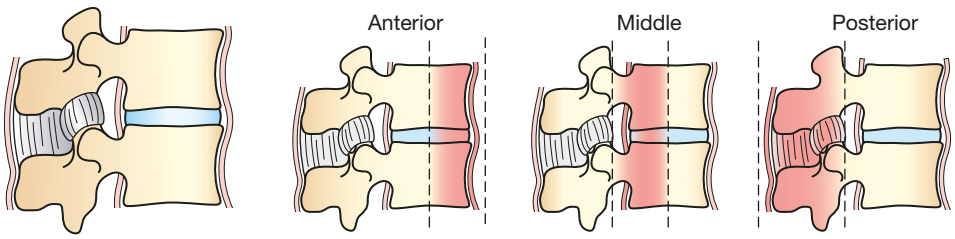

Figure 25.7 The three-column model of spinal stability.

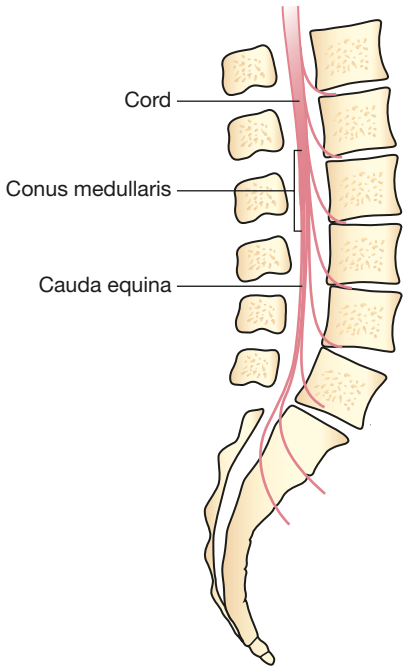

Figure 25.8 The spinal cord ends at T12/L1 at the conus medullaris, which gives rise to the cauda equina.

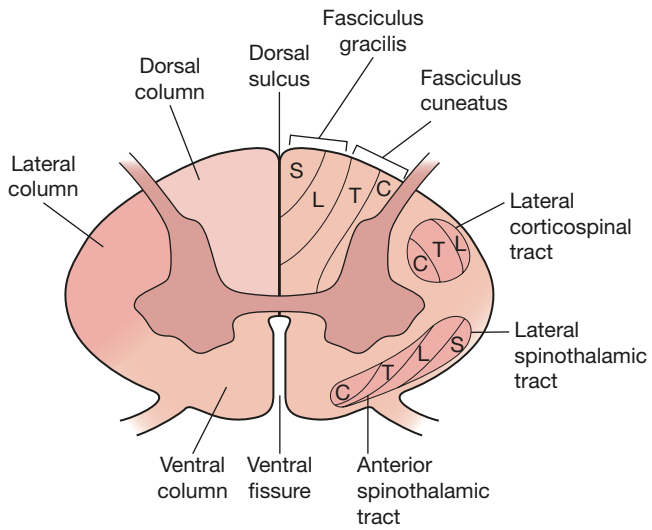

Figure 25.9 A cross-section of the spinal cord.

cord. The lateral spinothalamic tracts transmit the sensations of pain and temperature, the lateral corticospinal tracts are responsible for motor function and the posterior columns transmit position, vibration and deep pressure sensation.

The spinothalamic tracts cross to the opposite side of the spinal cord within three levels of entering the cord. In contrast, the corticospinal tracts and the posterior columns decussate proximally at the craniocervical level. The tracts are topographically arranged; proximal body function is represented centrally, with distal body function arranged peripherally.

PATIENT ASSESSMENT

Basic points

The advanced trauma life support (ATLS) principles apply in all cases (see Chapters 22 and 23). The spine should initially be immobilised using full spinal precautions, on the assumption that every trauma patient has a spinal injury until proven otherwise (**Figure 25.10**). The finding of a spinal injury makes it more (not less) likely that there will be a second injury at another level.

Spinal boards lead to skin breakdown in insensate patients, and are very uncomfortable for those with normal sensation (**Figure 25.11**). They should only be used for transferring patients.

Figure 25.10 Spinal immobilisation.

Figure 25.11 Pressure sores may develop rapidly in insensate patients.

The unconscious patient

Definitive clearance of the spine may not be possible in the initial stages and spinal immobilisation should then be maintained, until MRI or equivalent can be used to rule out an unstable spinal injury.

Summary box 25.2

Patient assessment

- Use ATLS principles in all cases of spinal injury
- In polytrauma cases suspect a spinal injury
- A second spinal injury at a remote level may be present in 10% of cases
- Spinal boards cause pressure sores

PERTINENT HISTORY

The mechanism and velocity of injury should be determined at an early stage. A check for the presence of spinal pain should be made. The onset and duration of neurological symptoms should also be recorded.

PHYSICAL EXAMINATION

Initial assessment

The primary survey always takes precedence, followed by a careful systems examination paying particular attention to the abdomen and chest. Spinal cord injury may mask signs of intra-abdominal injury.

Spinal examination

The overlying skin should be inspected (e.g. for possible penetrating wounds) and the entire spine must be palpated. A formal spinal log roll must be performed to achieve this (**Figure 25.12**). Significant swelling, tenderness, palpable steps or gaps suggest a spinal injury. A rectal examination should be undertaken to assess anal tone and perianal sensation (see Neurological examination). Seatbelt marks on the abdomen and chest must be noted, as these suggest a high-energy accident.

Neurological examination

The American Spinal Injury Association (ASIA) neurological evaluation system (**Figure 25.13**) is an internationally accepted method of neurological evaluation.

Motor function is assessed using the Medical Research Council (MRC) grading system (0–5) in key muscle groups (**Figure 25.13**). A motor score can then be calculated (maximum 100).

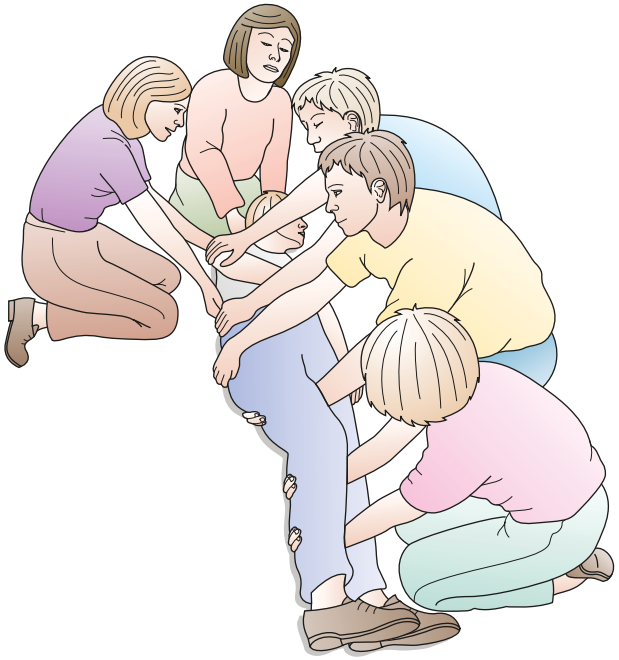

Figure 25.12 Spinal log roll.

Sensory function (light touch and pin prick) is assessed using the dermatomal map (**Figure 25.13**). A total sensory score is then calculated.

Rectal examination is performed to assess anal tone, voluntary anal contraction and perianal sensation.

Level of neurological impairment

The ASIA Neurological Impairment Scale is based on the Frankel classification of spinal cord injury:

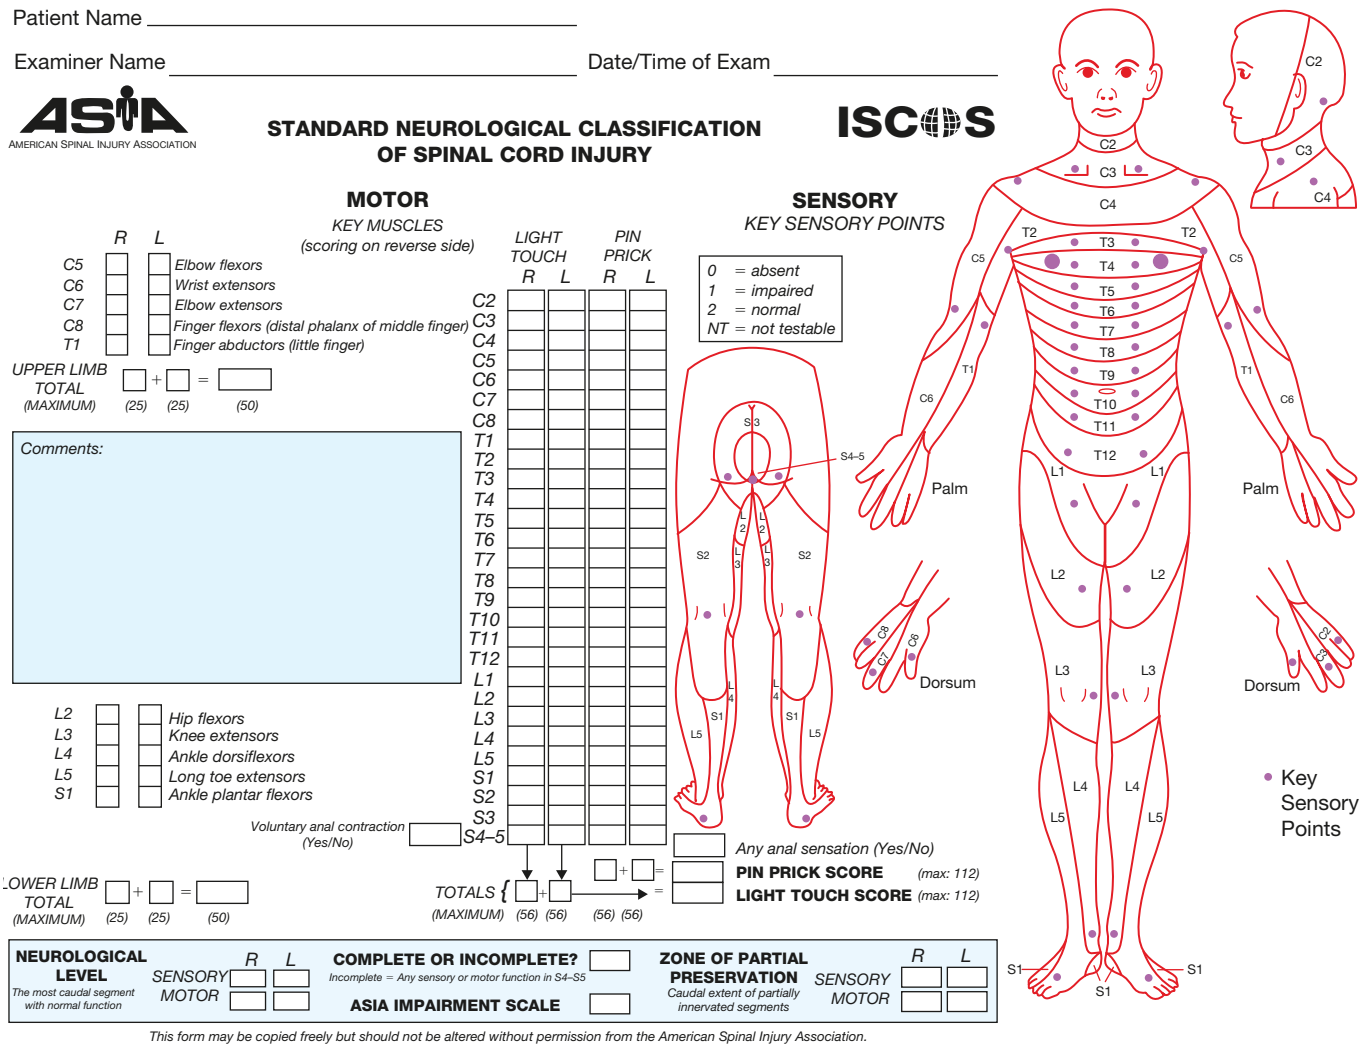
- **A**: complete spinal cord injury;
- **B**: sensation present, motor absent;
- **C**: sensation present, motor present but not useful (MRC grade <3/5);
- **D**: sensation present, motor useful (MRC grade ≥3/5);
- **E**: normal function.

Summary box 25.3

Physical examination

- There are three types of shock following spinal cord injury
- The ASIA neurological scoring system should be used
- Functional motor power is grade 3/5 or higher

Hans Ludwig Frankel, formerly Clinical Director, The National Spinal Injuries Centre, Stoke Mandeville, Buckinghamshire, UK.



This form may be copied freely but should not be altered without permission from the American Spinal Injury Association.

Figure 25.13 American Spinal Injury Association neurological evaluation.

DIAGNOSTIC IMAGING

Plain radiographs

A full cervical spine series includes anteroposterior and lateral radiographs of the whole cervical spine, and open mouth views. Clear visualisation of the cervicothoracic junction is essential in all cases of suspected spinal injury, as this is a common site for injury and often not seen on a plain radiograph. If a spinal fracture is identified then further imaging of the whole spine is required because there is a 15% incidence of a further spinal fracture.

A system for evaluation of the lateral cervical spine radiograph

1. Assess prevertebral soft tissue swelling (**Figure 25.14**).
2. Assess sagittal alignment using three imaginary lines (**Figure 25.15**).
3. Assess for instability (**Figure 25.16**):
   a. 3.5 mm of sagittal translation;
   b. Sagittal angulation of >11° (compared to adjacent level).

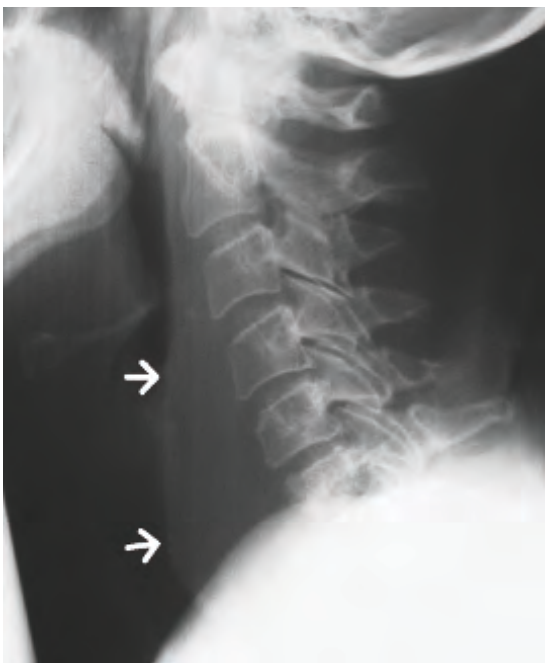


Figure 25.14 Large prevertebral haematoma (arrows).

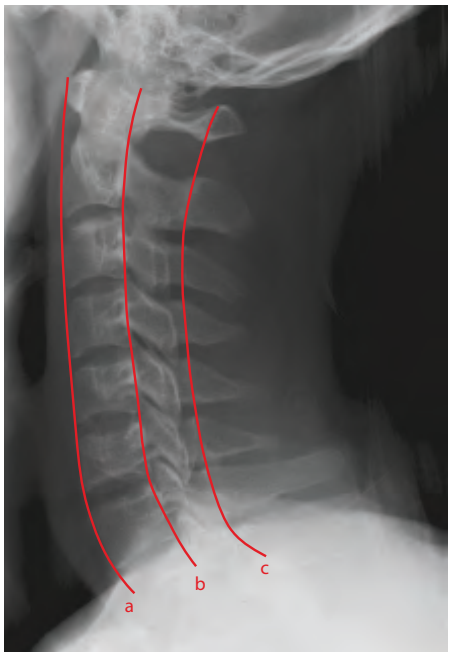

Figure 25.15 The anterior **(a)**, posterior **(b)** and spinolaminar **(c)** lines are useful in identifying anterior translation on lateral x-rays of the neck.

Figure 25.16 Lateral cervical spine x-ray showing obvious spinal instability with marked sagittal angulation and translation. This patient walked into the outpatient department.

Computed tomography

Computed tomography (CT) scanning with two-dimensional (2D) reconstruction remains the gold standard in spinal trauma and is indicated for patients with suspected or visible injuries on plain radiographs (Figure 25.17). Patients undergoing a head CT scan for closed head injury should also have a cervical screening CT. Often CT scans of the chest and abdomen are performed as part of the assessment of polytrauma patients and will usually include the spine.

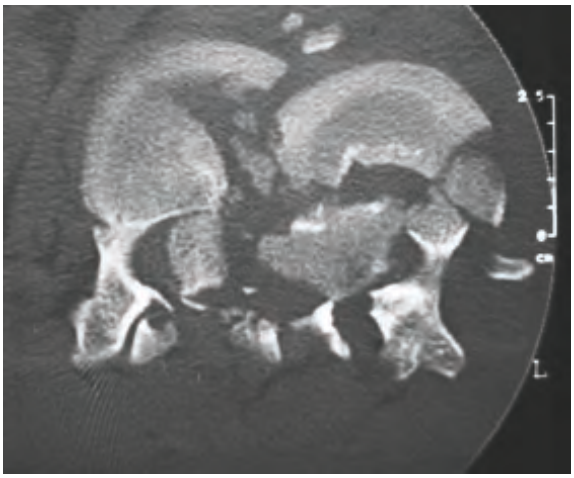

Figure 25.17 Axial computed tomography demonstrating a thoracolumbar fracture dislocation.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is indicated in all cases with neurological deficit and where assessment of ligamentous structures is important (Figure 25.18).

Dynamic imaging

Lateral flexion–extension radiographs of the cervical spine should not be undertaken acutely although they can have a role in assessing spinal stability in the longer term.

Figure 25.18 Sagittal T2-weighted magnetic resonance imaging scan demonstrating a cervical spine subluxation and spinal cord contusion.

Summary box 25.4

Diagnostic imaging of spinal injuries

- Clear visualisation of the cervicothoracic junction is mandatory
- Plain cervical spine radiographs fail to identity 15% of injuries

CLASSIFICATION AND MANAGEMENT OF SPINAL AND SPINAL CORD INJURIES

Basic management principles

Spinal realignment

In cases of cervical spine subluxation or dislocation, skeletal traction is necessary to achieve anatomical realignment. This is done using skull tongs (Figure 25.19).

In many cases of spinal trauma, formal open reduction and stabilisation using internal fixation is also required (Figure 25.20).

Figure 25.19 Skeletal traction using skull tongs.

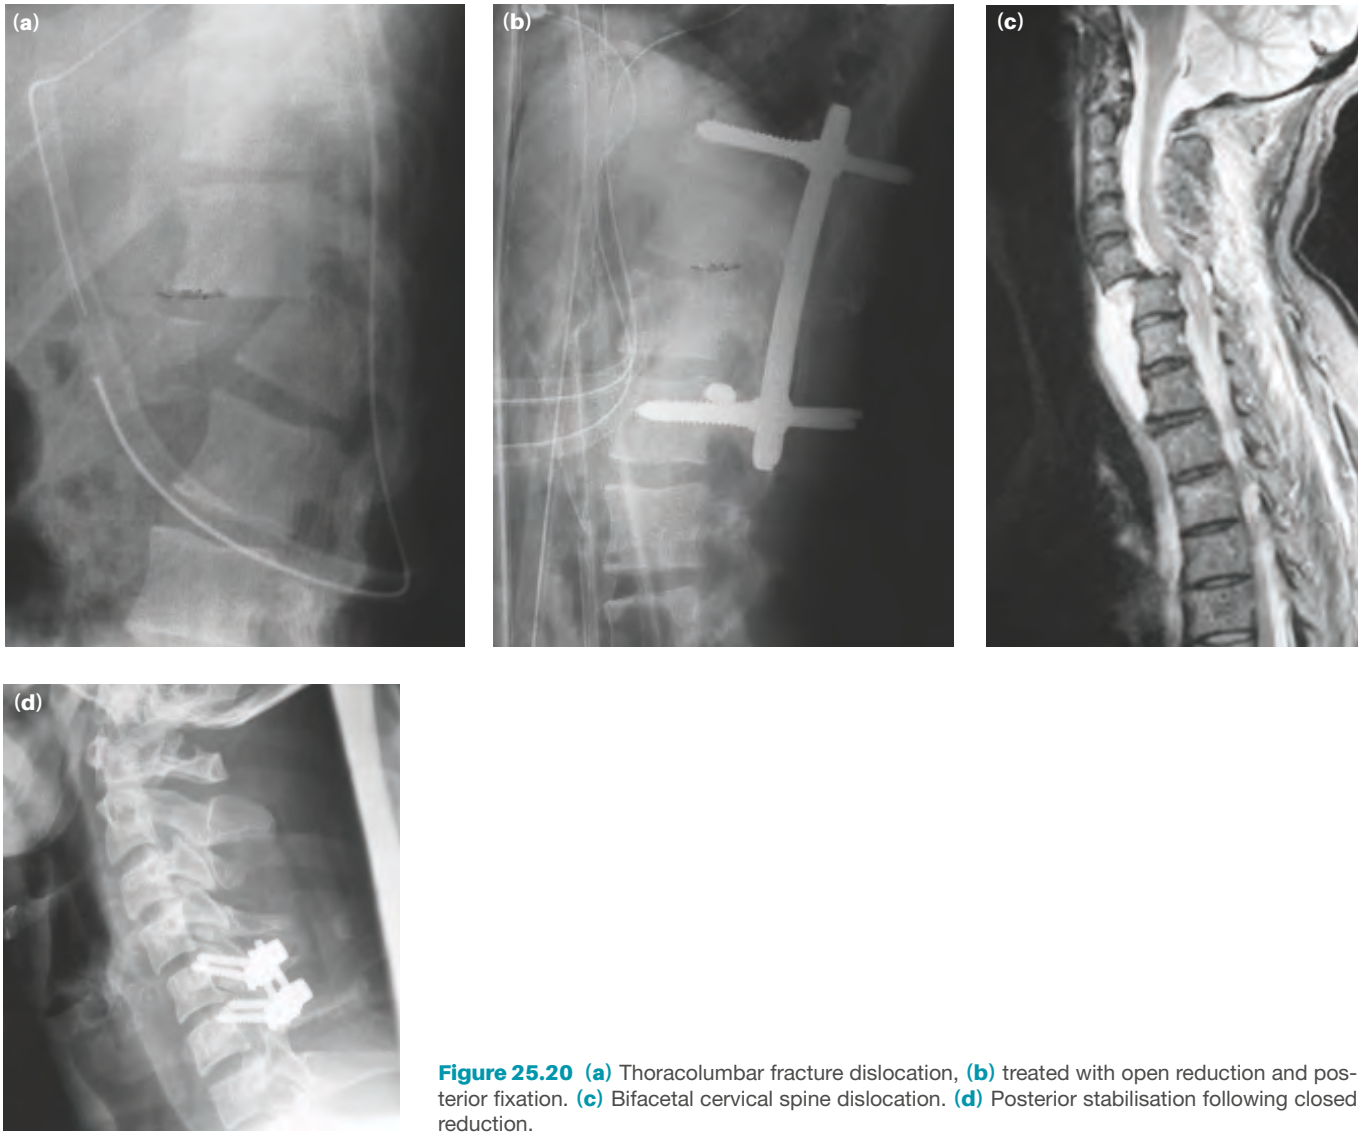

Figure 25.20 **(a)** Thoracolumbar fracture dislocation, **(b)** treated with open reduction and posterior fixation. **(c)** Bifacetal cervical spine dislocation. **(d)** Posterior stabilisation following closed reduction.

A halo brace can be used to perform a closed realignment and immobilisation of cervical fractures (Figure 25.21).

Stabilisation

The indication for operative intervention is influenced by the injury pattern, level of pain, degree of instability and the presence of a neurological deficit. The only absolute indication for surgery in spinal trauma is deteriorating neurological function.

Decompression of the neural elements

Realignment of the spine and correction of the spinal deformity may achieve an indirect decompression. A direct decompression of the neural elements may also be indicated if there are bone fragments causing residual compression or a significant haematoma (Figure 25.22). The timing of surgery in spinal cord trauma remains controversial.

Corticosteroids

Corticosteroids are no longer indicated in acute spinal cord injury because of a lack of evidence to support efficacy. Steroids do have a role in non-traumatic spinal cord compression e.g. malignant spinal cord compression (MSCC).

Figure 25.21 External immobilisation using a halo jacket.

Summary box 25.5

Management of spinal trauma

- Neurological deficit determines management
- Deteriorating neurological status requires surgical intervention
- Corticosteroids are ineffective

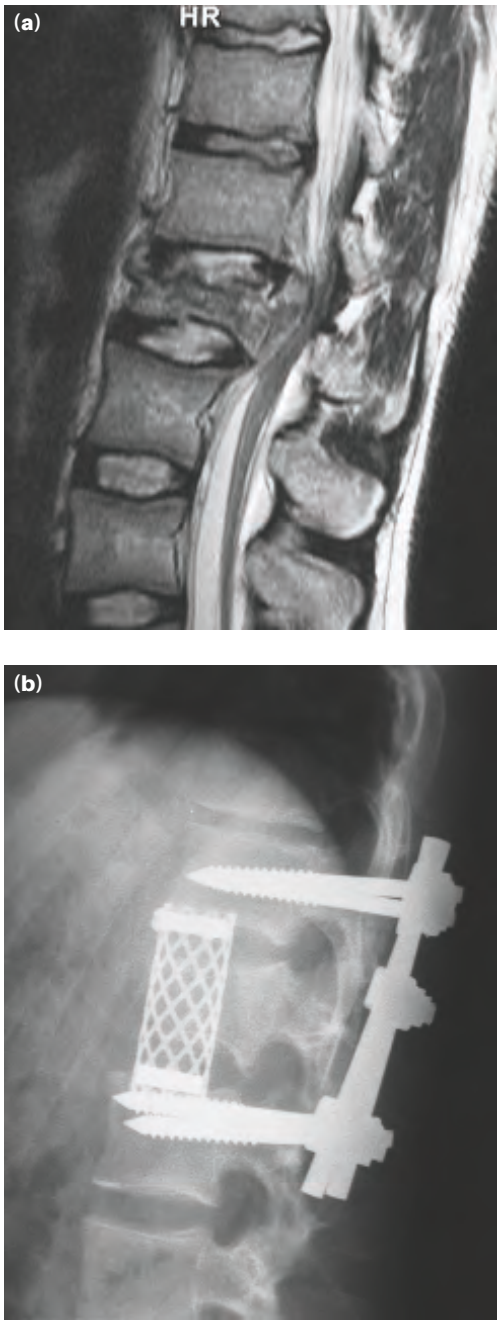

Figure 25.22 **(a)** Sagittal T2-weighted magnetic resonance imaging scan showing an L1 burst fracture and neural compression; **(b)** treated with combined anterior and posterior surgery.

SPECIFIC SPINAL INJURIES

Upper cervical spine (skull–C2)

Occipital condyle fracture

This is a relatively stable injury often associated with head injuries and is best treated in a hard collar for 6–8 weeks.

Occipitoatlantal dislocation

This injury is usually caused by high energy trauma and is often fatal. The dislocation may be anterior, posterior or

vertical (Figure 25.23). Power's ratio (Figure 25.24) is used to assess skull translation. Treatment is with a halo brace or occipitocervical fixation.

Atlas fracture (Jefferson fracture)

Fracture of the C1 ring is associated with axial loading of the cervical spine and may be stable or unstable (Figure 25.25a, b). Associated transverse ligament rupture may occur (Figure 25.25c). Most are treated non-operatively in a cervical collar or halo brace.

Figure 25.23 Vertical occipitocervical dislocation.

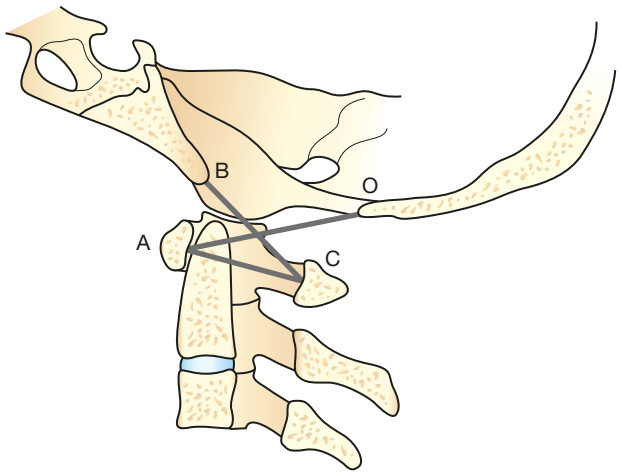

Figure 25.24 Power's ratio. BC/OA ≥1 indicates anterior translation, ≤0.75 indicates posterior translation.

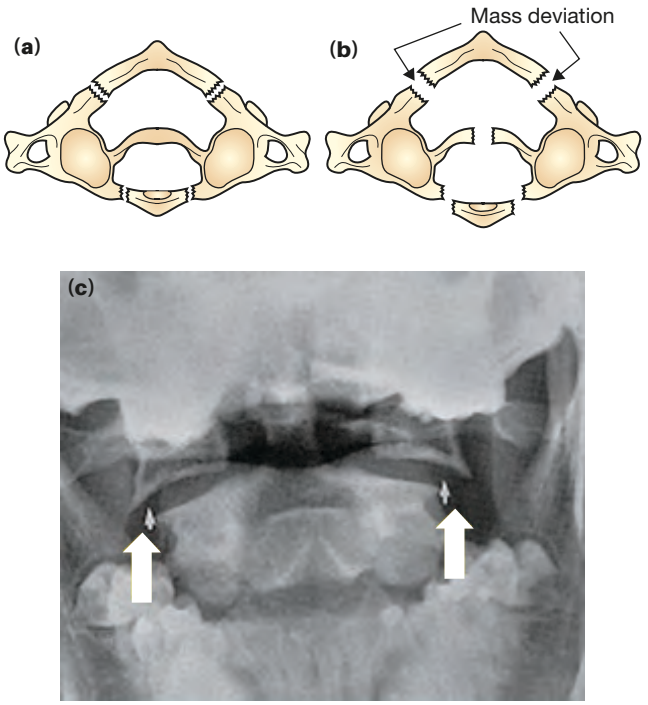

Figure 25.25 Stable **(a)** versus unstable **(b)** Jefferson's fracture of C1. **(c)** Open mouth view of C1/2 demonstrating C1 lateral mass deviation (arrows). Rupture of the transverse ligament is present when the combined lateral mass deviation exceeds 6.9 mm.

Atlantoaxial instability

This is defined as non-physiological movement between C1 and C2. It can be translational or rotatory and resolves either spontaneously or with traction followed by a cervical collar. Isolated, traumatic transverse ligament rupture leading to C1/2 instability is uncommon and is treated with posterior C1/2 fusion (Figure 25.26).

Odontoid fractures

There are three types of odontoid peg fracture (Figure 25.27). Neurological injury is rare. The majority of acute injuries are treated non-operatively in a hard collar or halo jacket for 3 months. Internal fixation with an anterior compression screw is indicated for displaced fractures (Figure 25.28), and a posterior C1/2 fusion is considered in cases of non-union. In the elderly, treatment in a soft collar should be considered on the basis that a relatively stable pseudarthrosis will occur.

Barry Powers, contemporary, Chief and Clinical Professor of Radiology, Duplin General Hospital, Kenansville, NC, USA, described his ratio in 1979.
Sir Geoffrey Jefferson, 1886–1961, Professor of Neurosurgery, University of Manchester, UK, became the UK's first Professor of Neurosurgery in 1939. In 1947 he was elected a Fellow of the Royal Society, a rare distinction for a practising surgeon. Although he became a neurosurgeon, he performed the first successful embolectomy in England in 1925 at Salford Royal Hospital.

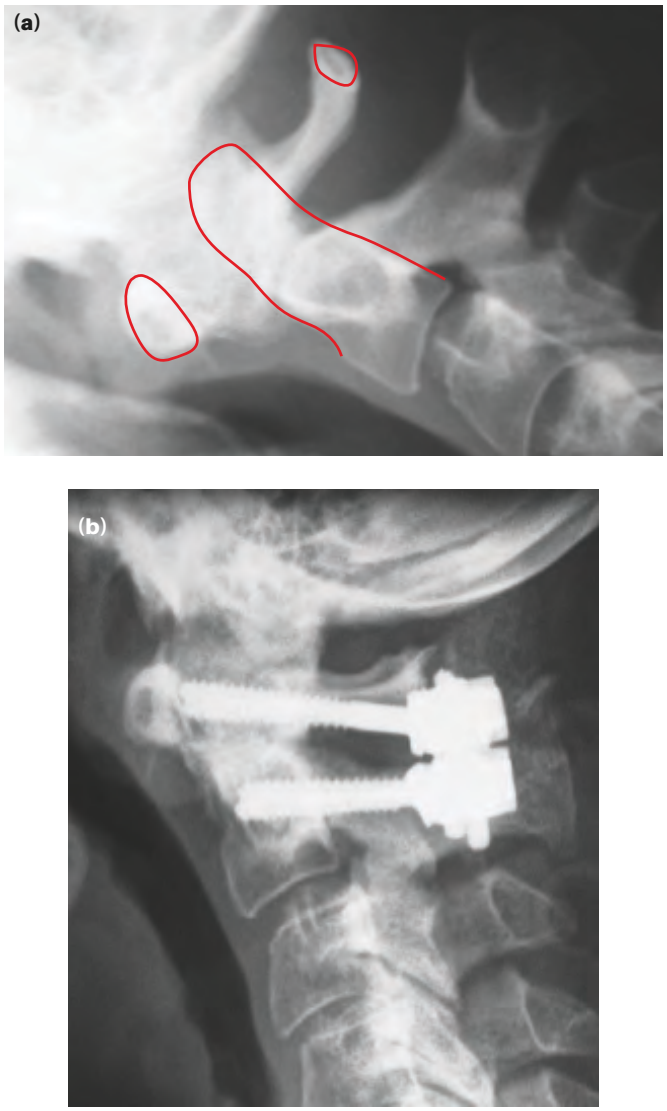

Figure 25.26 **(a)** Atlantoaxial subluxation. **(b)** C1/2 posterior fusion using C1 lateral mass and C2 pedicle screws.

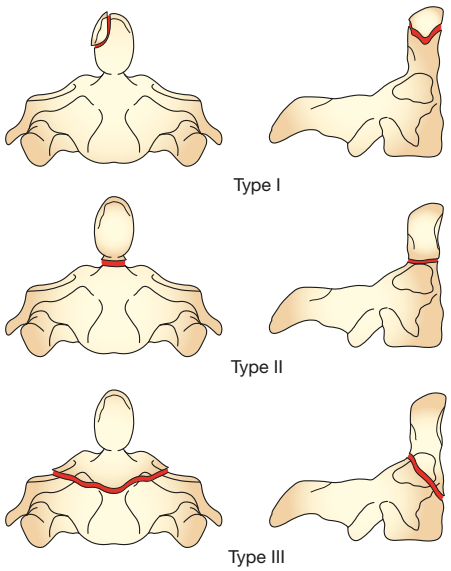

Figure 25.27 Types of odontoid fracture.

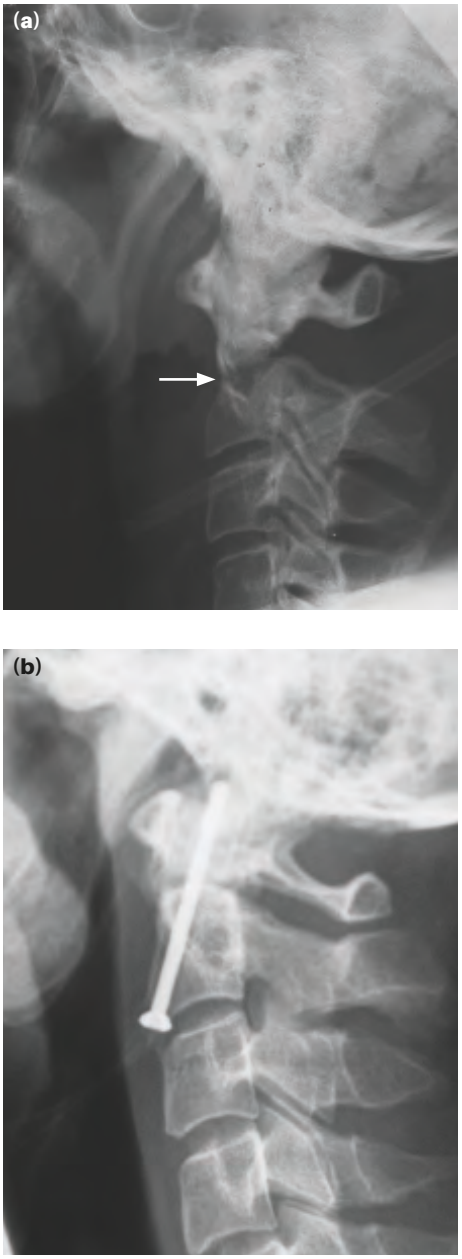

Figure 25.28 **(a)** Type II odontoid fracture (arrow); **(b)** treated with an anterior compression screw.

Traumatic spondylolisthesis of the axis (hangman's fracture)

This is a traumatic spondylolisthesis of C2 on C3. There a four types with varying degrees of instability (Figure 25.29). Those with significant displacement or associated facet dislocation are treated operatively, usually with posterior stabilisation.

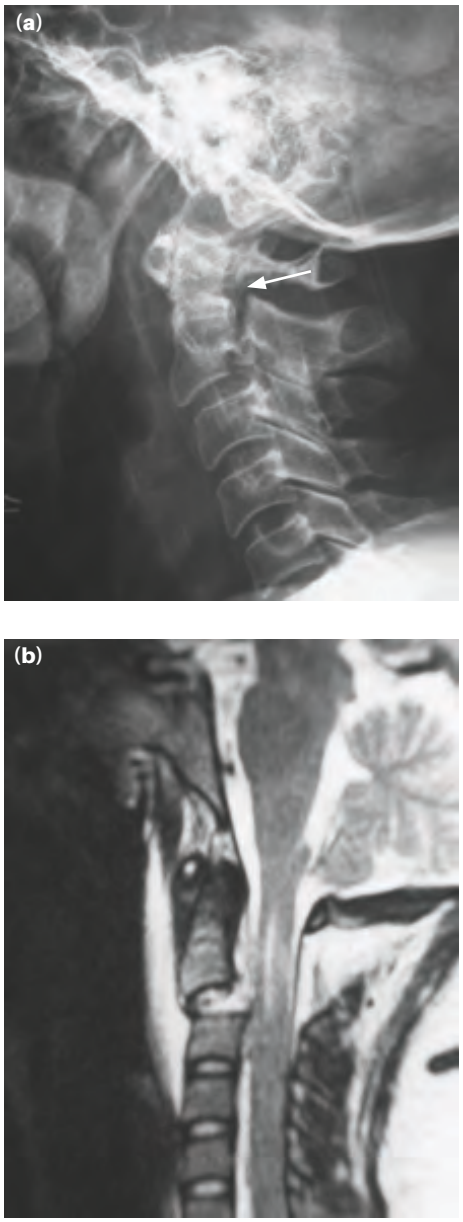

Figure 25.29 **(a)** Hangman's fractures of C2 with minimal forward translation (arrow). **(b)** C2/3 subluxation with spinal cord contusion.

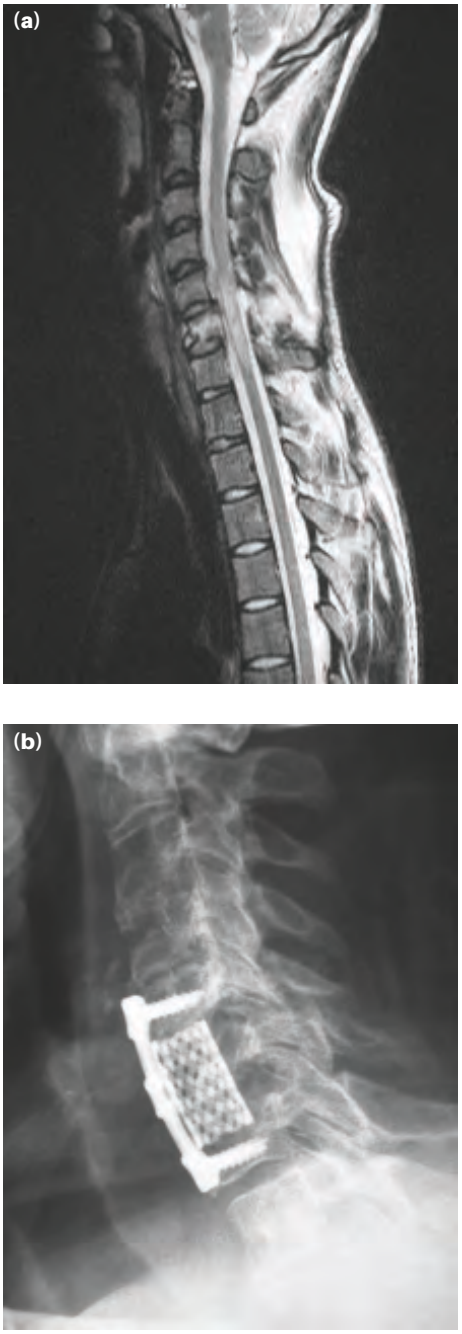

Figure 25.30 **(a)** Cervical burst fracture with spinal cord contusion; **(b)** treated by anterior decompression and reconstruction.

Subaxial cervical spine (C3–C7)

The pattern of lower cervical spine injury depends on the mechanism of trauma. These include compression fractures (hyperflexion), burst fractures (axial compression) and facet subluxation/dislocation injuries (distraction–flexion), teardrop fractures (hyperextension) and fracture of posterior elements. The more severe injuries are accompanied by spinal cord injury (Figure 25.30a). Operative intervention may be required to decompress the spinal cord, and to stabilise the spine with internal fixation (Figure 25.30b).

Facet subluxation/dislocation ranges in severity from minor instability to complete dislocation with spinal cord injury (Figure 25.31).

Fractures in patients with ankylosing spondylitis

Ankylosing spondylitis is a seronegative inflammatory disorder that causes autofusion of the spine. These patients have a higher risk of spinal fractures and spinal cord injury than the normal population. Senior advice should be obtained, because application of a cervical collar may be contraindicated, and patients should be managed instead in a position of comfort. Surgical stabilisation is commonly indicated.

Figure 25.31 C5/6 bifacetal dislocation (arrows).

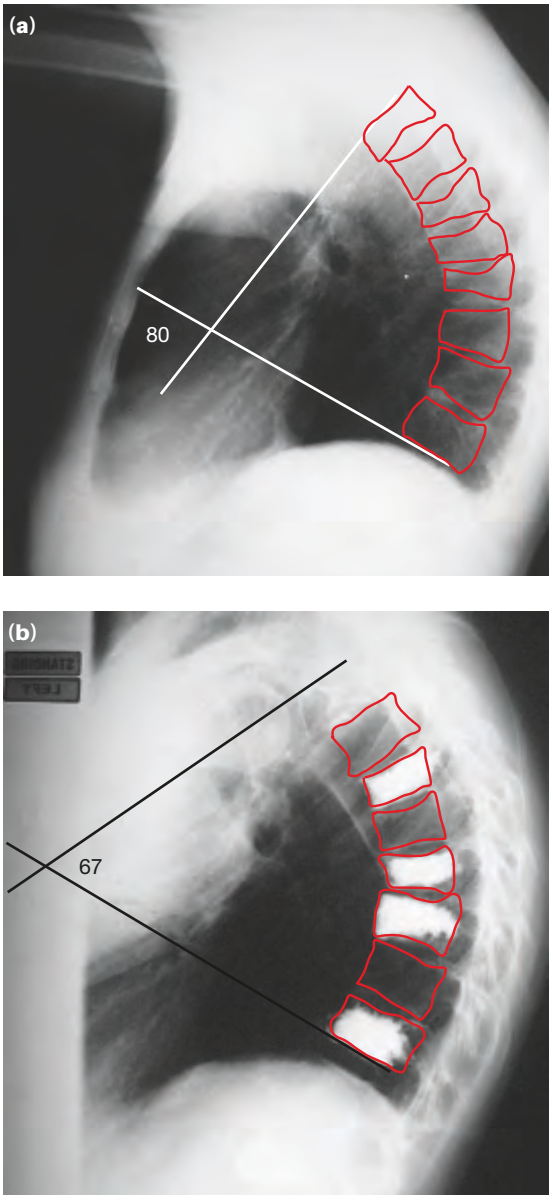

Figure 25.32 **(a)** Lateral x-ray showing multiple osteoporotic compression fractures. **(b)** Reduction in thoracic kyphotic deformity following four-level kyphoplasty.

Summary box 25.6

Cervical spine injuries

- The majority of upper cervical spinal injuries are treated non-operatively
- Spinal cord injury is more commonly associated with subaxial cervical spinal injuries

Thoracic and thoracolumbar fractures

The system developed by the AO (Arbeitsgemeinschaft für Osteosynthesefragen) can be used to classify these fractures. There are three main injury types, A, B and C, with increasing instability and risk of neurological injury.

Type A fractures are vertebral body compression fractures. Type B injuries involve distraction of the anterior or posterior elements and type C injuries are rotational and often coexist with Type A or Type B injuries. The majority of type B and type C injuries require surgical stabilisation.

Thoracic spine (T1–T10)

Osteoporotic wedge compression fractures in the elderly are the commonest injury in this group. Most of these fractures heal, but symptomatic fractures can be treated with percutaneous bone cement augmentation, known as vertebroplasty or kyphoplasty **(Figure 25.32)**.

In trauma cases, unstable fractures are associated with significant energy transfer to the patient and may be associated with major internal injuries, such as pulmonary contusion and spinal cord injury. The combination of thoracic spine disruption and a sternal fracture **(Figure 25.33)** also carries a significant risk of aortic rupture. Multiple posterior rib fractures and rib dislocations above and below a thoracic spinal injury signify a major rotational injury to the chest and can be associated with vascular injury and significant pulmonary contusion **(Figure 25.34)**. Multimodality diagnostic imaging is recommended. Surgery is appropriate for most thoracic injuries if unstable.

AO, *Arbeitsgemeinschaft für Osteosynthesefragen*, may be translated from the German as 'Working Party on Problems of Bone Repair'.

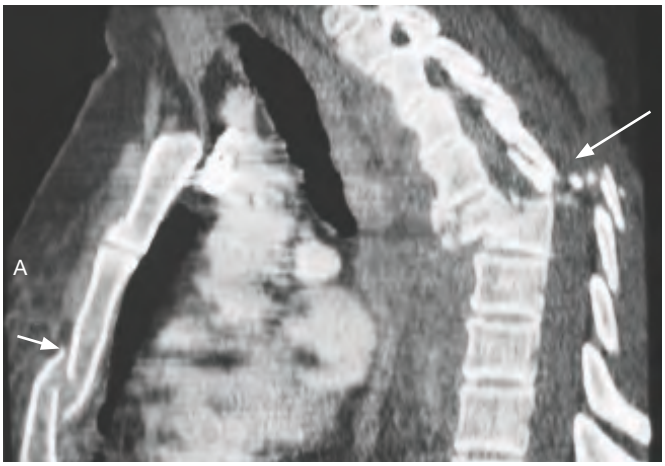

Figure 25.33 Sagittal CT reconstruction showing an upper thoracic spine fracture dislocation (long arrow) and associated sternal fracture (short arrow).

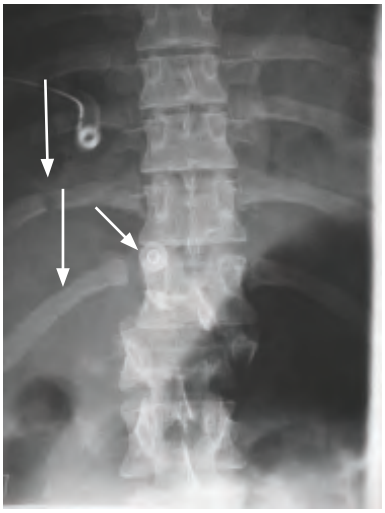

Figure 25.34 Rotational (type C) injury at the thoracolumbar junction. Note rib fractures (long arrows) and dislocation (short arrow), and presence of chest tube.

Thoracolumbar spinal fractures (T11–L2)

The thoracolumbar junction is especially prone to injury. This can vary from a from minor wedge fracture to spinal dislocation **(Figure 25.35)**. Burst fractures are comminuted fractures of the vertebral body. They are characterised by widening of the distance between the pedicles, and can be associated with retropulsion of bone fragments into the spinal canal **(Figure 25.36)**. Anterior surgery for this type of fracture is now very rarely used and the current treatment principles involve posterior fixation **(Figure 25.37)**. Chance fractures

Figure 25.35 Total spinal sagittal computed tomography reconstruction demonstrating a thoracolumbar fracture dislocation (long arrow) and fracture of L5 (short arrow).

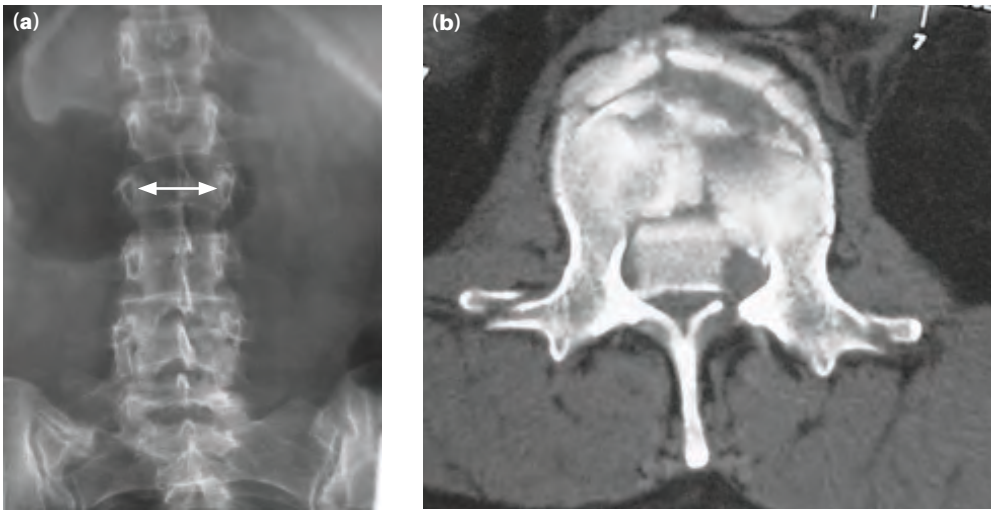

Figure 25.36 Lumbar burst fracture with increase in interpedicular distance **(a)** (arrow) and spinal canal compromise **(b)**.

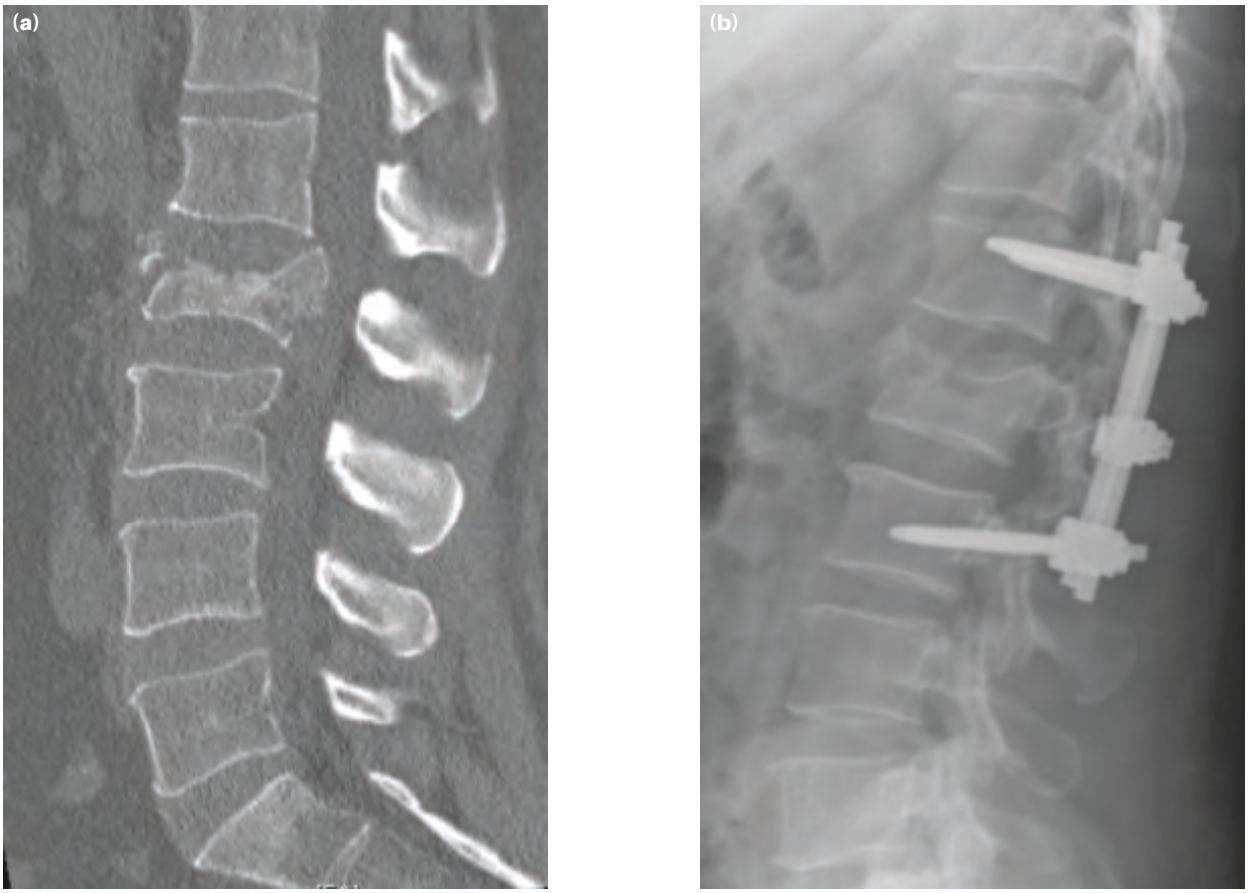

Figure 25.37 Lumbar burst fracture at L2 **(a)**, and posterior instrumentation with indirect reduction **(b)**.

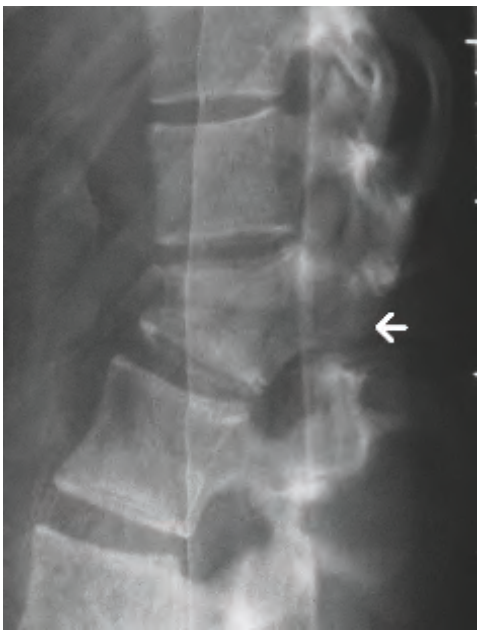

Figure 25.38 A bony Chance fracture at the thoracolumbar junction (arrow) secondary to a lap-belt injury.

are flexion–distraction injuries of the thoracolumbar junction and are classically associated with the use of lap-belts (**Figure 25.38**). Duodenal, pancreatic and/or aortic ruptures are also associated with these injuries.

Lumbar spinal fractures (L3–S1)

Most fractures of the lower lumbar spine can be treated non-surgically because the incidence of neurological injury is lower. The neural canal is more capacious at this level (the spinal cord terminates at L1/L2). Owing to the lumbar lordosis, patients with these injuries are less likely to develop a kyphotic deformity than those with injuries at the thoracolumbar junction.

Summary box 25.7

Thoracic and thoracolumbar fractures

- Unstable thoracic spine fractures and thoracolumbar flexion–distraction injuries are commonly associated with vascular and/or visceral injuries

George Quentin Chance, formerly Director of Diagnostic Radiology, The Derby Group of Hospitals, Derbyshire, UK.

EPIDEMIOLOGY OF SPINAL CORD INJURY

The incidence and causation of spinal cord injury (SCI) vary globally and reflect the demographics and industrialisation of society. The worldwide annual incidence is 15–40 cases per million (according to the National Spinal Cord Injury Statistical Center, University of Alabama at Birmingham: spinal cord injury facts and figures, April 2009). Road traffic accidents remain the leading cause of spinal cord injuries worldwide. Males in the third decade of life are the most likely group to sustain serious spinal cord injury.

EVOLUTION OF THE MANAGEMENT OF SPINAL CORD INJURY

The development of specialised SCI centres has dramatically improved the survival rates, health and functional outcomes of individuals with SCI. The first SCI centre was established in the USA in 1936 by Dr Donald Munro. In 1944 The National Spinal Injuries Centre was established at Stoke Mandeville, England, by Sir Ludwig Guttmann.

Summary box 25.8

Spinal cord injury

- The incidence of spinal cord injury remains constant
- The outcome is improved in regional/national spinal cord injury centres

PATHOPHYSIOLOGY OF SPINAL CORD INJURY

The primary injury

This is the direct insult to the neural elements and occurs at the time of the initial injury.

The secondary injury

Haemorrhage, oedema and ischaemia result in a biochemical cascade that causes the secondary injury. This may be accentuated by hypotension, hypoxia, spinal instability and/or persistent compression of the neural elements. Management of spinal cord injury must focus on minimising secondary injury.

Summary box 25.9

Pathophysiology of spinal cord injury

- The spinal cord contains various tracts that are topographically arranged
- Spinal cord injury involves both primary and secondary phases
- Therapeutic strategies are directed at reducing the secondary injury

Identification of shock

Three categories of shock may occur in spinal trauma

- **Hypovolaemic shock**. Hypotension with tachycardia and cold clammy peripheries. This is most often due to haemorrhage. It should be treated with appropriate resuscitation.
- **Neurogenic shock**. This presents with hypotension, a normal heart rate or bradycardia and warm peripheries. This is due to unopposed vagal tone resulting from cervical spinal cord injury at or above the level of sympathetic outflow (T1/T5). It should be treated with inotropic support, and care should be taken to avoid fluid overload.
- **Spinal shock**. Spinal shock is a temporary physiological disorganisation of spinal cord function that starts within minutes following the injury. The length of effect is variable, but it can last 6 weeks or longer. It is characterised by paralysis, decreased tone and hyporeflexia. Once it has resolved the bulbocavernosus reflex (Figure 25.39) returns.

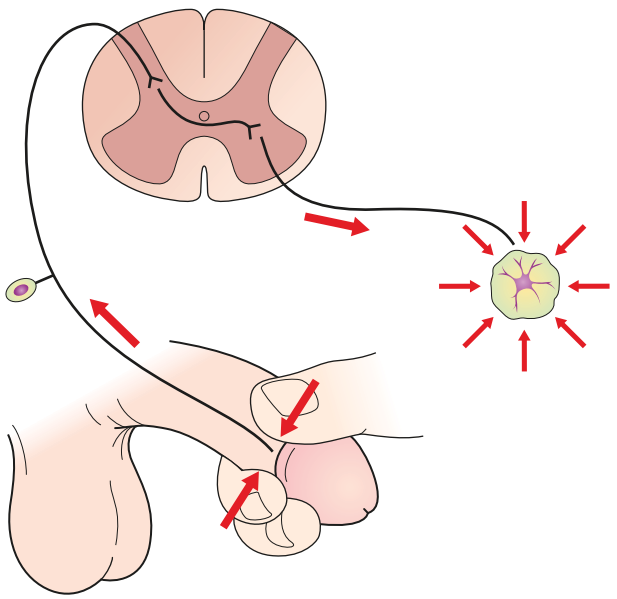

Figure 25.39 The bulbocavernosus reflex (this can be elicited in females by traction on the Foley catheter).

Sir Ludwig Guttmann is considered by many to be the father of spinal cord medicine. He was a leading neurosurgeon in Germany, working at the Jewish Hospital in Breslau. He fled to England in 1939.

Level of neurological injury

The level of neurological injury is simply the most caudal neurological level with normal neurological function.

Complete versus incomplete spinal cord injury

A spinal cord injury is incomplete when there is preservation of perianal sensation.

Types of incomplete spinal cord injury

There are several types of incomplete spinal cord injuries. These include:

- central cord syndrome;
- Brown-Séquard syndrome (hemisection);
- anterior spinal syndrome;
- posterior cord syndrome;
- cauda equina syndrome.

REHABILITATION AND PATIENT OUTCOME

The goal of spinal cord injury rehabilitation is based on a multidisciplinary approach. There is a focus on goal-setting, maximising remaining neurological function and reintegration into employment and society. The level of neurological impairment determines the functional outcome (*Table 25.1*).

Prognosis of spinal cord injury

Despite continuing improvements in patient care, life expectancy remains below normal following SCI. The median life expectancy is 33 years, but varies considerably (*Table 25.2*).

The prognosis for neurological recovery is strongly influenced by factors such as the level and completeness of the injury, ventilator dependence and the age at presentation.

TABLE 25.1 Expected functional outcome versus level of cervical spinal cord injury.

Level of injury	Functional goal
C3–C4	Power wheelchair with mouth or chin control. Verbalise care, communicate through adaptive equipment. May be ventilator dependent
C5	Power wheelchair, dress upper body, self-feed with aids, wash face with assistance
C6	Propel power wheelchair, possibly push manual wheelchair, transfer with assistance, dress upper body (lower body with assistance), self-groom with aids, bladder/bowel care with assistance, self-feed with splints, able to drive
C7	Manual wheelchair, independent transfer, dressing (with aids), feeding, bathing, self-care. Bladder and bowel care with assistance
C8–T4	Independent with most activities of daily living, and bowel and bladder care
T5–T12	As above but with more ease. Independent with all self-care
L1–L5	Independent. Walk with short or long leg braces
S1–S5	Independent, able to walk if able to push off (S1) (may need brace). Bladder, bowel and sexual function may remain compromised

TABLE 25.2 Life expectancy (years) post injury by severity of injury and age at injury.

Age at injury	No SCI	Motor functional at any level	Para	Low tetra (C5–C8)	High tetra (C1–C4)	Ventilator-dependent at any level
(a) For people who survive the first 24 hours						
20	58.4	52.8	45.6	40.6	36.1	16.6
40	39.5	34.3	28.0	23.8	20.2	7.1
60	22.2	17.9	13.1	10.2	7.9	1.4
(b) For people surviving at least 1 year post injury						
20	58.4	53.3	46.3	41.7	37.9	23.3
40	39.5	34.8	28.6	24.7	21.6	11.1
60	22.2	18.3	13.5	10.8	8.8	3.1

SCI, spinal cord injury.

Charles Edward Brown-Séquard, 1817–1894, physiologist and neurologist who held a number of academic posts, amongst them Physician, The National Hospital for Nervous Diseases, Queen's Square, London, UK (1860–1864), Professor of Medicine at Harvard University, Boston, MA, USA (1864–1878) and at the College de France, Paris, France (1878–1894). He described his syndrome in 1851.

Complications associated with spinal cord injury

Pressure ulcers

Many are preventable. Patients should be turned regularly on an appropriate mattress to minimise the risk of skin breakdown

Pain and spasticity

Neurogenic pain is common. Once reflex activity returns following cord injury, spasticity may occur and can be problematic. Intrathecal infusion of baclofen may be required in resistant cases.

Autonomic dysreflexia

This is a paroxysmal syndrome of hypertension, hyperhydrosis (above level of injury), bradycardia, flushing and headache in response to noxious visceral and other stimuli. It is most commonly triggered by bladder distension or rectal loading from faecal impaction.

Neurological deterioration

Post-traumatic syringomyelia (PTS) may occur in up to 28% of SCI patients up to 30 years following injury. Approximately 30% of cases are symptomatic. Clinically, patients present with segmental pain at or above the level of injury, sensory loss, progressive asymmetrical weakness or increased spasticity. This warrants early MRI assessment. Expanding cavities require neurosurgical intervention.

Thromboembolic events

Deep vein thrombosis (DVT) occurs in 30% of patients with SCI. Fatal pulmonary embolus is reported in 1–2% of cases. Thomboprophylaxis with compression stockings and low molecular weight heparin is indicated, provided there are no contraindications.

Osteoporosis, heterotopic ossification and contractures

Disuse osteoporosis is an inevitable consequence of SCI and fragility fractures may occur. Heterotopic ossification may affect the hips, knees, shoulders and elbows. It occurs in 25% of spinal cord injured patients. Surgery is appropriate in selected cases. Soft tissue contractures around joints may occur due to spasticity but can be avoided by appropriate physical therapy, positioning and splinting.

Chapter 26

Maxillofacial trauma

Learning objectives

To be able to:
- Identify and understand the significance of potentially life-threatening injuries to the face, head and neck

To have:
- A systematic methodology for examining facial injuries

To know:
- The classification of facial fractures

To understand:
- The diagnosis and management of fractures of the middle third of the facial skeleton and the mandible
- The principles of the diagnosis and management of facial soft tissue injuries

To appreciate:
- The management of dental injuries

EMERGENCY ASSESSMENT AND TREATMENT

The management of a patient with facial trauma must begin with an immediate assessment of the airway, breathing and circulation in keeping with the advanced trauma life support (ATLS) principles (see Chapter 23). If the patient has facial or midface bleeding they may sit forward or be placed on their side (**Figure 26.1**) to minimise the risk of blood and/or dental fragments obstructing the airway. The use of good light and high volume suction is often helpful.

The midface, when fractured, is displaced downwards and backwards (**Figure 26.2**), and if this occurs in combination with a mandibular fracture, particularly if the anterior mandible is comminuted, the tongue is also displaced downwards and backwards, adding to the airway compromise and creating the risk of obstruction (**Figure 26.3**). In these circumstances intubation is indicated, but emergency procedures can be employed to buy time. In the obtunded or unconscious patient the maxilla can be grasped by hand, disimpacted and pulled forwards. In addition, the tongue can be pulled forwards and held forwards, with a large suture or towel clip, to help clear the airway. If intubation is not possible a surgical airway is indicated.

Massive, life-threatening bleeding is usually only seen in the context of major trauma, lacerations, blast, ballistic, penetrating or gunshot injuries. Significant bleeding, usually from the pterygoid venous plexus and/or the rich blood supply of the nose, can be seen in central midface injuries.

Management of massive midface bleeding may require intubation and the placement of anterior and or posterior nasal packs. There are specific inflatable nasal balloons that

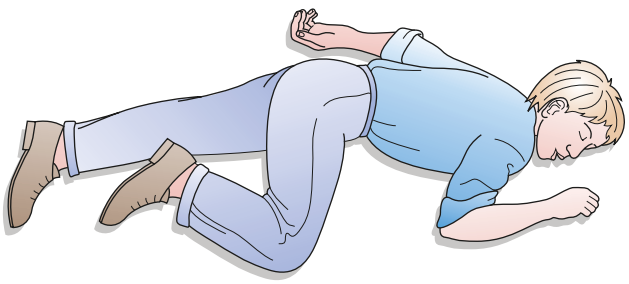

Figure 26.1 The patient should be nursed in the semiprone position to allow secretions, blood and foreign bodies to fall from the mouth.

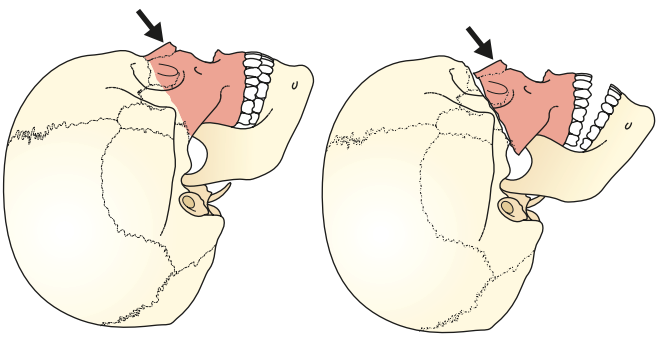

Figure 26.2 A blow from the front of the face may separate the facial skeleton from the base of the skull and thrust it downwards and backwards.

can facilitate the immediate management, however Foley catheters may also be utilised.

Once the patient has been stabilised a more formal assessment may be performed.

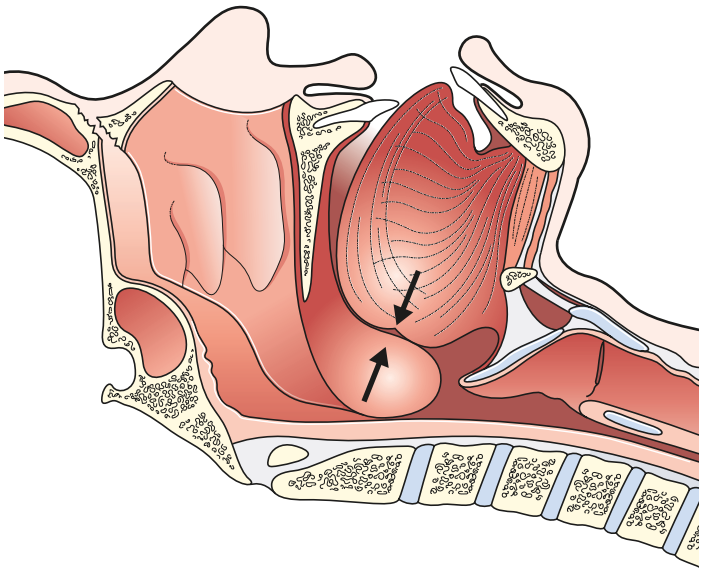

Figure 26.3 Loss of nasopharyngeal space and oedema of the soft palate and tongue (arrows) may close off the airway in severe maxillofacial injuries, 2–3 hours after injury.

Summary box 26.1

Emergency assessment

- Airway, breathing, circulation with cervical spine control is the starting point
- Do not let dramatic facial injuries distract from other potentially life-threatening injuries

CLASSIFICATION OF FACIAL INJURIES

Bony injuries and fractures

The facial skeleton can be divided into thirds vertically:

- upper face (from level of canthi upwards);
- midface (from maxillary teeth to canthi);
- lower face (mandible and mandibular teeth).

In addition, the midface can be divided into central and lateral portions. The central midface is the naso-orbital–ethmoidal complex and the lateral portion comprises the cheekbones (Malar bones, zygomatic bones or zygomatic–maxillary complex).

The eye socket can be considered as a separate entity, because orbital fractures can occur in isolation or as part of a constellation of multiple fractures. Orbital fractures can affect the orbital floor, medial and/or lateral walls and the roof of the orbit.

Where skull fractures occur in combination with facial fractures or the fractures extend into the frontal or ethmoidal sinuses, they are classified as craniofacial, and a joint neurosurgical and maxillofacial approach is necessary.

If fractures occur at all levels of the face the term panfacial is utilised. This does not necessarily alter the management of the individual fracture components, however it does imply a significant degree of force and one must be suspicious of other injuries, especially head injuries. As with all trauma patients, associated injuries, including chest and abdominal trauma, must be actively excluded.

In considering the bony injuries, the fractures may be displaced or undisplaced and comminuted or non-comminuted. In the past, and with particular reference to mandibular fractures, stability was also considered, however with modern treatment methods this is a less important factor.

Soft tissue injuries and lacerations

Lacerations are crushing injuries where the soft tissues are compressed between the underlying bone and some form of blunt object. Incised wounds are caused by a cutting implement, such as a knife or glass. Often the injuries are a combination of the two. Either type of wound can occur with or without tissue loss. Where the injury results in a communication between the skin and the mucosa of the oral cavity the wound is termed ‘through and through’.

Summary box 26.2

Classification of facial injuries

- Divide the face into thirds
- Assess orbit independently
- Assess bony and soft tissue injuries

CLINICAL ASSESSMENT

History

As with all aspects of surgical diagnosis, the history is paramount. As much information as possible should be obtained about the mechanism of injury, the past medical history and the postinjury course. This will be directly from the patient, friends, family, witnesses and emergency services.

Knowledge of the mechanism of injury will often help to identify the potential occult injuries that are not obvious on first inspection. As the craniofacial region is so richly vascularised, the often dramatic appearance seen in major facial trauma has the potential of distracting the unwary clinician from potentially more important injuries.

Examination

Primary survey

Initially, the primary survey is aimed at the airway: controlling bleeding, restoring and maintaining the circulation and

assessing for neurological deficits, with cervical spine control. The more detailed secondary survey is aimed at a definitive examination, with the clear expectation that this will need to be repeated on several occasions.

The face, head and neck should be inspected and wounds cleaned and assessed for tissue loss, and then dressed to control any bleeding not addressed in the primary survey. Their size, location and depth should be carefully recorded in the case notes. Large and obvious foreign bodies should be removed but care should be exercised with penetrating wounds involving large fragments or blades which potentially penetrate deep structures. These should be removed in the operating theatre, in more controlled conditions, after imaging (note also glass that may injure the assessing surgeon). On occasions it is helpful to administer local anaesthetic for the examination and (temporary) repair of facial lacerations, particularly if a single vessel continues to bleed. In these circumstances it is very helpful to perform a thorough examination of the key sensory and motor nerves that may have been injured, before the local anaesthetic makes this assessment meaningless.

This principle also applies to the management of those patients for whom intubation is imminent. While this may be difficult, a brief assessment of Glasgow Coma Scale (GCS) score, eye function (motility and acuity), facial and trigeminal nerves and cervical spine pain and function prior to the induction of anaesthesia can be very helpful in ongoing management.

Secondary survey

The secondary survey examination should be systematic because it is easy to be distracted and miss potentially important injuries that leave only a small external sign, e.g. a small entry wound from a stabbing to the back of the neck. The surface inspection should include the back of the neck, the whole scalp and then move to the frontal view. At this time it is helpful to perform a formal cranial nerve examination; of particular importance are cranial nerves II, III, IV, VI, V and VII.

Further examination

Examination of the eyes should then take place to exclude globe or retinal injury, as well as to assess acuity, test for diplopia and assess motility. This is possible even in the most swollen of eyes because one can gently prise the eyelids apart with cotton wool buds (or microbiology swabs). These are held parallel to the eyelids and gently pushed into the oedematous tissue close to the eyelashes, rotating the swabs to open the eye. A colleague can then examine the eye.

The position of the globe – whether there is proptosis or enophthalmos – and visual acuity (utilising a Snellin chart) in each eye, and whether there is diplopia in all nine positions of gaze, should be recorded.

The intraoral examination is facilitated by the use of good light (a headlight is helpful) and suction to allow removal of blood and saliva. The teeth should be examined and their presence or absence noted. Dental injuries should be classified. Teeth may be knocked out in an injury (termed avulsion), displaced but still attached to soft tissues and/or bone (termed subluxation) or fractured. If a tooth is mobile it may be subluxated or have a root fracture (detected on a radiograph). It is important to account for all missing teeth or tooth fragments as aspiration of an avulsed tooth or tooth fragment is a major risk. If there is any doubt about the location of missing teeth a chest radiograph should be obtained.

If there is a fracture of the mandible, the overlying mucosa is often torn and there may be an associated haematoma in the floor of the mouth **(Figure 26.4)**. A key assessment is that of the dental occlusion (the way in which the teeth bite together). Patients are able to discriminate tiny alterations in their occlusion. These occlusal changes may represent dental injuries or, more commonly, displaced fractures of the maxilla and/or mandible.

Palpation of the bony contours of the facial bones should identify sites of tenderness, steps and asymmetry. This can start at the supraorbital margins, move around the infraorbital margins and then along the zygomatic arches, moving onto the condylar heads of the mandible and then running along the lower border of the mandible.

Investigations

The investigations required fall into two major categories: first, those required to confirm the provisional and specific clinical diagnosis with regard to the facial injuries and, second, those to assess and manage the systemic condition of the patient.

Systemic investigations will be governed by the general state of the patient and the past medical history. Typically, they will include routine laboratory (haematological and biochemical) investigations and radiological (for example the cervical spine) and other imaging.

Specific head and neck investigations are utilised and the general trend is away from plain radiology towards computed tomography (CT) scanning. If the clinical picture suggests an isolated mandibular fracture, plain radiographs at right angles to each other (rotational tomograph, orthopantomogram **(Figure 26.5)** and a posteroanterior (PA) mandible) may suffice, but clinicians should have a low threshold for cross-sectional imaging, particularly if a head or cervical spine CT

Figure 26.4 A fracture of the right parasymphysis of the mandible, demonstrating a tear of the gingivae in the lower right lateral incisor/canine region.

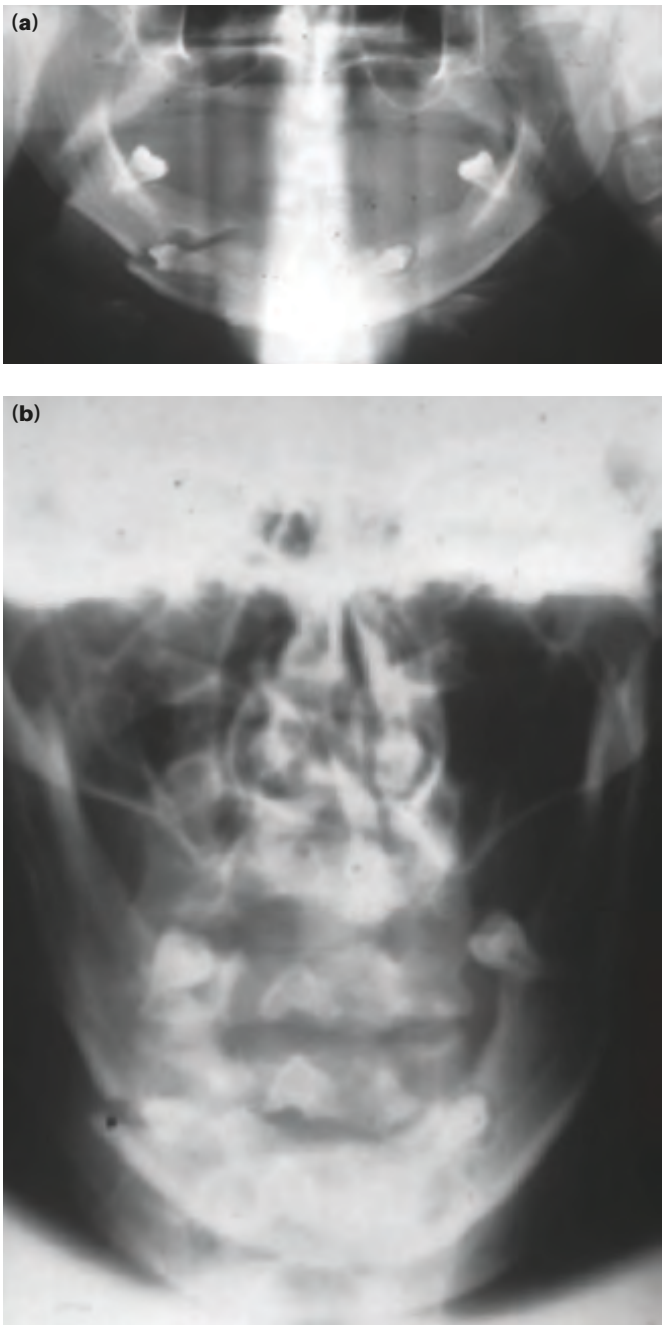

Figure 26.5 **(a)** Rotational tomogram showing a right mandibular body fracture. **(b)** Posterioanterior (PA) mandible showing the same mandibular body fracture.

is indicated. The additional information from 1 mm imaging cuts through the facial skeleton is worth the additional radiation dose, especially if plain radiography has been avoided.

Summary box 26.3

History, examination and investigation

- The history, particularly the mechanism of injury, is vital
- For simple injuries radiographs in two planes are required, but increasingly cross-sectional imaging is the norm: CT scanning

SPECIFIC INJURIES

Mandibular fractures

Mandibular fractures typically occur at specific sites (**Figure 26.6**). As with all fractures the principles of reduction, fixation, immobilisation and then rehabilitation apply to facial fractures. In previous years the reduction and immobilisation was often achieved by wiring the teeth together, known as intermaxillary fixation (IMF). However, in recent years this technique has largely been superseded by the use of open reduction and internal fixation (ORIF) techniques (**Figure 26.7**) utilising titanium fixation plates secured with screws. In general, the facial bones heal well and undisplaced fractures or those treated with ORIF heal after about 4 weeks. If the patient has had IMF a liquid diet is required and those who have had an ORIF procedure must also remain on a very soft sloppy diet for the same period.

In general, straightforward mandibular fractures treated with ORIF techniques have 2 mm diameter screws engaging a single bone cortex (monocortical). These small plates are said to be load sharing, in that the fractures are reduced and load is shared between the native bone and the plate. With more complex or comminuted fractures, larger plates and screws (up to 2.7 mm diameter) may be utilised; these are termed fracture or reconstruction plates. They are regarded as load bearing, and bicortical fixation may also be utilised.

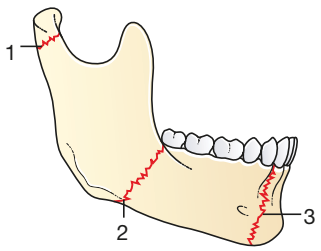

Figure 26.6 The patterns of fracture of the mandible. (1) The neck of the condyle is the most common site, followed by (2) the angle of the mandible through the last tooth. (3) The third point of weakness is in the region of the canine tooth.

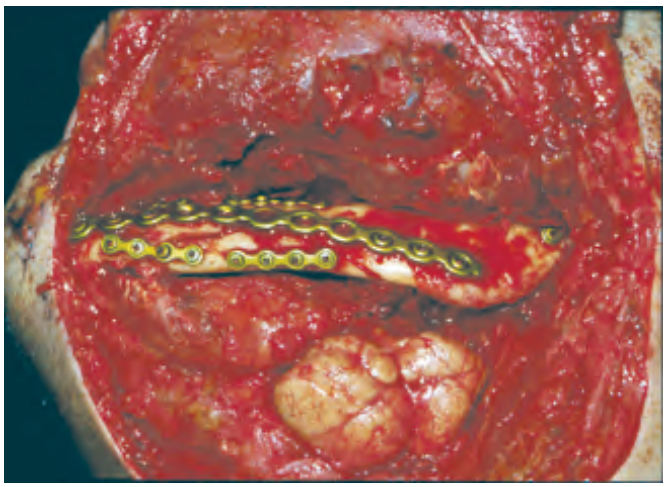

Figure 26.7 Intraoperative photograph showing a comminuted mandibular fracture reduced and fixed with a combination of 2 mm mini plates (monocortical) and a larger fracture plate with bicortical screws.

The timing of the definitive treatment of mandibular fractures is dependent on the general state of the patient; however, optimal timing is for treatment within 24–48 hours post injury.

Condylar neck fractures are increasingly being treated with open reduction and internal fixation techniques, with better technology and the use of endoscopically assisted surgery. This can be done via intraoral approaches. Undisplaced or minimally displaced condylar neck fractures can be treated non-operatively or with elastic IMF.

Summary box 26.4

Mandibular fractures

- Mandibular fractures are diagnosed clinically, often because of deranged dental occlusion
- Numbness over the distribution of the mental nerve is common
- Treatment is primarily with open reduction and internal fixation

Fractures of the zygomatico-orbito complex (ZMC)

ZMC (malar/cheekbone) fractures are the commonest facial fractures and have been classified in a variety of different ways. However, from a clinical perspective, considering the cheekbone as a four-legged stool is helpful – the four legs are comprised of the zygomatic arch running anteroposteriorly, the zygomatic process running vertically (to join the frontozygomatic process of the frontal bone at the frontozygomatic (FZ) suture), the infraorbital rim running horizontally and the maxillary buttress running vertically (Figure 26.8).

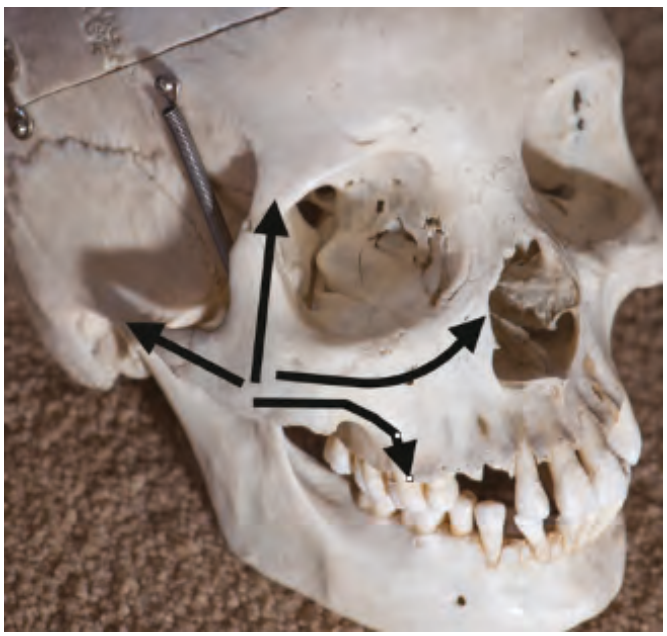

Figure 26.8 The 'four legs of the stool'.

With the exception of isolated zygomatic arch, isolated infraorbital rim and extensively comminuted fractures, if the ZMC is fractured then all four legs of the stool are fractured and displacement occurs about two axes, running vertically through the line from the FZ suture to the maxillary buttress or running anteroposteriorly along the zygomatic arch.

All ZMC fractures (with the exception of isolated zygomatic arch and isolated infraorbital rim fractures) involve the bony orbit, and careful assessment of ocular position and function is necessary.

On examination there is often periorbital bruising and swelling and subconjunctival haemorrhage with no posterior limit is often seen (Figure 26.9). On palpation (or inspection), bowing or depression of the zygomatic arch may be detected. Bony steps and tenderness at the frontozygomatic suture, the infraorbital rim or the zygomatic buttress may also be detected. Altered sensation over the distribution of the infraorbital nerve is common, as a result of either direct trauma or crushing of the nerve as it exits the maxilla or runs along the orbital floor.

As with mandibular fractures, the role of plain radiography is diminishing and cross-sectional imaging utilising CT scanning is the standard investigation except for the simplest fractures.

In terms of management, the mainstay of treatment is ORIF with fixation at one of the four 'legs of the stool', namely the frontozygomatic suture, the buttress region, the infraorbital rim or the zygomatic arch. The necessity for single, double, triple or four-point fixation will depend on the stability of the fracture post reduction and the degree of comminution. Uncomplicated ZMC fractures are generally treated within 10 days of injury.

Summary box 26.5

Fractures of the ZMC

- Fractures of the zygomatico-orbital complex are common
- Eye injuries should be actively excluded
- CT scanning is the investigation of choice

Figure 26.9 Fractures of the zygoma may often be associated with subconjunctival haemorrhage. This example shows no posterior border to the haemorrhage as the patient looks away from the side of the fracture.

Maxillary fractures

Maxillary fractures are traditionally classified after René Le Fort's work, in which he recreated the maxillary fractures utilising cadavers and a sandbag. Interestingly, the numbering, in modern usage, has become reversed from the original: the Le Fort I fracture being inferior and the Le Fort III being superior (Figure 26.10). While the classification is simple, real life presentations are often not. CT scanning and the use of open surgical techniques have demonstrated that the described patterns are not often adhered to and that comminution is the norm.

Midface fractures are often accompanied by significant facial swelling and this makes palpation of the skeleton difficult. The characteristic finding is of a mobile maxilla which tends to be displaced backwards and inferiorly. This can compromise the airway (see above) and results in an anterior open bite (inability to close the front teeth together). There is often infraorbital nerve injury resulting in altered sensation and, with upper level (Le Fort II and III) fractures, the orbit is involved to a greater or lesser degree.

The treatment of maxillary fractures, in all but the entirely undisplaced fractures, involves ORIF techniques utilising a variety of miniplates (1.5/1.7 mm diameter screws) and/or microplates (1.0/1.2 mm diameter screws). Fixation is usually placed along the main facial buttresses (the 'four legs of the stool') for optimal strength and bone quality to be able to hold the screws (Figure 26.11).

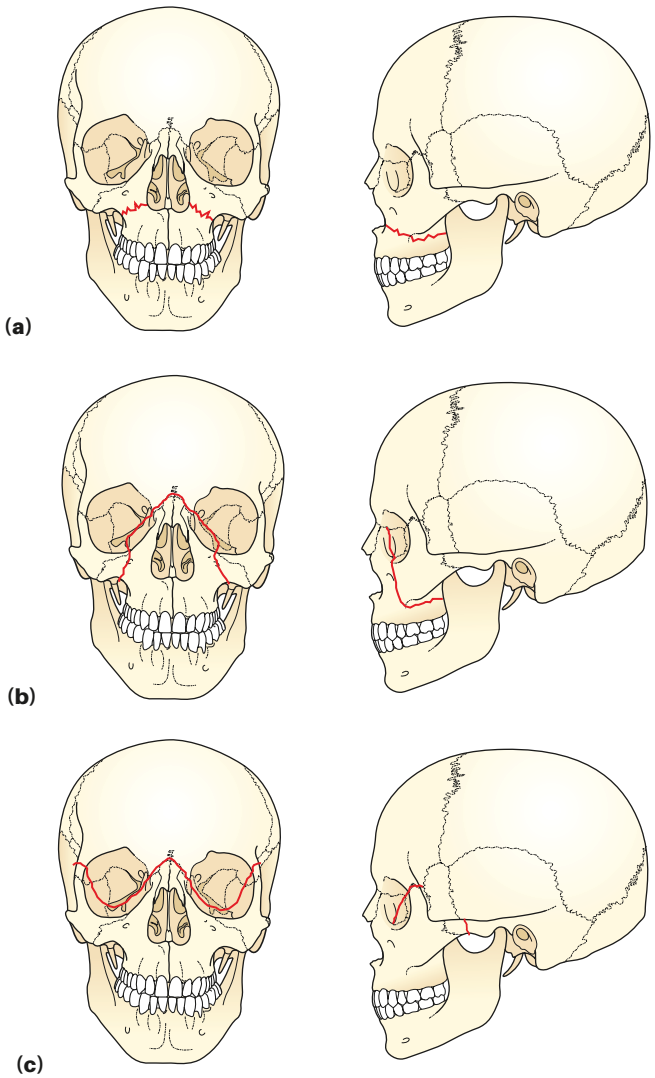

Figure 26.10 Maxillary fractures as classified by Le Fort. **(a)** Le Fort I; **(b)** Le Fort II; **(c)** Le Fort III.

Summary box 26.6

Maxillary fractures

- Maxillary fractures indicate significant force transfer – other associated injuries should be excluded
- Bleeding from the pterygoid venous plexus may be occult

Orbital fractures

The bones that comprise the orbit can be fractured and, in order of frequency, the floor, medial wall, lateral wall and roof may be disrupted either in combination or as isolated injuries. The mechanism of this is unclear and, particularly with isolated injuries, it may be that a rapid increase in pressure within the confined space of the orbit, typically, for example, when a squash ball hits the eye, results in fracture of the very thin floor and/or medial wall. Alternatively, forces are transmitted from the outer bony orbital rim, which is possibly

Figure 26.11 The buttresses of the face.

René Le Fort, 1869–1951, French surgeon, classified facial fractures after macabre research in which he dropped rocks and other heavy objects on the faces of cadavers.

temporarily deformed, causing the buckling and fracturing of the thin, vulnerable walls. It is likely that both of these mechanisms have a role in the genesis of orbital fractures.

In any orbital injury the eye must be examined carefully, even if there is significant swelling. Pupillary response, visual acuity (utilising a pinhole to correct for missing glasses), ocular motility and the results of careful ophthalmoscopy (including the anterior chamber, lens and fundus) should be documented. Binocular diplopia indicates a motility issue; however, monocular diplopia suggests a problem within the globe such as a dislocated lens or retinal detachment.

In general, orbital floor fractures lead to ocular motility problems, primarily restriction of upgaze due to trapping of the orbital fat and associated fibrous septae. However, on occasion the inferior rectus or inferior oblique muscles may also be trapped. Inferior rectus entrapment is much more common in children and this needs to be treated as an emergency because muscle necrosis can occur, leading to irreversible damage. In these cases the orbital floor appears, on imaging, undisplaced, i.e. a trap door defect has opened and then closed again, entrapping the muscle. In addition to motility problems, orbital wall fractures can lead to changes in globe position, with dropping of the globe (hypoglobus) or sinking in of the globe (enophthalmos) (Figure 26.12). In many cases such changes in globe position are masked in the immediate postinjury phase by oedema and only become obvious as this resolves.

A retrobulbar haemorrhage is a surgical emergency because when left untreated it can lead to blindness. It presents with decreasing visual acuity, increasing pain, loss of pupillary response and a tense proptosis. Should this diagnosis be suspected medical management should be initiated with acetazolamide, mannitol and steroids; however, the main treatment is surgical, with lateral canthotomy and cantholysis forming the initial intervention.

Investigation of orbital injuries requires CT scanning (Figure 26.13) but if a retrobulbar haemorrhage is suspected treatment should be given prior to scanning.

With the exception of retrobulbar haemorrhages and paediatric orbital fractures, the definitive treatment can be delayed for 7–10 days (Figure 26.14). This allows oedema to settle and globe motility and position to be assessed more accurately. Reconstruction of the orbital rim is usually accomplished with ORIF techniques and the orbital walls repaired with autologous materials such as cranial bone or rib grafts, but proving more popular are preformed titanium implants or patient-specific custom-made implants.

Figure 26.12 Previously undiagnosed left orbital blow-out fracture, presenting 3 months after the initial injury. Enophthalmos and lowered pupillary level are evident.

Figure 26.13 Coronal computed tomography scan showing a left orbital blow-out fracture, with evident soft tissue herniation into the maxillary antrum (arrrow).

Summary box 26.7

Orbital fractures

- Visual acuity and motility must be assessed
- In children, orbital floor injuries should be assessed and treated as emergencies because muscle injury may be permanent, resulting in reduced ocular motility

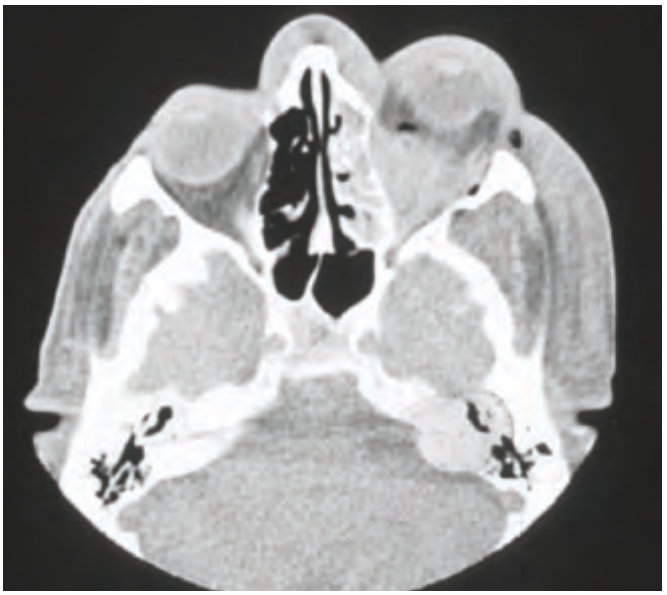

Figure 26.14 Computed tomography scan showing retrobulbar haemorrhage and severe proptosis.

Naso-orbito ethmoidal fractures

These central upper midface fractures can range from simple undisplaced nasal bone fractures to complex comminuted fractures, impacted into the anterior cranial fossa, in the region of the cribriform plate. Typically they are caused by a blow to the bridge of the nose. The more severe fractures present with periorbital ecchymosis, swelling and nasal bleeding with the bridge of the nose depressed and the nasal tip rotated upwards, allowing the nostrils to be seen straight on ('piggy nose'). The nasal septum is often disrupted and should be inspected for haematomas. Cerebrospinal fluid (CSF) may be seen to be leaking. However, in the initial assessment it is often difficult to make this diagnosis with any certainty.

Disruption of the attachment of the medial canthal ligaments can result in traumatic telcanthus – this is due to traumatic detachment of the ligament from its bony insertion or, more commonly, comminution of the naso-orbital ethmoidal complex with the canthal insertion intact, but with a small fragment of displaced bone.

Investigation is necessary with CT scanning (**Figure 26.15**) for all but the simplest nasal bone fractures. Treatment is usually delayed for 7–10 days post injury and generally necessitates ORIF and repositioning of the fragments with the medial canthi attached. If a formal canthopexy is required, this can be achieved with stainless steel wires or specialised canthopexy wires.

Figure 26.15 Coronal computed tomography scan showing posteriosuperior impaction of the naso-orbito complex.

Summary box 26.8

Naso-orbito ethmoidal fractures

- Naso-orbito ethmoidal injuries indicate significant force transfer
- Other associated injuries should be excluded, particularly craniofacial/anterior cranial fossa injuries

Craniofacial fractures

These are fractures that involve the cranial cavity and the facial bones in continuity. In many cases they involve the frontal and ethmoidal sinuses, creating a communication between the cranial cavity and the nasal air sinuses. If this is combined with a dural tear, CSF will leak into the nose and is detected as CSF rhinorrhoea with or without a salty taste. In these circumstances antibiotics are not indicated and the threshold for surgical intervention is quite variable between surgeons. The most common site of injury is the posterior wall of the frontal sinus, however fractures of the ethmoid and sphenoid sinus can also cause CSF leaks.

Most surgeons would treat persistent leaks lasting 10 days with surgical intervention, and mostly this is done with an open anterior fossa repair (necessitating a frontal craniotomy). In a limited number of cases the CSF leak can be repaired endoscopically. In most patients the treatment involves cranialisation of the frontal sinus with obliteration of the frontonasal duct. Although some surgeons advocate reconstruction of the posterior sinus wall, others will obliterate the sinus with fat or bone. Unless there are other pressing imperatives treatment is usually delayed for 7–14 days.

Summary box 26.9

Craniofacial fractures

- Usually managed by a multispecialty team involving neurosurgery, ear, nose & throat (ENT) and oral & maxillofacial surgery
- Significant head injuries are common

Panfacial fractures

In cases where there are fractures at all levels of the facial skeleton (upper, mid and lower face) the term panfacial fracture is used, and these fractures can present particular management challenges. First, multiple-level fractures indicate a significant amount of force and therefore energy transfer, hence associated injuries to the brain, cervical spine and other organs are much more common. Second, reconstruction of the multiple fractures is much more difficult because there is little normal anatomy to act as a guide. Each component of the panfacial fracture is treated in the same way as an isolated fracture would be, but sequencing the repair is challenging. The options are top down (craniofacial, zygomatico-orbital, maxillary and finally mandibular), bottom up, inside out (starting centrally and working laterally) or outside in. Most surgeons experienced in managing this type of injury would tailor the sequence to the particular fracture pattern to optimise the use of normal or near normal anatomy as a guide.

There are some particular pitfalls: obtaining adequate cheekbone projection anteroposteriorly while making the zygomatic arch too prominent, over-impacting the anterior maxilla, and an anterior mandibular fracture being fixed with the mandibular angles flared outwards.

Dental injuries

The primary (deciduous) dentition is usually fully erupted by 2.5 years, and the first permanent teeth (lower incisors) usually erupt at about the age of 6. Between the ages of 5 and 13 the primary dentition is shed and replaced by the secondary teeth.

If an adult whole tooth is avulsed it should be cleaned gently in saline and reimplanted; the sooner that this can happen the better the prognosis (avulsed deciduous teeth are not reimplanted). This is best achieved under local anaesthesia and after irrigation and debridement of the socket. The patient should then be referred urgently to a dentist for ongoing care; in many cases the tooth may need to be splinted to immobilise it and ensure that it is protected from the dental occlusion.

Fractures of the teeth may involve the enamel only, the enamel and dentine or the enamel, dentine and pulp. Once the dentine is exposed the fractured tooth can be exquisitely painful and benefits from a simple dental dressing – in the first instance local anaesthetic infiltrated in the region of the apex of the root is helpful in reducing pain pending a specialist dental assessment. If the pulp is exposed, local anaesthetic applied topically to the exposed pulp can also give some pain relief.

Summary box 26.10

Dental injuries

- It is important to account for all missing teeth and/or dental fragments – a chest radiograph may be indicated
- Exposed dentine and pulp can be exquisitely painful and referral for emergency dental treatment can be very helpful
- Avulsed teeth should be reimplanted as soon as possible

Soft tissue injuries

Lacerations and wounds

Facial lacerations and incised wounds often bleed quite profusely as a result of the excellent blood supply. This has the benefit of excellent healing and therefore wounds should only be debrided of frankly necrotic tissue.

In assessing facial soft tissue wounds it is important to check the function of the facial nerve and the patency of the parotid duct because both of these structures require repair should they be involved in the injury.

Uncomplicated wounds with no tissue loss should be cleaned and closed in layers under either local or general anaesthesia. If the skin is contaminated with dirt it should be scrubbed clean with a brush to prevent dirt tattooing. Usually, absorbable sutures are utilised intraorally and for the deep layers. It is important for good closure that the muscle layers are accurately opposed. The final skin layer should be closed with a monofilament suture (in children this can be absorbable). For some small linear incised wounds cyanoacrylate glue can be utilised.

Wounds involving the eyelid margins and crossing the vermillion of the lip need special attention to detail and very careful approximation of all the involved layers such that referral to a specialist should be considered by the inexperienced surgeon.

Where there has been skin loss the management depends on the size of the defect, the elasticity of the surrounding skin and the circumstances. Small defects can be closed with direct closure, but for larger defects the mobilisation of local skin flaps may be necessary. When there is greater tissue loss, skin grafting and/or free tissue transfer may be required.

Parotid duct

The parotid duct may be damaged as a result of an incised wound or a crushing injury. This is usually obvious as saliva leaking into the wound and should this be the case the buccal branch of the facial nerve is often injured at the same time. If the duct is transected or damaged this should be repaired over a cannula inserted into the parotid papilla. This is usually best achieved with magnification (loupes or microscope) under the controlled conditions of general anaesthetic.

Facial nerve

Facial nerve injuries are best repaired primarily, and the biggest challenge to achieving this is not identifying the motor deficit at presentation. In general, injuries that lie behind a line from lateral canthus or the eye to the angle of the mouth are repairable and this should be attempted. Again, this is best achieved under microscope magnification and a nerve stimulator/monitor is very helpful in identifying the cut nerve ends.

Animal and human bites

Unlike those elsewhere on the body, facial bites should be closed primarily and not left open. The abundant blood supply renders this normal precaution unnecessary. All bites should be debrided carefully and closed in the usual way; however, antibiotics, in accordance with local protocols, should be prescribed. If there is significant tissue loss consideration should be given to a staged reconstruction.

Summary box 26.11

Soft tissue injuries

- Examination of both motor and sensory nerve function should be conducted prior to the administration of local anaesthetic
- Tissue loss can occur and usually warrants specialist referral
- Careful cleaning (debridement) with removal of all dirt minimises the chances of wound tattooing

Chapter 27

Torso trauma

Learning objectives

To understand:

- That the management of trauma is based on physiology as well as anatomy (as in general surgery)
- The gross and surgical anatomy of the chest and abdomen
- The pathophysiology of torso injury
- The strength and weaknesses of clinical assessment in the injured patient
- The use of special investigations and their limitations
- The operative approaches to the thoracic cavity
- The special features of an emergency room thoracotomy for haemorrhage control
- The indications for and techniques of the trauma laparotomy
- The philosophy of damage control surgery
- The management of trauma to the pelvis

INTRODUCTION

Because injury does not respect anatomical boundaries, division of the body into abdomen and thorax is artificial, and injury to the torso, with its associated physiological consequences, is more appropriate. The torso is generally regarded as the main part of the human body, primarily made up of the chest, abdomen and pelvis, not including the head, neck, arms and legs. About 42% of all deaths are the result of brain injury, but some 39% of all trauma deaths are caused by major haemorrhage, usually from torso injury (**Figure 27.1**).

Although initially, injury was treated on an anatomical basis, it has become clear that physiology should be the over-riding consideration, and the driver of successful resuscitation is therefore the preservation of normal physiology. Techniques such as 'damage control resuscitation' and 'damage control surgery' have dramatically improved survival through an understanding of the best techniques required to restore physiological stability (see Chapters 1, 22 and 23).

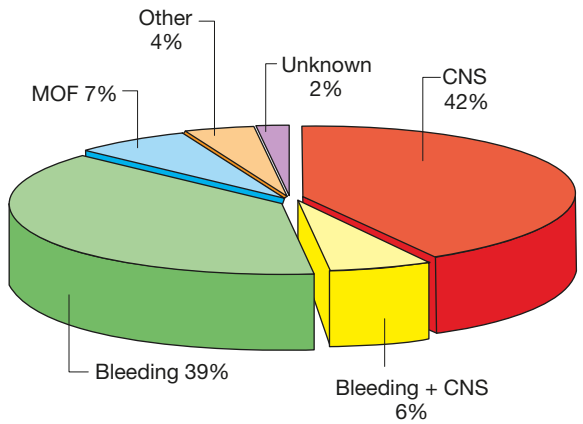

Figure 27.1 Causes of death in trauma. CNS, central nervous system; MOF, multiple organ failure.

INJURY MECHANISMS ASSOCIATED WITH TORSO TRAUMA

Injury often traverses different anatomical zones of the body, affecting structures on both sides of traditional anatomical zones. These zones are known as junctional zones.

Junctional zones

The key junctional zones are:

- between the neck and the thorax;
- between the thorax and the abdomen;
- between the abdomen, the pelvic structures and the groin.

These zones represent surgical challenges in terms of both the diagnosis of the area of injury and the surgical approach, which have to be balanced against the physiological stability of the patient.

Root of the neck

Most injuries affecting the base of the neck also affect the upper mediastinum and thoracic inlet. Choice of access is determined by the need for surgical control of the vascular structures contained within.

The mediastinum

The zone overlying the mediastinum with its major vessels and the heart is also an extremely high-risk area for penetrating wounds. Any wound in this region should immediately raise the suspicion of a major vascular or an associated cardiac injury, even in the absence of initial gross physical signs.

Diaphragm

The thorax and abdomen are separated by the diaphragm, which is mainly responsible for breathing, and moves during breathing between the fourth and eighth interspace. Any penetrating injury of the lower half of the chest may therefore have penetrated the diaphragm and entered the abdomen. Injuries in this junctional zone, therefore, should be investigated as if both cavities had been penetrated (**Figure 27.2**). In blunt trauma, rupture of the diaphragm can result in migration of abdominal viscera into the chest.

Pelvic structures

The pelvis contains a large plexus of vessels, both venous and arterial. Should injury occur, control of haemorrhage can prove to be exceptionally difficult and may require control of both arterial inflow and venous outflow. Angioembolisation can be a very useful adjunct to treatment, especially with deep pelvic injuries.

Summary box 27.1

Junctional zones

- Between neck and the thorax
- Between thorax and the abdomen
- Between the abdomen, the pelvic structures and the groin

CRITICAL PHYSIOLOGY

Resuscitation of all injuries to the chest and abdomen should follow traditional ATLS® principles (*Table 27.1* and Chapters 22 and 23).

Bleeding is the major problem. This may be obvious at the time of evaluation; however, in the young physically fit individual, bleeding may only produce subtle changes in vital measures and therefore be difficult to assess (*Table 27.2*). Although obvious injury may be present, traditional indicators (such as pulse rate), in isolation, are unreliable.

Bleeding occurs from five major sites – **'one on the floor and four more':**

- external – 'floor';
- chest;
- abdomen (including the retroperitoneum);
- pelvis;
- extremities.

TABLE 27.1 ATLS® principles of resuscitation.

A	Airway
B	Breathing
C	Circulation
D	Disability (neurology)
E	Environment and Exposure

THORACIC INJURY

Thoracic injury accounts for 25% of all severe injuries. In a further 25%, it may be a significant contributor to the subsequent death of the patient. In most of these patients, the cause of death is haemorrhage. About 80% of patients with chest injury can be managed non-operatively. The key to a good outcome is early physiological resuscitation followed by a correct diagnosis.

TABLE 27.2 Clinical indicators of potential ongoing bleeding in torso trauma.

Physiological	Increasing respiratory rate
	Increasing pulse rate
	Falling blood pressure
	Rising serum lactate
Anatomical	Visible bleeding
	Injury in close proximity to major vessels
	Penetrating injury with a retained missile

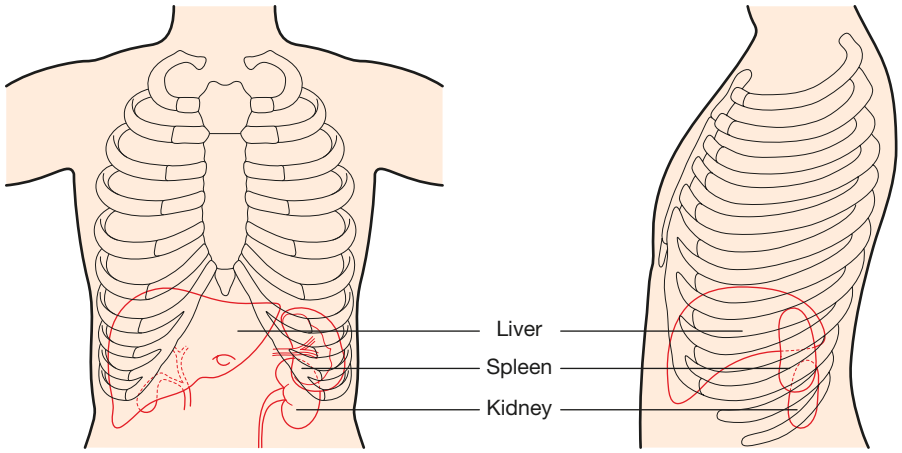

Figure 27.2 The anatomical extent of the abdomen.

Investigation

Routine investigation in the emergency department of injury to the chest is based on clinical examination, supplemented by chest radiography.

Ultrasound – extended focused assessment with sonar for trauma

Ultrasound can be used to differentiate between contusion and the actual presence of blood. Extended focused assessment with sonar for trauma (eFAST) is becoming the most common investigation. The technique uses sonar assessment in the chest, looking for a cardiac tamponade or free blood and air in the hemithorax on each side, and assessment for blood in the abdominal cavity, in the paracolic gutters, subdiaphragmatic spaces and pelvis.

Underwater chest drain

In the physiologically grossly unstable patient, where physical examination is inconclusive and there is no time for radiological investigations, insertion of an underwater chest drainage tube can be a diagnostic procedure as well as a therapeutic one, and the benefits of insertion often outweigh the risks.

Chest radiograph

In those cases where the patient is haemodynamically unstable or the spine is at risk, an anteroposterior (AP) supine chest radiograph is usually the simplest initial investigation, and will provide good information regarding tracheal deviation, lung and mediastinal pathology, as well as skeletal injury.

In penetrating injury, it may be more helpful for the radiograph to be performed with the patient positioned erect, as this will best reveal a small pneumothorax, fluid meniscus, air–fluid level or the presence of free gas under the diaphragm, indicating the presence of a hollow abdominal viscus perforation. Note that up to 300 mL of blood may pool behind the domes of the diaphragm, and may not be visible even in the erect view.

The presence of thoracic skeletal injury should alert the clinician to the possibility of adjacent thoracic or abdominal visceral injury. Rupture of the thoracic aorta can be related to fractures of the first and second rib, bilateral clavicular fracture and fracture of the sternum, thoracic spine or scapula. Fracture of the lower ribs can be related to injury of liver or spleen. Fracture of ribs, irrespective of site, can be related to injury to the lung parenchyma or thoracic wall vasculature, causing pneumothorax, haemothorax or lung contusion.

Computed tomography scan

The computed tomography (CT) scan with contrast allows for three-dimensional reconstruction of the chest and abdomen, as well as of the bony skeleton. It has become the principal and most reliable examination for major injury in thoracic trauma. In blunt chest trauma, the CT scan will allow the definition of fractures, as well as showing haematomas, pneumothoraces and pulmonary contusion. In penetrating trauma, the scan may show the track or presence of the missile and allow the proper planning of definitive surgery. However, although the presence of an isolated rupture of the diaphragm with migration of abdominal contents into the chest can be detected by CT scan, in injury without migration the diagnosis will not be obvious. CT scanning has replaced angiography as the diagnostic modality of choice for the assessment of the thoracic aorta and mediastinal vessels.

The pitfalls of investigation are:

- failure to assess tracheal shift immediately above the sternal notch clinically (deviation of the trachea occurs **away** from the affected side in tension pneumothorax, and **towards** the affected side in lung collapse);
- failure to percuss and auscultate both front and back in a supine patient (an inflated lung will 'float' on a haemothorax, so auscultation from the front may sound normal);
- failure to pass a nasogastric tube if rupture of the diaphragm is suspected; a chest radiograph will show the nasogastric tube apparently within the chest cavity;
- a supine chest radiograph can show a haemothorax as a homogenous increase in opacity of the hemithorax; this can cause confusion between the darker side and the lighter side, as to which may be a haemothorax (less radiolucent), or a pneumothorax (more radiolucent). Look carefully for lung markings, and don't drain the wrong side;
- pursuing radiological investigation (radiography or CT scan) instead of resuscitation in the unstable patient.

Summary box 27.2

Investigation of chest injuries

- Directly or indirectly involved in >50% of trauma deaths
- 80% can be managed non-operatively
- A chest radiograph is the investigation of first choice
- A chest drain can be diagnostic as well as therapeutic
- A spiral CT scan provides rapid diagnoses in the chest and abdomen

Management

In penetrating injury, most patients who have suffered injury to the chest can be managed with appropriate resuscitation and insertion of an intercostal drain.

If a sucking chest wound is present, this should not be fully closed but should be covered with a piece of plastic, closed on three sides, to form a one-way valve, and thereafter an underwater chest drain should be inserted remote from the wound. No attempt should be made to close a sucking chest wound until controlled drainage has been achieved, in case a stable patient with an open pneumothorax is converted into an unstable patient with a tension pneumothorax.

In blunt injury, most bleeding occurs from the intercostal or internal mammary vessels and it is relatively rare for these to require surgery. If bleeding does not stop spontaneously, the vessels can be tied off or encircled. In blunt chest compressive injury, particularly in the presence of a flail chest, there can be an associated lung contusion.

The patient *in extremis* with exsanguinating chest haemorrhage will be discussed in the section on Emergency department thoracotomy (EDT) later in the chapter.

Summary box 27.3

Closed management of chest injuries

- About 80% of chest injuries can be managed with the insertion of an intercostal drain only
- Do not close a sucking chest wound until a drain is in place
- If bleeding persists, the chest will need to be opened and direct haemostatic control is obtained

Life-threatening injuries can be remembered as the '**deadly dozen'**. Six are immediately life threatening and should be sought for and managed during the primary survey and six are potentially life threatening and should be detected during the secondary survey (*Table 27.3*). A high index of suspicion must be maintained thereafter to diagnose the potential threats to life, as their symptoms and signs can be very subtle. Early consultation and referral to a trauma centre is advised in cases of doubt.

Immediate life-threatening injuries

Airway obstruction

Early intubation is very important, particularly in cases of neck haematoma or possible airway oedema. Airway distortion can be insidious and progressive and can make delayed intubation more difficult if not impossible.

Tension pneumothorax

A tension pneumothorax develops when a 'one-way valve' air leak occurs either from the lung or through the chest wall. Air is sucked into the thoracic cavity without any means of escape, completely collapsing then compressing the affected lung. The mediastinum is displaced to the opposite side, decreasing venous return and compressing the opposite lung.

The most common causes are penetrating chest trauma, blunt chest trauma with a parenchymal lung injury and air leak that did not spontaneously close, iatrogenic lung injury (e.g. due to central venepuncture) and mechanical positive pressure ventilation.

TABLE 27.3 The 'deadly dozen' threats to life from chest injury.

Immediately life threatening	Airway obstruction
	Tension pneumothorax
	Pericardial tamponade
	Open pneumothorax
	Massive haemothorax
	Flail chest
Potentially life threatening	Aortic injuries
	Tracheobronchial injuries
	Myocardial contusion
	Rupture of diaphragm
	Oesophageal injuries
	Pulmonary contusion

The clinical presentation is dramatic. The patient is increasingly restless with tachypnoea, dyspnoea and distended neck veins (similar to pericardial tamponade). Clinical examination may reveal tracheal deviation; this is a late finding and is not necessary to clinically confirm diagnosis. There will also be hyper-resonance and decreased or absent breath sounds over the affected hemithorax. Tension pneumothorax is a **clinical** diagnosis and treatment should never be delayed by waiting for radiological confirmation (**Figure 27.3**).

Treatment consists of immediate decompression, initially by rapid insertion of a large-bore cannula into the second intercostal space in the mid-clavicular line of the affected side, then followed by insertion of a chest tube through the fifth intercostal space in the anterior axillary line.

Pericardial tamponade

Pericardial tamponade needs to be differentiated from a tension pneumothorax in the shocked patient with distended neck veins. It is most commonly the result of penetrating trauma. Accumulation of a relatively small amount of blood into the non-distensible pericardial sac can produce compression of the heart and obstruction of the venous return, leading to decreased filling of the cardiac chambers during diastole. All patients with penetrating injury anywhere near the heart plus shock must be considered to have a cardiac injury until proven otherwise. Classically, the presentation consists of central venous pressure elevation, decline in arterial pressure with tachycardia and muffled heart sounds. However, in cases in which major bleeding from other sites has taken place, the neck veins may be flat. A central line should be inserted, checking for a rising central venous pressure. A high index of suspicion and further diagnostic investigations will be needed to make the diagnosis is those cases that are not clinically obvious. These include an eFAST showing fluid in the pericardial sac. This is the most expeditious and reliable diagnostic tool, or chest radiography looking for an enlarged heart shadow.

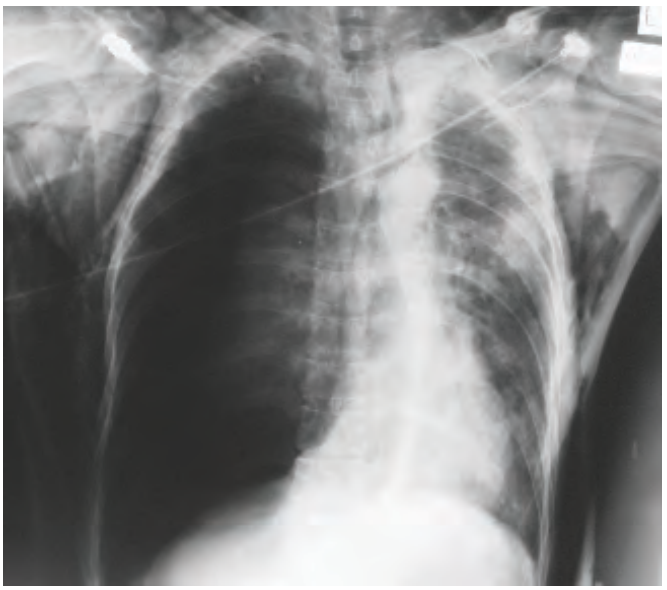

Figure 27.3 Radiological appearance of a tension pneumothorax.

Needle pericardiocentesis has been suggested. However, in penetrating injury to the heart there is usually a substantial clot in the pericardium, which may prevent aspiration. A dry pericardiocentesis proves only that there is a 'clot' on both ends of the needle! Pericardiocentesis has a high potential for iatrogenic injury to the heart and it should, at the most, be regarded as a desperate temporising measure in a transport situation (under electrocardiogram (ECG) control). The correct immediate treatment of tamponade is operative, either via a subxiphoid window, or by open surgery (sternotomy or left thoracotomy), with repair of the heart in the operating theatre if time allows or otherwise in the emergency room.

Summary box 27.4

Pericardial tamponade

- The presentation is similar to a tension pneumothorax – deteriorating cyanosis, tachycardia and agitation
- eFAST is diagnostic and may also detect free fluid in the abdomen or pericardium
- The central venous pressure may not be elevated if the circulating volume is depleted, e.g. because of other injuries
- Pericardiocentesis is a temporising measure only, with a high complication rate and is not a substitute for immediate operative intervention

Open pneumothorax ('sucking chest wound')

This is due to a large open defect in the chest (>3 cm), leading to immediate equilibration between intrathoracic and atmospheric pressure. If the opening in the chest wall exceeds about two-thirds of the diameter of the trachea, then with each inspiratory cycle, air will be preferentially drawn through the defect, rather than through the trachea. Air accumulates in the hemithorax (rather than in the lung) with each inspiration, leading to profound hypoventilation on the affected side and hypoxia. If there is a valvular effect, increasing amounts of air in the pleura will result in a tension pneumothorax (see above).

Initial management consists of promptly closing the defect with a sterile occlusive plastic dressing (e.g. Opsite®), taped on three sides to act as a flutter-type valve. A chest tube is inserted as soon as possible in a site remote from the injury site.

Massive haemothorax

The most common cause of massive haemothorax in blunt injury is continuing bleeding from torn intercostal vessels or occasionally from the internal mammary artery secondary to fractures of the ribs. In penetrating injury, a variety of viscera, both thoracic and abdominal (with blood leaking through a hole in the diaphragm from the positive pressure abdomen into the negative pressure thorax) may be involved.

Accumulation of blood in a haemothorax can significantly compromise respiratory efforts, compressing the lung and preventing adequate ventilation. Presentation is with haemorrhagic shock, flat neck veins, unilateral absence of breath sounds and dullness to percussion. The initial treatment consists of correcting the hypovolaemic shock, insertion of an intercostal drain and, in some cases, intubation. Initial drainage of more than 1500 mL of blood or ongoing haemorrhage of more than 200 mL/h over 3–4 hours is generally considered an indication for urgent thoracotomy.

Blood in the pleural space should be removed as completely and rapidly as possible to prevent ongoing bleeding, an empyema or fibrothorax later. Clamping a chest drain to tamponade a massive haemothorax is not helpful.

The following points are important in the management of an open pneumothorax/haemothorax:

- a common problem is using too small a tube – a 28FG or larger tube should be used in an adult;
- if the lung does not reinflate, the drain should be placed on low-pressure (5 cm water) suction;
- clot occlusion of a chest drainage tube may result in 'no' drainage, even in the presence of ongoing bleeding;
- a second drain is sometimes necessary (but see Tracheobronchial injuries);
- a chest radiograph can help identify the presence of blood;
- physiotherapy and active mobilisation should begin as soon as possible.

Flail chest

This condition usually results from blunt trauma associated with multiple rib fractures, and is defined as three or more ribs fractured in two or more places. The blunt force typically also produces an underlying pulmonary contusion. The diagnosis is made clinically in patients who are not ventilated, not by radiography. To confirm the diagnosis the chest wall can be observed for paradoxical motion of a chest wall segment. On inspiration, the loose segment of the chest wall is displaced inwards and therefore less air moves into the lungs. On expiration, the segment moves outwards (paradoxical respiration). Voluntary splinting of the chest wall occurs as a result of pain, so mechanically impaired chest wall movement and the associated lung contusion all contribute to the hypoxia. There is a high risk of developing a pneumothorax or haemothorax. The CT scan, with contrast to display the vascular structures and a 3-D reconstruction of the chest wall, is the gold standard for diagnosis of this condition.

Traditionally, mechanical ventilation was used to 'internally splint' the chest, but had a price in terms of intensive care unit resources and ventilation-dependent morbidity. Currently, treatment consists of oxygen administration, adequate analgesia (including opiates) and physiotherapy. If a chest tube is *in situ*, topical intrapleural local analgesia introduced via the tube, can also be used. Ventilation is reserved for cases developing respiratory failure despite adequate analgesia and oxygen. Surgery to stabilise the flail segment using internal fixation of the ribs may be useful in a selected group of patients with isolated or severe chest injury and pulmonary contusion.

in situ is Latin for 'in place'.

Potentially life-threatening injuries

Thoracic aortic disruption

Traumatic aortic rupture is a common cause of sudden death after an automobile collision or fall from a great height. The vessel is relatively fixed distal to the ligamentum arteriosum, just distal to the origin of the left subclavian artery. The shear forces from a sudden impact disrupt the intima and media. If the adventitia is intact, the patient may remain haemodynamically stable. For this subgroup of immediate survivors, salvage is frequently possible if aortic rupture is identified and treated early. Aortic disruption should be clinically suspected in patients with gross asymmetry in systolic blood pressure (between the two upper limbs, or between upper and lower limbs), widened pulse pressure and chest wall contusion. Erect chest radiography can also suggest thoracic aortic disruption, the most common radiological finding being a widened mediastinum (**Figure 27.4**). The diagnosis is confirmed by a CT scan of the mediastinum (**Figure 27.5**), or possibly by transoesophageal

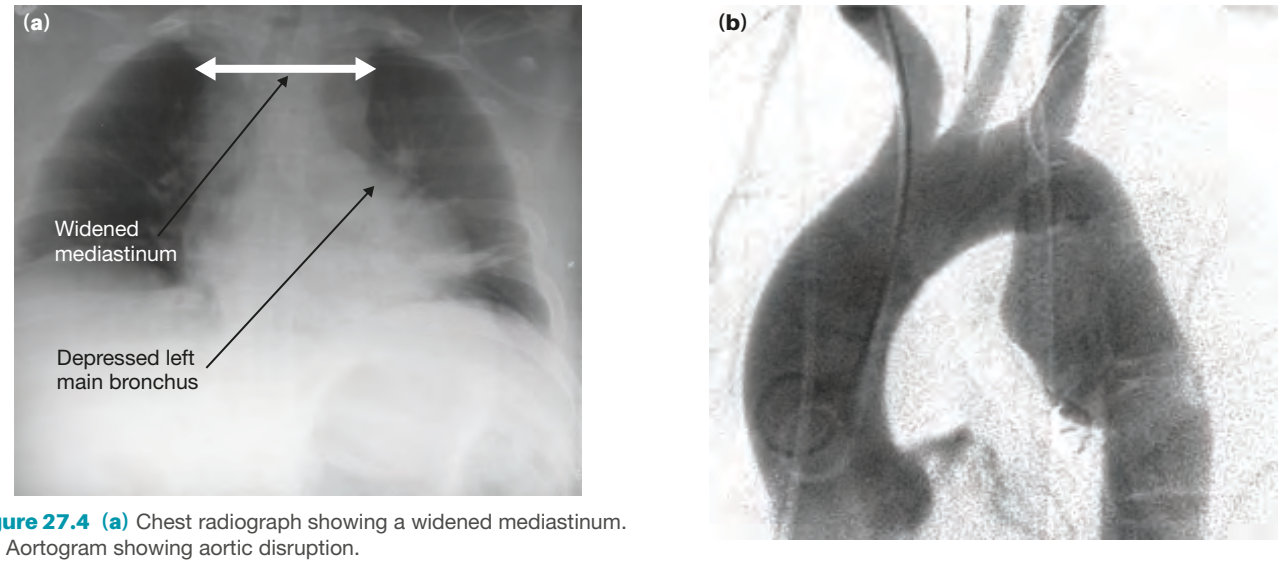

Figure 27.4 **(a)** Chest radiograph showing a widened mediastinum. **(b)** Aortogram showing aortic disruption.

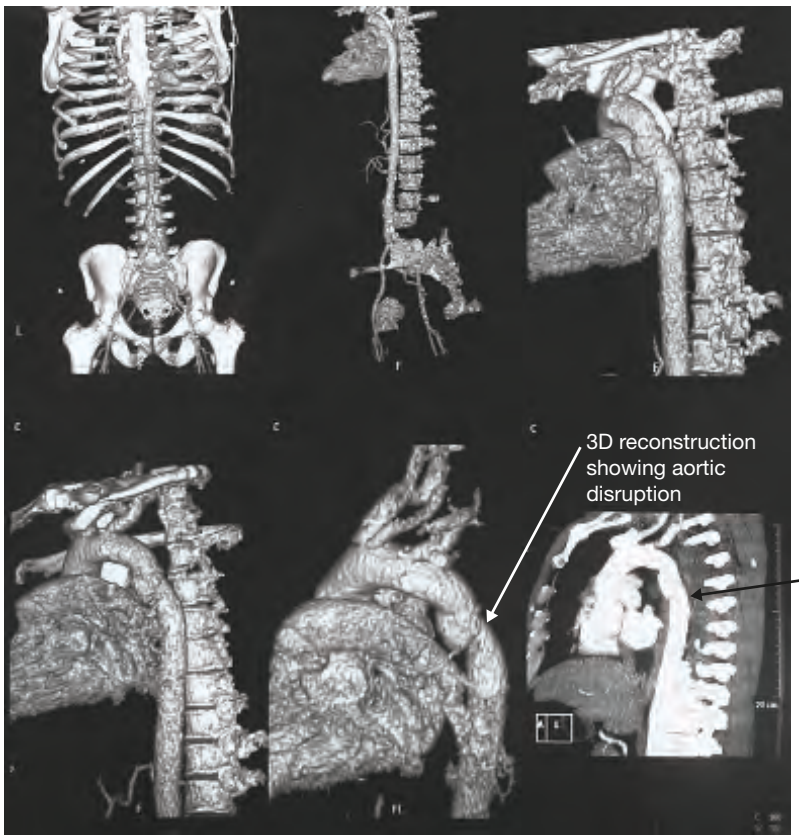

Figure 27.5 Computed tomography scans showing aortic disruption.

echocardiography, in unstable patients who cannot be moved to the scanner.

Initially, management consists of control of the systolic arterial blood pressure (to less than 120 mmHg). Thereafter, an endovascular intra-aortic stent (Figure 27.6) can be placed, or the tear can be operatively repaired by direct repair or excision and grafting using a Dacron graft.

Tracheobronchial injuries

Severe subcutaneous emphysema with respiratory compromise can suggest tracheobronchial disruption. A chest drain placed on the affected side will reveal a large air leak and the collapsed lung may fail to re-expand. Bronchoscopy is diagnostic. Treatment involves intubation of the unaffected bronchus followed by operative repair. Referral to a trauma centre is advised.

Blunt myocardial injury

Significant blunt cardiac injury that causes haemodynamic instability is rare. Blunt myocardial injury should be suspected in any patient sustaining blunt trauma who develops early ECG abnormalities.

Two-dimensional echocardiography may show wall motion abnormalities. A transoesophageal echocardiogram may also be helpful. There is very little evidence that enzyme estimations have any place in diagnosis.

All patients with myocardial contusion diagnosed with conduction abnormalities are at risk of developing sudden dysrhythmias and should be closely monitored.

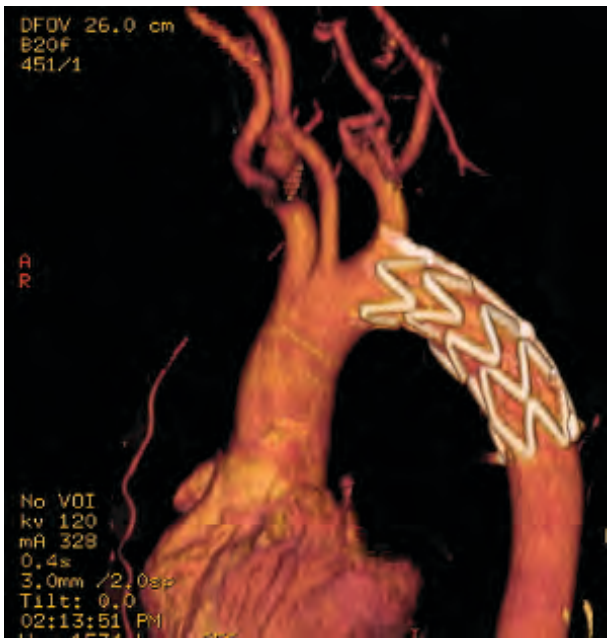

Figure 27.6 Aortic tear showing the presence of a stent.

Diaphragmatic injuries

Any penetrating injury below the fifth intercostal space should raise suspicion of diaphragmatic penetration and, therefore, injury to abdominal contents.

Blunt injury to the diaphragm is usually caused by a compressive force applied to the pelvis and abdomen. The diaphragmatic rupture is usually large, with herniation of the abdominal contents into the chest. Diagnosis of diaphragmatic rupture can easily be missed in the acute phase, and may only be discovered at operation, or through the presentation of complications.

Most diaphragmatic injuries are silent and the presenting features are those of injury to the surrounding organs. There is no single standard investigation. Chest radiography after placement of a nasogastric tube may be helpful (as this may show the stomach herniated into the chest). Contrast studies of the upper or lower gastrointestinal tract, CT scan, ultrasound and diagnostic peritoneal lavage all lack positive or negative predictive value. The most accurate evaluation is by video-assisted thoracoscopy (VATS) or laparoscopy, the latter offering the advantage of allowing the surgeon to proceed to a repair and additional evaluation of the abdominal organs.

The thorax is at negative pressure and the abdomen is at positive pressure. A complication of a breach of the diaphragm is herniation of abdominal contents into the chest. This may present much later, and strangulation of any of the contents can then occur, with a high mortality rate.

Operative repair is recommended in all cases. All penetrating diaphragmatic injury must be repaired via the abdomen and not the chest, to rule out penetrating hollow viscus injury.

Oesophageal injury

Most oesophageal injuries result from penetrating trauma; blunt injury is rare. A high index of suspicion is required. The patient can present with odynophagia (pain on swallowing saliva, foods or fluids), subcutaneous or mediastinal emphysema, pleural effusion, air in the perioesophageal space and unexplained fever. Mediastinal and deep cervical emphysema are evidence of an aerodigestive injury until proven otherwise.

The mortality rate rises exponentially if treatment is delayed. A combination of oesophagogram in the decubitus position and oesophagoscopy confirm the diagnosis in the great majority of cases. The treatment is operative repair of any defect and drainage.

Pulmonary contusion

Pulmonary contusion occurs more frequently following blunt trauma, usually associated with a flail segment or fractured ribs. This is a very common, potentially lethal injury and the major cause of hypoxaemia after blunt trauma. Following gunshot wounds, there is an area of contusion from the shock wave of the bullet.

The natural progression of pulmonary contusion is worsening hypoxaemia for the first 24–48 hours. Chest radiographic

Charles Thomas Stent, 1805–1885, dentist, Brighton, UK.

findings may be typically delayed. Contrast CT scanning can be confirmatory. Haemoptysis or blood in the endotracheal tube is a sign of pulmonary contusion.

In mild contusion, the treatment is oxygen administration, pulmonary toilet and adequate analgesia. In more severe cases mechanical ventilation is necessary. Normovolaemia is critical for adequate tissue perfusion and fluid restriction is not advised.

EMERGENCY THORACIC SURGERY

Emergency thoracic surgery is an essential part of the armamentarium of any surgeon dealing with major trauma. A timely surgical intervention for the correct indications can be the key step in saving an injured patient's life.

It is important to make a distinction between:

- immediate thoracotomy in the ED for the control of haemorrhage, cardiac tamponade or internal cardiac massage;
- emergency sternotomy for anterior mediastinal structures and heart;
- planned thoracotomy for definitive correction of the problem – this usually takes place in the more controlled environment of the operating theatre.

The clinical decision as to whether a patient requires ED surgery or can be transferred to the operating room can be complex. It is far better to perform a thoracotomy in the operating room, either through an anterolateral approach or a median sternotomy, with good light and assistance and the potential for autotransfusion or bypass, than it is to attempt heroic emergency surgery in the resuscitation area. However, if the patient is *in extremis* with a falling systolic blood pressure, there is no choice but to proceed immediately with a left anterolateral thoracotomy. In certain circumstances, when care is futile, it may not need to be performed at all. A resuscitation room thoracotomy following blunt trauma has limited indications and is rarely successful.

Emergency department thoracotomy or sternotomy

EDT should be reserved for those patients suffering **penetrating** injury **in whom signs of life are still present**. Patients who have received cardiopulmonary resuscitation (CPR) in the prehospital phase of their care are unlikely to survive, and electrical activity must be present.

In certain situations, EDT is considered futile:

- CPR in the absence of endotracheal intubation for more than 5 minutes;
- CPR for more than 10 minutes (despite endotracheal intubation);
- blunt trauma when there have been no signs of life at the scene (see above).

The survival rates for EDT in patients with penetrating trauma in whom the blood pressure is falling despite adequate resuscitation are shown in *Table 27.4*.

TABLE 27.4 Survival rates for thoracotomy in patients with penetrating trauma.

Blood pressure despite resuscitation	Survival (%)
>60 mmHg	60%
>40 mmHg	30%
<40 mmHg	3%

The aim of EDT is to perform:

- internal cardiac massage;
- control of haemorrhage from injury to the heart or lung;
- control of intrathoracic haemorrhage from other sources;
- control of massive air leak;
- clamping of the thoracic aorta to preserve the blood supply to the heart and brain, and cutting off the arterial supply distally, in a moribund patient with a major distal penetrating injury.

Planned emergency thoracotomy

Planned emergency thoracotomy implies an emergency thoracotomy performed as a planned procedure in the operating room, directed at the management of a specific injury. As such, the approach chosen is dependent on the indication for surgery and the organ injured (*Table 27.5*). Some organs are best approached through a median sternotomy. Otherwise the thoracotomy may be right- or left-sided, and these may be joined, producing the so called 'clamshell incision'. This gives excellent exposure for any surgeon who is not routinely entering the chest.

Posterolateral thoracotomy is not used in the emergency situation because of the difficulties in positioning of the patient, except for specific access to certain posterior mediastinal organs.

TABLE 27.5 Different approaches to the contents of the chest cavity.

Approach	Best for
Left anterolateral thoracotomy	Left lung and lung hilum Thoracic aorta Origin of left subclavian artery Left side of heart Lower oesophagus
Right anterolateral thoracotomy	Right lung and lung hilum Azygos veins Superior vena cava Infracardiac inferior vena cava Upper oesophagus Thoracic trachea
Median sternotomy	Anterior aspect of heart Anterior mediastinum Ascending aorta and arch of aorta Pulmonary arteries Carina of the trachea

ABDOMINAL INJURY

Patients who have suffered abdominal trauma can generally be classified into the following categories based on their physiological condition after initial resuscitation:

- haemodynamically 'normal' – investigation can be completed before treatment is planned;
- haemodynamically 'stable' – investigation is more limited. It is aimed at establishing whether the patient can be managed non-operatively, whether angioembolisation can be used or whether surgery is required;
- haemodynamically 'unstable' – investigations need to be suspended as immediate surgical correction of the bleeding is required.

A trauma laparotomy is the final step in the pathway to delineate intra-abdominal injury. Occasionally it is difficult to determine the source of bleeding in the shocked, multiple injured patient. If doubt still exists, especially in the presence of other injuries, a laparotomy may still be the safest option.

The patient's physiology must be assessed at regular intervals and, if there is an indication that the patient is still actively bleeding, then the source must be identified, unless the patient is unstable, requiring immediate surgery. Blood loss into the abdomen can be subtle and there may be no clear clinical signs. Blood is not an irritant and does not initially cause any abdominal pain. Distension is subjective, and a drop in the blood pressure may be a very late sign in a young fit patient. Examination in unstable patients should take place either in the ED or in the operating theatre if the patient is deteriorating rapidly.

Investigation

Investigations are driven by the cardiovascular status of the patient. In torso trauma, the best and most sensitive modality is a CT scan with intravenous contrast; however, in the unstable patient, this is generally not possible.

In patients with penetrating injury, metal markers (e.g. bent paper clips) should be placed on all external wounds before plain films are taken, irrespective of the area being radiographed, as this allows an assessment of the trajectory and helps to correlate the number of holes and the number of missiles that can be seen within the patient. This will help determine whether two holes are indicative of one missile passing through the patient, or two missiles, both retained internally (Figure 27.7). A single hole implies that the projectile has been retained.

Focused abdominal sonar for trauma and extended FAST

Focused abdominal sonar for trauma (FAST) is a technique whereby ultrasound (sonar) imaging is used to assess the torso for the presence of free fluid, either in the abdominal cavity, and is extended into the thoracic cavities and pericardium (eFAST). There should be no attempt to determine the nature or extent of the specific injury. eFAST is usually a rapid, reproducible, portable and non-invasive bedside test and can be performed at the same time as resuscitation. eFAST is accurate at detecting >100 mL of free blood; however, it is very operator dependent and, especially if the patient is very obese or the bowel is full of gas, it may be unreliable. Hollow viscus injury and solid organ injury are difficult to diagnose, even in experienced hands, as small amounts of gas or fluid are difficult to assess, and eFAST a low sensitivity (29–35%) for organ injury without haemoperitoneum. eFAST is also unreliable for excluding injury in penetrating trauma. If there is doubt, the eFAST examination can be repeated.

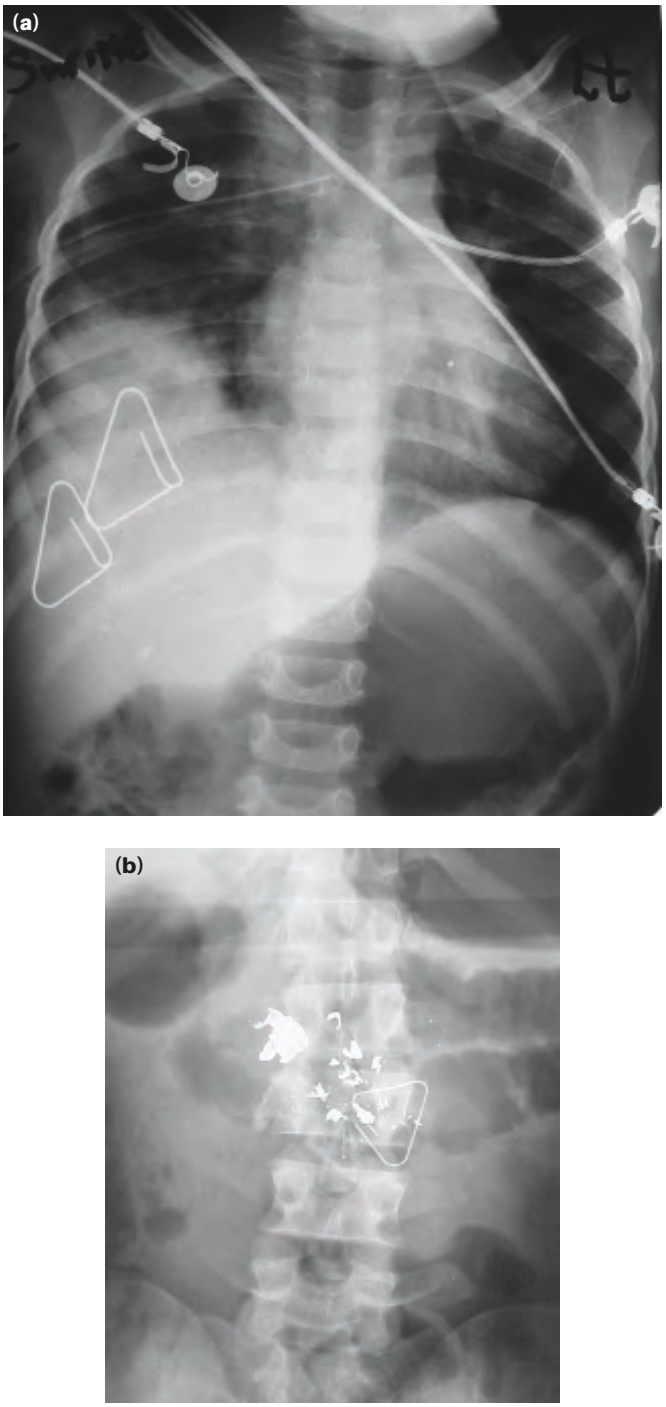

Figure 27.7 **(a)** Chest radiograph showing a gunshot wound with bullet markers. **(b)** Abdominal radiograph of a gunshot wound showing bullet markers.

Summary box 27.5

Utilisation of eFAST

- Detects free fluid in the abdomen or pericardium
- Will not reliably detect less than 100 mL of free blood
- Does not directly identify injury to hollow viscus
- Cannot reliably exclude injury in penetrating trauma
- May need repeating or supplementing with other investigations
- Is unreliable for assessment of the retroperitoneum

Diagnostic peritoneal lavage

Diagnostic peritoneal lavage (DPL) is a test used to assess the presence of blood or contaminants in the abdomen. A gastric tube is placed to empty the stomach and a urinary catheter is inserted to drain the bladder.

A cannula is inserted below the umbilicus, directed caudally and posteriorly. The cannula is aspirated for blood (>10 mL is deemed as positive) and, following this, 1000 mL of warmed Ringer's lactate solution is allowed to run into the abdomen and is then drained out via the same route. The presence of >100 000 red cells/μL or >500 white cells/μL is deemed positive (this is equivalent to 20 mL of free blood in the abdominal cavity), as is the presence of vegetable fibre or a raised amylase level. In penetrating trauma, a minimum of one-tenth of the above would be regarded as evidence of peritoneal penetration or intraperitoneal injury. In the absence of laboratory facilities, a urine dipstick may be useful. Drainage of lavage fluid via a chest drain indicates penetration of the diaphragm.

Although DPL has largely been replaced by eFAST (see above), it remains the standard in many institutions where eFAST is not available or is unreliable. DPL is especially useful in the hypotensive, unstable patient with multiple injuries as a means of excluding intra-abdominal bleeding.

Computed tomography scan

CT has become the 'gold standard' for the intra-abdominal diagnosis of injury in the stable patient. The scan can be performed using intravenous contrast. CT is sensitive for blood and individual organ injury, as well as for retroperitoneal injury. An entirely normal abdominal CT is usually sufficient to exclude intraperitoneal injury.

The following points are important when performing CT:

- it remains an inappropriate investigation for unstable patients;
- if duodenal injury is suspected from the mechanism of injury, oral contrast may be helpful;
- if rectal and distal colonic injury is suspected in the absence of blood on rectal examination, rectal contrast may be helpful.

Laparoscopy

Laparoscopy or thoracoscopy may be a valuable screening investigation in stable patients with penetrating trauma, to detect or exclude peritoneal penetration and/or diaphragmatic injury.

Laparoscopy may be divided into:

- **Screening**: used to exclude a penetrating injury with breach of the peritoneum.
- **Diagnostic**: finding evidence of injury to viscera.
- **Therapeutic**: used to repair the injury.

In most institutions, evidence of penetration requires a laparotomy to evaluate organ injury, as it is difficult to exclude all intra-abdominal injuries laparoscopically. When used in this role laparoscopy reduces the non-therapeutic laparotomy rate. There is no place for laparoscopy in the unstable patient.

INDIVIDUAL ORGAN INJURY

Liver

Blunt liver trauma occurs as a result of direct injury. The liver is a solid organ and compressive forces can easily burst the liver substance **(Figure 27.8)**. The liver is usually compressed between the impacting object and the rib cage or vertebral column. Most injuries are relatively minor and can be managed non-operatively.

Penetrating trauma to the liver is relatively common. Bullets have a shock wave and when they pass through a solid structure such as the liver they cause significant damage some distance from the actual track of the bullet. Not all penetrating wounds require operative management and may stop bleeding spontaneously.

In the stable patient, CT is the investigation of choice. It provides information on the liver injury itself, as well as on injuries to the adjoining major vascular and biliary structures.

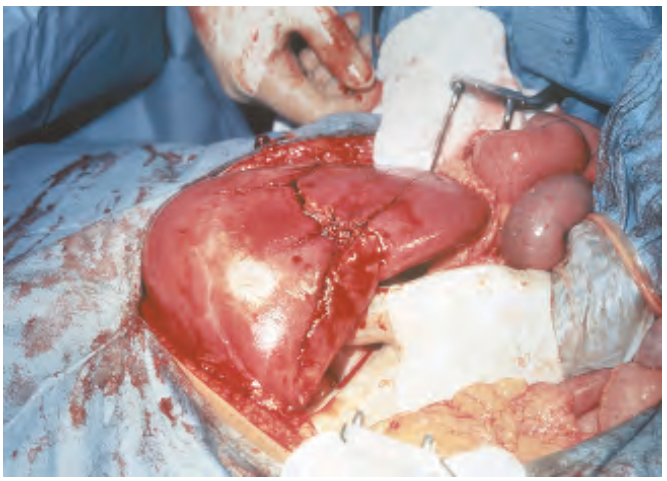

Figure 27.8 Compression injury to the liver, bursting the liver substance.

Sydney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, UK.

Injury in which there is a suggestion of a vascular component should be reimaged, as there is a significant risk of the development of subsequent ischaemia, false aneurysms, arteriovenous fistulae or haemobiliary fistula. It is advised that all patients should be rescanned prior to discharge.

Liver injury can be graded and managed using the American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS) (www.aast.org/injury).

Management

The operative management of liver injuries can be summarised as 'the four Ps':

- push;
- Pringle;
- plug;
- pack.

At laparotomy the liver is reconstituted and bleeding is controlled by direct bimanual compression to achieve its normal architecture as best as possible (push). The inflow from the portal triad is controlled by a Pringle's manoeuvre, with direct compression of the portal triad, either digitally or using a soft clamp (**Figure 27.9**). This has the effect of reducing arterial and portal venous inflow into the liver, although it does not control the backflow from the inferior vena cava and hepatic veins. Any holes due to penetrating injury can be plugged directly using silicone tubing or a Sengstaken–Blakemore tube, and, after controlling any arterial bleeding, the liver can then be packed (see Damage control surgery, below).

Bleeding points should be controlled locally when possible, and such patients if required, subsequently undergo subsequent angioembolisation. It is not usually necessary to suture penetrating injuries of the liver, unless haemostasis cannot be controlled by other means. If there has been direct damage to the hepatic artery, it can be tied off. Damage to the portal vein must be repaired, as tying off the portal vein carries a greater than 50% mortality rate. If it is not technically feasible to repair the vein at the time of surgery, it should be shunted and the patient referred to a specialist centre. A closed suction drainage system must be left *in situ* following hepatic surgery. Finally, the liver can be definitively packed, restoring the anatomy as closely as possible. Placing omentum into cracks in the liver is not recommended.

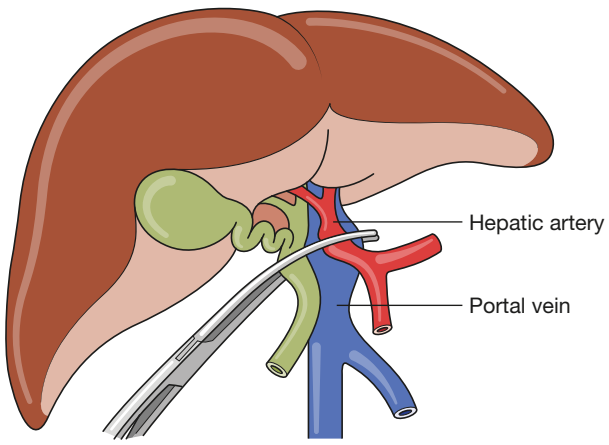

Figure 27.9 The Pringle manoeuvre.

Summary box 27.6

Liver trauma

- Blunt trauma occurs as the result of direct compression
- Penetrating trauma of the upper abdomen or lower thorax can damage the liver
- CT scanning is the investigation of choice in the stable patient
- Surgical management consists of push, Pringle, plug and pack
- The hepatic artery can be tied off but not the portal vein (which should be stented)
- Closed suction drainage should always be used

Biliary injuries

Isolated traumatic biliary injuries are rare and occur mainly from penetrating trauma, often in association with injuries to other structures that lie in close proximity. The common bile duct can be repaired over a T-tube or drained and referred to appropriate care as part of damage control, or even ligated.

Spleen

Splenic injury occurs from direct blunt trauma. Most isolated splenic injuries, especially in children, can be managed non-operatively. However, in adults, especially in the presence of other injury or physiological instability, laparotomy should be considered. The spleen can be packed, repaired or placed in a mesh bag. Splenectomy may be a safer option, especially in the unstable patient with multiple potential sites of bleeding. In certain situations, selective angioembolisation of the spleen can play a role.

Following splenectomy there are significant, though transient, changes to blood physiology. The platelet and white count rise and may mimic sepsis. Innoculation against *Pneumococcus* is advisable within 2–3 weeks, by which time the patient's immune system has recovered.

James Hogarth Pringle, 1863–1941 (Australian born), surgeon, The Royal Infirmary, Glasgow, UK.
Robert William Sengstaken, 1923–1978, surgeon, Garden City, NY, USA and **Arthur Hendley Blakemore**, 1897–1970, Associate Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA, designed a tube with two in-built balloons for the treatment of oesophageal varices. The tube was passed and the distal balloon inflated. The tube was drawn backwards until the distal balloon was held at the oesophageal hiatus. The proximal balloon was inflated, allowing the tamponade of any varices in the distal oesophagus.

Pancreas

Most pancreatic injury occurs as a result of blunt trauma. The major problem is that of diagnosis, because the pancreas is a retroperitoneal organ. CT remains the mainstay of accurate diagnosis. Amylase or lipase estimation is insensitive. In penetrating trauma, injury may only be detected during laparotomy.

Classically the pancreas should be treated with conservative surgery and closed suction drainage. Injuries are treated according to the OIS system of the AAST. Injuries to the pancreatic body to the left of the superior mesenteric vessels and to the tail are treated by closed suction drainage alone, with distal pancreatectomy if the duct is involved. Proximal injuries (to the right of the superior mesenteric artery) are treated as conservatively as possible, although partial pancreatectomy may be necessary. The pylorus can be temporarily closed (pyloric exclusion) in association with a gastric drainage procedure, to minimise pancreatic enzyme stimulation by gastric juice or distension. A Whipple's procedure (pancreaticoduodenectomy) is rarely needed and should not be performed in the emergency situation because of the very high associated mortality rate. A damage control procedure with packing and drainage should be performed and the patient referred for definitive surgery once stabilised.

Stomach

Most stomach injuries are caused by penetrating trauma. Blood presence is diagnostic if found in the nasogastric tube, in the absence of bleeding from other sources.

Surgical repair is required but great care must be taken to examine the stomach fully, as an injury to the front of the stomach can be expected to have an 'exit' wound elsewhere on the organ.

Duodenum

Duodenal injury is frequently associated with injuries to the adjoining pancreas. Like the pancreas, the duodenum lies retroperitoneally and so injuries are hidden, discovered late or at laparotomy performed for other reasons. CT is the diagnostic modality of choice. The only sign may be gas or a fluid collection in the periduodenal tissue, and leakage of oral contrast, administration of which may improve accuracy of diagnosis.

Smaller injuries can be repaired primarily. The first, third and fourth parts of the duodenum behave like small bowel, and can be repaired in the same fashion. The second part of the duodenum is fixed to the head of the pancreas with a common blood supply, and may have a poorer blood supply compared to the remainder. Major trauma, especially if the head of the pancreas is simultaneously injured, should be treated as part of a damage control procedure and be referred for definitive care.

Small bowel

The small bowel is frequently injured as a result of blunt trauma. The individual loops may be trapped, causing high-pressure rupture of a loop or tearing of the mesentery. Penetrating trauma is also a common cause of injury.

Small bowel injuries need urgent repair. Haemorrhage control takes priority and these wounds can be temporarily controlled with simple sutures. In blunt trauma with mesenteric vessel damage, the bowel ischaemia that results will dictate the extent of a resection. Resections should be carefully planned to limit the loss of viable small bowel, but should be weighed against an excessive number of repairs or anastomoses. Haematomas in the small bowel mesenteric border need to be explored to rule out perforation. With low-energy wounds, primary repair can be performed, whereas more destructive wounds associated with military type weapons require resection and anastomosis. Damage control 'clip and drop' of damaged or resected bowel may be necessary.

Colon

Injuries to the colon from blunt injury are relatively infrequent, and are more frequently a penetrating injury. If relatively little contamination is present and the viability is satisfactory, such wounds can be repaired primarily. If, however, there is extensive contamination, the patient is physiologically unstable or the bowel is of doubtful viability, then the bowel can be closed off ('clip and drop'). A defunctioning colostomy can be formed later or the bowel reanastomosed once the patient is stable.

Rectum

Only 5% of colon injuries involve the rectum. These are generally from a penetrating injury, although occasionally the rectum may be damaged following fracture of the pelvis. Digital rectal examination will reveal the presence of blood, which is evidence of intestinal or rectal injury. These injuries are often associated with bladder and proximal urethral injury.

With intraperitoneal injuries, the rectum is managed as for colonic injuries. Full-thickness extraperitoneal rectal injuries should be managed with either a diverting end-colostomy and closure of the distal end (Hartmann's procedure) or a loop colostomy. Presacral drainage is no longer used.

Renal and urological tract injury

In the stable patient, CT scanning with contrast is the investigation of choice.

For assessment of bladder injury a cystogram should be performed. A minimum of 300 mL of contrast is instilled into the bladder via a urethral catheter. The large volume is

Allen Oldfather Whipple, 1881–1963, Valentine Mott Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.
Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery, Faculty of Medicine, The University of Paris, Paris, France.

essential because a small volume may not distend the bladder enough to produce a leak from a small bladder injury once the cystic muscle is contracted. It is important to assess the films as follows:

- two views – AP and lateral (and sometimes oblique);
- two occasions – full and postmicturition.

Generally, renal injury is managed non-operatively unless the patient is unstable. The kidney can be angioembolised if required.

Ureteric injury is rare and is generally due to penetrating trauma. Most ureters can be repaired or diverted if necessary, or may even be ligated as part of Damage control procedures.

Intraperitoneal rupture of the bladder, usually from direct blunt injury, will require surgical repair. Extraperitoneal rupture is usually associated with a fracture of the pelvis and will heal with adequate urine drainage via the transurethral route. Suprapubic drainage is reserved for when this is not possible.

Summary box 27.7

Injuries to structures in the abdomen

- In children, splenic injury can be managed non-operatively in most cases, but not if haemodynamically unstable
- Duodenal injuries are often associated with pancreatic trauma
- Bowel injuries need urgent definitive repair, or isolation using resection or by stapling
- Rectal injuries may be best managed initially with a diverting colostomy
- Kidney and urinary tract injury is best diagnosed with enhanced CT scanning
- Intraperitoneal bladder tears need formal repair and drainage

Retroperitoneum

Injury to the retroperitoneum is often difficult to diagnose, especially in the presence of other injury, when the signs may be masked. Diagnostic tests (such as ultrasound and DPL) may be negative. The best diagnostic modality is CT, but this requires a physiologically stable patient. The retroperitoneum is divided into three zones (**Figure 27.10**) for the purposes of intraoperative management:

In blunt trauma:

- Zone 1 (central): central haematomas should always be explored, once proximal and distal vascular control has been obtained.
- Zone 2 (lateral): lateral haematomas should only be explored if they are expanding or pulsatile. They are usually renal in origin and can be managed non-operatively, though they may sometimes require angioembolisation.
- Zone 3 (pelvic): as with zone 2, these should only be explored if they are expanding or pulsatile. Pelvic haematomas are exceptionally difficult to control and, whenever possible, should not be opened; they are best controlled with compression or extraperitonea packing, and if the bleeding is arterial in origin, with angioembolisation.

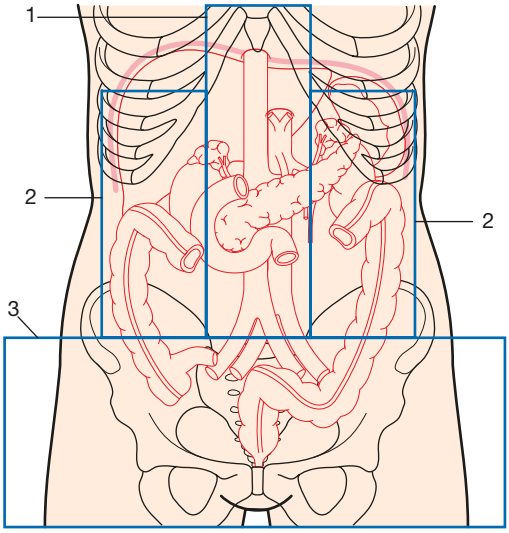

Figure 27.10 The zones of the retroperitoneum. Zone 1: central; zone 2: lateral; zone 3: pelvic.

In penetrating trauma, every injury should be explored for damage to structures along the wound track (e.g. ureter), unless preoperative investigation allows non-surgical management of the injury.

THE PELVIS

Although mortality following severe pelvic fractures has decreased dramatically with better methods of controlling haemorrhage, these patients still represent a significant challenge to every link of the treatment chain. Mortality rates exceeding 40% have recently been reported. Further, pelvic bleeding as one of the 'hidden bleeding sources' is still underestimated or missed, as retrospective chart analyses of potentially preventable deaths have revealed. Extreme force is required to disrupt the pelvic ring, and associated injuries and extrapelvic bleeding sources are common (up to 50% of cases). The haemodynamically unstable patient with severe pelvic fracture has a 90% risk of associated injuries, and a 30% risk of intra-abdominal bleeding.

To save these patients, three questions need to be addressed:

- Is the patient at high risk of massive bleeding?
- Where is the source of the bleeding?
- How to stop the bleeding?

Anatomy

The surgical anatomy of the pelvis is a key to the understanding of pelvic injuries.

- The pelvic inlet is circular, a structure that is immensely strong, but routinely gives way at more than one point should sufficient force be applied to it. Therefore, isolated fractures of the anterior or posterior pelvic ring are uncommon.
- The forces required to fracture the pelvic ring do not respect the surrounding organ systems.

- The pelvis has a rich collateral blood supply, especially across the sacrum and posterior part of the ileum. The cancellous bone of the pelvis also has an excellent blood supply. Most pelvic haemorrhage emanates from venous injury and fracture sites. However, in the haemodynamically unstable patient with severe pelvic injury, arterial bleeding is more frequent. Important for the treatment is that the surgeon has to deal both with arterial and venous bleeding.
- Postmortem examination has shown that the extrapelvic peritoneal space can accommodate more than 3000 mL. However, in the case of a severe pelvic fracture where the retroperitoneal compartment is disrupted and the external bony barrier is not stable, haematoma may extend upwards towards the mediastinum ('chimney effect') or downwards into the medial thigh in case of rupture of the pelvic floor.
- All iliac vessels, the sciatic nerve roots (including the lumbosacral nerve) and the ureters cross the sacroiliac joint; disruption of this joint may cause severe haemorrhage and sometimes cause arterial obstruction of the internal iliac artery and sciatic nerve palsy. Injuries to the ureters are rare.
- The pelvic viscera are suspended from the bony pelvis by condensations of the endopelvic fascia. Shear forces acting on the pelvis will transmit these to pelvic viscera, leading to avulsion and shearing injuries.
- The pelvis also includes the acetabulum, a major structure in weight transfer to the leg. Inappropriate treatment will lead to severe disability.

Classification

Pelvic ring fractures can be classified into three types, using the Tile classification (for subtypes and other classifications see Further reading), based on the severity of the fracture (and reflecting the energy required to cause it) (**Figure 27.11**). However, no fracture pattern can exclude significant haemorrhage.

Type A

Type A are the most common fractures and are completely stable. They result from lateral compression, which causes compression fractures of the pubic rami or compression fracture of the sacrum posteriorly.

Type B

These fractures are partially stable, and there is disruption of the anterior pelvis and partial disruption of the posterior pelvis. The pelvis can open and close 'like a book', but because the sacroiliac ligaments remain intact, there is no vertical displacement. Internal or external stabilisation is required. Blood loss can be significant.

Type C

This fracture is completely unstable. Both anterior pelvis and the entire posterior pelvic complexes are disrupted and the disrupted pelvic bones are free to displace horizontally and vertically. In both type B and type C pelvic injuries, there is a high risk of associated abdominal injuries (bowel perforation or mesenteric laceration) and rupture of the diaphragm.

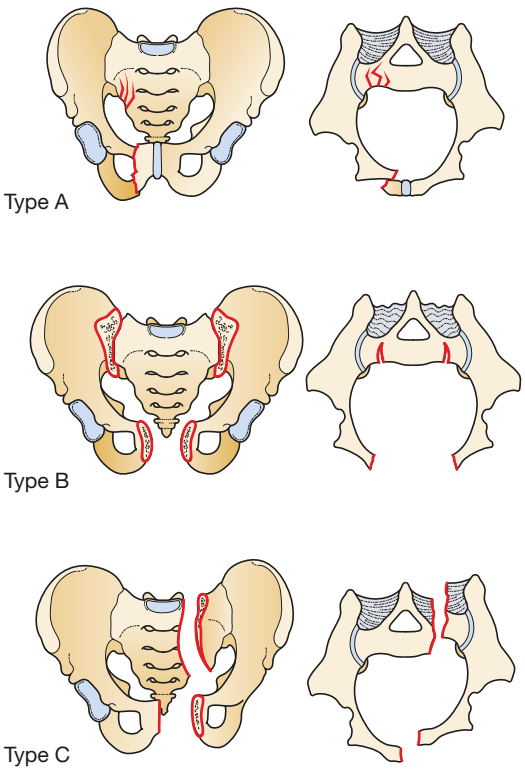

Figure 27.11 Tile classification of fractures of the pelvis.

Clinical examination

Pelvic fractures should be easily identified if ATLS guidelines are followed (i.e. clinical palpation and compression of the pelvic brim from sacroiliac joint to pubic symphysis, and a routine chest and pelvic radiograph for any blunt injury in a patient unable to walk). Clinical examination may reveal instability. Any instability felt indicates the presence of major pelvic fracture, associated with life-threatening blood loss, and requires appropriate measures. The absence of clinical instability does not, however, preclude an unstable pelvic fracture. One-third of such trauma victims with pelvic ring fractures present with circulatory instability on arrival.

Inspection of the skin may reveal lacerations in the groin, perineum or sacral area, indicating an open pelvic fracture, the result of gross deformation. Evidence of perineal injury or haematuria mandates radiological evaluation of the urinary tract from below upwards (retrograde urethrogram followed by cystogram or CT cystogram and an excretory urogram, as appropriate) when the physiology allows. Inspection of the urethral meatus may reveal a drop of blood, indicating urethral damage.

Marvin Tile, b.1933, orthopaedic surgeon, Sunnybrook Medical Centre, Toronto, Canada.

Inspection of the anus may reveal lacerations to the sphincter mechanism. Rectal examination may reveal blood in the rectum and/or discontinuity of the rectal wall, indicating a rectal laceration. In male patients, the prostate is palpated; a high-riding prostate indicates a complete urethral avulsion. A full neurological examination is performed of the perineal area, sphincter mechanism and femoral and sciatic nerves.

Diagnosis

Radiograph

Examination of a plain radiograph of the pelvis requires an understanding of the mechanism of injury and a decision on the stability of the pelvic rim.

An open book type mechanism causes one or both ilea to rotate externally (opening, like a book). A lateral compression mechanism causes the pelvis to collapse. An 'open-book fracture' is seen as a widening of the pubic symphysis or widening at the site of a fracture in the pubic ramus. Not only is there disruption of the bony pelvis, but also tearing of the pelvic floor and thus the pelvic venous plexus is at risk. The more unstable the pelvis, the more likely the structures are to be damaged. When the pelvis collapses from a lateral compression injury, the pubic bones usually fracture. Displacement of the anterior pelvis by greater than 2 cm indicates at least partial instability. A vertical shear disruption of the sacroiliac joint, with apparent shortening of the limb on the affected side implies significant energy of injury.

FAST may be unreliable as it does not localise intra-abdominal bleeding in these patients.

CT is the diagnostic modality of choice in the haemodynamically stable patient, and CT angiography is particularly helpful to provide details of both the anatomy of the facture, as well as details of the origin of the bleeding (venous or arterial).

Management

The treatment of bleeding is to stop the bleeding!

The priorities for resuscitating patients with pelvic fractures are no different from the standard. These injuries can produce a real threat to the circulation, and management is geared toward controlling this threat. Initial management requires the use of a compression binder or a sheet, applied around the true pelvis at the level of the greater trochanters ('reduce the pelvic volume'), a potentially lifesaving procedure that has to be done in the emergency room.

85% of bleeding originating from the pelvis is of venous origin and can be controlled by non-operative means, including compression either by binding or external fixator, or by extraperitoneal packing (i.e. packing the loose space between the bony wall of the pelvis and the peritoneum) to compress the pelvic veins. If other sources of bleeding have been ruled out, the extraperitoneal pelvic packing is done without entering the peritoneal cavity. This may be combined with external fixation.

If the bleeding is of arterial origin, interventional angioembolisation is the next choice for bleeding control. The techniques for bleeding control (compression, packing, fixation and angioembolisation) do not exclude each other but rather may complement each other. Persistent bleeding after packing may require angioembolisation and vice versa.

Severe pelvic injuries require a multidisciplinary team approach. If adequate orthopaedic experience is unavailable, consideration should be given towards early transfer of this patient to an institution with the necessary expertise.

If the source of the bleeding is in doubt or FAST/CT results are positive, showing a significant amount of blood in the peritoneal cavity, concurrent intra-abdominal injury cannot be excluded, and it is wise to perform an exploratory laparotomy to treat or rule out intra-abdominal bleeding.

Summary

In summary, a haemodynamically normal patient can be safely transferred for stabilisation of unstable fractures within hours after injury and following control of the associated damage.

Summary box 27.8

Pelvic injury

- Associated injuries can only be managed once the patient is haemodynamically stable
- Decision on the stability is of paramount importance
- Procedures for damage control may be the only available option
- External stabilisation of the pelvic ring is the basis of all treatment
- If necessary, further bleeding control can be achieved either by angioembolisation or extraperitoneal packing
- Most associated injuries can be managed once the patient is haemodynamically stable

DAMAGE CONTROL

Following major injury, protracted surgery in the physiologically unstable patient can in itself prove fatal. Patients with the 'deadly triad' (hypothermia, acidosis and coagulopathy) are those at highest risk. 'Damage control' or 'damage limitation surgery' is a concept that originated from naval shipbuilding strategy, whereby ships were designed so that the damage was kept 'local' and which allowed only the minimal repairs needed to prevent it from sinking, while definitive repairs waited until it had reached port. The technique has been adopted following major trauma, and includes initial care and resuscitation (damage control resuscitation) and the surgical correction of the injury (damage control surgery).

The minimum amount of surgery needed to stabilise the patient's condition may be the safest course until the physiological derangement can be corrected. Damage control surgery is restricted to only two goals:

- stopping any active surgical bleeding;
- controlling any contamination.

Once these goals have been achieved then the operation is suspended and the abdomen temporarily closed. The patient's resuscitation then continues in the intensive care unit, where other therapeutic interventions can take place.

Once the physiology has been corrected, the patient warmed and the coagulopathy corrected, the patient is returned to the operating theatre for any definitive surgery.

Damage control resuscitation

The concept of damage control has been broadened to include the techniques used in resuscitation as well as in surgery. The time in the ED is minimised and the majority of resuscitation of the patient is carried out in the operating room and not in the resuscitation bay (*Table 27.6*). The resuscitation is individualised through repeated point of care testing, of haemoglobin, acidosis (pH and lactate) and clotting, and is therefore directed towards the early delivery of biologically active colloids, clotting products and whole blood in order to buy time. The physiological disturbances that are associated with the downward spiral of acidosis, coagulopathy and hypothermia in these serious injuries are predicted and attempts are made to avoid them rather than react to them.

Damage control surgery

The decision whether damage control surgery is the appropriate course should be made early (*Table 27.7*) and allows the whole surgical and anaesthetic team to work together to limit the time in surgery and the earliest possible admission of the patient to the intensive care unit. Damage control is a staged process.

The initial focus is haemorrhage control, followed by control and limitation of contamination, achieved using a range of abbreviated techniques including simple ligation of bleeding vessels, shunting of major arteries and veins, drainage, temporary stapling of bowel and therapeutic packing.

Following the above, the abdomen is closed in a temporary fashion using a sheet of plastic (e.g. Opsite®) over the bowel, an intermediate pack to allow suction and a further sheet of adherent plastic drape to the skin to form a watertight and airtight seal. Suction is applied to the intermediate pack area to collect abdominal fluid. This technique is known as the 'Vacpac' or 'Opsite® sandwich' (**Figure 27.12**). As soon as control has been achieved the patient is transferred to the intensive care unit where resuscitation is continued.

The next stage following damage control surgery and physiological stabilisation is definitive surgery. The team should aim to perform definitive anastomoses, vascular reconstruction and closure of the body cavity within 24–72 hours of injury. However, this must be individualised to the patient, the response to critical care resuscitation and the progression of injury complexes.

TABLE 27.6 The stages of damage control surgery.

Stage	
I	Patient selection
II	Control of haemorrhage and control of contamination
III	Resuscitation continued in the intensive care unit
IV	Definitive surgery
V	Abdominal closure

TABLE 27.7 Indications for damage control surgery.

Anatomical	Inability to achieve haemostasis
	Complex abdominal injury, e.g. liver and pancreas
	Combined vascular, solid and hollow organ injury, e.g. aortic or caval injury
	Inaccessible major venous injury, e.g. retrohepatic vena cava
	Demand for non-operative control of other injuries, e.g. fractured pelvis
	Anticipated need for a time-consuming procedure
Physiological (decline of physiological reserve)	Temperature <34°C pH <7.2
	Serum lactate >5 mmol/L (normal: <2.5 mmol/L)
	Prothrombin time (PT) >16 s
	Partial thromboplastin time (PTT) >60 s
	>10 units blood transfused
	Systolic blood pressure <90 mmHg for >60 min
Environmental	Operating time >60 min (core temperature loss in usually 2°C/h)
	Inability to approximate the abdominal incision
	Desire to reassess the intra-abdominal contents (directed relook)

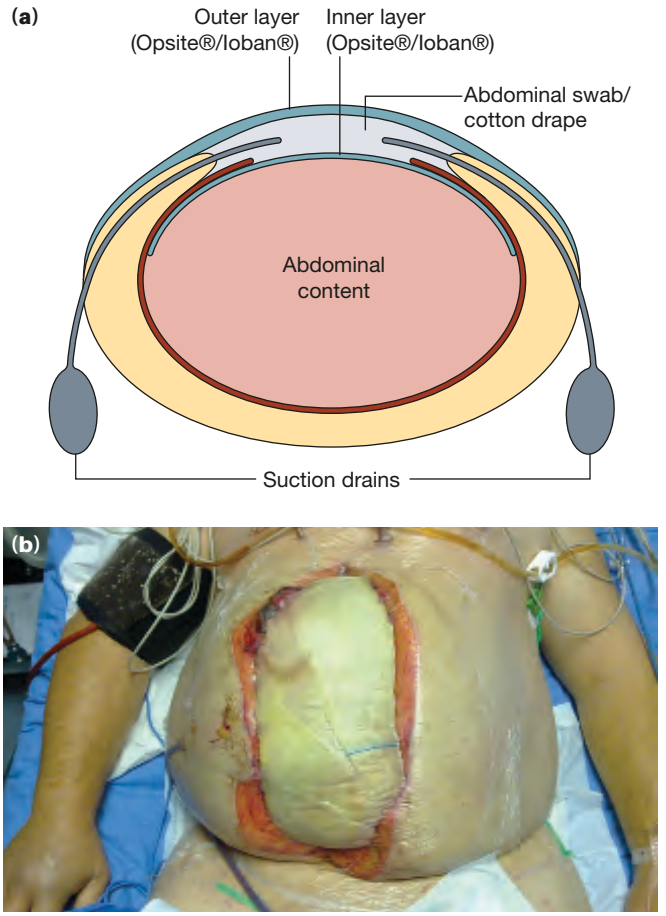

Figure 27.12 **(a)** Diagram showing temporary skin closure in damage control. **(b)** Abdominal closure following damage control surgery showing an Opsite® closure.

The abdomen is closed as soon as possible, bearing in mind the risks of abdominal compartment syndrome (ACS). The closure is not without its own morbidity. Successful closure may require aggressive off-loading of fluid and even haemofiltration to achieve this if the patient will tolerate it. The best situation is closure of the abdominal fascia, or, if this cannot be achieved, then skin closure only. Occasionally, mesh closure can be used, with skin grafting over the mesh and subsequent abdominal wall reconstruction.

Thoracic damage control is conceptually based on the same philosophy. This is that haemorrhage control and focused surgical procedures minimise further surgical insult and lead to improved survival in the unstable trauma patient. The aim is to control bleeding and limit air leaks using the fastest procedures available, such as staplers, to minimise the operative time. Often, damage control surgery **is** the definitive surgery.

The indications and techniques for emergency thoracic surgery have already been described.

Damage control applies equally to the extremities. In this case, it is shunting of blood vessels, identifying and marking damaged structures such as nerves, fasciotomy and removal of contaminated tissue that are the main tasks. Subsequent definitive management can be carried out at a later stage.

Summary box 27.9

Damage control

- Resuscitation is carried out in the operating room using biologically active fluids (i.e. blood) – damage control resuscitation (DCR)
- The surgery performed is the minimum needed to stabilise the patient
- The aims of surgery are to control haemorrhage and limit contamination
- Secondary surgery is aimed at definitive repair

ABDOMINAL COMPARTMENT SYNDROME AND THE OPEN ABDOMEN

Raised intra-abdominal pressure has far-reaching consequences for the patient; the syndrome that results is known as ACS. ACS is a major cause of morbidity and mortality in the critically ill patient and its early recognition is essential (*Table 27.8*).

In all cases of abdominal trauma in which the development of ACS in the immediate postoperative phase is considered a risk, the abdomen should be left open and managed as for damage control surgery.

INTERVENTIONAL RADIOLOGY

Interventional radiology can be useful in the management of torso trauma as both an investigative and a therapeutic tool for patients with vascular injury. Angioembolisation following demonstration of ongoing bleeding in splenic and renal injury is a valuable technique.

TABLE 27.8 Effect of raised intra-abdominal pressure on individual organ function.

Organ	Effect
Renal	Increase in renal vascular resistance leading to a reduction in glomerular filtration rate and impaired renal function
Cardiovascular	Decrease in venous return resulting in decreased cardiac output because of both a reduction in preload and an increase in afterload
Respiratory	Increased ventilation pressures because of splinting of the diaphragm, decreased lung compliance and increased airway pressures
Visceral perfusion	Reduction in visceral perfusion
Intracranial effects	Severe rises in intracranial pressures

NON-OPERATIVE MANAGEMENT

Non-operative management is generally preferred for the management of solid organ injury in haemodynamically stable children. Non-operative management of solid abdominal organ injury has rapidly gained acceptance in the management of adults as well. A stable patient and accurate CT imaging are prerequisites for this approach. Failure of non-operative management is uncommon and typically occurs within the first 12 hours after injury. Therefore, if correctly selected, the vast majority of these patients will avoid surgery, require less blood transfusion, and sustain fewer complications than operated patients.

ANTIBIOTICS IN TORSO TRAUMA

There is no level 1 evidence to recommend the use of antibiotics for the insertion of chest drains. However, prophylactic antibiotics prior to surgery should be used in all cases of penetrating abdominal trauma. Unless there is major contamination, a single dose is sufficient.

Chapter 28

Extremity trauma

Learning objectives

To gain an understanding of:

- How to identify whether an injury exists
- The important injuries not to miss
- The principles of the description and classification of fractures
- The range of available treatments
- How to select an appropriate treatment

INTRODUCTION

In several chapters the importance of life-threatening trauma is emphasised, but numerically for every patient that dies following a traumatic event, there are three that are left with a lifelong functional impairment.

Appropriate treatment of extremity trauma is important to return the patient to optimal function as quickly and as safely as possible. The management of extremity trauma is step-wise and involves initially saving the patient's life by the identification and treatment of life and limb threatening injuries first, according to the Advanced Trauma Life Support (ATLS) principles.

Treatment depends on injury specific factors, patient factors and surgeon factors, including the resources available.

It is imperative for the clinician to involve the patient in the decision making process when it comes to the choice of treatment for that individual. Moreover, treatment priorities, functional demands and risk versus benefit vary from individual to individual.

DIAGNOSIS

The diagnosis of extremity trauma begins with the taking of a pertinent history followed by focussed physical examination and appropriate special tests.

History

It is important to ascertain the mechanism of injury and the amount of force involved in the injury. Take time to gather sufficient detail in order to do this. Certain injury mechanisms result in classical injury patterns; for example, electrocution or seizure activity may lead to a posterior dislocation of the shoulder. In your mind translate the mechanism of injury into the common anatomical injury patterns. For example, a head on collision between two cars each travelling at 40 miles per hour coming to a dead stop should be interpreted by the history taker as a rapid deceleration injury, which then allows anticipation of likely injuries, such as rupture of the aortic arch. Similarly, a fall on the outstretched hand might be associated with wrist, elbow, shoulder and clavicular injuries.

Following the history of the presenting complaint, it is important to collect information beyond that of the injury and the AMPLE mnemonic is an abbreviated system taught in ATLS.

A: Allergies
M: Medication – important to ask about anticoagulant and antiplatelet therapies, corticosteroid use and any possible immunosuppressive treatment
P: Past medical and surgical history – has the patient had an anaesthetic in the past and were there any complications
L: Last time – something to eat or drink
E: Events – events that led to the injury

In the multiply injured patient or patients with altered levels of consciousness, gain as much collateral history as possible. Listen to the account of pre-hospital personnel; for example, the amount of cabin intrusion in a vehicle or whether a collision was head on or a side on.

Examination

An initial general examination, including vital signs and general assessment, should be conducted. Is this an isolated injury or do you need to start right at the beginning, considering the A, B, C approach as advocated by ATLS? Examination of the individual extremity only begins once you are sure the patient is stable and life- and limb-threatening conditions have been excluded.

It is crucial to undertake a thorough top to toe evaluation in the secondary survey. Often the minor extremity injuries are missed (**Figure 28.1**) and can cause significant long-term problems (*Table 28.1*).

A top to toe evaluation is is achieved by a systematic approach (see Chapter 31 and *Apley's system of orthopaedics and fractures* [Further reading]) to the injured extremity:

- look;
- feel;
- move (active and passive);
- special tests;
- special investigations.

Figure 28.1 **(a)** Missed dislocation of metatarsophalangeal joint of the little toe, picked up at 8 weeks. **(b)** Initial trauma computed tomography angiogram. In retrospect, on close inspection the dislocation is visible on the angiogram; do not be distracted by the obvious femoral shaft fracture.

TABLE 28.1 Extremity injuries that are notorious for being missed.

Posterior dislocation of the shoulder
Lateral condylar mass fracture of the distal humerus
Perilunate dislocation
Scaphoid fracture
Tarsometatarsal fracture dislocation
Compartment syndrome
Vascular injury with knee dislocation
Talar neck fracture
Slipped upper femoral epiphysis
Achilles tendon rupture

Ensure you examine the joint above and the joint below the site of injury. Consider the events and mechanism of injury and examine the areas that could possibly be affected. For example, a patient who falls from a height may fracture the calcaneus, which is an obvious diagnosis with a very swollen hindfoot and extremely tender heel. The concomitant lumbar spine fracture may not become evident until a few days later when the distracting pain in the heel starts to subside.

Look

It is important to look at the whole limb, back and front, noting any localised swelling, bruising and any obvious deformity. A shortened externally rotated leg in an older patient suggests a fracture of the proximal femur. A slightly flexed, adducted internally rotated leg might suggest a posterior dislocation of the hip.

Any break in the skin or abrasion needs to be noted and the treating orthopaedic surgeon informed, even if you do not think it communicates with the fracture. A graze over the knee in a closed tibial fracture may preclude intramedullary nailing until the wound has healed over, or perhaps an alternative treatment may have to be considered.

Ideally a photograph (with appropriate consent) should be taken to document the injury and obviate the need for repeated manipulation of the dressings (see Open fractures).

Note the colour of the limb and the degree of general swelling. A compartment syndrome may still be present even when a limb does not appear to be very swollen (see Compartment syndrome), but if it is grossly swollen, note, document and pass on the information.

Look for pre-existing scars; a scar at the back of the elbow or over the cubital tunnel might signify an anterior transposition of the ulna nerve. Scars might signify previous metalwork that remains in situ or has been removed in the past.

Feel

Start gently examining the limb away from the zone of obvious injury, gaining the patients trust and gathering as much information as possible before and without causing the patient pain or discomfort. Feel for bony tenderness and note

Achilles, the Greek hero was the son of Peleus and Thetis. When he was a child, his mother dipped him in the Styx, one of the rivers of the Underworld so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel received at the seige of Troy.

the degree of swelling and tenseness of the compartments. It should be noted that it is not possible to exclude a compartment syndrome based on how tense the limb feels. The deep posterior compartment of the lower leg cannot be felt when palpating the skin.

The characteristic crepitus of subcutaneous air can be felt in the setting of open fractures, air jet injuries and around the chest in the presence of a pneumothorax.

The examiner should feel for pulses and assess capillary return (see Neurovascular examination) as well as feeling for temperature changes.

Move

Movement as part of the examination should once again be approached carefully and without causing the patient pain and discomfort. Two types of movement can be assessed:

1 active – active movement is movement initiated and maintained by the patient;
2 passive – passive movement is when the examiner moves the limb.

Special tests

There are often special tests to detect injury in precise anatomical locations and many are described elsewhere in the book; for example, looking for a ruptured Achilles tendon by placing the patient prone with the foot over the edge of the bed and squeezing the calf; plantarflexion of the foot and ankle then suggests the Achilles tendon is intact.

The examiner should be aware of gravity simulating active movements. For example, a leg lying flat, fully extended on the couch does not mean the extensor mechanism of the knee is intact. In all knee injuries make sure the patient can actively straight leg raise and get their leg off the couch.

Similar pitfalls exist in the upper limb with gravity straightening the elbow. In order to assess triceps function and elbow extension, ensure the patient can actively extend against resistance from the examiner or against gravity.

Beware of trick movements. Patients with a complete rupture of the quadriceps can still walk with the leg locked in full to slight hyperextension by using the iliotibial band. Patients with complete rupture of the Achilles tendon can still actively plantar flex the foot and ankle using the long toe flexors.

Neurovascular examination

This is an important part of extremity examination and summary terms such as 'neurovascularly intact' are best avoided. It is preferable to clearly document the examination performed and its findings, along with a conclusion about the function of the particular neurological or vascular anatomy tested. On occasion you may not be able to examine all movements due to injury or casts.

It is important to examine and document findings before and after any manipulation or cast application, to ensure no change. A radial nerve palsy in association with a humeral shaft fracture that occurs at the time of injury may be treated expectantly. If, however, radial nerve function is lost after application of a cast or brace, the nerve should be explored. Most peripheral nerves have a motor and sensory component; document both sensibility and motor function.

Laceration or rupture of major vessels may result in life- and limb-threatening injury and should be dealt with as an emergency (see ATLS guidelines). Complete laceration or occlusion of a major vessel is obvious and seldom missed. In contrast, occult vessel injuries must be considered and actively excluded. In 30% of knee dislocations (tibio–femoral dislocation) a vascular injury will occur **(Figure 28.2)**.

The presence of palpable pulses does not exclude a significant vascular injury and an intimal flap may develop, progress and thrombose over time. Repeated evaluation is necessary, before and after any intervention (manipulation/cast).

In injuries commonly associated with vascular injury, such as knee dislocations, occult injury should be actively excluded with an angiogram. If an angiogram is not performed, repeated thorough vascular evaluation of the limb should be undertaken for the first 24–48 hours.

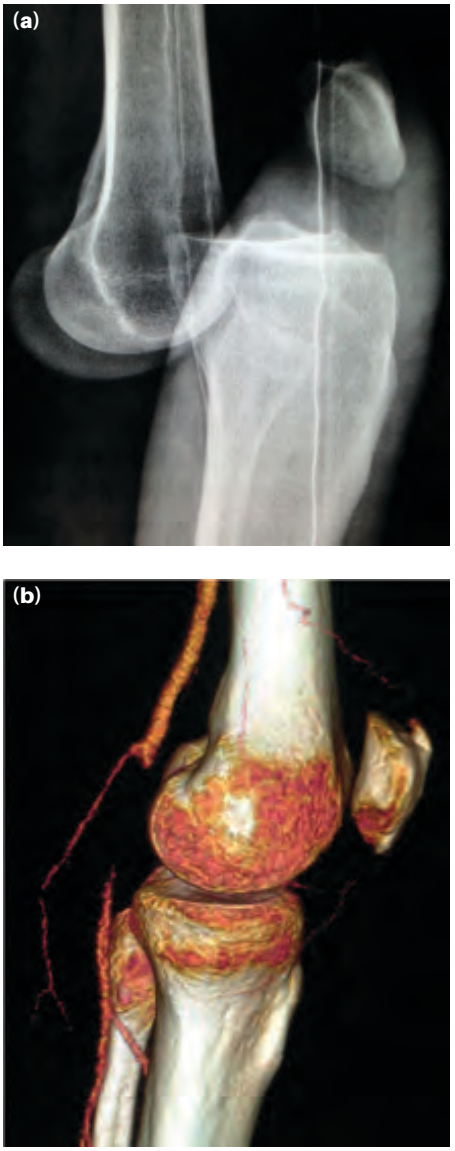

Figure 28.2 **(a)** Initial anterior tibio–femoral dislocation. **(b)** Post-reduction computed tomography angiogram showing complete blockage of the popliteal artery with reconstitution distally from a collateral blood supply.

Investigations

The mainstay of extremity trauma investigation remains radiography of the affected limb to see if there is a bony injury. However, this is not the sole investigation available.

Haematological investigations

Simple haematological investigations are seldom useful in the evaluation of single limb injury. In the polytrauma patient a full blood count, serum biochemistry, clotting factor and creatinine kinase may be useful. A blood gas, including PH, base excess and lactate, can be useful to show the severity of the injury and the response to resuscitation.

Ultrasound

Ultrasound is very useful to define soft tissue injuries. Fractures of the bones can be visualised on ultrasound but generally it is reserved for the soft tissues. One limitation of ultrasound is the variability depending on the experience of the sonographer.

Radiography

Radiographs are the mainstay in the initial evaluation of suspected extremity trauma. The rule of 2's should be remembered:

- 2 views – ensure acquisition of 2 views in orthogonal planes to avoid missing a fracture out of plane on the first radiograph view. For shoulder injuries ensure at least an AP and axillary or modified axillary view (**Figure 28.3**);
- 2 joints – radiographs are required of the joint above and the joint below the fracture;
- 2 occasions – sometimes the fracture may not be initially visible; a second series of radiographs should be undertaken after 10–14 days if suspicion of bony injury persists. The classic injury here is a scaphoid fracture. If initial scaphoid views are normal, consider repeating them 10–14 days later, if pain and tenderness in the anatomical snuff box persists;
- 2 sides – in paediatric injuries it can be useful to consider a radiograph from the opposite and uninjured side if doubt exists. With improved access to atlases of normal variants this is less important.

Computed axial tomography

Computed axial tomography (CT) is very good for characterising the bony anatomy of injuries, allowing for multiplanar reconstruction of injury anatomy and providing other 3D information. It is very useful for periarticular injuries, where the exact characterisation of the bony injury is essential.

Surface volume rendering is a useful addition allowing for easier visualization of the injury (see **Figure 28.1b**). CT angiography (see **Figure 28.2b**) may be added, providing information on the vascular anatomy. One disadvantage of CT is the dose of radiation involved.

Figure 28.3 Radiographic series of the same patient demonstrating the value of 2 views in 2 planes and the true value of the axillary view in shoulder trauma. **(a)** Anteroposterior radiograph of the shoulder, initially reported as normal. **(b)** Lateral scapula radiograph, initially reported as normal; humeral head slightly posteriorly directed. **(c)** Axillary view – true value of axillary view shown with obvious posterior dislocation of the glenohumeral joint.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) provides 3D information without the radiation involved in CT. It provides useful information, particularly about the soft tissues. MRI can provide information on the blood supply to the bone; for example, avascular necrosis of the proximal pole of the scaphoid.

One disadvantage of MRI is the time taken to acquire the image; patients suffering from claustrophobia find the experience traumatic. Another issue is that the magnetic field may be disrupted by non-ferrous metal and the presence of ferrous metal contraindicates an MRI.

MRI angiography can also be performed providing information about the vascular anatomy.

Nuclear medicine scans

Technetium 99 nuclear medicine scans register osteoblastic activity and may be used to demonstrate occult fractures; for example, an undisplaced scaphoid fracture.

Summary box 28.1

History, examination and investigations

- Follow a systematic approach
- History requires sufficient detail of injury
- History can be organised in the AMPLE format
- Examination follows look, feel, move, special tests approach
- Investigations will include radiographs with rule of 2s observed
- Selective use of special investigations can help diagnosis

DESCRIPTION AND CLASSIFICATION OF THE INJURY

Soft tissue injury

There are several classification systems for soft tissue injuries, the Tscherne classification for closed injuries, the Gustilo and Anderson for open injuries (*Table 28.2*) and the Ganga classification of severe open injuries.

The first step of soft tissue injury characterisation is to decide if this is an open or closed fracture. An open fracture being any fracture where the fracture haematoma communicates with a breach in the epithelial lining, not just skin. For example, an open pelvic fracture may communicate with the vagina or rectum and a mandibular fracture through the mucosa of the mouth (see Open fractures).

Consider all the soft tissues crossing the zone of injury, as it is possible to get a closed rupture or avulsion of tendons without a break in the skin. Consider the possibility of a neurovascular injury. (see Neurological injury). Severe soft tissue injury in the presence or absence of a fracture may still lead to compartment syndrome (see Compartment syndrome).

TABLE 28.2 Gustilo and Anderson open fracture classification.

Type	
I	A low energy open fracture with a wound less than 1 cm long and clean
II	An open fracture with a laceration more than 1 cm long without extensive soft tissue damage, flaps or avulsion
III	Characterised by high energy injury irrespective of the size of the wound. Extensive damage to soft tissues, including muscles, skin, and neurovascular structures, and a high degree of contamination. Multifragmentary and unstable fractures
Subgroups of type III	
A	Adequate soft tissue cover of a fractured bone after stabilisation
B	Inadequate soft tissue cover of a fractured bone after stabilisation (i.e. flap coverage required)
C	Open fracture associated with an arterial injury requiring repair

Source: Gustilo RB, Mendoza RM, Williams DN. Problems in the management of type III (severe) open fractures: a new classification of type III open fractures. *J Trauma* 1984; **24**: 742–6.

Neurological injury

Seddon classified nerve injuries into neurapraxia, axonotmesis and neurotmesis:

- neurapraxia – no loss of nerve sheath continuity or peripheral Wallerian degeneration. Recovery potential good may take months if the pressure is removed from the nerve;
- axonotmesis – nerve sheath remains intact, with internal nerve fibre damage with Wallerian degeneration. The neural tube (endoneurium) can guide the regenerating nerve fibres to their target. Good potential for recovery; nerve fibre regrowth is at 1 mm per day;
- neurotmesis – complete division of the nerve, nerve sheath and nerve fibre. Functionally poor outcome without surgical intervention to restore continuity of the nerve sheath.

Although the Seddon classification is useful in understanding the pathoanatomy, the critical discriminator in defining recovery, and need for possible surgical intervention, is the presence or lack of continuity of the enveloping nerve sheath.

Bony injury

Description

Describing the bony injury depends on several characteristics and includes the:

- name of the bone that has been injured;
- region of bone injured;
- pattern of fracture line: transverse, oblique, spiral, segmental or multifragmentary (**Figure 28.4**);

Ramon Balgoa Gustilo, surgeon, Hennepin County Medical Center, Minneapolis, MN, USA.
John T Anderson, surgeon, Hennepin Medical Center, Minneapolis, MA, USA.
Sir Herbert J Seddon, trained at St Barts, London University, and the Royal National Orthopaedic Hospital, Stanmore, UK. He became the second Nuffield Professor of Orthopaedic Surgery in Oxford.

- presence of compression; compression fractures occur when cancellous bone collapses; vertebral wedge compression fracture;
- presence of displacement of the fracture fragments, undisplaced or displaced;
- type and degree of displacement (Figure 28.4):
  - angulation;
  - translation;
  - rotation (Figure 28.5);
  - shortening;
- presence of pre-existing pathology;
- associated joint pathology, dislocation or subluxation.

In children and adolescents the fracture line may be incomplete due to the plastic, less brittle nature of their bones (Figure 28.6) These incomplete fractures are called greenstick fractures, where one tension cortex fails. If the compression cortex buckles, they are called torus or buckle fractures. Paediatric bone may also simply undergo plastic deformation without a visible fracture line.

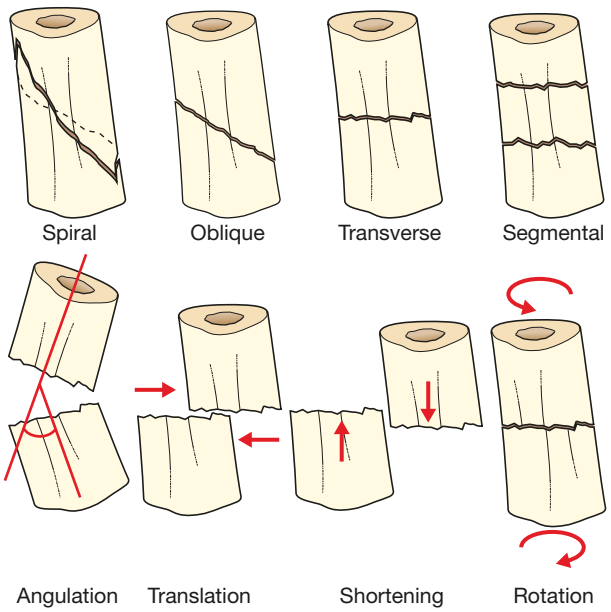

Figure 28.4 Descriptive terms for fractures.

Summary box 28.2

Describing an injury

Use plain language to describe:

- Location
- Soft tissue component
- Bony injury

Classification

For each specific bony injury there may be several injury specific classification systems.

Figure 28.5 Describing fractures: the importance of rotation. **(a)** Anteroposterior (AP) view of the knee seen at the top of the radiograph and lateral view of the ankle at the bottom, showing a spiral fracture at the junction of the middle and distal thirds of the tibia. **(b)** AP radiograph of the ankle on the same patient. Note the varied diameter of the fracture fragments; this implies rotational deformity. The distal fragment has translated laterally by 50%. There is no significant angulation on this view.

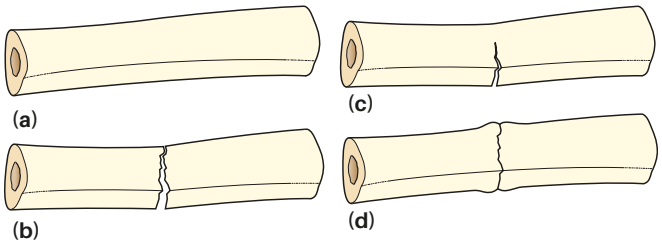

Figure 28.6 Types of bony injury: **(a)** uninjured bone; **(b)** adult transverse fracture failure across the whole bone; **(c)** greenstick fracture; the bone has failed on the tension side; **(d)** torus or buckle fracture; the bone has failed on the compression side.

AO CLASSIFICATION

The AO (*Arbeitsgemeinschaft fur Osteosynthesefragen)* system provides a comprehensive classification of all fractures (Figure 28.7). The first number defines the bone injured and the second number the segment of bone injured: proximal metaphysis, diaphysis, distal metaphysis. The letter and number that follows further defines the nature of the injury (Figure 28.8). For example, the previously described humeral fracture would be 12-A1 (1 humerus, 2 diaphysis, A simple, 1 spiral). (For more detail see Further reading.)

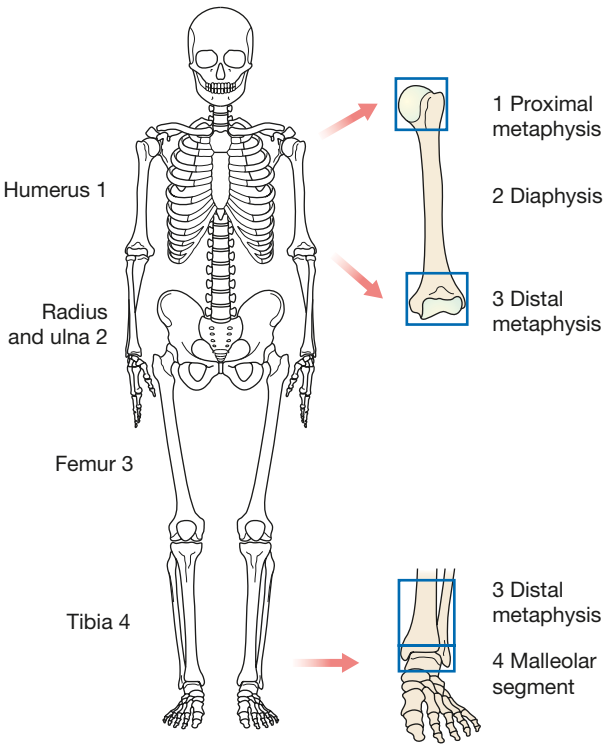

Figure 28.7 The AO classification system: the first two numbers specify the site of the fracture.

GROWTH PLATE INJURY CLASSIFICATION

In children and adolescent injuries involvement of the growth plate (physis) can lead to abnormal growth or growth arrest, either complete or partial. Complete growth arrest will result in length abnormalities and partial growth arrest might result in angular deformities. The severity of injury to the physis is classified in the Salter–Harris classification which considers whether the fracture line passes through the epiphysis, physis, metaphysis or combinations of all above. Salter–Harris described five and Mercer Rang added the sixth (**Figure 28.9**):

- Type I – simple fracture line just involving the physis. Seldom affects growth.
- Type II – fracture line through the physis exiting through the metaphysis, producing a metaphyseal fragment. Seldom affects growth.
- Type III – fracture line through the physis exiting through the epiphysis (intra-articular). Seldom affects growth, but intra articular affecting joint surface.
- Type IV – fracture line across epiphysis, cross physis and across metaphysis. This injury can cause focal fusion of the physis leading to abnormal growth.
- Type V – a crush injury of the physis. Growth disturbance is common and may be the first radiological sign of an injury.
- Type VI – injury to perichondral structures by direct trauma. Rare injury, high chance of abnormal growth.

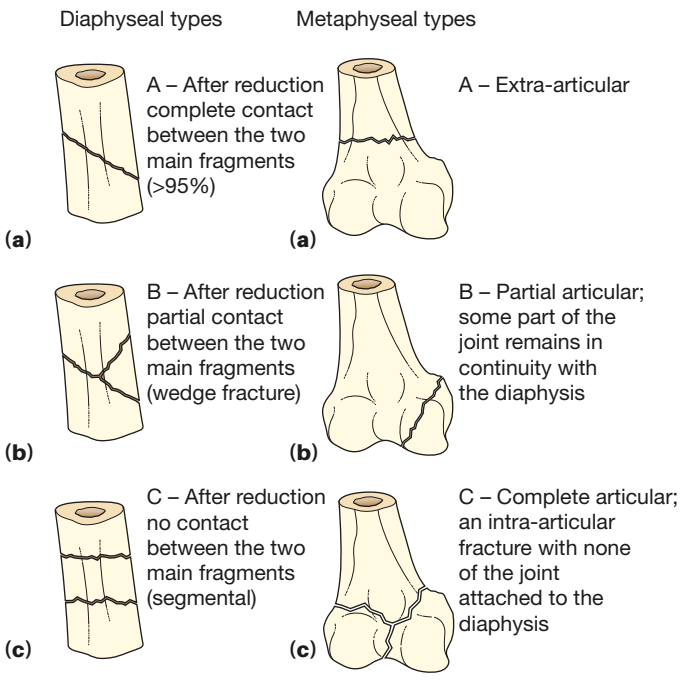

Figure 28.8 The AO classification system: the letter defines the nature of the fracture.

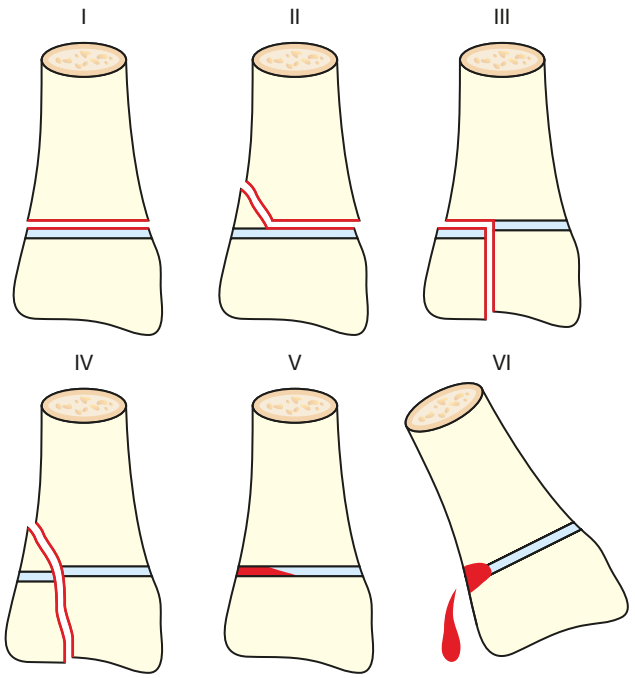

Figure 28.9 The Salter–Harris classification of growth plate injuries.

FRACTURE HEALING

It is useful to review fracture healing, as it relates to treatment and outcome. Following a fracture, bone can heal in two different ways: direct (primary) bone healing or indirect (secondary) bone healing:

- **Direct bone healing**, as the name implies, heals directly with bone and without callus formation. It happens in an environment of cortical apposition and absolute stability with no movement or gap between the fracture fragments. The normal osteoclastic-mediated remodelling of bone is directed across the fracture interface. Osteoclastic cutting cones cut across the fracture line, with following osteoblasts laying down lamellar bone across the fracture.
- **Indirect bone healing** involves a transition from one tissue to another with callus formation. It is the most common form of bone healing. Following the injury, haematoma fills the gap at the fracture site. In response to a varying strain and under the influence of bone stimulating factors, the tissue undergoes differentiation, from haematoma to fibrous tissue and then to soft callus, followed by mineralisation and formation of mature bone. The amount of strain determines the nature of tissue it differentiates into; under 100% leads to fibrous tissue, under 10% soft callus, less than 2% hard callus and progressive mineralisation. Hence a little movement is good, too much movement is bad.

Terminology of bone healing after fracture

Union

The fracture has healed sufficiently from a clinical perspective to withstand physiological loads, with very little pain and minimal tenderness at the fracture site. Radiologically a fracture has united when the callus bridges the fracture site.

Delayed union

This description can be applied to a fracture that is slow to heal and which has not healed in the expected time frame.

Non-union

This description can be applied to a fracture that has not healed and shows no potential to heal without further intervention. A non-union can also be defined as a fracture that fails to demonstrate clinical or radiological improvement over 3 months. In general, you do not describe a fracture as 'non-union' until 6 months after the injury.

There are a number of different types of non-union: atrophic, hypertrophic and infected. It is useful to consider certain factors with regard to the non-union; the biology of the fracture, the mechanical environment and the host (patient factors like diabetes and smoking).

In an atrophic non-union, the problem is generally a biological one, with a lack of stimulus or blood supply. A hypertrophic non-union generally occurs when there is too much movement at the fracture site.

Consolidation

Follows union and demonstrates that the bone has returned to normal strength. Radiologically it is demonstrated by the return of the normal cortical pattern.

Remodelling

In children, and to a lesser degree in adults, bone remodels based on the forces passing through it.

Summary box 28.3

Fracture healing

- Direct - cortical apposition and absolute stability
- Indirect – secondary bone healing, requires some movement

TREATMENT

The main principle of extremity fracture management builds on the classical concept of reduction and stabilisation of the fracture. Treatment can be considered under the following headings (see *Apley's system of orthopaedics and fractures* [Further reading]):

- reduce;
- hold;
- heal;
- rehabilitate.

The main objective of any treatment is to return the patient to normal function as soon and as safely as possible. Broadly speaking, treatment may be operative or non-operative, with differing risks and benefits (*Table 28.3*).

Reduce

The first thing to consider is the degree of displacement of the fracture fragments. It is useful to ask the following question: if the bone were to heal in this position, would it be compatible with optimum function in the short and long term?

In general, fractures involving the articular joint surface need to be reduced perfectly back to their original anatomical

TABLE 28.3 Risks and benefits of fracture treatment.

Benefits	Risks
Pain relief	Anaesthesia
Prevention of infection	Introduction of infection
Restoration of anatomy	Damage to soft tissues and neurovascular structures
Early movement of the limb	
Early movement of the patient	Devitalising bone
Improved function	Need for implant removal
Reduced risk of secondary arthritis	Financial cost (cost of treatment)
Financial cost (time off work)	

position, to restore normal joint movement in the short term and avoid degenerative joint disease in the long term – **intra-articular fracture = anatomical reduction**.

Fractures that do not involve the joint surface generally require restoration of mechanical alignment of the joints above and below. The fracture fragments do not need to be reduced perfectly. Focus on acceptable alignment, length and rotation – **extra-articular fracture = mechanical alignment**.

In children an extra articular fracture has the ability to remodel, and therefore an increased degree of displacement can be accepted.

If a fracture requires reduction, it can be reduced open or closed. A closed reduction is where the bones are manipulated and moved without exposing the bone. Often the best way to reduce a fracture is to reverse the sequence of injury, without tearing or further damaging the intact soft tissues and periosteum. On occasion this may mean exaggerating the deformity (Figure 28.10).

Open reduction is utilised if an acceptable closed reduction is not achieved or likely to succeed. A combination of closed and open methods can be used to reduce a fracture. Care should be taken during an open reduction not to unduly devitalise the fracture fragments by stripping intact periosteum. A balance between maintaining a blood supply to the fracture fragments (biology) and achieving anatomical reduction needs to be maintained.

Adequacy of reduction is complex and depends on many factors. If intra-articular, the joint surface involved needs to be considered. By way of an example, 2 mm of residual displacement of the articular surface may be accepted in the patella and tibial plateau and may be acceptable in fractures involving the distal radius, but is not acceptable in the condylar joints of the fingers. In general consider the relative thickness of the articular surface involved.

On occasion consideration on how you intend to subsequently hold the fracture may affect the primary form of reduction.

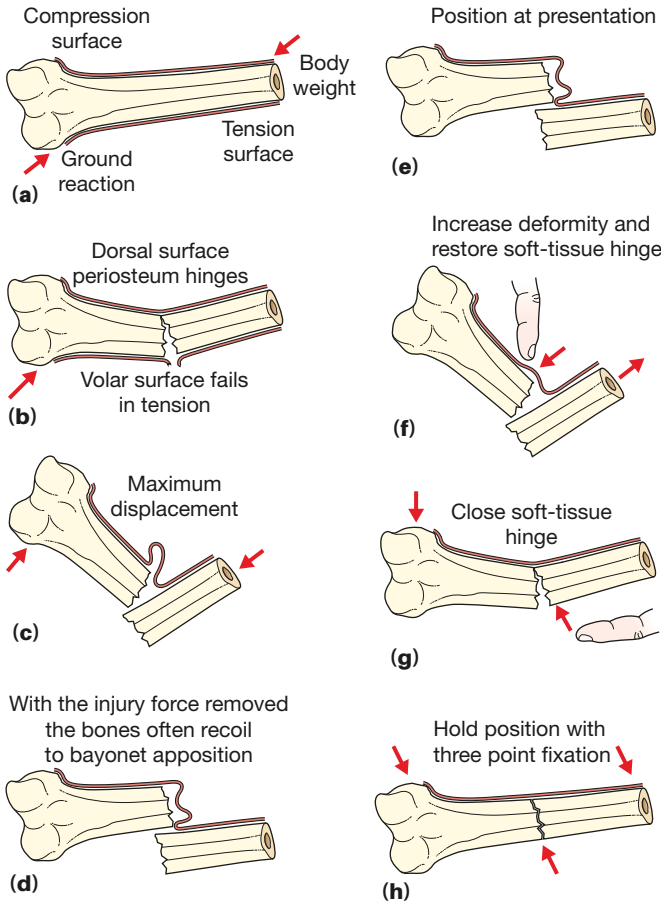

Figure 28.10 **(a-d)** Representation of how the mechanism of injury causes the bony and soft-tissue injury. **(e-h)** Representation of how the residual mechanical properties of the tissues may be used to effect and hold a reduction.

Summary box 28.4

Reduction

- Reduction has two components: reducing the fragments and assessing adequacy of reduction
- Reduction can be performed open or closed
- The principle is to reverse the movement which created the fracture
- Over-angulation allows the intact periosteum to guide the fragments into position

Hold

If the fracture fragments are in an acceptable position, or have been reduced into an acceptable position, they then need to be held in that position until they heal. When choosing a method to hold a fracture the aim is to:

- optimise the biological and mechanical environment to create the most favourable conditions possible for fracture healing;
- minimise the period of disability by speeding up the healing process or providing enough stability to return to normal function while the fracture heals.

There are several methods of holding fracture fragments in place:

- plaster cast/ splints;
- traction;
- Kirschner (K-) wires;
- external fixation;
- plates and screws
- intramedullary nails.

Note: Arthroplasty may be used where fragments cannot be held together.

On occasion a combination of holding methods may be used; for example, K-wires and a moulded cast in the case of a simple extra-articular distal radial fracture. It is important to consider the way of holding the reduction in terms of outcome and ensure this is part of the overarching goal to optimise the patient's return to function as safely and fast as possible.

For example, a displaced clavicle fracture in a 10 year old has a 99% chance of sound union within a few months if treated non-operatively. In contrast, a displaced multifragmentary mid-third clavicle in a 35-year-old female will carry a 35% chance of going on to a non-union at 6 months. Therefore, even though this fracture may heal with non-operative treatment, with appropriate explanation and shared decision making, a patient may choose to have surgery early in order to get back to normal function as soon as possible.

Stability can be absolute or relative:

- **Absolute stability.** Implies no displacement or movement and is achieved by accurate anatomical reduction with compression across the fracture fragments to optimise the environment for direct bone healing. This is desirable in intra-articular fractures, where callus at the fracture site might inhibit movement. Intra-articular fractures require an anatomical reduction and absolute stability.
- **Relative stability.** Allows a little movement at the fracture site, optimising the environment for callus formation and indirect bone healing.

Selected examples of achieving absolute and relative stability are shown in **Figure 28.11**.

Plaster cast and splints

Plaster casts and splints are generally used to hold stable fractures or supplement the fixation of unstable fractures (e.g. below elbow cast applied to a distal radial fracture after K-wire fixation [see below]).

Plaster casts come in two forms: plaster of Paris and synthetic casting materials. Plaster of Paris is the preferred method in acute fractures and, where more support is needed, it is easier to mould plaster of Paris than a synthetic cast. In acute injuries, where there is a risk of swelling and compartment syndrome, a backslab will often be applied. A backslab is not always positioned on the dorsal surface as the name suggests, but is a partial cast where a layer of plaster of Paris or synthetic cast is applied along roughly half the circumference. An alternative to a backslab includes a full cast that is split along its full length to allow for swelling. The use of an incomplete cast does not remove the risk of swelling and compartment syndrome and must always be accompanied by close clinical observation.

Moulding of the cast is an art form requiring appropriate skill to achieve the desired effect. Three point moulding is used to control the position, often using the intact dorsal periosteal hinge to mould against (see **Figure 28.11**). Often, a correctly moulded cast will look crooked, leading to the adage 'Bent casts make straight bones' **(Figure 28.12)**.

Commercially available upper limb and lower limb splints provide comfort, support and social protection to stable fractures. Ease of application and the ability to remove make them very useful for patients to return to activities of daily living including bathing and showering.

The advantages and disadvantages of plaster cast and splint usage are described in *Table 28.4*.

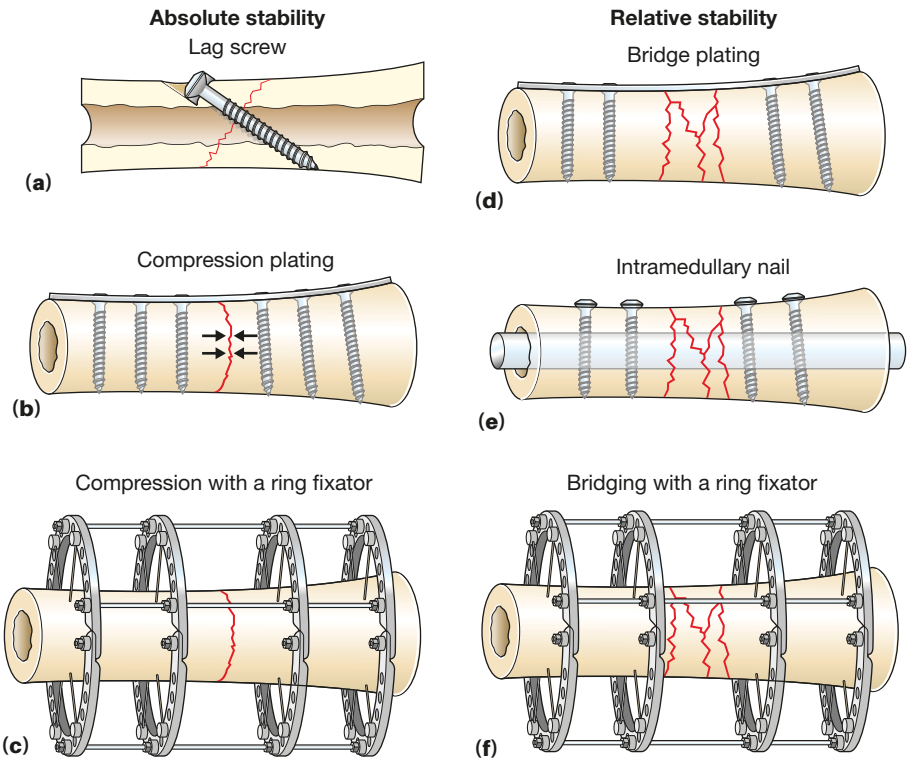

Figure 28.11 (a-f) How absolute and relative stability can be achieved. The same implants may be used to achieve different mechanical effects.

Plaster of Paris is a white crystalline powder, calcium sulphate hemihydrate $CaSO_4$-$0.5H_2O$, which sets hard when water is added to it.

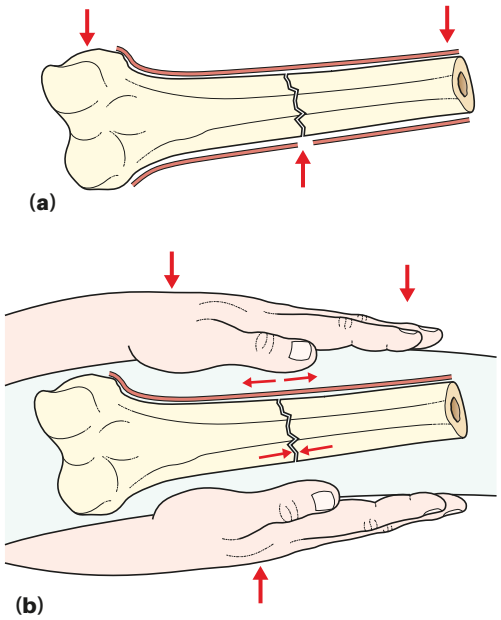

Figure 28.12 **(a)** The position achieved at the end of the manipulation described in Figure 28.10. **(b)** Demonstration of how by moulding the cast the intact periosteum is kept under tension and the bone under compression; thus, the remaining mechanical properties are used to achieve stability.

TABLE 28.4 Advantages and disadvantages of casting and splinting.

Advantages	No wound
	No interference with fracture site
	Cheap
	Adjustable
	No implants to remove
Disadvantages	Limited access to the soft tissues
	Cumbersome (particularly in the elderly)
	Interferes with function
	Poor mechanical stability
	'Plaster disease' – joint stiffness and muscle wasting

Traction

Traction is defined as a stretching force on a limb to pull a fracture straight. After appropriate pain control, simply pulling on the limb using manual traction will help realign fracture fragments, returning overall length and alignment. If the fracture is simple and off ended, it may require more than simply pulling to reduce it (see reduction in **Figure 28.10**). Once reduced, however, continued longitudinal traction will often hold it reduced.

A traction force can be applied and maintained by a variety of systems and techniques. It is easy to apply traction to any extremity; however, it is cumbersome and requires a fixed point to pull on. This can require the patient to be fixed to one place and limit return to normal function. (See *Table 28.5* for advantages and disadvantages.)

TABLE 28.5 Advantages and disadvantages of traction.

Advantages	No wound in zone of injury
	No interference with fracture site
	Materials cheap
	Adjustable
Disadvantages	Restricts mobility of patient
	Expensive in hospital time
	Skin pressure complications
	Pin site infection
	Thromboembolic complications

Traction is often used in the treatment of femoral shaft fractures in adults as a temporary measure for comfort and to allow transfer of the patient, until definitive fixation can be undertaken. A Thomas splint is applied to the limb initially in a static fashion **(Figure 28.13a)** and then, once in bed, balanced traction is applied to help pull the leg out to length and pull the splint off the ischial tuberosity **(Figure 28.13b)**.

The anchor point on the limb may be either skin, by applying an adhesive or non-adhesive bandage, or skeletal traction, where a pin is placed in the proximal tibia or distal femur.

A common everyday example of traction is the use of a collar and cuff in proximal humeral fractures. When the patient is upright, the lower part of the arm, under the action

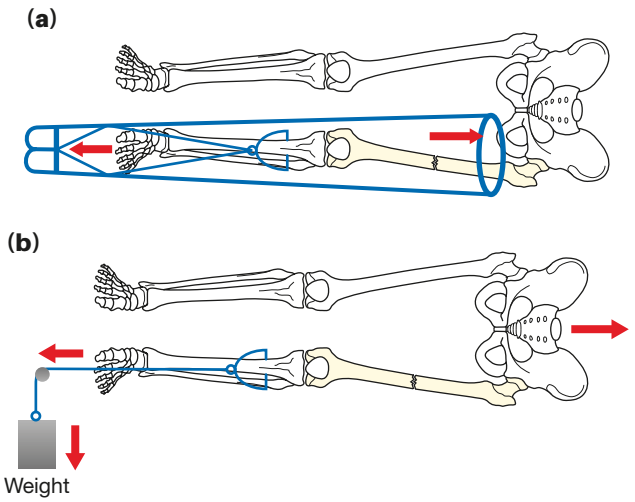

Figure 28.13 **(a)** Static traction with a Thomas splint. The force and counterforce are contained within a static system. The load is applied to the patient through the tibial traction pin via a cord tightened with a Spanish windlass. The counterforce is applied through pressure by the splint on the ischial tuberosity. **(b)** A dynamic system in which the load is applied by weights suspended from the tibial pin and the counterforce is the patient's own weight.

Hugh Owen Thomas, 1834–1891, general practitioner of Liverpool, UK, is regarded as the 'founder of orthopaedic surgery', although never holding a hospital appointment preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

of gravity, provides longitudinal traction, thus aligning the fracture fragments.

Kirschner wires

Kirschner wires (also called K-wires) are smooth, non-threaded, thin flexible wires often between 0.9 and 2.5 mm in diameter. They are used to hold small fragments in place. They may be used in a temporary fashion intraoperatively to hold fracture fragments in place until definitive fixation with plates and screws can be performed. They are inexpensive and simple to use. Moreover, they are extensively used for definitive fixation of injuries around the hand and wrist. The flexible nature of the wires can often require supplementation, as a hybrid construct of K-wires and plaster cast fixation.

In distal radial fractures the wires are placed percutaneously after closed reduction, the trailing end of the wire is left proud of the skin and the end bent to limit wire migration. K-wires around the distal radius can be removed in the clinic setting 4–6 weeks after insertion. Complications of K-wires include pin site infection, wire breakage, loss of fixation and wire migration. Wire migration may be a potentially serious problem in certain locations. It is not advisable to use non-threaded K-wires around the shoulder girdle and clavicle as migration into the thoracic cavity and heart has been reported (*Table 28.6*).

External fixation

External fixation involves percutaneous placement of metal rods or fine wires into bone to anchor a metal frame on the outside (*Table 28.7*). The frame construct itself may be comprised of tubular rods with connectors, or circular ring constructs 'ilizarov' type of frame. Hybrid variations are infinite, with combinations of anchor fixation modalities and frame constructs. The Taylor spatial frame allows for gradual correction of deformity (**Figure 28.14**).

The major drawback of external fixation is that they can be cumbersome to the patient and pin site infection can be a problem (*Table 28.7*).

Specific indications for external fixators include:

- emergency stabilisation of a long bone fracture in the polytrauma patient thought too unwell to have other interventions; 'damage control orthopaedics';
- stabilisation of a dislocated joint after reduction (e.g. a spanning fixator across the knee joint while the vascular surgeons repair an arterial injury with a knee dislocation);
- complex periarticular fractures to provide temporary stabilisation and allow the soft tissue damage to recover before definitive fixation (e.g. a distal tibial [pilon] fracture);
- fractures associated with infection;
- treating fractures with bone loss.

TABLE 28.6 Indications for K-wire insertion.

Temporary fixation
Definitive fixation – with small fracture fragments (e.g. wrist fractures and hand injuries)
Tension band wiring (fractures of the patella and olecranon)
Temporary immobilisation of a small joint

TABLE 28.7 Advantages and disadvantages of external fixation.

Advantages	No interference with fracture site
	Adjustable after application: alignment; biomechanics
	Soft tissues accessible for plastic surgery
	Rapid stabilisation of fracture
	Hardware easy to remove
Disadvantages	Pin site infection
	Interferes with plastic surgical procedures
	Soft-tissue tethering
	Cumbersome for the patient

Plates and screws

Plates and screws can be used in many different ways. A 'lag screw' can be used to generate compression across a fracture site, optimising the environment for direct bone healing. Similarly, compression can be achieved using a dynamic compression plate. A plate might also be used simply to neutralise forces, buttress a fracture or work as an internal external fixator (see **Figure 28.11**).

In general, plates and screws are used where possible in articular and periarticular fractures where an anatomical reduction is required, often via open means, followed by the application of the plate and screws to achieve a rigid construct. In extra-articular fractures, where mechanical alignment is required together with relative stability, one option is the use of locking plate technology. This allows a closed reduction and percutaneous placement of the plate with locking screws to create an internal construct, which behaves like an external fixator. Injury-specific plating systems have revolutionised the ability to treat certain injuries, with plates pre-bent and pre-shaped for specific anatomical regions and specific injury patterns. (See *Table 28.8* for the advantages and disadvantages of plate fixation.)

Intramedullary nails

Diaphyseal fractures are best suited for intramedullary nailing. Where mechanical alignment is required together with relative stability, they allow for indirect bone healing. After nail insertion, mechanical alignment is checked particularly for length, alignment and rotation. Locking screws are then placed proximally and distally to maintain length and alignment. Intramedullary nailing of metaphyseal and articular fractures is a challenge. However, with improved implant

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany, introduced the use of skeletal traction wires in 1909.
Gavriil Abramovich Ilizarov, 1921–1993, orthopaedic surgeon, Kurgan, Western Siberia, Russia. He did not attend school until he was 11 years old as his family was too poor to buy him shoes.

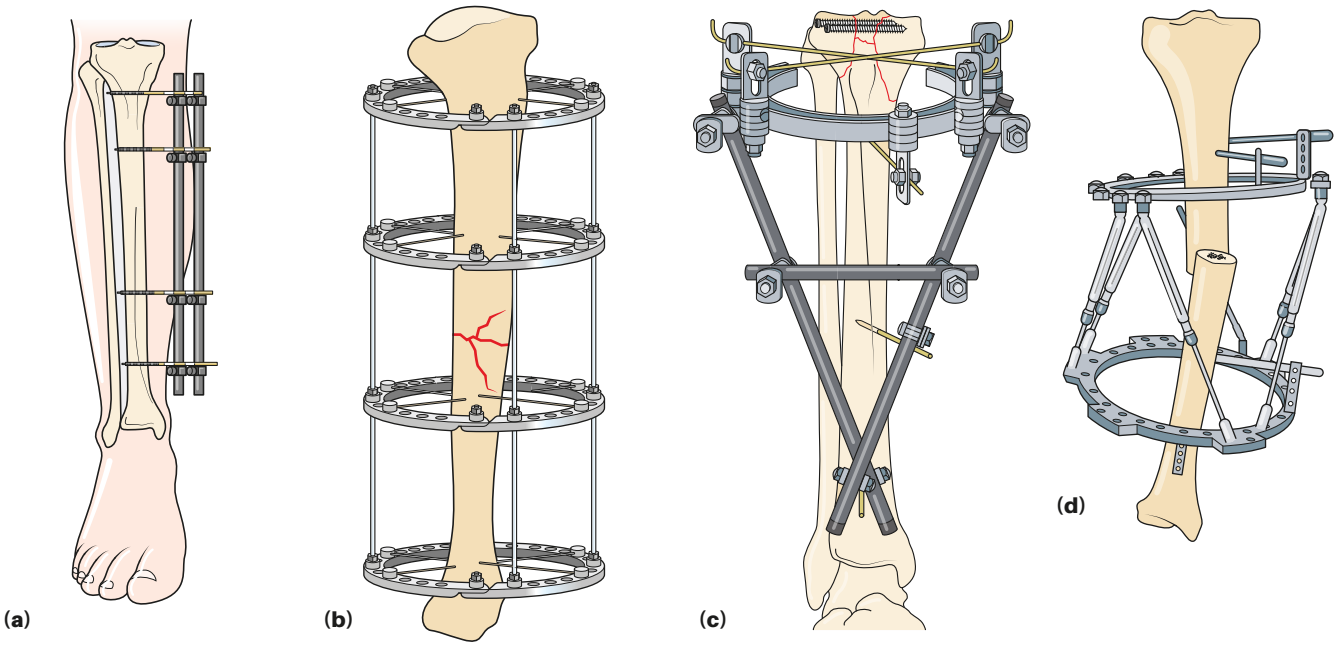

Figure 28.14 **(a)** Monolateral tubular frame with metal rod (half pin anchorage to bone. **(b)** Circular ring fixator with fine wire anchorage to bone. **(c)** Hybrid circular/tubular rod frame construct with combination of half pin and fine wire anchorage to bone. **(d)** Taylor spatial frame; allows for gradual correction of deformity.

TABLE 28.8 Advantages and disadvantages of plate and screw fixation.

Advantages	Can be used when anatomical reduction is required
	Allows early mobilisation
	Can provide absolute or relative stability
Disadvantages	May interfere with fracture site
	Periosteal/soft-tissue damage
	Does not normally allow for immediate load-bearing
	Potential for infection
	Metalwork complications
	Possible need for plate removal

TABLE 28.9 A comparison of reamed versus unreamed nailing (an assumption is that nails used unreamed are usually thinner than those used reamed).

	Reamed IMN	Unreamed IMN
Insertion time	Longer	Quicker
Time to union	Shorter	Longer
Size of implant	Larger	Smaller
Reduction of distal fractures	Easier	More difficult
Strength of construct	More	Less

IMN, intramedullary nail.

TABLE 28.10 Advantages and disadvantages of intramedullary nailing.

Advantages	Minimally invasive
	Early weight-bearing
	Less periosteal damage than open reduction and internal fixation
	Seldom need removal
Disadvantages	Increased risk of fat emboli/chest complications
	Infection difficult to treat
	Difficult to remove if broken

design and the ability to lock the nails very distally and in multiple directions, the indications for intramedullary nailing is expanding.

Intramedullary nails may be placed in an unreamed or reamed fashion. Reaming is the process whereby the intramedullary canal is widened slightly to allow passage of a larger diameter nail, relating to the last reamer size used. *Table 28.9* compares reamed to unreamed nails.

Intramedullary nailing can be a technically demanding procedure. The advantages and disadvantages are summarised in *Table 28.10*.

Arthroplasty

Arthroplasty is indicated in certain acute circumstances: articular fractures that are not reconstructible, or injuries where the vascularity of the articular segment is compromised (e.g. displaced intracapsular femoral neck fracture in an older patient).

The patient demographics and functional demands need to be considered in choosing arthroplasty as a treatment option. Implant longevity and level of activities following implant insertion need to be matched. Traditionally, arthroplasty for trauma was limited to hip and shoulder hemiarthroplasty.

Total hip replacement, acute distal femoral replacement, radial head replacement, total and hemi-elbow arthroplasty, and reverse polarity shoulder arthroplasty are current treatment options for older patients with osteoporotic periarticular fractures. The selection of a particular technique will depend on clinical evidence and our previously stated aim to return patients to optimal function as soon as possible. It should be considered in the context that it can be expensive and require considerable other resources to make the procedure safe and long lasting.

Heal

Time to fracture healing depends on several factors: patient co-morbidities, the age of the patient, bone involved (upper limb or lower limb), patient factors (diabetes), choice of treatment. Well known factors that slow down bone healing include diabetes mellitus (doubles time to union), diminished blood supply (peripheral vascular disease, vascular injury at time of injury), smoking, non-steroidal anti-inflammatory drugs and infection at the fracture site.

Several chemical and mechanical methods have been attempted to enhance fracture healing, including bone marrow injections into the fracture site and other orthobiologics such as bone morphogenic proteins. Mechanical methods include controlled axial micromotion (using an external fixator), electromagnetic stimulation and low intensity pulsed ultrasound. There is good basic scientific evidence to support their theoretical benefit; however, to date there is little clinical evidence for their use in the primary treatment of closed fractures.

Rehabilitate

The main aim of treatment is to return the patient to a similar level of pre-morbid function as quickly as possible. Rehabilitation begins as soon as feasible. It is often not necessary to wait until bone union before beginning rehabilitation. It is important to move the affected joints and the joints in close proximity to the fracture (e.g. elbow and shoulder exercise while in a cast for a distal radial fracture), limiting global stiffness and wasting of the muscles on that limb.

TREATMENT BY FRACTURE LOCATION

In general, the principles of treatment described above are dependent on the fracture location: diaphyseal, metaphyseal and intra-articular.

Table 28.11 outlines some indications for operative stabilisation.

TABLE 28.11 Indications for surgery in limb trauma. The main indication is that operation will produce a better outcome; the principles are given below.

A fracture requiring treatment that is unsuitable for non-operative measures
Open fractures
Failed non-operative management
Multiple injuries
Pathological or impending pathological fractures
Displaced intra-articular fractures
Fractures through the growth plate, where arrest is possible (Salter–Harris type III–V)
Avulsion fractures that compromise the functional integrity of a ligament/tendon around a joint (e.g. olecranon fracture)
Established non-unions or malunions

Diaphyseal fractures

Extra articular fractures do not require an anatomical reduction, but rather a mechanical restoration by correction of length, alignment and rotation (**Figure 28.15**).

Angular malunion of a diaphyseal fracture of the weight-bearing long bones will lead to abnormal joint forces on the joint above and below, leading to pain and secondary degenerative joint disease.

Diaphyseal fractures are generally well suited to intramedullary fixation techniques, as previously discussed.

Summary box 28.5

Diaphyseal fractures

- Restore length, alignment and rotation
- Consider whether primary or secondary bone healing is the objective
- Radius and ulna need precise reduction to function

Metaphyseal fractures

In the AO classification metaphyseal fractures are classified into A type – extra-articular, B type – partial articular, and C type – complete articular.

In A type fractures, joint congruity is not an issue and as such the principles of mechanical alignment, length and rotation need to be considered. Fixation of metaphyseal fractures is less predictable with intramedullary nailing, therefore plate and screw fixation, external fixation or, in the smaller joints, K-wire fixation is used. Metaphyseal fractures are close to the joint and so consideration is given to stable fixation to allow early joint movement and rehabilitation.

Intra-articular fractures

AO type B and type C fractures are intra-articular and as such the principles of treating intra-articular fractures need to be respected; namely, anatomical reduction of the articular sur-

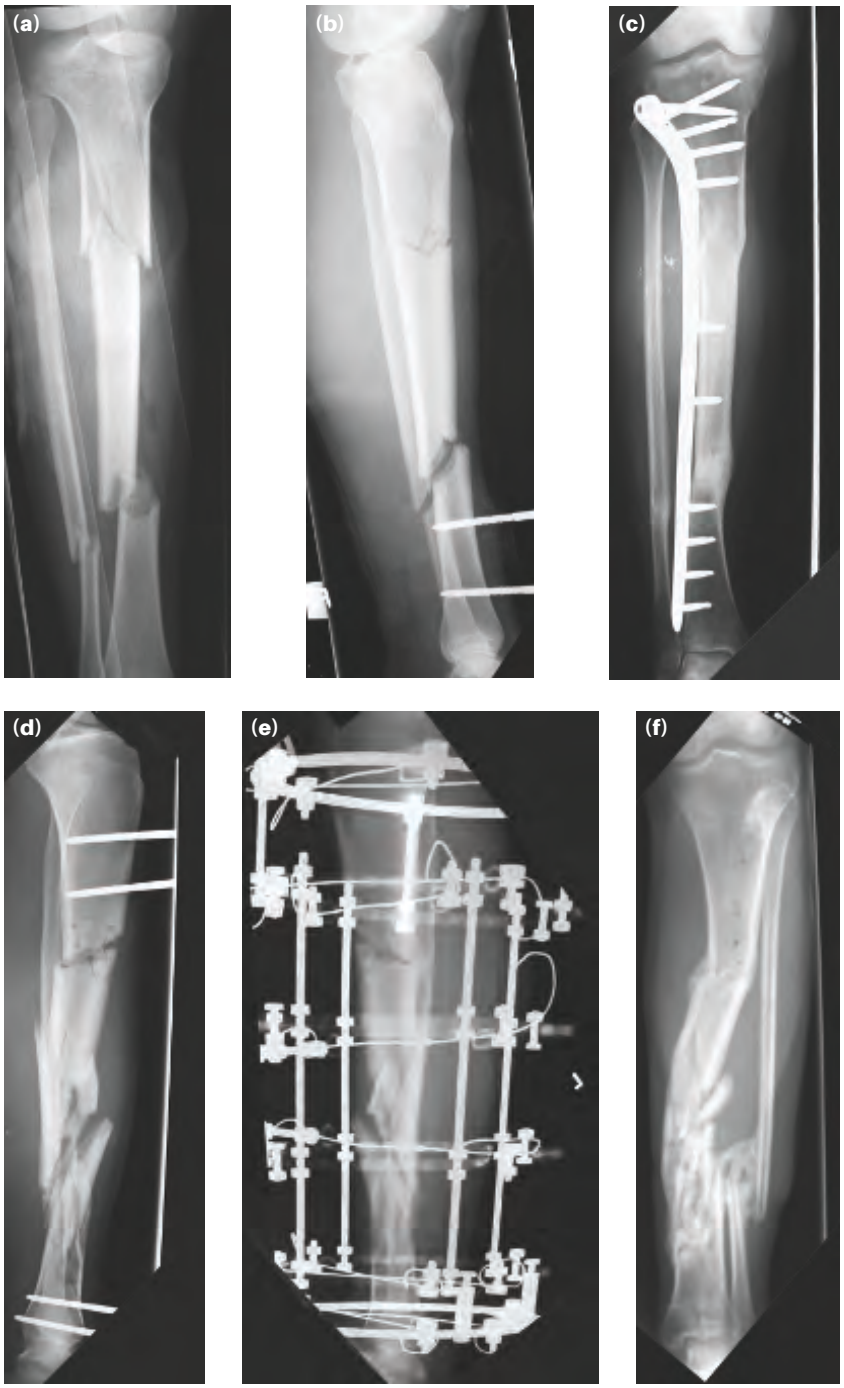

Figure 28.15 **(a)** and **(d)** are C-type or segmental tibial fractures. Each was a high-energy injury; **(b)** and **(e)** show a temporary spanning external fixator applied in each case; **(c)** and **(f)** show definitive relative stability was achieved with different methods of bridging fixation. Healing was by indirect means in both cases. Despite irregularities at the fracture sites the overall position was satisfactory and function was good.

face and rigid stabilisation to allow early joint movement and avoidance of degenerative joint disease (Figure 28.16). However, these principles have to be balanced with the increased wound complications of open surgery and devitalising bone fragments with excessive exposure of the bone.

Osteoporotic intra-articular fractures are a considerable challenge. Although anatomical reduction may be achieved, rigid fixation devices may cut out of soft bone. Injectable bone substitutes may be used to fill bone voids and augment fixation. If stable fixation is not possible, then consideration might be given to non-operative treatment and delayed joint replacement or, on occasion, primary joint replacement may be undertaken.

In type C fractures where the articular surface has separated from the metaphysis, the articular surface is initially anatomically reduced with temporary K-wires or lag screws and then the articular block is reattached to the shaft (Figure 28.17).

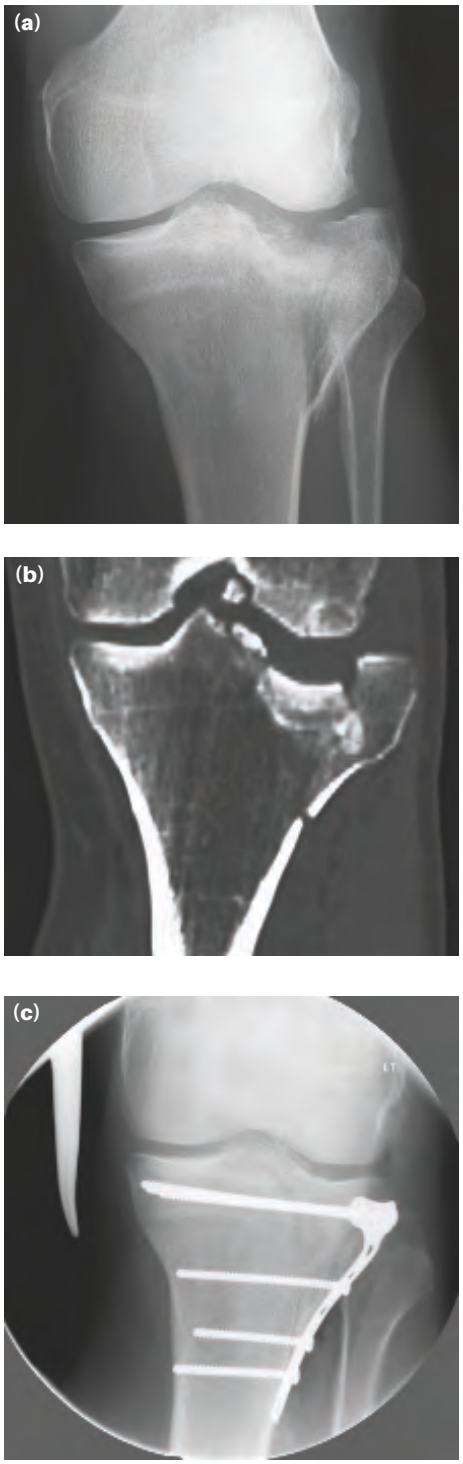

Figure 28.16 A B-type or partial articular fracture. **(a)** Plain radiograph; **(b)** computed tomography clarifies the injury; **(c)** fixation with plate and screws achieving compression across a previously reduced fracture.

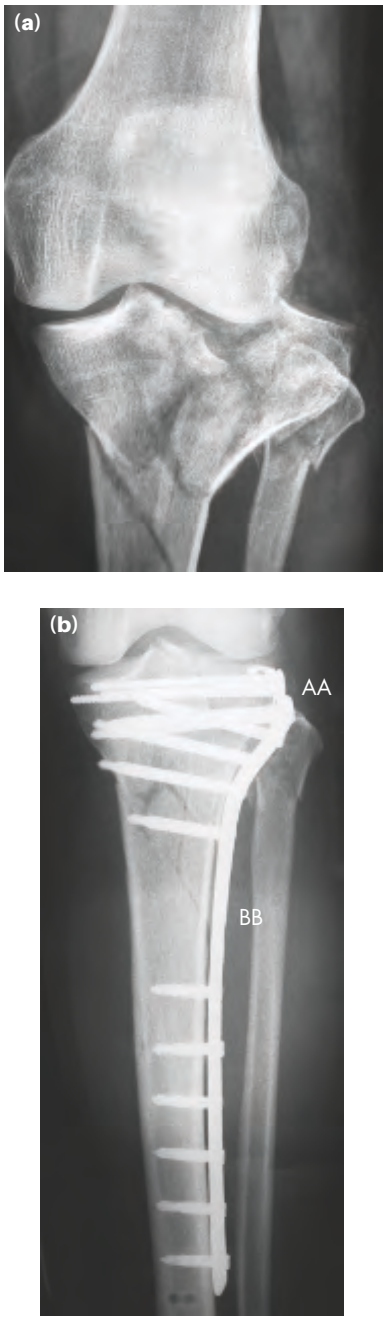

Figure 28.17 **(a)** A C-type proximal tibial articular fracture (i.e. none of the joint remains attached to the diaphysis). **(b)** The small plate and screws (AA) are used to compress the joint fragments, aiming for absolute stability. The heavy duty fixed angled device (BB) spans the fracture and provides relative stability

TREATMENT BY REGION (FROM TOP TO TOE)

Scaphoid fracture

The blood supply to the scaphoid enters distally and supplies the scaphoid in a retrograde fashion. As such, a displaced waist of scaphoid fracture interrupts the blood supply to the proximal pole, leading to avascular necrosis. An undisplaced fracture of the scaphoid may not be visible on the initial

radiographs. If a patient is tender in the anatomical snuff box following a fall on the outstretched hand, special scaphoid view radiographs should be requested (**Figure 28.18**).

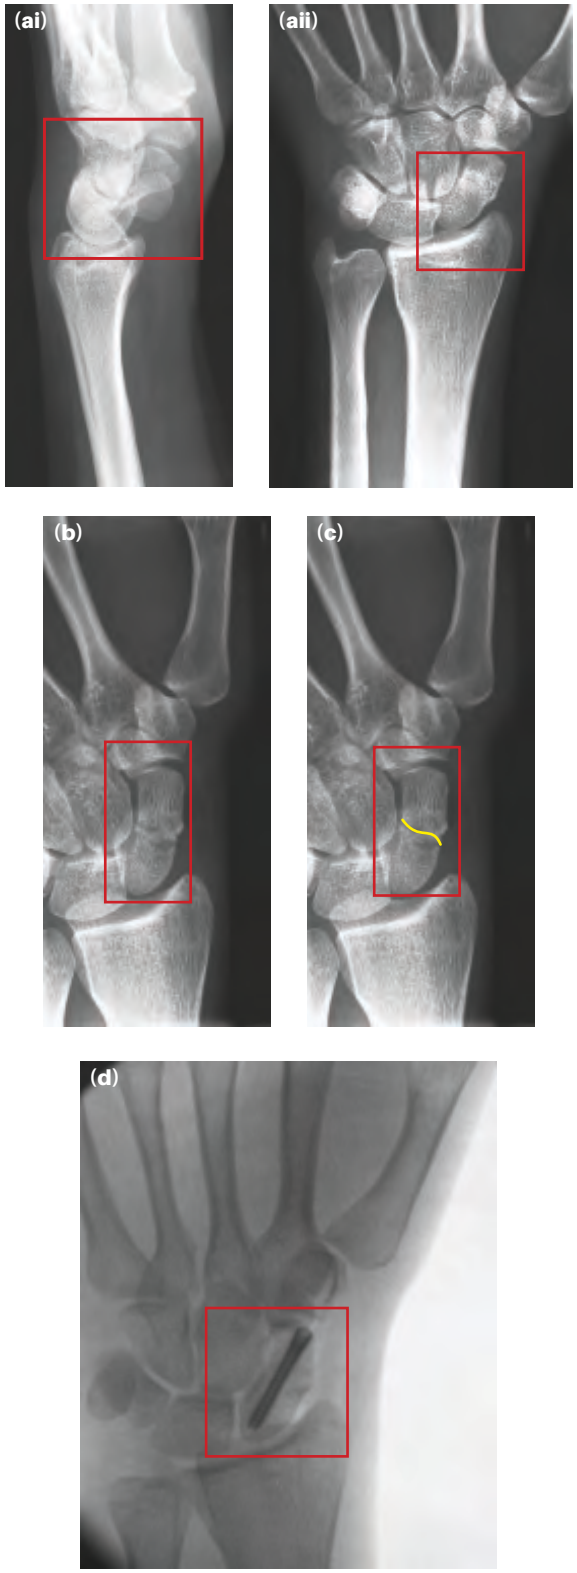

Figure 28.18 Scaphoid fracture. **(ai, aii)** Anteroposterior and lateral views in which the injury is difficult to see; **(b, c)** oblique views with the fracture line highlighted; **(d)** in this case of a young patient, the fracture was treated with early fixation.

If a fracture is not evident on the initial radiographs and the patient remains tender in the anatomical snuff box, then treat as a suspected scaphoid fracture until a fracture is actively excluded. The standard protocol of a suspected scaphoid fracture is to immobilise the wrist and examine again 10–14 days later. If tenderness remains, repeat the scaphoid views. If facilities and resources allow, an earlier diagnosis may be made with a bone scan, MRI or CT.

Undisplaced fractures can be treated non-operatively in a below elbow cast. It is not necessary to include the thumb as a routine. In displaced or unstable fractures (>1 mm) consideration should be given to open reduction and rigid fixation with a headless compression screw. Complications of scaphoid fractures include: non-union, avascular necrosis, malunion and carpal instability.

Carpal instability

The most commonly involved carpal bone is the lunate. A lunate dislocation is where the lunate bone dislocates out of the radiocarpal joint. In a perilunate dislocation the lunate remains in the radiocarpal joint and the rest of the carpus dislocates around the lunate. Lunate and perilunate dislocations are easily missed unless careful attention is paid to carpal alignment on the lateral radiograph (**Figure 28.19**). Review of the radiographs should particularly ensure the anatomical location of the lunate in the radiocarpal fossa and that the capitate in the 'cup' of the lunate is maintained.

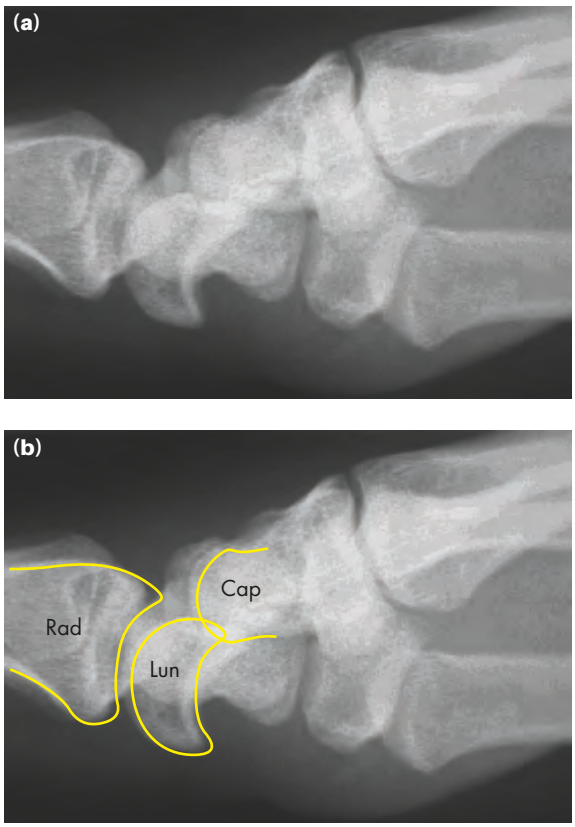

Figure 28.19 Perilunate dislocation. **(a)** A plain lateral radiograph of the wrist; **(b)** the outline of the perilunate dislocation is highlighted. Cap, capitate; Lun, lunate; Rad, radius.

Acute injuries should be reduced closed initially to remove pressure from the median nerve. Anatomical carpal alignment is difficult to hold and therefore surgical reconstruction of damaged intrinsic ligaments, together with K-wire fixation of the carpal bones, is often undertaken. Ligamentous healing is slow and may be incomplete. K-wires are kept in place for 8 weeks and the wrist casted or splinted for 3 months.

Thumb metacarpophalangeal ulnar collateral ligament.

Injury to the thumb metacarpal ulnar collateral ligament is a unique injury often termed 'game keepers' thumb or 'skiers' thumb. Due to the unique anatomical arrangement of adductor policis, if the ligament undergoes complete rupture the aponeurosis may become interposed, inhibiting ligament to bone healing. A rupture of the ulnar collateral ligament should be suspected when an ulnar directed force is directed across the metacarpophalangeal (MCP) joint. A tender swelling on the ulna side of the MCP joint may signify the 'Stener' lesion. Increased laxity may be clinically evident, and if there is uncertainty, stress radiographs can demonstrate the degree of injury. Complete ruptures with a Stener lesion (interposed aponeurosis) require open reduction of the ligament to restore bone contact, with a suture anchor repair of the associated ulnar collateral ligament.

Distal radial fractures

Extra-articular (type A) fractures of the distal radius may displace in a volar or dorsal direction. It is possible to reduce volar displaced fractures (Smith's fracture) of the distal radius with a closed technique. However they tend to be unstable and displace if held in a cast. Hence most volar displaced extra articular distal radial fractures are reduced and held with a volar buttress plate (**Figure 28.20**).

Most dorsally displaced fractures (Colles' fracture) can be addressed with closed reduction and held in a cast. However, some will slip or collapse with cast treatment, and so close review for the first few weeks is advocated.

Fractures with significant initial displacement and dorsal comminution are at risk of early and late collapse. After thorough counselling the patient may choose to have the fracture reduced and then held surgically with K-wires, plate and screw fixation (volar or dorsal) or external fixation. The K-wires may be placed across the fracture fragments or intrafocally, going through the fracture site. The latter can be used to help reduce the fracture and then used to lock the fracture fragments in place (**Figure 28.21**)

Treatment is individualised based on patient and fracture pattern factors. Intra-articular fractures (types B and C) of the distal radius require anatomical reduction of the joint surface; a gap or step of less than 2 mm can be accepted in the radius. The distal radius fails fairly predictably with splitting of the lunate fossa fragment in the coronal plane and separation of the radial styloid.

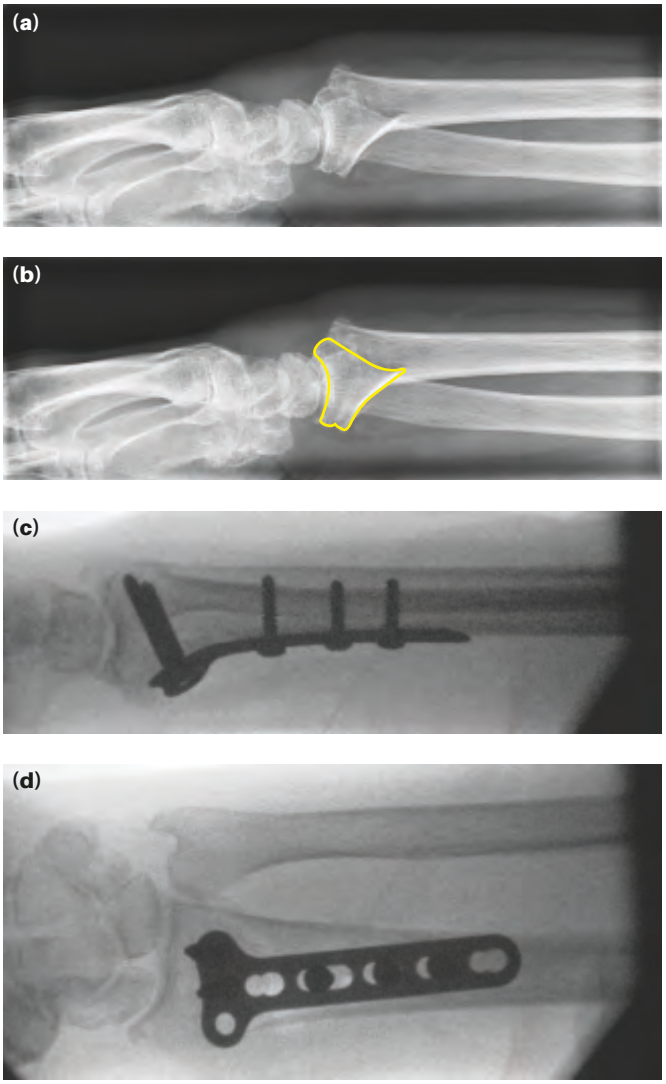

Figure 28.20 An A-type or extra-articular metaphyseal fracture. A plain lateral radiograph of this Smith-type fracture **(a, b)**. Fracture fixed to a plate. There is no interfragmental compression. The plate is pushing against or buttressing the distal fragment **(c, d)**.

If a closed reduction can be achieved with manipulation, the fracture fragments can subsequently be held with K-wires, plate and screw fixation or external fixation. The most common form of treatment is closed reduction and percutaneous K-wire fixation, supplemented with a plaster cast for 4–6 weeks.

Forearm fractures (radius and ulna)

Fractures of the diaphyseal shaft of the radius and ulna are technically, in the anatomic sense of the word, extra-articular. However, the forearm bones work together, being coupled at the proximal and distal radioulnar joints to allow

Robert William Smith, 1807–1873, Professor of Surgery, Trinity College, Dublin, Ireland, described the reverse Colles fracture in 1847.
Abraham Colles, 1773–1843, President of the Royal College of Surgeons of Ireland (1802), Professor of Anatomy Physiology and Surgery (1804) and described distal radial fracture in 1814.

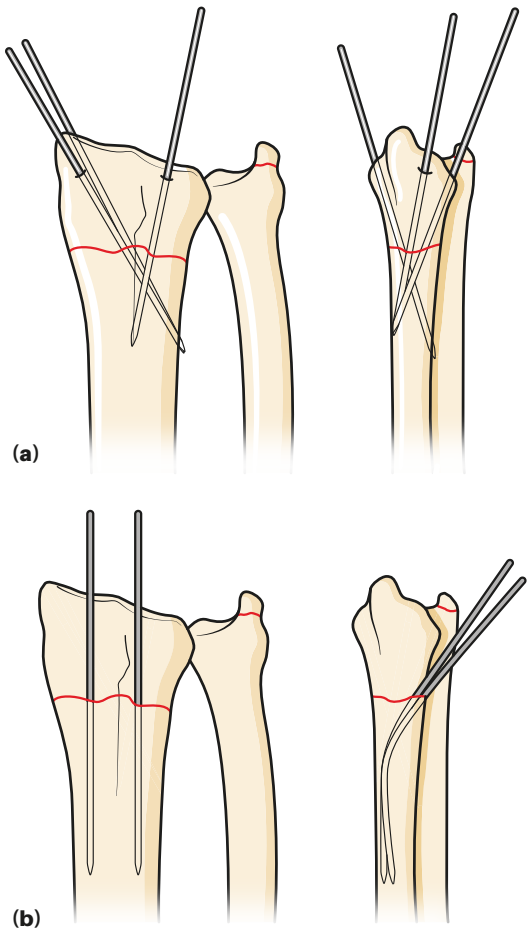

Figure 28.21 **(a)** K-wires placed across fracture fragments; **(b)** intrafocal K-wire used to help reduce the fracture.

for forearm pronation and supination. Therefore, when considering treatment the principles that apply to intra-articular fractures need to be considered: anatomic reduction and rigid fixation to allow for early joint motion. Most fractures that involve both radius and ulna in adults require open reduction, anatomic alignment and rigid plate fixation.

Isolated fractures of the ulna, the so-called nightstick fracture, are a little more controversial, as non-operative management is possible but in this location risks delayed union and non-union, hence treatment depends on patient factors. Operative fixation with plate and screw fixation is technically simple and allows early predictable return to function.

Olecranon fractures

Olecranon fractures may be displaced or undisplaced. Undisplaced fractures <2 mm gap or step at the articular surface can be treated non-operatively. In displaced fractures the extensor mechanism is interrupted and the articular surface requires anatomical reduction and stable fixation to allow early movement. Fixation may comprise K-wire and figure-of-eight tension band wiring or plate fixation. In multifragmentary fractures or fractures associated with an elbow dislocation, increased stability is required with the use of a plate and screws.

Humeral fractures

Fractures of the diaphyseal portion of the humeral shaft are extra-articular fractures and as such require mechanical alignment. Non-operative treatment with functional bracing will achieve union in an acceptable position within 12 weeks in over 80% of cases. Gravity can provide traction on the arm and in conjunction with a humeral brace help to hold alignment and allow early range of motion of the elbow. Active shoulder abduction is avoided until fracture union, to prevent varus deformity.

Shoulder movement must not be absent during treatment and so gravity assisted pendulum exercises are instituted early on to prevent shoulder stiffness. As the fracture approaches the metaphyseal region of the humerus it becomes more difficult to control with humeral bracing. Distal third extra-articular fractures of the humerus can be treated non-operatively in a humeral brace but have a tendency to go into varus. Articular fractures of the distal humerus require anatomical reduction and stable fixation to allow early joint movement.

Internal fixation is indicated for displaced intra-articular fractures, non-union or delayed union, open fractures, multiple injuries and those fractures not held in an acceptable position with brace treatment. Fixation of diaphyseal fractures can be achieved with intramedullary nailing or plate and screw fixation. Plate fixation is associated with higher union rates and lower rates of reintervention. (Figure 28.22).

Figure 28.22 **(a-c)** A B-type humeral shaft fracture. This fracture could not be controlled by non-operative means and was treated with lag screws protected by a plate.

The radial nerve is the most commonly injured nerve in humeral shaft fractures. Treatment of a humeral shaft fracture with a concomitant radial nerve palsy remains topical. Most will recover spontaneously. In general, if the nerve injury occurs at the time of the original injury, non-operative treatment can be considered. If it occurs after the injury, for example at the time of brace application, then it should be explored. When exploring the radial nerve, plate and screw fixation is then undertaken to stabilise the humerus.

Fractures of the proximal humerus

In fractures of the proximal humerus consideration is given to the vascularity of the humeral head. The most common classification of the proximal humerus is the Neer classification looking at the four individual pieces of the proximal humerus (articular head fragment, lesser tuberosity, greater tuberosity and the shaft).

If a fragment is displaced by more than 1 cm or angulated by more than 45 degrees in respect of another fragment, it is considered a part. As such, based on the fracture pattern, it may be undisplaced, 2 part, 3 part or 4 part. Consideration is then given to potential joint dislocation, anterior or posterior. The greater the number of parts, the higher the chances of interruption of the vascularity to the humeral head and the more complex the injury.

Three factors can be used to predict avascularity of the humeral head:

- fracture through the anatomical neck;
- loss of the medial hinge;
- less than 8 mm of bone along the medial calcar.

With displaced fractures, where the head is avascular, occurring in older patients who may have osteoporosis and other co-morbidities, consideration may be given to replacing the humeral head. This may take the form of an anatomical hemi-arthroplasty. One of the limitations of trauma hemi-arthroplasty for proximal humeral fractures involves reliable healing of the tuberosities and the rotator cuff. Increasingly, a primary reverse polarity shoulder prosthesis is being used. This implant does not rely on tuberosity healing, as it functions under the power of the deltoid muscle.

In younger patients reduction and fixation may be considered. A variety of fixation methods are available: percutaneous fixation, intramedullary nails and plate fixation.

Clavicle fractures

Diaphyseal fractures of the middle third of the clavicle have traditionally been treated non-operatively with a broad arm sling for comfort and social protection, followed by increasing use of the arm.

Most mid-third fractures of the clavicle will unite with non-operative treatment. There is, however, a subset of clavicle fractures that may be slow to heal and that do impact on shoulder girdle function. Displaced, comminuted fractures show a propensity to be slow to heal and increasing age and female gender further negatively impact on fracture healing. It has been shown that 2 cm of shortening of the clavicle impacts on shoulder girdle function, with weakness and fatigability when working above shoulder height.

Internal fixation with an intramedullary device or plate and screw construct can restore length, alignment and rotation. This can improve the speed and amount of functional restoration, but carries all the risks of surgical treatment. Treatment is individualised to patient needs and expectations.

Proximal femoral fractures

The blood supply to the femoral head is a prime consideration in treating femoral neck fractures. The blood supply comes via the hip capsule. The joint capsule anteriorly inserts along the intertrochanteric line and posteriorly half way along the femoral neck. Fractures proximal to the hip capsule are intracapsular and those distal to the capsule are extracapsular fractures.

Intracapsular femoral neck fractures

Intracapsular fractures are further broken down into whether they are displaced or undisplaced. Undisplaced intracapsular fractures are generally stable and interruption of the blood supply to the femoral head is rare. Therefore, treatment is aimed at ensuring the head fragment does not displace during rehabilitation. This can be achieved with cannulated screws inserted along the femoral neck into the head.

A displaced intracapsular fracture disrupts the blood supply to the femoral head and risks avascular necrosis. If the patient is physiologically young, reduction and internal fixation with cannulated screws or a dynamic hip screw might be attempted to preserve the native head.

If the patient is older and would benefit from a single operation, then the head may be sacrificed and replaced with a prosthetic head. Arthroplasty of the proximal femur may take the form of hemi-arthroplasty or total hip replacement, depending on patient's functional demands and surgical expertise available.

Extracapsular femoral neck fractures

If the fracture is extracapsular, vascularity of the head is not an issue. Extracapsular femoral neck fractures are subdivided into stable or unstable. Unstable fractures include a reverse oblique pattern or where the medial calcar is comminuted (lesser trochanter) fracture. Stable extracapsular fractures simply require connection of the head to the shaft, often using a dynamic hip screw (**Figure 28.23**).

In unstable fractures a dynamic hip screw can also be used, but due to the unfavourable mechanical environment relating to the loss of the medial calcar or a reverse oblique pattern, an intramedullary device might be considered.

Femoral shaft fractures

It is possible to treat diaphyseal fractures of the femoral shaft non-operatively. The fracture can be reduced and held in position until union with traction; however, it takes 3 months. This is a long time to be in hospital and carries all the potential risks of prolonged bed rest. Most femoral shaft fractures are treated with a locked intramedullary nail.

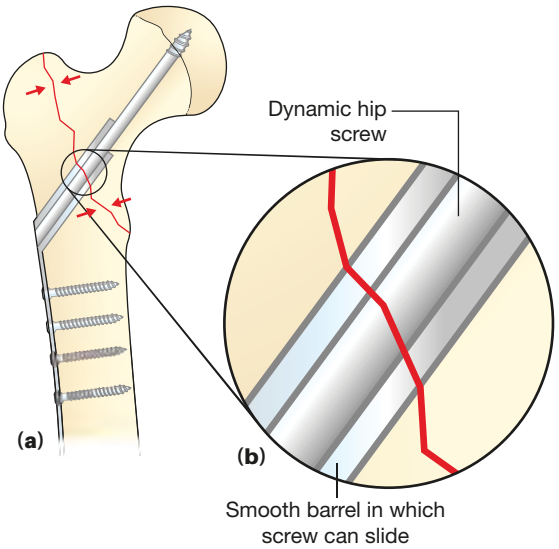

Figure 28.23 (a) A dynamic hip screw for fixing a trochanteric proximal femoral fracture. This allows for compression at the fracture site on load-bearing and protects the femoral head from penetration by the screw when the osteoporotic bone settles; **(b)** insert to show the sliding screw in the barrel.

With modern locked intramedullary implants, the patient will be up and out bed the following day and, if it is an isolated injury, home within a few days. Weight bearing depends on the fracture pattern and implant used. If there is a simple fracture pattern with cortical apposition, it will be possible to mobilise with crutches, weight bearing as comfort allows. Although it may still take 3 months or more for the fracture to unite, the implant will be able to carry the load until union, allowing earlier return to function out of the hospital.

Distal femoral fractures

Metaphyseal osteoporotic fractures of the distal femur are amenable to internal fixation with locked intramedullary nails or plate and screw fixation. If the fracture extends into the articular surface, reconstruction may be undertaken with cannulated screws augmented with intramedullary nailing or injury specific locking plates for the distal femur. More recently, arthroplasty has been considered in these situations, to allow early mobilisation.

Patellar fractures

Similar to olecranon fractures, undisplaced fractures where the extensor mechanism is intact can be treated non-operatively. Displaced fractures require anatomical reduction of the articular surface and reconstitution of the integrity of the extensor mechanism. The cartilage on the patella is very thick and as such increased amounts of displacement compared with other joints may be accepted.

Surgical treatment of simple displaced fractures can be achieved with two K-wires and figure-of-eight tension band wiring.

Multifragmentary patellar fractures can be very challenging. Patellar excision is an option but significantly reduces the mechanical advantage of the extensor apparatus. A tension band construct may be augmented by using circumferential wiring of the patella.

Tibial plateau fractures

Intraarticular fractures of the tibial plateau are common. Injuries may involve the lateral or medial side, or both. The joint articular surface may be split, depressed or a combination of both. A CT scan should be performed to see the full extent of the injury. Undisplaced fractures may be treated non-operatively with a hinged knee brace and progressive protected weight bearing over 8–12 weeks.

Displaced fractures require reduction and stabilisation. The articular surface once reduced is often held with plate and screw fixation or fine wire external fixation.

Tibial shaft fractures

For an undisplaced non-comminuted fracture of the tibial shaft, closed reduction and above knee cast is a safe and inexpensive treatment. At 4–6 weeks this may be converted to a patellar tendon below knee cast to allow knee movement. Prolonged casting can lead to stiffness of the knee and the subtalar joint. Cast treatment requires close and constant monitoring of the position of the fracture site. To correct minor angular deformities the cast can be wedged.

A patient may choose to have an intramedullary nail to allow free knee and ankle movement. This, however, risks infection of the implant and anterior knee pain. This is another situation where information and shared decision making can allow the patient to select the most appropriate treatment option.

For comminuted and complex fractures of the tibial shaft, although cast treatment is possible, intramedullary nailing is preferred despite the potential complications of infection and anterior knee pain. Fractures at the diaphyseal metaphyseal junction at the knee and ankle are difficult to hold with an intramedullary nail and as such may be held with a plate and screws.

Tibial fractures are also very amenable to external fixation with either a monolateral frame or fine wire circular construct, particularly where surgical skills and implants are not available for intramedullary nailing.

Ankle fractures

Ankle fractures are very common. As with all intra-articular fractures one should strive for an anatomical reduction. Due to the biconvex saddle shape of the articular surface, small amounts of talar shift significantly increase joint surface contact pressures.

It is useful to think of the ankle mortise as having two columns, a medial and lateral. Each column has a bony and a soft tissue component. On the lateral side there are the lateral malleolus, lateral collateral ligament and syndesmotic ligaments. On the medial side there are the medial malleolus and medial collateral ligament (deltoid ligament).

If only one column (either bony or soft tissue component) has been injured, then it is considered a stable injury and can be treated non-operatively with cast or splint protection for 6–8 weeks.

If both columns are involved or there is evidence of talar shift, it is an unstable injury. Depending on patient age and risk factors for wound complications, in general unstable fractures are treated with open reduction and rigid fixation to hold the fracture anatomically.

Non-operative treatment may be used for unstable fractures in elderly patients or patients with poor skin and unfavourable soft tissues, but this approach requires close observation and careful attention to casting technique.

Calcaneal fractures

The os calcis injury is most frequently caused by a fall from a height. It is important to exclude associated injuries to the lumbar spine that occur in 20% of cases. Most os calcis fractures involve the posterior facet of the subtalar joint. The severity of the injury is often best appreciated with CT scans (Figure 28.24). Treatment depends on the severity of injury to the subtalar joint and widening of the heel leading to peroneal impingement. An os calcis fracture is a significant injury and outcomes following surgical or non-operative treatment are unpredictable. On occasion in severe injuries, primary fusion of the subtalar joint may be considered.

Talus fracture

The talus consists of a head, neck and body. The most common injury is a talar neck fracture. This is caused by forced dorsiflexion of the forefoot (aviator's astralgus). The blood supply to the body of the talus is interrupted in displaced talar neck fractures. To optimise outcome and reduce the possibility of avascular necrosis, anatomical reduction and stable fixation of the talar neck should be performed.

Tarsometatarsal (Lisfranc) joint injuries

Injuries to the mid-foot are associated with significant morbidity ranging from a mid-foot sprain to complete rupture of the ligaments connecting the forefoot to the mid-foot. Injury

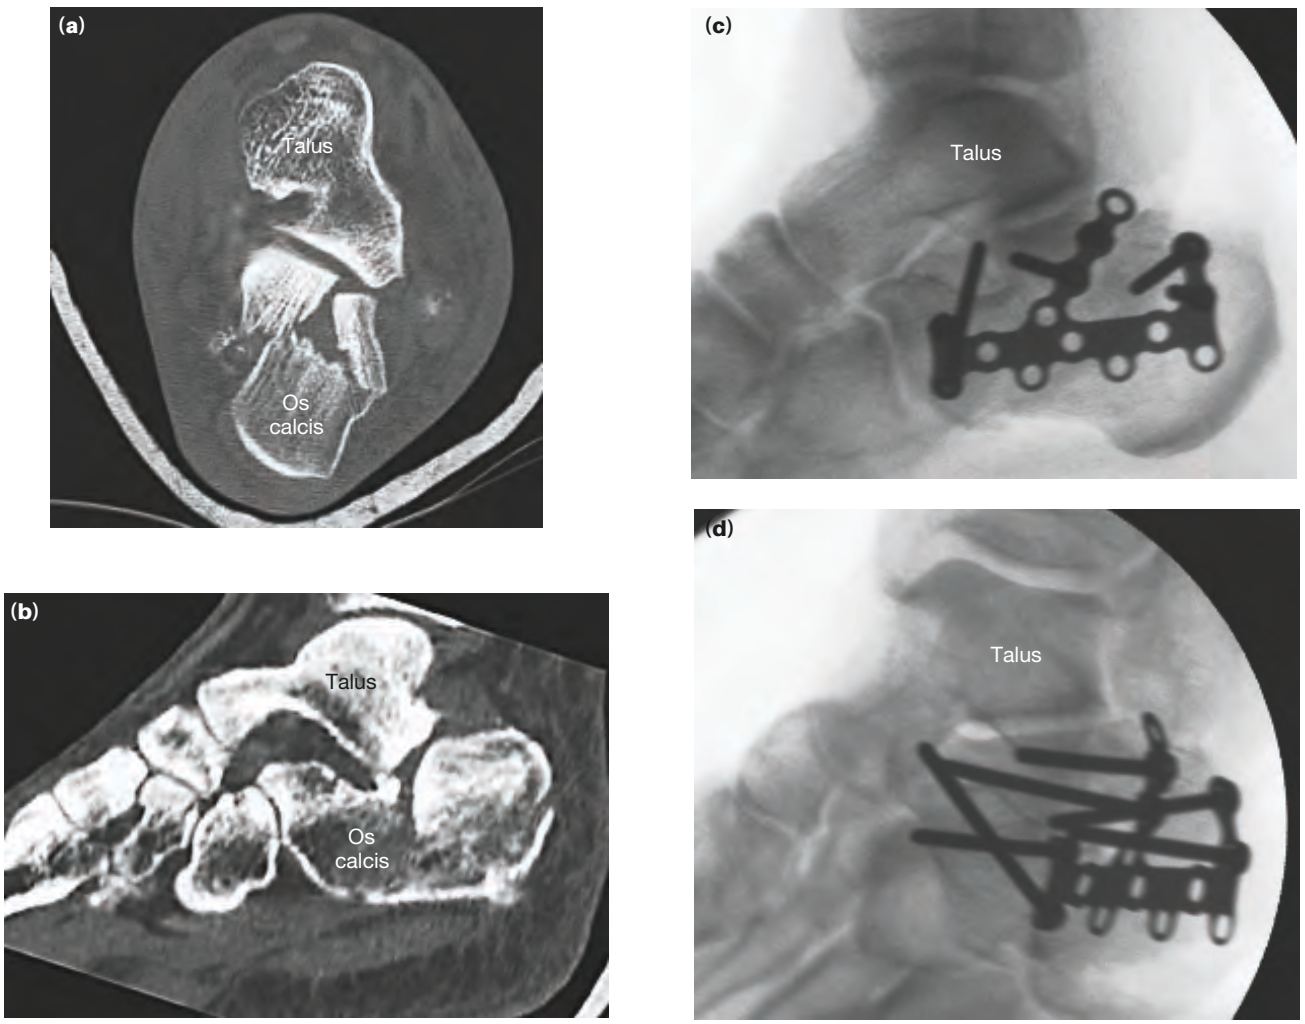

Figure 28.24 Axial **(a)** and sagittal **(b)** views of a displaced intra-articular fracture of the os calcis. **(c, d)** Intraoperative views of the reconstruction. Both the overall shape and the articular surface have been restored.

classically follows forced plantar flexion of the mid-foot. An alternative mechanism of injury are crush injuries where the foot is forced flat by a heavy weight. Lisfranc's ligament connects the second metatarsal to the medial cuneiform. Poorly treated injuries to the mid-foot lead to significant morbidity and if suspected, a CT of the foot should be undertaken. Treatment options range from closed reduction and plaster cast application to K-wire fixation. In severe cases primary tarsometatarsal fusion may be considered.

Achilles tendon rupture

Complete rupture of the tendo Achilles is a common injury; 20% of acute injuries are missed. Active plantar flexion of the ankle is still possible, although weak, through the use of the toe plantar flexors.

A classic history is a feeling as if kicked in the heel and feeling something go. The most common activity leading to Achilles tendon rupture is badminton or squash following sudden forced contraction of the calf.

On examination a palpable gap may be felt. The diagnosis is confirmed by placing the patient prone on the examination couch, feet off the edge of the bed; squeezing the calf fails to elicit passive plantar flexion of the foot. If doubt exists, an ultrasound can confirm the diagnosis.

Treatment of acute Achilles tendon rupture involves surgical repair or functional management. There is an increasing trend to functional management as opposed to direct surgical repair.

TREATMENT OF FRACTURES IN THE SKELETALLY IMMATURE

The treatment principles that were described for the adult, are equally applicable to the child (i.e. reduce, hold, heal, rehabilitate).

A major difference to consider is that in extra-articular fractures there is a remodelling potential, which means increased degrees of deformity may be accepted. Remodelling happens best in the plane of the joint and the closer the injury to the growth plate. Rotational and joint surface remodelling are poor. Fractures occurring near the site of greatest longitudinal growth will remodel the most (e.g. fractures around the distal femur have a greater remodelling potential than the proximal femur). The younger the patient the greater the remodelling potential. Significant remodelling essentially ceases when the growth plates have closed.

A further difference is that paediatric fractures heal more rapidly and as such do not need to be held as long as in the adult counterpart. Similarly, fixation does not need to be as rigid, as fracture union is more rapid.

Growth plate injuries require special mention (see Salter–Harris classification, **Figure 28.9**). In general, growth plate injuries should be anatomically reduced to minimise the potential for growth disturbance. However, in the process of reducing the fracture, further injury to the growth plate should be avoided.

Repeated manipulation of physeal injuries should be avoided. Injury to the perichondral ring and placing metal work across the physis (where possible) should similarly be avoided. If fixation necessitates crossing the physis, consider limited damage by using the smallest smooth K-wires with a single pass in the middle of the physis if possible.

The paediatric periosteum is often thick and very strong; this needs to be considered when reducing the fracture, requiring an exaggeration of the deformity and pushing the fracture back into place instead of just applying longitudinal traction. The perisosteal hinge should be preserved as it also allows for better holding of the fracture if it remains intact as previously described (see **Figure 28.9**).

Always consider the possibility of non-accidental injury, as discussed in Chapters 22 and 39.

SPECIFIC PAEDIATRIC INJURIES

Distal radial fractures

Fractures of the distal radius are very common in children. The bone either fails at the physis, leading to Salter–Harris type 2 fractures of the distal radius, or the metaphysis fails. The treatment principle of physeal fractures is to achieve an anatomical reduction. This can often be achieved with closed manipulation and the fracture held in position until healing with a below elbow plaster cast. Growth arrest is rare after physeal fractures of the distal radius.

Complete metaphyseal fractures of the distal radius require close attention **(Figure 28.25)**. In most cases an acceptable closed reduction can be achieved, but holding the distal fragment in an acceptable position can be challenging with cast immobilisation. Brachioradialis, which is attached to the radial styloid, is a continual deforming force. If non-operative treatment using a cast application is chosen, the position should be checked with radiographs weekly for the first 3 weeks, and if re-displacement occurs, then repeat manipulation and K-wire fixation may be required.

Distal humerus (supracondylar fracture)

Supracondylar humeral fractures are very common injuries in children. The distal humerus may go into flexion or extension, extension being by far the most common. Treatment depends on the degree of displacement. Undisplaced fractures may be protected in a collar and cuff or backslab for 3 weeks and then progressive mobilisation.

If displaced, the fracture can often be reduced with closed manipulation. If the dorsal periosteal hinge is intact, then above elbow cast immobilisation is often sufficient to hold the fracture until union in 4–6 weeks. If the periosteal hinge is broken, then percutaneous K-wires are used to hold the fracture, supplemented with an above elbow cast.

Jacques Lisfranc de St Martin, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

Figure 28.25 **(a)** AP and lateral radiographs of a 10-year-old showing a dorsally angulated metaphyseal fracture of the radius and undisplaced fracture of the ulna. **(b)** Injury treated with closed manipulation and cast application. Eight weeks' post-injury radiograph out of cast. Fracture is united, with residual 11 degree dorsal angulation. **(c)** Radiograph of the wrist following repeat injury 2 years later at age 12, showing complete remodelling. No residual deformity.

A very rare but feared complication of paediatric supracondylar fractures is Volkmann's ischaemic contracture. This is due to excessive swelling and missed compartment syndrome in the forearm. It is particularly important not to put the elbow into deep flexion if there is a lot of swelling. If deep flexion is the only way to hold the fracture, then K-wire fixation should be considered.

Neurovascular injury at the time of a supracondylar fracture is not uncommon. Careful attention should be paid to the neurovascular status of the limb. The white pulseless hand is a surgical emergency and requires emergent reduction. If the pulse does not return with reduction, then the vessels should be explored by appropriately trained surgeons.

The pink pulseless hand is more controversial and requires early senior decision making. If there is satisfactory perfusion of the limb, no suggestion of compartment syndrome and no neurological injury, then reduction and stabilisation of the fracture is warranted and a more expectant approach to the vascular injury can be taken. Often the pulse will return within 24–48 hours.

Neurological injury is common, most often a neuropraxia. They often resolve on fracture reduction, stabilisation and resolution of the swelling.

Malunion in varus or valgus remains a problem. Often the elbow will remodel the deformity in the anteroposterior flexion extension plane, but varus and valgus malunion remodels less. Careful attention needs to be paid to the adequacy of the reduction and K-wire placement to hold the fracture to avoid angular malunion.

Lateral condylar mass fracture of the elbow

Lateral condylar mass fractures of the elbow are easily missed and often considered benign as there is often only a small flake of bone visible. This thin sliver of metaphyseal bone on the lateral side of the elbow is very deceptive. Do not underestimate the significance of this injury (Figure 28.26).

Treatment depends on the stability of the lateral mass fragment. If stable, non operative treatment is acceptable. If unstable, anatomical reduction and fixation should be attempted to avoid complications.

Unstable fractures are suggested by significant soft tissue swelling, by fracture displacement of more than 2 mm or by the fracture being visible on both anteroposterior and lateral views of the elbow.

Unstable fractures require anatomical reduction and rigid fixation with K-wires or screw fixation to avoid displacement and complications. Avascular necrosis of the capitellum and non-union of the lateral condyle lead to the so- called 'fish tail' deformity.

Slipped upper femoral epiphysis

A slipped upper femoral epiphysis classically occurs in a child approaching puberty. It is easily missed as symptoms may be mild and the predominant symptom may be knee pain referred from the hip. A history of trauma may be offered and the child may limp.

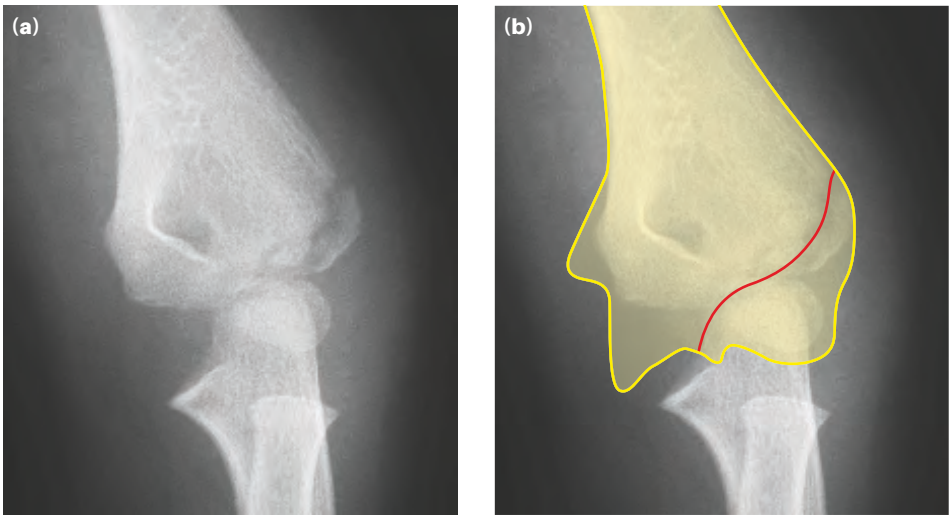

Figure 28.26 Lateral condylar mass fracture. **(a)** Plain radiograph showing the metaphyseal fracture. **(b)** The yellow shows the shape of the distal humerus including the cartilaginous analogue, and the red shows the true extent of the injury (i.e. a significant intra-articular fracture).

Examination of the limb reveals a hip that flexes into external rotation. Radiographs should include a good lateral view of the femoral head and neck (Figure 28.27). If the radiographs are normal, consider MRI, looking for a preslip, and prophylactic fixation. If treated in the early stages, the prognosis is very good. A severely displaced slipped upper femoral epiphysis might lead to avascular necrosis of the femoral head and chondrolysis. This is a very difficult condition to treat effectively in young patients.

Femoral shaft fractures

Femoral shaft fractures in children are treated based on the age and size of the child:

- infants (0–18 months);
- toddlers and small children (18 months–4 years);
- children (4–12 years);
- older children/adolescents.

In infants (0–18 months), ensure there is no evidence of non-accidental injury. In infants under 12–15 kg, gallows traction is acceptable. This traction involves suspension of the legs vertically with the buttocks just off the bed. In toddlers and small children treatment is by traction initially followed by hip spica application. Shortening of up to 1 cm and angulation of 15–20 degrees can be accepted depending on the age of the child due to extensive remodelling potential.

As the child gets older and time to union increases, so the non-operative measures of traction and hip spica become more cumbersome.

In children from 4 to 12 years several treatment options exist from traction and hip spica, elastic stable intramedullary nailing (ESIN), external fixation or plate fixation. Definitive treatment depends on surgeon skills, facilities and patient and parent needs.

In older children and adolescents, non-operative treatment with traction and hip spica cast application becomes less tolerable. Depending on patient size and build, operative treatment may include ESIN (Figure 28.28), external fixation or plate fixation. In larger overweight adolescents,

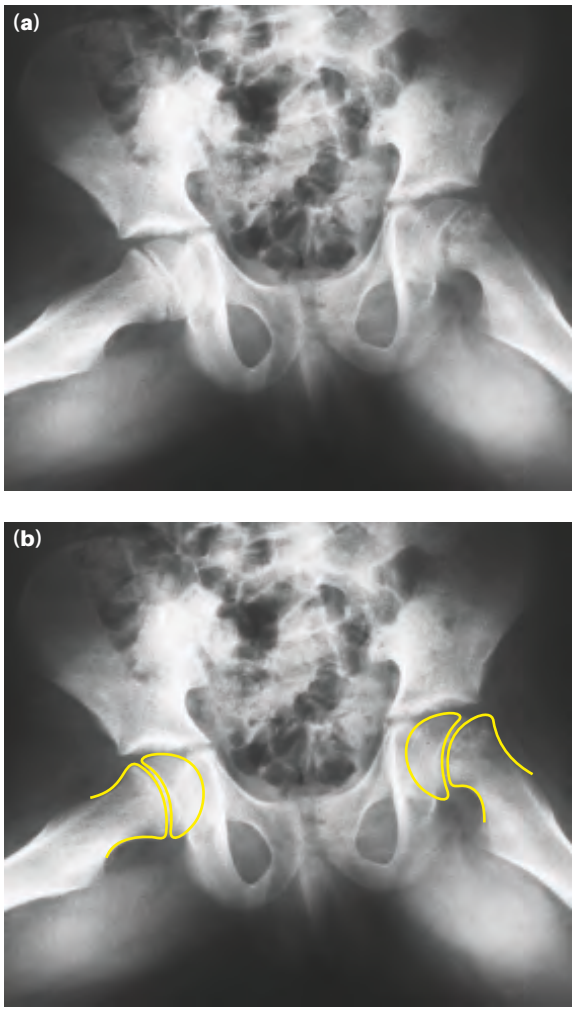

Figure 28.27 Slipped left upper femoral epiphysis. **(a)** Plain radiograph; **(b)** the injury highlighted.

Figure 28.28 **(a–c)** Femoral shaft fracture in a child, which has been stabilised with elastic nails.

Summary box 28.6

Fractures in the skeletally immature

- Do not forget non-accidental injury
- Be reluctant to remanipulate a physeal injury
- Elastic nails are a significant step forward in fracture treatment in children
- Not many fractures require operative intervention in children

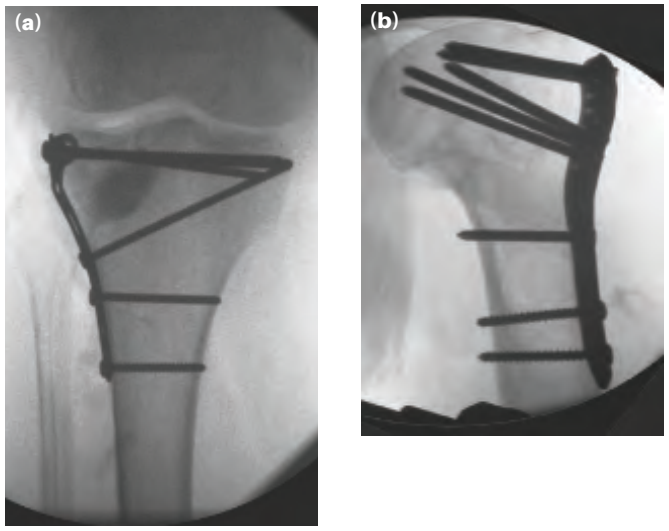

Figure 28.29 Variations in fixation technique suited to osteoporotic bone. **(a)** Norian bone substitute has been injected to support the lateral tibial plateau in the partial articular fracture. **(b)** A locking plate in a proximal humerus. The screws are threaded into the plate to make a fixed-angle device.

titanium elastic nails may not be strong enough to resist bending forces and locked intramedullary nailing may be considered.

It is important, however, to remember that there is a 1–2% chance of avascular necrosis of the femoral head if an antegrade intramedullary nail is used prior to or just after physeal closure. This is a rare but devastating complication in this age group. Far lateral entry point nails on the greater trochanter have been developed to limit the effect on the blood supply to the femoral head; however, the risk of avascular necrosis persists.

Tibial shaft fractures

Tibial fractures in children are often very amenable to non-operative treatment, starting with an above knee cast, followed by conversion to a Sarmiento patellar tendon below knee cast at 4–6 weeks. Remodelling in the tibia is somewhat limited and as such less angular deformity can be accepted, no rotational deformity and only 10–15 degrees of angular deformity. Some shortening of the tibia can be accepted as the tibia is expected to overgrow by 0.5 cm in response to injury. If it is not possible to hold the fracture in an acceptable position with a cast, then external fixation, ESIN TENS or plating is an option.

SPECIAL CONSIDERATIONS

Special consideration needs to be given to osteoporotic and pathological fractures, for example the ability to hold the fracture until union. Furthermore, open fractures require urgent appropriate treatment to ensure bone healing in the absence of infection.

Osteoporotic fractures

Osteoporosis is a condition characterised by low bone mineral density and reduced strength. Osteoporotic bone is liable to fracture with low energy injuries (e.g. a fall from standing height). Treatment of lower limb osteoporotic fractures in older patients are challenging. As there may be additional and pre-existing mobility problems, such patients are unable to partially weight bear and so fixation should be strong enough to allow immediate weight bearing and to hold the position until union. Locking plate technology improves fixation in osteoporotic bone, and bone void fillers can be utilised (Figure 28.29).

Pathological fractures

When abnormal bone fails under normal load this is referred to as a pathological fracture. Depending on the cause of the pathological fracture the bone may not heal and consideration should be given to a load-bearing device not load sharing. If involving the joint surface or close to the joint surface, the affected area may be excised *en bloc* and a joint replacement performed.

The bone may be weakened by a primary bone tumour, secondary metastatic deposits, haematological malignancy

(myeloma, lymphoma, leukaemia), osteomyelitis and metabolic bone disease (osteomalacia, Paget's disease, osteoporosis).

A pathological fracture should be suspected if the history is not consistent with the severity of the injury. The patient may give a history of low energy injury that normally would not cause a fracture. If a pathological fracture is suspected, the cause should be actively sought. Where a primary bone tumour is suspected, treatment should be planned to prevent disseminating the disease (see Chapter 37).

In patients with metastatic bone disease, the primary source should be sought if multiple metastatic deposits are identified. If life expectancy is poor, then stabilisation with a load bearing device may be considered. If an isolated metastasis is identified and an overall good prognosis is offered by the oncologists, then a more aggressive curative approach may be taken with en-bloc excision of the primary and the isolated secondary deposit.

If a metastatic deposit is identified prior to fracture, prophylactic fixation should be considered if impending fracture is likely. Prophylactic stabilisation with a load-bearing device is once again advocated. If life expectancy is good and the deposit periarticular, an en-bloc excision and joint arthroplasty may be considered to optimise return to near normal function as soon as possible.

Open fractures

Any fracture with an overlying wound should be considered an open fracture. The term previously used was a compound fracture. Open fractures require particular mention because adequate stabilisation of the bony injury and appropriate management of the soft tissue injury is paramount to ensure a good outcome with a low complication rate. The treatment of bone and joint infection is expensive, laborious and time-consuming for the professional as well as the patient. An infected femoral shaft fracture following intramedullary nailing will typically take 3 years and five operations to clear the infection and achieve union.

The Gustilo and Anderson classification of open fractures is the most frequently used classification (see *Table 28.2*). The definitive grade is determined intraoperatively after thorough debridement. It is not based on size of wound alone but takes into account several factors; a farmyard or heavily contaminated wound of under 1 cm may still be considered a grade III injury.

The aim of open fracture management is to achieve bony union, optimum function and avoid infection. The treatment of open fractures should be considered in two phases: the emergency department pre-surgical phase and the surgical phase.

Pre-surgical phase

1 Take a photograph to document the severity of the injury and limit the need for repeated opening of dressings. (Do not delay steps below unduly.)
2 Assess neurovascular status and if compromised and the fracture displaced, quickly remove any macroscopic dirt and reduce the fracture/dislocation. It is not essential to achieve an anatomical reduction; simply remove the pressure from the soft tissues (make a leg look like a leg and an arm look like an arm). If the bone was out of the skin and is reduced under the skin, then document clearly and inform the surgical team.
3 Once overall alignment is achieved, splint the affected limb; treatment of an open fracture is treatment of the soft tissues.
4 Apply a moist saline dressing to the wound. It is acceptable to irrigate the wound with saline in the emergency department to remove any macroscopic dirt, but definitive debridement and wash out of the wound should be undertaken in a theatre environment.
5 Administer intravenous antibiotics according to local protocols. It has been shown that early administration of intravenous antibiotics is one of the most important steps. A broad-spectrum antibiotic should be chosen covering gram-positive, gram-negative and if severe contamination, anaerobic organisms.
6 Obtain a tetanus immunisation history and treat accordingly.
7 Inform senior orthopaedic surgeon of the injury as soon as possible and make preparations for surgical phase.

Surgical phase

In the past an open fracture was considered a contraindication to internal fixation. It is increasingly evident that stable fixation of the bony injury is very important to prevent deterioration of the soft tissues, allowing recovery and healing.

Fracture stabilisation may come in the form of external fixation, internal fixation with screws/plates/intramedullary nails – depending on the setting.

Management of the soft tissues is critical to prevent the zone of injury spreading. Thorough debridement of any contaminated or non-vital soft tissue is important. Any loose or devitalised bone fragments should be discarded. Bone defects are easier to deal with than an infected non-union.

Summary box 28.7

Special considerations

- Osteoporotic fractures in the older patients may require specialised fixation techniques with locking screw/plate technology and injectable bone cement augmentation
- Pathological fractures may not heal and require load-bearing not load-sharing implants
- Arthroplasty in suitable patients bypasses the problems of blood supply, weak bone and allows early full weight bearing and return to function
- Open fractures require prompt debridement, stabilisation and adequate soft tissue cover to prevent infection.

Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK.

Soft tissue reconstruction may involve primary or delayed primary closure of the wound, or more sophisticated soft tissue reconstruction options including microvascular free tissue transfer.

Continue intravenous antibiotics until 48 hours after definitive wound closure.

COMPARTMENT SYNDROME

Compartment syndrome is raised pressure in an osseofascial compartment to a level that compromises tissue perfusion. There are several causes of compartment syndrome, fractures being the most common (70%), followed by soft tissue contusions (23%). Rarer causes include: bleeding disorders including anticoagulation, burns (particularly circumferential 3rd degree burns); post-ischaemic swelling (reperfusion injury); tight casts/dressings; and extravasation of intravenous infusions (contrast under pressure).

The pathophysiology involves increased tissue pressure, which leads to reduced microperfusion resulting in tissue ischaemia and irreversible muscle damage from cellular anoxia.

Compartment syndrome is a clinical diagnosis characterised by pain out of proportion, increasing pain and pain on passive stretch. Paralysis, paraesthesia and pallor are late signs and pulselessness is an extremely late sign.

Compartment pressure monitoring may be useful in cases of diagnostic uncertainty and in patients with altered levels of consciousness (intubated, head injury).

Measure multiple sites near but not in the fracture site, in all the compartments of the affected limb. Generally accepted pressure thresholds include an absolute pressure greater than or equal to 30 mmHg or pressure difference (diastolic pressure – compartment pressure) less than or equal to 30 mmHg.

Emergency treatment involves splitting casts and or dressings to the skin and elevating the extremity. Senior input should be sought and arrangements put in place to perform definitive treatment with fasciotomies.

There are some common pitfalls to remember. The incidence of compartment syndrome associated with high and low energy injuries is nearly equal. Compartment syndrome can occur in open fractures. Have a high index of suspicion and be particularly vigilant in patients with an altered level of consciousness.

CONCLUSION

The correct identification of extremity trauma, combined with timely and appropriate treatment, is essential to return patients to normal function as safely and as quickly as possible. The same injury may be treated in different ways based on patient factors, age, functional demands and co-morbidities. Surgeon and resource based factors also need to be considered.

Summary box 28.8

Summary of extremity trauma

- Realise that an injury exists
- Find the characteristics of the injury, describe and classify it
- Consider the natural history of the injury
- Treatment is guided by outcome if known or by principle if not
- Beware of injuries that are 'easily missed'

Chapter 29

Disaster surgery

Learning objectives

To recognise and understand:

- The common features of various disasters
- The principles behind the organisation of the relief effort and of triage in treatment and evacuation
- The role and limitations of field hospitals in disaster
- The features of conditions peculiar to disaster situations and their treatment

INTRODUCTION

Natural disasters provide a constant reminder of the power and capricious nature of our planet. The depletion of the ozone layer and global warming mean that the future may hold in store calamitous events with even greater magnitude than those experienced before. National conflicts and ideological differences have not lessened and the resultant 'unnatural disasters' have the potential to rival the natural ones in enormity (see Chapter 30). Disasters by their very nature are unpredictable and no two are alike. Nevertheless, there are numerous common elements and it has been shown that countries that invest in disaster preparedness are better equipped to cope with such catastrophes. Recent wars and disasters have highlighted the increasingly crucial role of surgeons in these scenarios.

COMMON FEATURES OF MAJOR DISASTERS

Any event that results in the loss of human life is disastrous, but most accidents, such as aeroplane and train crashes, are limited in the number of people involved. Conversely, natural disasters, such as earthquakes and tsunamis, leave in their wake massive destruction over large areas that can transcend national boundaries. All the apparatus of a society that responds to such disasters (the civil administration, emergency services, fire brigades and hospitals) may itself be involved and unable to respond (**Figure 29.1**). Large numbers of people may require immediate shelter, clean water and food, in addition to any medical needs.

A breakdown of communication is inevitable and can be accompanied by widespread panic and a disruption of civil order. Access to the disaster area may be limited because of the destruction of bridges, affecting road and rail links.

Figure 29.1 Damage to emergency medical services.

Summary box 29.1

Common features of major disasters

- Massive casualties
- Damage to infrastructure
- A large number of people requiring shelter
- Panic and uncertainty among the population
- Limited access to the area
- Breakdown of communication

FACTORS INFLUENCING RELIEF EFFORTS AND PROVISION OF MEDICAL AID

Good communication is critical for the authorities to respond quickly to a disaster. Wireless technology and satellite imag-

Figure 29.2 Satellite image showing destruction of a bridge as a result of flooding.

ery have revolutionised the way in which real-time information can be obtained (Figure 29.2). Nonetheless, there is an inevitable lag period between the occurrence of the disaster and the response from the establishment.

The location of the disaster area has a bearing on relief efforts. In large cities emergency and medical services are better developed. However, these areas are densely populated and may have limited access by road and air. Disasters in remote areas can be particularly difficult to manage because relief efforts are hampered by geographical isolation and the lack of infrastructure.

Summary box 29.2

Factors influencing rescue and relief efforts

- Status of communications
- Location, whether rural or urban
- Accessibility of the location
- Time-frame in which disaster occurs
- Economic state of development of the area

The time-frame in which a disaster occurs also impacts on the relief efforts. Earthquakes can unleash havoc in seconds but floods and hurricanes may continue for several days. Another important factor is the state of resources of the country; disasters in poorer countries can seldom be managed without significant outside assistance.

SEQUENCE OF RELIEF EFFORTS AFTER A DISASTER

Establishing a chain of command

Many countries have dedicated organisations that deal with disasters. In others, an administrative hierarchy is established to coordinate the efforts of the teams participating in relief efforts (Figure 29.3).

Damage assessment

The first objective in disaster management is an assessment of the damage and the number of casualties. All sources of information must be employed. The 24-hour news services

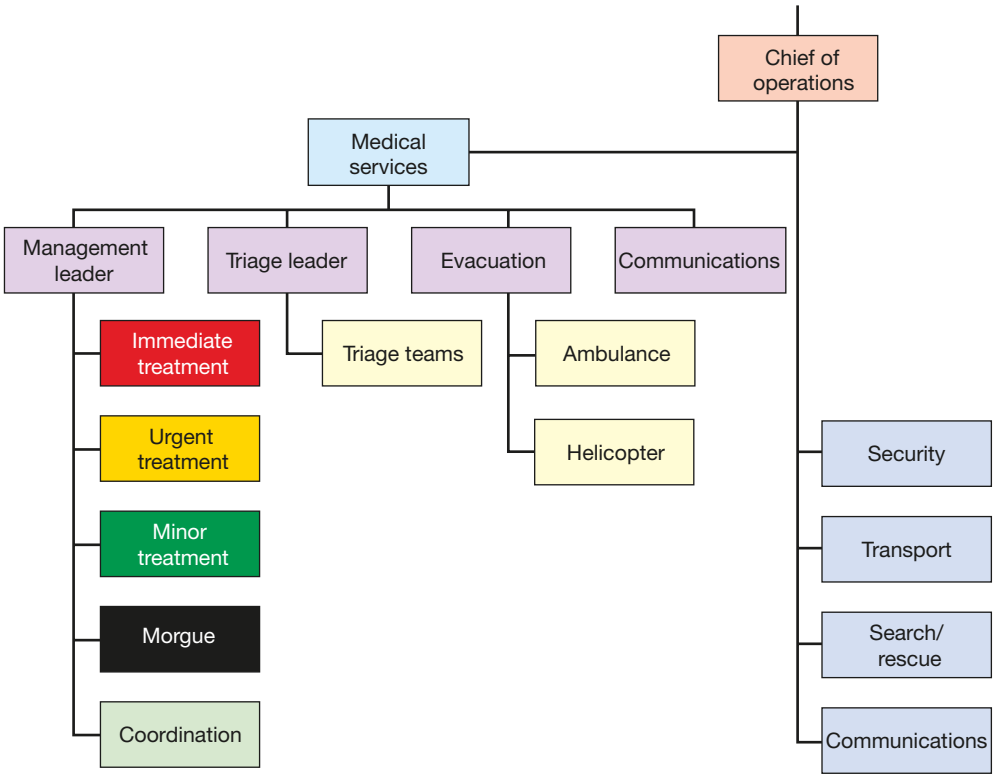

Figure 29.3 Organisation chart for disaster management.

are frequently the first on the scene and can be an important source of information.

Mobilising resources

The next step is mobilisation of human and material resources appropriate to the extent of the disaster. Although all modes of transport need to be considered, helicopters provide the quickest access for the first responders (Figure 29.4). The teams who make up the initial response must include experienced staff who can assess the situation and who have the authority to take immediate decisions.

Rescue operation

Early coordination of the rescue effort allows optimal use of resources. The first priority is to prevent further damage from occurring, both to people and to the infrastructure. The types of injuries encountered by rescue workers depends on the delay between the onset of the disaster and their arrival. Patients with head injuries and abdominal and thoracic trauma will either have been treated or have succumbed to their injuries within 48–72 hours of a disaster. After the first week, the only casualties requiring treatment are those with complex limb trauma and infected wounds (Figure 29.5).

Coordination with relief agencies

A laudable aspect of globalisation is the outpouring of help from governments and non-governmental organisations (NGOs) in response to a disaster. Some, like Rescue and Preparedness in Disasters (RAPID), deal with search and rescue whereas others, like the International Committee of the Red Cross (ICRC) and Oxfam, provide general disaster-related relief (Figure 29.6). The various United Nations (UN) agencies deal with medical care, food provision and refugees. Coordinating the efforts of these organisations is essential for optimal results, as medical aid in isolation is inadequate without the simultaneous provision of safe drinking water, food, clothing and shelter.

Figure 29.4 Heli-evacuation.

Summary box 29.3

Sequence of the relief effort in major disasters

- Establish chain of command
- Set up lines of communication
- Carry out damage assessment
- Mobilise resources
- Initiate rescue operation
- Triage casualties
- Start emergency treatment
- Arrange evacuation
- Start definitive management

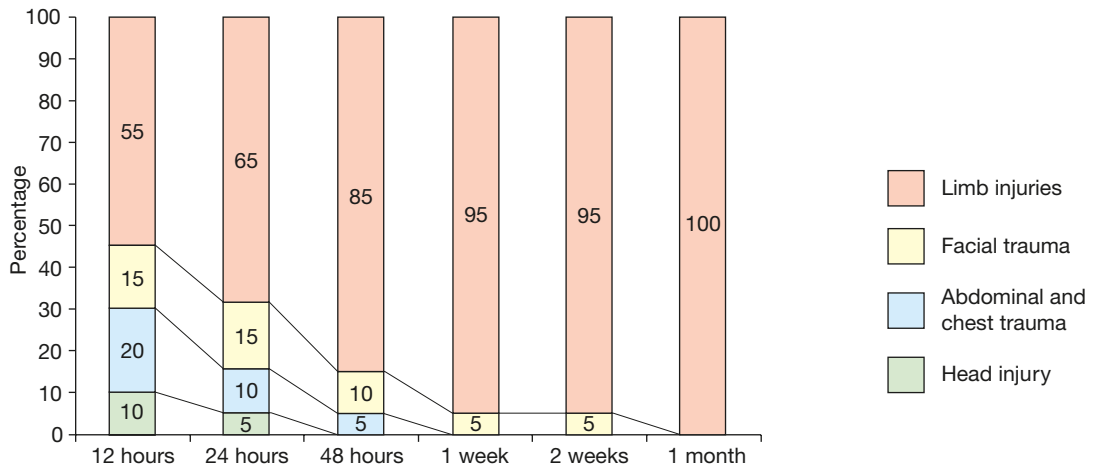

Figure 29.5 Time-line showing the type of injuries encountered at different times in a disaster.

Figure 29.6 Oxfam and the International Committee of the Red Cross provide generalised relief.

Dealing with the media

Disasters act like a magnet for the media which, in today's world of 24-hour news coverage, plays an important part in shaping public opinion. It is essential to establish a working relationship between the media and the rescue teams. With careful handling the media can become a powerful ally and play a constructive role in identifying problems, galvanising aid and keeping the public informed.

Triage

Derived from the French verb 'trier', triage means 'to sort' and is the cornerstone of the management of mass casualties. It aims to identify the patients who will benefit the most by being treated the earliest, ensuring 'the greatest good for the greatest number'. Numerous studies show that only 10–15% of disaster casualties are serious enough to require hospitalisation. By sorting out the minor injuries, triage lessens the immediate burden on medical facilities. Deciding who receives priority when faced with hundreds of seriously injured victims is a daunting prospect. Triage should be undertaken by someone senior, who has the experience and authority to make these critical decisions. To keep pace with the changing clinical picture of an injured person, triage needs to be undertaken in the field, before evacuation and at the hospital.

Triage areas

For efficient triage the injured need to be brought together into any undamaged structures that can shelter a large number of wounded. A good water supply, lighting and ease of access are useful. Separate areas should be reserved for patient holding, emergency treatment and decontamination (in the event of discharge of hazardous materials).

Practical triage

Emergency life-saving measures should proceed alongside triage and can actually help the decision-making process. The assessment and restoration of airway, breathing and circulation are critical and are discussed in Chapter 23. Vital signs and a general physical examination should be combined with a brief history taken by a paramedic or by a volunteer worker if one is available.

Documentation for triage

Accurate documentation is an inseparable part of triage and should include basic patient data, vital signs with timing, brief details of injuries (preferably on a diagram) and treatment given. A system of colour-coded tags attached to the patient's wrist or around the neck should be employed by the emergency medical services. The colour denotes the degree of urgency with which a patient requires treatment **(Figure 29.7)**.

Triage categories

All methods of triage use simple criteria based on vital signs. A rapid clinical assessment should be made taking into account the patient's ability to walk, their mental status and the presence or absence of ventilation or capillary perfusion. A commonly used four-tier system is presented in *Table 29.1*.

TABLE 29.1 Triage categories.

Priority	Colour	Medical need	Clinical status	Examples
First (I)	Red	Immediate	Critical, but likely to survive if treatment given early	Severe facial trauma, tension pneumothorax, profuse external bleeding, haemothorax, flail chest, major intra-abdominal bleed, extradural haematomas
Second (II)	Yellow	Urgent	Critical, likely to survive if treatment given within hours	Compound fractures, degloving injuries, ruptured abdominal viscus, pelvic fractures, spinal injuries
Third (III)	Green	Non-urgent	Stable, likely to survive even if treatment is delayed for hours to days	Simple fractures, sprains, minor lacerations
Last (0)	Black	Unsalvageable	Not breathing, pulseless, so severely injured that no medical care is likely to help	Severe brain damage, very extensive burns, major disruption/loss of chest or abdominal wall structures

Triage is the earliest example of clinical risk management. This is done on the basis of need so that resources can be allocated by good prioritisation. The process was first used in 1792 by Baron Dominique Jean Larrey, Surgeon in Chief to Napoleon's Imperial Guard. The concept of triage emerged from the French Service de Sante so that resources could be used to the optimum – "most for the most".

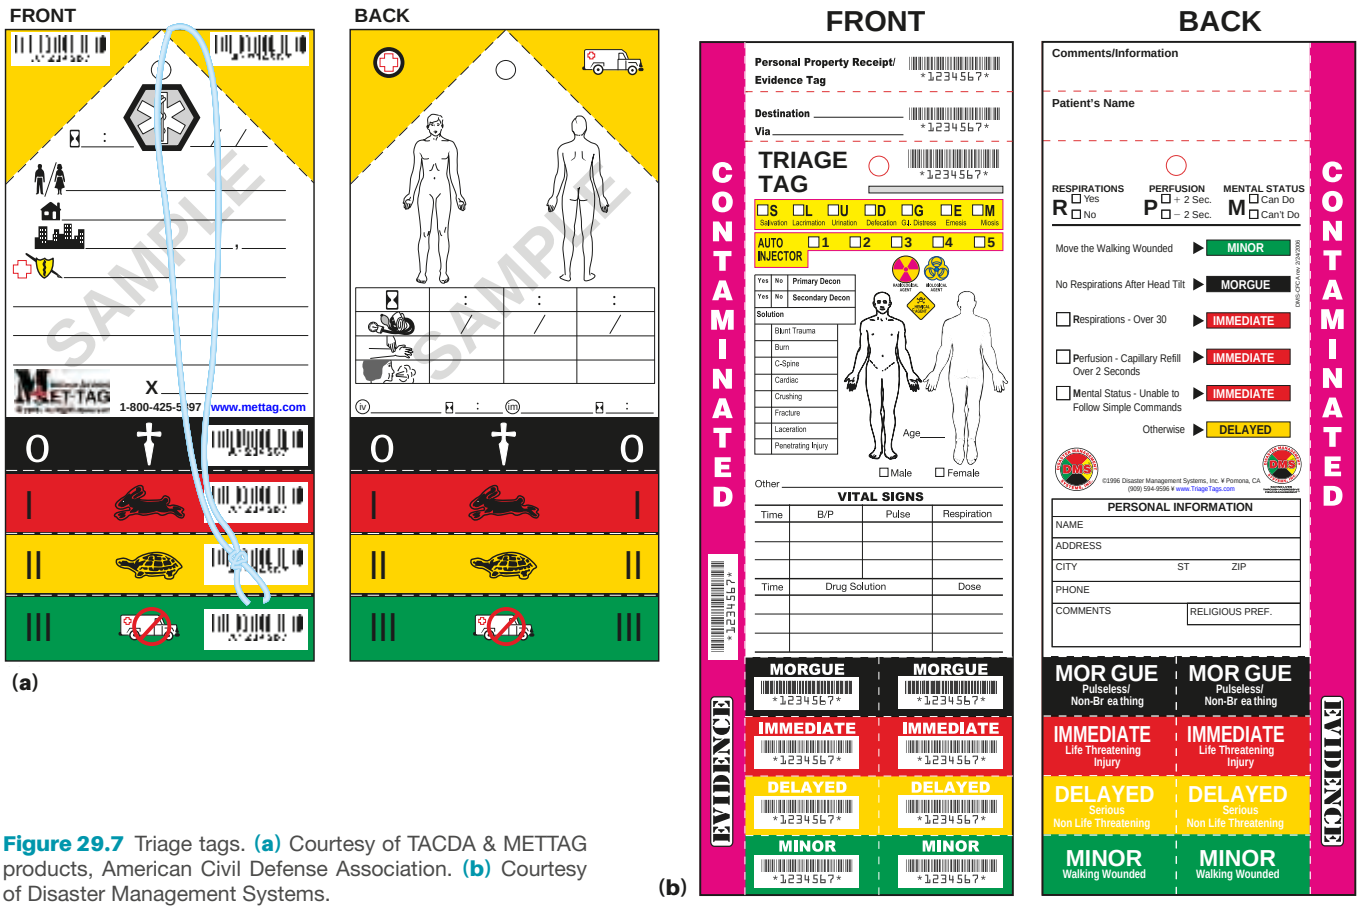

Figure 29.7 Triage tags. **(a)** Courtesy of TACDA & METTAG products, American Civil Defense Association. **(b)** Courtesy of Disaster Management Systems.

Evacuation of casualties

Decisions regarding the best destination for each patient need to be based on how far it is safe for them to travel and whether the facilities that they need for definitive treatment will be available. A quick retriage is very useful in this situation. The paramedics accompanying the casualties should be resolved to prevent the 'second accident' (damage caused inadvertently by transport and treatment). An adequate supply of essentials such as intravenous fluids, dressings, pain medication, and oxygen must be arranged (see Chapter 30).

Field hospitals

The decision to deploy field hospitals depends on the location, the number of casualties and the speed with which evacuation can be organised (**Figure 29.8**). Whether the traditional tented structure or the modular type housed in containers is employed, the facility must be equipped with radiograph capability, operating rooms, vital signs monitors, sterilising equipment, a blood bank, ventilators and basic laboratory facilities.

Summary box 29.4

Essentials of casualty evacuation

- Retriage to upgrade priorities amongst the injured
- Select appropriate medical facilities for transfer
- Choose appropriate means of transport
- Prevent the 'second accident' during transfer
- Ensure an adequate supply of materials to accompany the patient

Management in the field

Field hospitals principally function in three main areas (*Table 29.2*).

First aid

Care for patients with minor injuries involves cleaning and dressing wounds, suturing lacerations and splinting simple fractures. Most of these 'walking wounded' can be sent away with antibiotics and simple pain relief.

DAMAGE CONTROL SURGERY

Damage control surgery (DCS) is the concept that only life- and limb-saving surgery be performed in field hospitals to allow safe transfer of a patient to a definitive treating facility. This will include ensuring that the airway is secure, haemorrhage is under control and compartments are decompressed in the chest, skull, abdomen and the limbs. Devitalised tissue should be removed and any contamination prevented from

Figure 29.8 Field hospitals: **(a, b)** modular type; **(c)** tented structure; **(d)** interior of a tented field hospital.

TABLE 29.2 Type of treatment given in field hospitals.

	Examples	Further
First aid	Suturing cuts and lacerations, splinting simple fractures	Review at local hospital
Emergency care for life-threatening injuries	Endotracheal intubation, tracheotomy, relieving tension pneumothorax, stopping external haemorrhage, relieving an extradural haematoma, emergency thoracotomy/laparotomy for internal haemorrhage	After damage control surgery, transfer patients to base hospitals once stable
Initial care for non-life-threatening injuries	Debridement of contaminated wounds, reduction of fractures and dislocations, application of external fixators, vascular repairs	Transfer patients to base hospitals for definitive management

developing into infection. DCS is explained in more detail, in the context of early management and other settings, throughout the chapters in the trauma section (see Part 4: Trauma).

Emergency care for immediate life-threatening injuries

There are many patients who may be saved by relatively simple measures, provided that these are taken urgently. Endotracheal intubation and tracheotomy may be needed to provide a secure airway. A needle thoracocentesis will relieve a tension pneumothorax and a chest drain will be needed before a patient with a significant chest injury is transferred by air. An open pneumothorax should be closed. Damaged major vessels to limbs should be repaired if possible. Fasciotomies will be

Summary box 29.5

Principles of damage control surgery

- Do the minimum needed to allow safe transfer to a definitive facility
- Take actions that prevent deterioration of that patient during transfer
- Secure the airway – may require tracheostomy
- Control bleeding – may require craniotomy, laparotomy, thoracotomy, repair of major limb vessels
- Prevent pressure build up – may require burr holes, chest drain, laparotomy, fasciotomy
- Prevent infection by extensile exposure and removing dead and contaminated tissue

needed for muscle compartments that are swelling from injury or from reperfusion. Amputation for clearly devitalised limbs and gas gangrene should be undertaken at field hospitals as delay will be fatal.

Specific aspects of care are discussed in the relevant chapters elsewhere in this book.

Initial care for non-life-threatening injuries

Many patients sustain serious injuries that require prolonged care. These include compound limb fractures, degloving injuries, dislocations of major joints, major facial injuries and complex hand injuries. These patients will need specialised care requiring transfer to the appropriate facility. Replantations of amputated limbs and other extensive procedures should not be attempted in field hospitals as they are time-consuming and divert resources and personnel to the treatment of a few patients.

Debridement

Taken from the French, meaning to 'unleash or cut open', debridement plays a crucial part in the management of trauma. Wounds sustained in disasters are often heavily contaminated, containing foreign bodies and non-viable tissues (Figure 29.9). Debridement reduces the chances of anaerobic and necrotising infections and can prevent systemic sepsis. The following principles of debridement apply to all contaminated wounds:

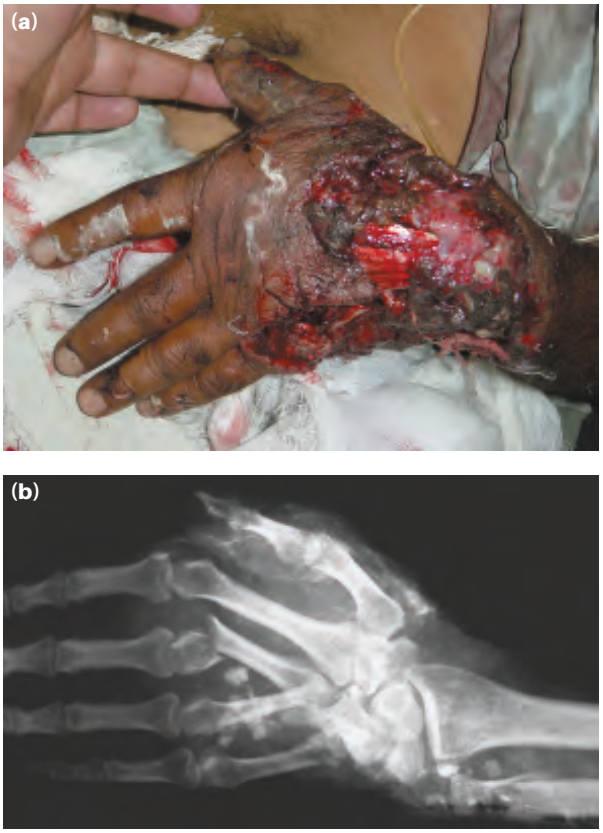

Figure 29.9 (a, b) Gross contamination typically seen in wounds sustained in disasters. The radiograph shows numerous radiopaque foreign bodies in the soft tissues.

- After the administration of anaesthesia, the injured area is copiously irrigated with normal saline. Lavage using a pressurised system is controversial, with concerns over tissue trauma and spread of debris (Figure 29.10). The wound is palpated and all foreign matter removed. Dirt and debris enmeshed in soft tissues can only be removed by excision of those tissues. Open joints should be thoroughly irrigated and all foreign material removed.
- Wounds with extensive cavitation should be enlarged longitudinally to gain better access and allow full decompression of the underlying muscles. This should be carried out under tourniquet. This helps to visualise the damaged structures, and allow the surgeon to gain proximal and distal control of vascular injuries, and to identify severed ends of major nerves and tendons.
- The next step is excision of all dead and devitalised tissue. At this stage the tourniquet is let down to check the vascularity of the tissues. Skin excision is kept to a minimum and only the margins of the wound need be trimmed back to healthy bleeding edges. Excision of devitalised muscle should be undertaken generously. Muscle that is pale or dark in colour, does not contract on pinching and does not bleed on cutting must be removed. In patients with traumatic amputations, the bone ends are tidied, the skin and muscle edges trimmed to the lowest level possible and the wound left open.
- In patients with associated fractures, skeletal stabilisation should be obtained before embarking on any repairs. External fixators are invaluable for this and make wound management much easier (Figure 29.11).

Figure 29.10 Lavage with normal saline to decontaminate a wound.

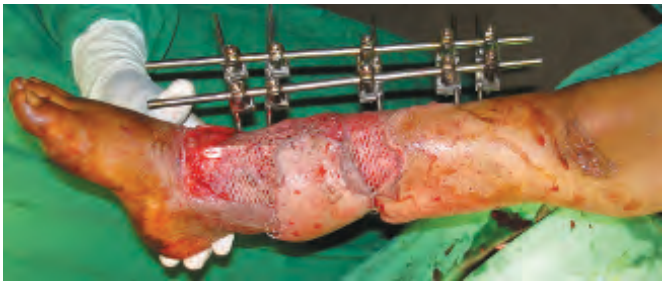

Figure 29.11 External fixators provide skeletal stabilisation and allow easy management of the soft tissues.

- In the acute setting, only vascular repairs are justified. For lacerated vessels the ends are trimmed and an anastomosis performed. In the case of loss of substance of the vessel wall, a vein patch or reversed vein graft may be employed. Silicone tubing may be used as a temporary bypass (stent) while vascular repair is being carried out in patients with critically compromised distal circulation.
- Nerves and tendons should not be dissected out nor should any attempt be made at definitive repair in wounds with tissue devitalisation, as this leads to poor results. The key structures should be identified and the edges trimmed and tagged with non-absorbable sutures to facilitate repair during subsequent exploration.
- Wounds sustained in disasters are heavily contaminated and are not suitable for primary closure. However, blood vessels and exposed joint surfaces need to be covered. This can be achieved by loosely tacking adjoining muscle over the exposed area. The wound is then covered with fluffed gauze and sterile cotton and the extremity splinted with a plaster of Paris slab. For extremity injuries, elevation is critical to reduce oedema.
- Broad-spectrum antibiotics, such as third-generation cephalosporins, are started prophylactically and continued for 5–7 days.
- The wound is reinspected at 24–48 hours to assess the viability of the tissues. Wounds are closed between the fourth and sixth day if there is no infection. Tension should be avoided and one should not hesitate to use skin grafts to obtain cover.
- In wounds with gross infection no attempt at closure is made until infection is eradicated. These wounds are re-explored to make sure that there are no residual foreign bodies or devitalised tissue. Tissue should be taken for microbiological culture. Vacuum-assisted closure (Vac-Pac) has emerged as a very useful tool for deeply cavitating wounds. It utilises low-pressure suction to evacuate exudate, promote granulation tissue and reduce the size of the wound (**Figure 29.12**). Once the wounds are free from infection secondary closure can be undertaken.

Figure 29.12 (a, b) Use of low-pressure vacuum therapy in preparing a wound for secondary closure.

DEFINITIVE MANAGEMENT

The hospitals designated to undertake definitive management should be selected on the basis of the facilities available and the number of injured that they can handle. The resources required for trauma patients are more than the typical case mix of a hospital. A rule of thumb is that only half the bed strength of a hospital can be utilised to provide optimum trauma care in an emergency situation.

Summary box 29.6

Principles of debridement and initial wound care

- Obtain generous exposure through skin and fascia
- Identify neurovascular bundles
- Excise devitalised tissue
- Remove foreign bodies
- Repair major vessels
- Obtain skeletal stabilisation with external fixators
- Only tag tendons and nerves that have been cut
- Leave the wound open and delay primary closure
- Avoid tight dressings
- Elevate the injured limb

Hospital reorganisation

In hospitals receiving mass casualties some reorganisation of services is unavoidable. This includes transferring patients with non-urgent conditions to other facilities, augmenting surgical services, reorganising the specialist rota and redesignating medical wards as surgical care areas. An appeal for blood donations should be broadcast.

SPECIFIC ISSUES

There is no injury that is peculiar to disasters and the whole spectrum of external injuries from minor cuts, compound fractures and amputations is seen. Internal organ damage is frequent and, unless immediate help is available, this accounts for the majority of early mortality figures. People trapped under fallen buildings may suffer crush injuries and crush syndrome if the duration is prolonged. Crush injuries and missile injuries cause extensive tissue damage and gross contamination, both favourable conditions for anaerobic and micro-aerophilic infections.

Limb salvage

The Mangled Extremity Severity Score (MESS) and its modifications are useful in deciding about limb salvage. Extensive tissue loss, neurovascular damage and loss of long fragments of bone are traditionally indications for amputation. Currently, wounds of any dimension can be covered with microvascular flaps and distraction osteogenesis and vascularised bone

can be used to restore bony continuity. If performed in time, vascular repairs can salvage most acutely ischaemic limbs. Because of these developments the indications for amputation in trauma have undergone a paradigm shift and the majority of patients who reach a tertiary-care facility within 24 hours are candidates for limb salvage (Figure 29.13). This assumes that debridement and, if required, vascular repairs have been performed in a field medical facility. A limb is unlikely to survive if the vascular repair of major limb vessels has been delayed for more than 4–6 hours.

Facial injuries

The management of facial injuries follows the same general principles of debridement and delayed closure as already outlined. Because of the functional and cosmetic importance of facial structures, skin and soft-tissue excisions are kept to a minimum. The face has a robust vascularity and a high ability to counter infection. Even in patients who present late with gross contamination, careful debridement followed by delayed primary closure can lead to good results (Figure 29.14).

Tetanus

This potentially fatal condition, also called 'lockjaw', is caused by *Clostridium tetani*, a gram-positive spore-forming bacillus occurring naturally in the intestines of humans and in the soil. It enters the body through a wound and replicates, thriving on the anaerobic conditions present in devitalised tissues. It produces tetanospasmin, an exotoxin that binds to the neuromuscular junctions of the central nervous system neurones, rendering them incapable of neurotransmitter release. This leads to failure of inhibition of motor reflex responses to sensory stimulation and generalised contractions of agonist and antagonist muscles produce tetanic spasms. The median incubation period is 7 days, ranging from 4–14 days.

Early symptoms are painful spasms of the facial muscles resulting in risus sardonicus (Figure 29.15). The spasms spread to involve the respiratory and laryngeal musculature. Spasms of the paravertebral and extensor limb musculature produce opisthotonus, an arching of the whole body. Laryngeal muscle spasm leads to apnoea and, if prolonged, to asphyxia and respiratory arrest. The spasms can be brought on by the slightest of sensory stimulus.

The diagnosis is obvious once it is fully manifest. There are three aspects of management:

- **Prevention.** Wounds contaminated with soil can harbour tetanus spores, and active immunisation is indicated by administering 0.5 mL of tetanus toxoid intramuscularly. Patients with gross contamination of cavitating wounds should also receive 250–500 U of human anti-tetanus globulin (ATG) intramuscularly to provide passive immunisation and to neutralise the circulating toxin. In full-

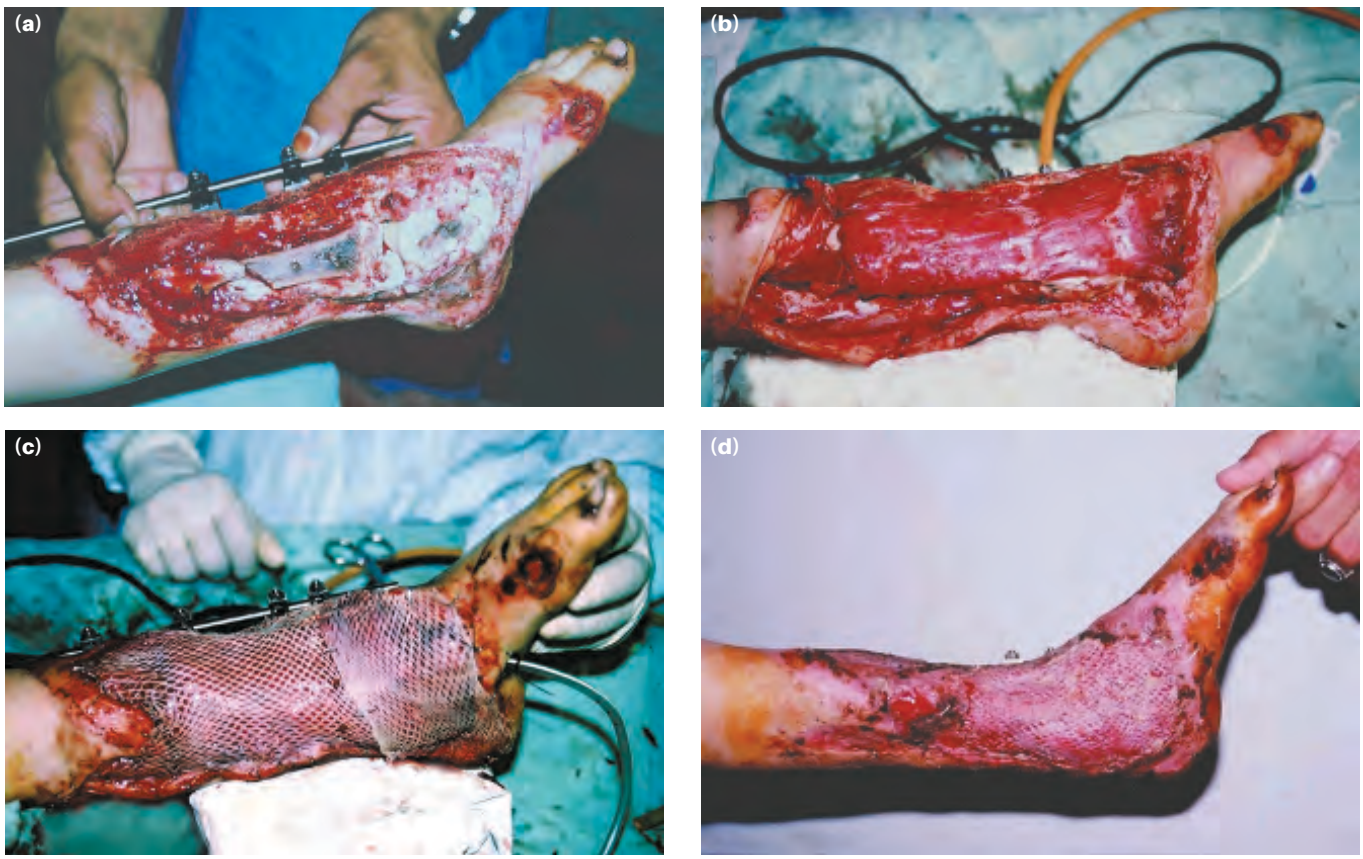

Figure 29.13 (a-d) Badly traumatised lower limb. Reconstruction has been performed using a microvascular rectus abdominis flap covered with a skin graft.

Figure 29.14 (a–d) Late-presenting facial injury with gross contamination. A thorough debridement followed by delayed primary closure has yielded good results.

Figure 29.15 Risus sardonicus of 'lockjaw' (courtesy of Dr Samira Ajmal, FRCS).

blown clinical tetanus, 3000–10 000 U of ATG should be administered. Wound manipulation should be avoided for 2–3 hours after ATG administration to minimise tetanospasmin release.

- **Local wound care.** This includes a thorough wound debridement to eliminate the anaerobic environment. Intravenous administration of 10–24 × 10^6 U per day of penicillin G should be continued for 10–14 days. The wound should be closed using the delayed primary or secondary closure techniques.
- **Supportive care for established disease.** These patients are nursed in an intensive care unit (ICU) environment, free from strong sensory stimuli. Diazepam is useful in preventing the onset of spasms but if these become sustained, the patient is paralysed, intubated and placed on a ventilator. The patient is then gradually weaned off the ventilator under cover of anticonvulsants. The overall mortality rate is around 45%, prognosis being determined by the

Summary box 29.7

Tetanus

- Caused by *Clostridium tetani*
- Spores are present in the soil
- Thrives in dead or contaminated tissue
- Produce tetanospasmin an exotoxin
- Produces spasm of muscles
- Make sure patients are immunised
- For heavily contaminated wounds give anti-tetanus globulin

incubation period and the time from the first symptom to the first tetanic spasm. In general, shorter intervals indicate a poorer prognosis.

Necrotising fasciitis

Necrotising fasciitisis is a rapidly spreading infection that produces necrosis of the subcutaneous tissues and overlying skin. It is caused by β-haemolytic streptococci and, occasionally, *Staphylococcus aureus* but may take the form of a polymicrobial infection associated with other aerobic and anaerobic pathogens, including *Bacteroides*, *Clostridium*, *Proteus*, *Pseudomonas* and *Klebsiella*. It is termed Fournier's gangrene when it affects the perineal area and Meleney's gangrene when it involves the abdominal wall. The underlying pathology includes acute inflammatory infiltrate, extensive necrosis, oedema and thrombosis of the microvasculature. The area becomes oedematous, painful and very tender. The skin turns dusky blue and black secondary to the progressive underlying thrombosis and necrosis **(Figure 29.16)**. The area may develop bullae and progress to overt cutaneous gangrene. It spreads contiguously but occasionally produces skip lesions that later coalesce. It is accompanied by fever and severe toxicity. Renal failure may occur as a result of hypovolaemia and cardiovascular collapse caused by septic shock. The rate of progression is dramatic and unless aggressively treated it leads to serious consequences with mortality approaching 70%.

The diagnosis is made on clinical grounds. Creatinine kinase levels may show enormous elevation and biopsy of the fascial layers will confirm the diagnosis. Patients should be admitted to the ICU and treated with careful monitoring of volume derangements and cardiac status. Oxygen supplementation is beneficial and endotracheal intubation is required in patients unable to maintain their airway.

High-dose penicillin G along with broad-spectrum antibiotics, such as third-generation cephalosporins and metronidazole, are given intravenously. The cornerstone of management is surgical excision of the necrotic tissue. The devitalised tissue is removed generously, going beyond the area of induration. The wound is lightly packed with gauze and dressed. This process is repeated daily as the necrosis is prone to spread beyond the edges of the excised wound. In patients who survive, this results in a large wound, which will require skin grafting or flap coverage.

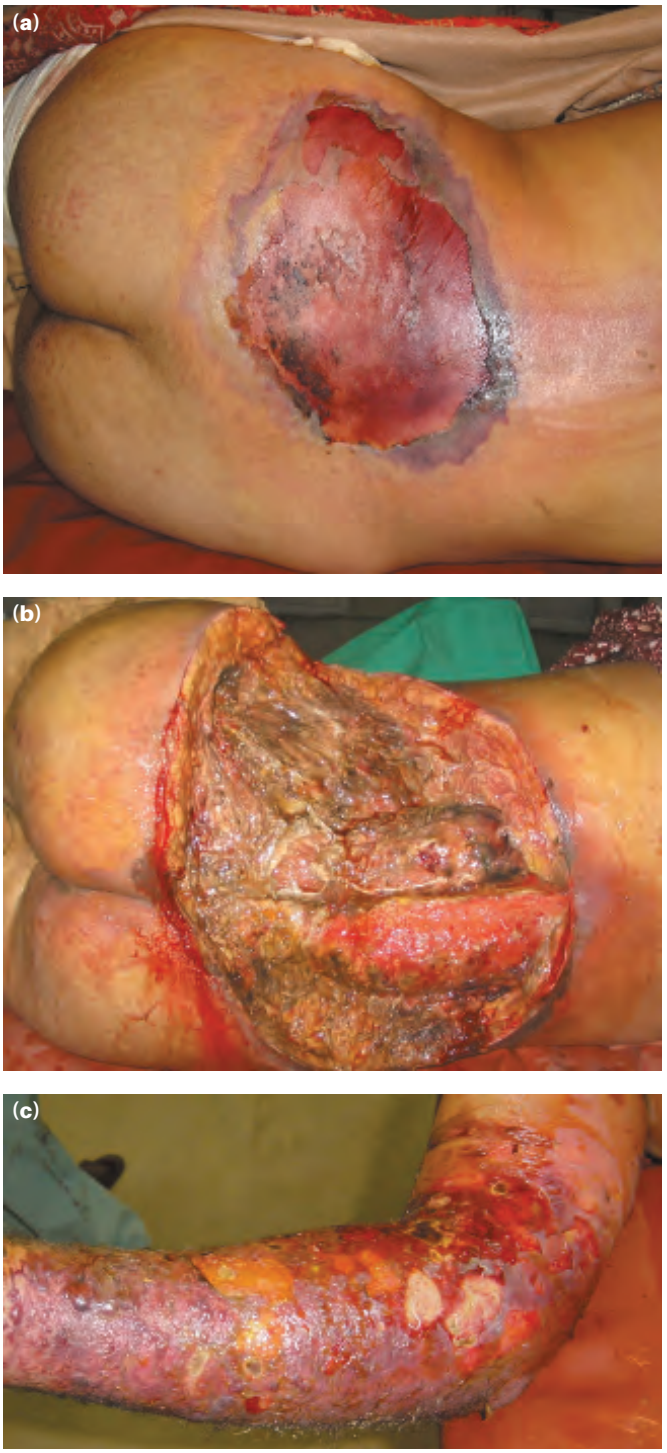

Figure 29.16 **(a)** Necrotising fasciitis at presentation and **(b)** rapid progression seen after 24 hours. **(c)** Typical bullae and induration.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia, Zurich, Switzerland and then the Rush Medical College, Chicago, USA.
Jean Alfred Fournier, 1832–1915, syphilologist, the Founder of the Venereal and Dermatological Clinic, Hospital St. Louis, Paris, France.
Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Coumbia University, New York, USA.

Summary box 29.8

Necrotising fasciitis

- Caused by β-haemolytic strep or is polymicrobial
- Also called Fournier's or Meleney's gangrene
- Progress is rapid and renal failure is an early complication
- Treat with radical surgical excision repeated every 24 hours
- Give oxygen and penicillin

Recently, the role of hyperbaric oxygen (HBO) has become more established with a reduction in mortality in patients treated with HBO (9–20%) compared with patients who did not receive HBO (30–50%).

Gas gangrene

Gas gangrene is a dreaded consequence of late presenting missile wounds and crushing injuries. It is a rapidly progressive, potentially fatal condition characterised by widespread necrosis of the muscles and soft-tissue destruction. The common causative organism is *Clostridium perfringens*, a spore-forming, gram-positive saprophyte that flourishes in anaerobic conditions. Other organisms implicated in gas gangrene include *C. bifermentans*, *C. septicum* and *C. sporogenes*. Non-clostridial gas-producing organisms such as coliforms have also been isolated in 60–85% of cases of gas gangrene.

C. perfringens produces many exotoxins but their exact role is unclear. Alpha-toxin, the most important, is a lecithinase, which destroys red and white blood cells, platelets, fibroblasts and muscle cells. The phi-toxin produces myocardial suppression while the kappa-toxin is responsible for the destruction of connective tissue and blood vessels.

Devitalised tissue or premature wound closure provides the anaerobic conditions necessary for spore germination. The usual incubation period is <24 hours but ranges from 1 hour to 6 weeks. A vicious cycle of tissue destruction is initiated by rapidly multiplying bacteria and locally and systemically acting exotoxins. This causes spreading necrosis of muscle and thrombosis of blood vessels. The typical feature of this condition is the production of gas that spreads along the muscle planes. Systemically, the exotoxins causes severe haemolysis and, combined with the local effects, this leads to the rapid progression of the disease, hypotension, shock, acute kidney injury and acute respiratory distress syndrome.

Pain that rapidly increases in severity is the earliest symptom. The limb swells up and the wound exudes a serosanguineous discharge. The skin is involved secondary to muscle necrosis, turning brown and progressing to a blue–black colour with haemorrhagic bullae (**Figure 29.17**). The characteristic sickly sweet odour and soft tissue crepitus appear with established infection but their absence does not exclude the diagnosis. These local signs are accompanied by pyrexia, tachycardia, tachypnoea and altered mental status.

Figure 29.17 Typical picture of spreading gas gangrene caused by a crush injury.

The diagnosis is made on the basis of history and clinical features: a peripheral blood smear may suggest haemolysis; a Gram stain of the exudate reveals large gram-positive bacilli without neutrophils; and the biochemical profile may show metabolic acidosis and renal failure. Radiography can visualise gas in the soft tissues and is particularly useful in patients with chest and abdominal involvement.

Patients should be admitted to the ICU and treated aggressively with careful monitoring. High-dose penicillin G and clindamycin, along with third-generation cephalosporins, should be given intravenously. Surgical treatment is the same as for necrotising fasciitis (see above). In established gas gangrene with systemic toxicity, amputation of the involved extremity is life saving and should not be delayed. No attempt is made at closure, amputation stumps are left open and the wound is lightly packed with saline-soaked gauze and then dressed.

The role of HBO is not as clear as in necrotising fasciitis, but it is recommended in severe cases if the facilities are available.

Crush injury and syndrome

A crush injury occurs when a body part is subjected to a high degree of force or pressure, usually after being squeezed between two heavy or immobile objects. Damage related to a

Summary box 29.9

Gas gangrene

- Caused by *Clostridium perfringens*
- Spores are present in the soil
- Thrives in anaerobic conditions and produces many exotoxins
- Treat with radical and regular surgical excision
- Give oxygen and penicillin
- Early amputation may be life-saving

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Figure 29.18 (a-c) Extensive crush injury in a man trapped in a fallen house. The depth to which the soft tissues have been devitalised is seen clearly.

crush injury includes lacerations, fractures, bleeding, bruising, compartment syndrome and crush syndrome **(Figure 29.18)**.

Crush syndrome

The association between crush injury, rhabdomyolysis and acute kidney injury was first reported in victims trapped during the 'London Blitz'. It is seen in earthquake and mining accident survivors and in battlefield casualties. Prolonged crushing of muscle leads to a reperfusion injury when the casualty is rescued. This releases myoglobin and vasoactive mediators into the circulation. It also sequesters many litres of fluid, reducing the intravascular volume and resulting in renal vasoconstriction and ischaemia. The myoglobinuria leads to renal failure from tubular obstruction.

The treatment of crushed casualties should begin as soon as they are discovered. Rescuers must be alert to the presence of associated injuries **(Figure 29.19)**. Aggressive volume-loading of patients, preferably before extrication, is the best treatment. After provision of first aid and starting intravenous fluids the patient should be catheterised to measure urine output. In adults, a saline infusion of 1000–1500 mL per hour should be initiated. This should be continued until myoglobin is no longer detectable in the urine. Mannitol administration can reduce the reperfusion component of this injury. Once a flow of urine is observed, a mannitol–alkaline diuresis of up to 8 litres per day should be maintained, keeping the urinary pH greater than 6.5. A late fasciotomy, when it is obvious that the muscles of that compartment must be dead, is only likely to cause a massive release of myoglobin, as well as potentially introducing infection into dead tissue. It therefore best not to perform a fasciotomy in cases where entrapment has been for over 12 hours.

Figure 29.19 Rescuers must be prepared for injuries to the spine. Treatment of crush syndrome should start before extrication.

The London Blitz is the name given to the German air raids on London between the 7th of September 1940 and the 17th of May 1941, during which it is estimated that more than 15 000 people were killed. Blitz is short for Blitzkrieg, the German for 'lightning war'.

Summary box 29.10

Crush syndrome

- Arises as a result of reperfusion
- Acute kidney injury and renal failure from myoglobinuria is a complication
- A late fasciotomy may make things worse not better

Intensive care is required with close attention to fluid balance and renal dialysis if required.

Compartment syndrome

A compartment syndrome develops when the pressure within a muscle compartment starts to rise as a result of trauma (see Chapter 28). This occurs in muscles enclosed in a fascia such as the calf and forearm muscles and the intrinsic muscles of the hand and foot. A tight bandage or plaster, haemorrhage from a fracture or severe blunt trauma leads to a rise in pressure in the compartment until it exceeds venous drainage pressure. If the pressure rises further, it will cut off perfusion of the muscle. Passive stretching of the affected muscle will cause extreme pain and this is diagnostic of the condition. If the condition is left unrelieved, then nerves passing through the compartment will cease to function and the muscle will die and then undergo fibrosis and shortening, producing a Volkmann's ischaemic contracture. Removal of any constricting agent and, if necessary, a fasciotomy will relieve the pressure and muscle perfusion will restart. Pressure studies are not reliable and if in doubt, perform a fasciotomy.

Summary box 29.11

Compartment syndrome

- Commonest in a closed fracture or soft-tissue crush injury
- Pain on passive extension of the muscles is diagnostic
- Intra-compartmental pressure studies are not reliable
- If there is any suspicion, then fasciotomy must be performed early

Frost bite and immersion injuries (trench foot)

Frost bite occurs when a part of the body freezes. The cells are disrupted and the tissue dies. It is in effect a 'cold' burn and can be categorised according to the depth that it affects in the same way as a conventional burn. Other mechanisms at play include vasoconstriction caused by cold, capillary sludging and reperfusion injury with the release of free radicals, which occurs on rewarming the part. It commonly involves the fingers, toes, cheeks, the tip of the nose and the ears. When frozen the tissue feels hard and cannot be indented. Immersion injury is a cold injury, which does not involve actual freezing of the tissue and is commonly caused by prolonged immersion in cold water (hence trench foot). The patient may also be hypothermic. Warming should be gentle as the heat used may actually cause a burn! Rehydration with warm fluids and use of non-steroidal anti-inflammatory drugs like ibuprofen are beneficial. Demarcation will occur between dead and viable tissue and at this stage no surgery should be undertaken as there is often considerable deep recovery. The injured area should be kept clean and dry and efforts made to prevent further injury, as well as to prevent infection. Definitive surgery to excise dead tissue can be left for many months. Recent developments, such as the use of tissue plasminogen activator (TPA) and nerve blocks, show promising results in reducing amputations, but have to be started within 24 hours and are seldom possible in the field.

Summary box 29.12

Frostbite

- Can be superficial or deep like a burn
- Rewarm gently
- Allow demarcation to occur naturally
- Protect against further trauma and infection

HANDING OVER

Follow-up and secondary problems

The medical aspect of disaster management does not involve a single short-term effort. It requires a long-term commitment and involvement of various disciplines. Because of the large numbers of casualties, the initial treatment is directed towards the anatomical restoration of damaged structures. There are therefore numerous patients who will need secondary procedures for functional restoration. This second wave of patients is encountered 3–6 months following a major catastrophe and arrangements should be made to deal with this.

Designated centres

Initially, the casualties may be scattered amongst many hospitals. After the first few weeks most of the acute problems have been dealt with and only those patients who require longer-term treatment remain. At this point it is advisable to designate a particular hospital as a centre for these patients. It concentrates resources and expertise and makes to follow up easier.

DISASTER PLANS

Disasters are unforeseen events and planning for them may seem paradoxical. It has, however, been shown that disaster planning not only works but also saves lives. Disaster planning is a wide field but a résumé of the important aspects follows.

Establishment of a national disaster management organisation

This is the first step in the planning for disasters. Most resource-rich countries already have such an agency, which

can formulate policy at the national level and has the infrastructure to react quickly when the need arises.

Anticipating disasters

Areas near active volcanoes and geological fault lines are at risk from seismic disturbances, whereas regions along major rivers are liable to flooding. The urban centres of all countries are now potential targets for terrorist attacks. It is important to not only carry out threat assessments but also, if possible, set up an early warning system.

Evacuation planning

Evacuation of large population centres as a prelude to, or in the wake of, an impending disaster is a complex exercise. Yet it may be the most prudent course of action to remove as many people as possible from harm's way. Clear identification of exit routes must be determined and communicated to the populations at risk.

Organisation of emergency services

Emergency services such as the fire brigade, police and ambulance service must have defined roles and areas of responsibility to ensure a coordinated response during a crisis. Members of these teams must be included in the planning phase to ensure that the final plan is practicable and reflects the situation on the ground.

Summary box 29.13

Disaster planning

- Disaster can be anticipated and should be prepared for
- Evacuation of a whole population may be a best option
- Coordination between military, police,fire, ambulance and medical services is important

Medical planning

Identification of hospitals able to take large numbers of casualties and the location of areas that can be used for patient holding and triage in case of mass casualties is important. Hospitals that offer specialised services should be identified and their role during a major crisis defined. Suitable hospitals in the surrounding areas must be designated as overflow hospitals in the eventuality of a very large volume of patients.

Chapter 30

Conflict surgery

Learning objectives

To understand and appreciate:

- Fundamental differences of war surgery
- Injury patterns of modern warfare
- Principles of war surgical management
- Blast and ballistic injury

INTRODUCTION

'He who wishes to be a surgeon must first go to war.'
Hippocrates, (c. 460–377 BC)

The treatment of war wounds is as ancient as warfare itself. The Edwin Smith papyrus has been dated to between 1600 BC and is the oldest known treatise on trauma surgery and anatomy.[1] The history of battlefield surgery is the history of surgical advancement and the importance of the medical lessons learned from war have long been recognised.

While almost every conflict has served to increase our knowledge of the treatment of war injuries, and many individuals have played significant parts is the development of war surgery, Dominque Jean Larrey is considered by many to be the first modern military surgeon. Larrey, a French battlefield surgeon and favourite of Napoleon, devised some of the first systems of triage and casualty care that still form the fundamentals of modern military medicine.

HOW IS WAR SURGERY DIFFERENT?

While civilian trauma surgery bears some of the hallmarks of the battlefield, there are fundamental contrasts in environment and injury pattern that must be appreciated:

- The environment of war is likely to be austere. While recent long-term deployment has led to the establishment of some well-equipped field hospitals, logistical and personnel restrictions mean that sophisticated diagnostic and therapeutic techniques may not be available.
- War is hostile and potentially dangerous. Necessary workforce protection must be considered to ensure safety of medical personnel and patients alike. Modern fighting forces employ physician-led resuscitation, along with forward surgical teams. Moving medical personal closer to the fighting may increase their personnel risk.
- War injuries are different to civilian trauma. Modern weapons may deliver such amounts of energy that the tissue destruction and patterns of injury seen are unlike all but the most extreme of civilian trauma practice.
- War is a mass casualty situation. Although casualty numbers vary between treatment facilities, triage is an important aspect of military surgery. The dictum 'do the best for the most, not everything for everyone' is important and may require a change in thinking for many used to civilian practice.
- War surgery is usually delivered in stages. The principles of damage control are often applied to allow transfer of patients between echelons of care. Careful planning, coordination and communication is essential.

ETHICAL AND LEGAL CONSIDERATIONS

International Humanitarian Law (IHL) regulates humanitarian issues during armed conflict. Modern IHL is derived from a variety of sources, notably the Geneva Conventions and its additional protocols, along with further specific regulations from the United Nations and The Hague. IHL provides medical personnel with rights in times of armed war, but also assigns duties to them surrounding the rights of protected personnel under their care.

The papyrus is named after Edwin Smith, the Egyptologist who discovered it in 1866 and held at the New York Academy of Medicine.
Dominique Jean Larrey, 1766–1842, French surgeon in Napoleon's Grand Armée.

Importantly, medical personnel are bound by medical ethics and IHL to treat patients solely based on need and without regard for their nationality, race and class, religious or political beliefs.

Along with providing medical support to deployed forces, treatment is offered to both home nation and enemy combatants. The treatment of such patients may require a change in the approach to the definitive care. Evacuation of these personnel to certain categories of subsequent facility (see below) may not be possible and the staged approach to care may need modification. Transfer to host nation medical facilities may be possible but dependent on local capability.

This scenario may require an adaption to clinical thinking. As an example, consider the ethical and logistical dilemma in performing revascularisation and orthoplastic procedures for a local patient in a country without rehabilitation facilities.

Medical personnel and facilities are protected under IHL and should not be attacked. However, the nature of modern conflict is unconventional; guerrilla warfare and the inability of deployed forces to define the enemy combatant requires security of facilities and personnel to be of the highest priority.

MEDICAL SUPPORT ROLES

The term 'role' is used to designate the tiers of medical support that integrate into a modern military operation. An appreciation of the capabilities and limitations of these roles is essential to improving the care of casualties at each stage. Different nations and forces will have medical support configured with some variability but overall, systems are similar in order to ensure those basic treatment, supply and evacuation needs that are essential for a military operation.

- **Role 1** medical support provides for routine primary health care, specialised first aid, triage, resuscitation and stabilisation. It is integrated within a small unit. The capabilities of role 1 care will depend greatly on the size of the unit and the training of the personnel within it.
- **Role 2** provides an intermediate capability for the reception and triage of casualties, as well as being able to perform resuscitation and treatment of shock to a higher technical level than role 1. It is prepared to provide evacuation from role 1 facilities. It has capability for damage control surgery (DCS) and may include a limited holding facility for the short-term holding of casualties until they can return to duty or evacuated.
- **Role 3** medical support is deployed hospital care and the elements required to support it. This includes a mission-tailored variety of clinical specialties including primary surgery and diagnostic support. In recent conflicts role 3 facilities grew and evolved into sophisticated hard-built hospitals.
- **Role 4** provides the full spectrum of definitive medical care that cannot be deployed to theatre or is too time-consuming to be conducted there. It is normally provided in the country of origin or an allied nation depending on the location of deployment and time-lines of transfer.

Summary box 30.1

Medical support roles

- R1– unit level medical care including first aid and primary health care
- R2 – intermediate unit for resuscitation, damage control and stabilisation
- R3 – deployed hospital care with multi-speciality capability
- R4 – definitive hospital care within home or allied nation

It is important to appreciate that these roles are highly variable both within and between different nations. The size and scale of the operations as a whole, along with predictions of both civilian and military medical requirements, will dictate the structure of the medical support.

MEDICAL EVACUATION

Medical evacuation refers to the movement and en-route care of casualties within a conflict zone. The evacuation may be the initial movement from a battlefield or between other more sophisticated echelons of care, up to and including repatriation to a home nation.

Aeromedical evacuation using either fixed or rotary wing aircraft has had a major impact on the evacuation timelines. Certain considerations must be made prior to and during aeromedical evacuation:

- the patient should be sufficiently stabilised for the anticipated mode and duration of travel;
- the patient's airway and breathing are adequate for movement;
- intravenous access, surgical drains, urinary catheters and any other tubes should be firmly secured;
- patients at high risk for thoracic barotrauma should be considered for prophylactic chest tube placement before prolonged aeromedical evacuation;
- blankets and/or warmers should cover the patient securely to mitigate against hypothermia.

The capability of different evacuation platforms may vary from highly sophisticated mobile critical care units to the simple transportation of casualties by non-medical personnel. These capabilities, along with the time-lines and distances involved in casualty movement should be major considerations for the planning of medical support operations.

PATTERNS OF MODERN WAR SURGERY

Modern warfare has changed over recent decades. Cause of injury is particular to individual conflict, nation and armed service.[2] Historically, the predominance of penetrating trauma was sustained by combat infantry, while naval and air personnel sustained more blunt injuries (*Table 30.1*).

Improvements in trauma scoring systems and the development of a concise system for the recording of injuries and casualty care have increased the ability of modern armed

TABLE 30.1 Historical causes of injury amongst US service personnel. Adapted from Champion *et al*.[2]

	Service			
Mechanism	Infantry (%)	Armoured (%)	Sea (%)	Air (%)
Ballistic	90	50	25	5
Blunt	2–3	5	10	50
Blast	2–3	5	10	<10
Thermal	2–3	25	30	25
Combined	<5	15	25	10

services to analyse the injury patterns of their deployed personnel.

A cohort analysis of combat injuries sustained by US forces[3] showed significant differences in injury patterns sustained in the most recent Afghanistan and Iraq conflicts compared with World War 2, Korea and Vietnam. Head and neck injuries were far more common in recent conflict while thoracic and extremity injuries were less so. This is probably due to increased use of body armour and similar personnel protective equipment.

Mechanism of injury has also changed. While ballistic injuries remain an important contributor to battlefield trauma, injuries due to explosions (which includes improvised explosive devices [IEDs], landmines, mortars, grenades and rockets) have become increasingly common and are now the predominant mode of wounding and fatality. The relative proportions of injuries caused by explosive and ballistic weapons is shown in *Table 30.2*.

The emergence of explosive patterns of injury is due to the increasing use of IEDs within conflict. IEDs have been the signature weapon within operations in Afghanistan and Iraq; however, their use has not been limited to these regions. The relative low cost, ease of production and widespread expertise means that IEDs will likely play significant roles in most contemporary and future conflicts.

PRINCIPLES OF WAR SURGERY

Battlefield death occurs early (or immediately) due to devastating central nervous system injury and haemorrhage, or late due to infection. Some of the injuries causing immediate death (including brain, heart and great vessel injury) are non-survivable[4] and may only be managed with prevention.

TABLE 30.2 Relative proportion of injuries caused by gunshot wounds and explosions amongst US personnel. Adapted from Owens *et al*.[3]

	Gunshot wound	Explosion
US Civil War	91	9
World War I	65	35
World War II	27	73
Korea	31	69
Vietnam	35	65
Iraq/Afghanistan	19	81

Treatment of haemorrhage is therefore the mainstay of military trauma medicine. Bleeding should be recognised and managed from point of wounding.[5] Tourniquets are indicated for the control of catastrophic extremity bleeding. Non-compressible torso haemorrhage carries a poor prognosis,[6] although it may be amenable to methods of endovascular control not yet commonly used.[7]

An approach to surgery must be employed to stop bleeding, to remove necrotic tissue and foreign material and to reduce contamination. In addition to life-saving surgery, procedures to salvage limbs, including revascularisation (or temporary shunting) and fasciotomy, should be considered early, when physiology allows.

DAMAGE CONTROL SURGERY

DCS was first formerly described by Rotondo *et al*[8], although the idea of an abbreviated laparotomy for the unwell patient was not totally novel. The concepts of DCS were initially applied to complex trauma patients with combined vascular and visceral injuries. Improved outcomes were seen following DCS principles compared with conventional definitive surgery.

The DCS approach is to restore physiology over anatomy and is typically divided into several phases:

- **Phase 1**. Recognition of injury severity and need for damage control principles, both surgical and resuscitative. Features of phase 1 include rapid-sequence induction of anaesthesia and intubation, early rewarming and prompt movement to the operating theatre.
- **Phase 2**. Immediate laparotomy with rapid control of bleeding and contamination, abdominal packing and temporary wound closure.
- **Phase 3**. Movement to the intensive care unit (ICU) for ongoing resuscitation with normalisation of biochemical and physiological parameters.
- **Phase 4**. Re-exploration in theatre to perform definitive repair of all injuries. Multiple procedures on multiple occasions may be required. Even at this stage, non-essential procedures may be truncated or delayed if physiology deteriorates.

Selection of patients for damage control management may not be straightforward. While various physiological and biochemical markers of injury have been suggested, there is no validated threshold. Hypothermia, coagulopathy, acidosis,

blood loss and anticipated operative time should all be considered (see Chapters 22 and 23).

The benefits of a DCS approach to those patients that need it has been repeatedly shown, but liberal, and perhaps overzealous use of DCS is unlikely to be beneficial to those who would tolerate definitive repair. DCS puts a heavy toll on theatre and ICU resources. In addition, multiple trips to theatre may increase the likelihood of morbidity including abdominal wall hernias, fistulae and infection.

Damage control resuscitation (DCR) should be concurrent with DCS. The principles of DCR include permissive hypotension, avoidance of crystalloid with haemostatic resuscitation, and recognition and management of acute traumatic coagulopathy (ATC). The application of these principles to military patients is uncertain because of longer time-lines. Prolonged periods of permissive hypotension are likely to be harmful[9] while haemostatic resuscitation and management of ACT is ineffectual in the absence of haemorrhage control.[10]

MASSIVE TRANSFUSION

While haemorrhage control prior to the need for massive transfusion is ideal, this is often not the case. The degree of injury and associated massive blood loss associated with war injuries may necessitate large volume transfusion. The use of crystalloids to resuscitate exsanguinating patients is strongly discouraged, but the optimal ratio of blood products has not yet been ascertained. Massive Transfusion Protocols exist within most deployed units. Use of such a protocol at a UK role 3 facility, along with aggressive resuscitation and use of blood products, has been associated with improved trauma outcomes.[11] The success of such a protocol is highly dependent on a steady stream of blood products and reflects the sophisticated transfusion infrastructure that should be woven into a deployed capability,

Blood transfusion is increasingly administered in a more forward location (within both role 1 and role 2 environments) with limited volumes of blood transported to the point of wounding by aeromedical response teams. The future will almost certainly include more alternatives to conventional blood components, which can combine adequate oxygen carriage with positive or neutral effects on patient coagulation.

DECISION-MAKING WITHIN THE DEPLOYED ENVIRONMENT

The damage control approach is vital in a proportion of war injuries, but thought must be given to available resources. Within a well-established role 3 unit, both DCS and definitive procedures are likely to be possible. Blood and blood products are also likely to be available and restocked regularly. In this scenario, patient physiology is the major determinant of mode of care.

In contrast, decision-making becomes more crucial within the austere environment. Theatre space, intensive care beds, equipment and blood products may be limited. Long evacuation times may contraindicate permissive hypotension.

Limited resources, such as blood, may need to be divided between casualties. Within a role 1 or role 2 facility, immediate evacuation may be undertaken in preference to a more thorough stabilisation.

Decision-making of this nature is complex and difficult and requires practice in the context of simulation, exercises and courses.

WEAPON EFFECTS

Ballistics

The ability to manage conflict injuries relies on an understanding of the underlying mechanism of wounding, which is likely to be different to civilian trauma. As stated, while ballistic injuries are no longer the most common cause of battlefield injury, firearms remain a common element in all conflict. Civilian trauma practice, depending on local firearm laws, may well encompass a significant volume of gunshot wounds, although patterns of injury with war wounds may well differ due to the weapons used. An understanding of the mechanism of ballistic wounding is required to treat these wounds effectively.

The earliest recorded depiction of a firearm is from 1326, but firearms became ubiquitous on the battlefield during the 17th century.[12] Ballistic weapons all work with the same principles – an explosion is used to propel a projectile along and out of a straight tube – but have evolved considerably from rudimentary cannons to sophisticated modern day firearms. The explosive force within a modern firearm comes from propellant encased within a cartridge. The basic design of a cartridge is shown in **Figure 30.1**.

Internal ballistics describes the characteristics of a projectile, while inside the hammer mechanism of the weapon strikes a primer at the base of the cartridge, which ignites the propellant. Hot gas produced by the explosion expands and forces the bullet away from the cartridge and along the barrel. Spiral grooves, or rifling, imparts spin on the bullet, which aids in accuracy and stabilisation.

While the basic principles apply to nearly all firearms, advances in firearm design have served predominantly to improve accuracy, reliability and rate of fire. Ammunition is normally held within a magazine or belt that loads directly into the chamber of the weapon. The loading mechanism determines the rate of fire. In a semi-automatic or fully automatic system, the recoil forces of the spent cartridge eject the

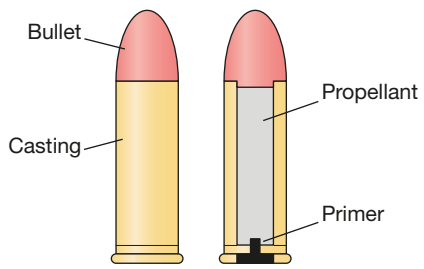

Figure 30.1 Diagram of basic cartridge structure.

cartridge while resetting the chamber and accepting a new cartridge from the magazine, such that the process may be repeated rapidly.

Shotguns utilise a similar mechanism except that a collection of smaller projectiles – 'shot' – are expelled rather than a single bullet. These smaller projectiles disperse away from one another after leaving the barrel. The degree of dispersal is dependent on the relative length of the barrel.

External ballistics describe the characteristics of a projectile in free flight. It may be influenced by ammunition type and ambient conditions. Ammunition differs widely with the most pronounced difference between pistol and rifle ammunition. Rifles are expected to be accurate at ranges up to and beyond 1000 metres, while pistols are intended for far shorter ranges. Rifle cartridges are longer and typically have a greater proportion of propellant to projectile. The characteristics of ammunition that determine wound effects are the size or calibre (which describes the internal diameter of the weapon barrel) and the material components of the bullet:

- full metal jacket ammunition has an outer coating of harder metal around a softer core. This reduces breakdown of the bullet along the barrel and improves accuracy, reliability and target penetration;
- soft tip and hollow point ammunition have a degree of exposed lead that flattens and deforms on impact. These bullets have less penetrating ability but rapidly transfer energy to the impacted tissue and cause large wounds.

Ballistic injuries

Terminal ballistics (or wound ballistics) describes the interaction between projectiles and target tissue. This interaction and subsequent transfer of energy cause injury. The kinetic energy of the bullet is related to the mass and velocity of the impacting projectile. Both the mass and velocity of military firearms may be considerably greater than those commonly seen in civilian trauma, leading to higher energies and more severe wounds. While the weapon and ammunition type may be a determinant in the potential injury caused, many other factors, including range, angle, clothing, armour and anatomical variation, will determine the actual wound pattern. Although an understanding of ballistic science may allow a surgeon to anticipate possible injuries, each should be evaluated and managed individually.

In consideration of the damage done, tissue may be described by the areas of disruption caused by the projectile – the permanent and temporary wound cavity, which are illustrated in **Figure 30.2**.

The permanent cavity is the localised area of definitive tissue injury caused by contact with the projectile. This area of cell necrosis is the result of direct contact, crushing and laceration of tissues in the path of the projectile. The size and trajectory of the projectile determines the cavity size. This type of cavity is the predominant wound effect of pistol bullets that have relatively low energy. Higher energy projectiles, including military rifle and machine gun bullets, may be subject to greater degrees of deformation and tumbling as they travel through tissue. This increases the effective cross-sectional area of the projectile and may lead to a larger and less regular permanent wound cavity.

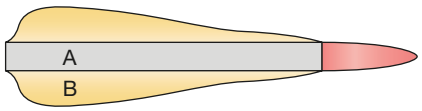

Figure 30.2 Diagram showing permanent wound cavity (A) and temporary wound cavity (B). This relatively large temporary cavity would be more typical of a higher-energy weapon.

In contrast, the temporary wound cavity is created by lateral displacement of tissue that has not been in direct contact with the bullet. The degree of damage in this area is dependent on the amount of energy transferred by the bullet and the material properties of the tissue itself. Individual tissues have an elastic strength that resists the stretching caused by a projectile. As the energy increases, the tissue is no longer able to rebound and above certain thresholds, contusion, laceration and permanent damage may occur. Skin, muscle, lung and bowel wall tissues have good elastic strength and may rebound well following stretch, with minimal damage within the temporary wound cavity. In contrast, liver, brain and spleen have poor elasticity and are more likely to shatter when stretched. Incompressibility of fluids within hollow organs (bowel and bladder) means that they are vulnerable to stretch despite favourable properties of the tissue wall itself.

Summary box 30.2

Ballistics

- Internal ballistics – characterise projectile within weapon during firing
- External ballistics – characterise projectile in free flight
- Terminal ballistics – characterise projectile/tissue interaction

MANAGEMENT OF GUNSHOT WOUNDS

The management of gunshot wounds in a conflict setting may differ to civilian practice. The typical low energy wounds caused by pistols are sometimes managed conservatively in civilian trauma centres with adequate wound care, cleaning and antibiotics. Military wounds are associated with higher energies, higher rates of infection and more severe injury. The extent of these injuries, including the size of the wound cavities, may not be adequately assessed without thorough surgical examination (**Figure 30.3**). As such, most penetrating wounds in the military setting are explored under anaesthetic. The extent and capacity for recovery of the temporary wound cavity may not be appreciated at the time of the first operation. A damage control approach should be adopted if the physiology of the patient dictates so. An interval period may also allow for adequate appreciation of the permanent wound cavity, along with response of the surrounding structures and demarcation of non-viable tissue.

Figure 30.3 Entry wound to the right shoulder **(a)** with the wound extended in order to assess adequately **(b)**.

such as fireworks and flares. Low explosives more commonly cause burns than typical blast injuries and will not be discussed further.

In contrast, high explosives degrade via detonation. Shockwaves are passed through the material at supersonic speeds and the resultant energy is expelled at very high rates. High explosives include plastic explosive and trinitrotoluene (TNT). The input of a relatively small amount of energy results in the production of a very large volume of gas, at high speed and pressure. The outward expansion causes a wave of compressed air that moves away from the point of detonation at supersonic speeds and in a uniform sphere (within a free field).

The change in surrounding pressure is described as the blast overpressure. Following detonation within a free field, there is a near instantaneous pressure rise, which falls exponentially. This is classically described by the Friedlander curve **(Figure 30.4)**.

This characteristic pressure peak is only seen during a truly free (almost theoretical) scenario. Enclosure of the blast or reflection of blast waves by people, vehicles or buildings is likely to change the overpressure profile such that high pressures may be sustained for longer periods and have a greater propensity to cause injury. For this reason, blasts within enclosed spaces are notable for causing a greater range and severity of injury.

In addition to expanding gases, detonation of explosives may result in the expulsion of fragments. These fragments may be part of a device casing, separate material deliberately added with the intention of fragmentation, or environmental material flung by the blast.

Blast winds are generated by the displacement of surrounding air. The direction of these winds may change as the blast overpressure drops transiently beneath ambient pressure and creates a partial vacuum.

BLAST

As previously discussed, blast has become the predominant mechanism of injury in recent conflict. Unfortunately, terrorist attacks within urban centres mean that these injuries are increasingly encountered within civilian practice.

While explosives come in many forms and their effects vary as a result, fundamental principles underlie all blast events.

An explosive may be defined as 'a substance that can be made to undergo a rapid chemical reaction that will transform a liquid or solid into gas, liberating a large amount of energy'.[13] The explosive properties of such a material are determined by the chemical composition of the material and the speed at which energy is expelled. Low explosives react by a process called deflagration whereby the reaction is propagated by flame passing through the material at a rate significantly slower than the speed of sound. They are made up of a combustible material and an accompanying oxidant. Low explosives include gunpowder, gasoline and pyrotechnics

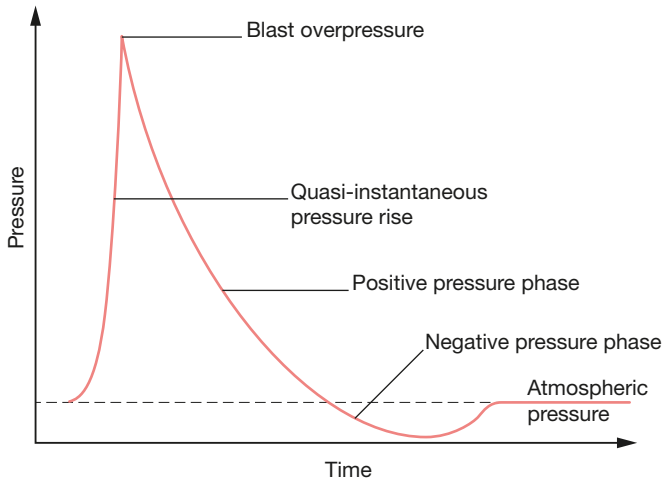

Figure 30.4 Theoretical blast overpressure changes within a free field.

Improvised explosive devices

The characteristic weapon of modern warfare has been the IED, which was the leading cause of death amongst coalition troops in Iraq and Afghanistan.[14] These devices may range from rudimentary homemade explosives to sophisticated devices containing high explosives. Within this broad range of devices are further categories including roadside explosives and blast mines, suicide bombers, and explosive formed projectiles (EFPs). EFPs are a particular form of device with a deformable plate on the uppermost surface. The detonation of the device and expansion of the explosive products deforms this plate into a missile shape, while simultaneously accelerating it upwards to very high velocities. Alternatively, copper plates may melt to create a high-speed molten jet (a shaped charge). Upon contact with a target (typically a vehicle), the missile impacts the hull of the vehicle with a degree of penetration dependent on the device and vehicle armour. Huge amounts of kinetic energy are dispersed through the vehicle and occupants. Injuries may be caused by both direct impact of the deforming hull and gross upwards acceleration, followed by downwards deceleration of the whole vehicle.

BLAST INJURIES

Blast injuries are classified by the blast mechanism (*Table 30.3*).

Primary blast injury

Primary blast injuries result from the overpressure and are, as such, unique to blast. The effect of blast overpressure is most marked at the interface between air and tissue or liquid.

Tympanic membrane (TM) rupture is the most common primary blast injury. Patients may be asymptomatic or have a degree of transient hearing loss and otorrhoea. Previously, the presence of TM rupture was used as a marker for other occult blast injuries. This has been challenged recently by findings that show TM injury is not ubiquitous in the presence of more severe primary blast injury. The blast environment and orientation of the ear canal to the shockwave are likely to determine the chance of injury.

TABLE 30.3 Classification of blast injuries.

Classification	Injury type	Examples
Primary blast	Overpressure	Tympanic membrane injury, blast lung, intestinal blast injury
Secondary blast	Penetrating/ fragmentation	All penetrating injuries
Tertiary blast	Blunt	Blunt and crush injuries. Traumatic amputation.
Quaternary blast	Miscellaneous	Burns, inhalation injury
Quinary blast	Effect of device additions	Radiation sickness, infection

Primary blast lung injury, or blast lung, is the most widely researched blast phenomenon. The exact mechanism of blast lung remains contested but it depends on the propagation of energy from the shockwave into the lung tissue, where it causes disruption. Proposed mechanisms of injury include spalling (disruption of tissues at air–liquid interfaces), implosion (compression and re-expansion of air-filled structures) and rapid acceleration of tissues of different densities. Large animal models have demonstrated that the level of injury is related to the rate of chest wall displacement, rather than the maximal depth of deflection.[15] Severity of injury is dependent on strength of the blast, range from detonation and surrounding environment.

Those working closely with explosives may wear personal armour that assists in decoupling the effect of primary blast. Current examples of such armour tend to be cumbersome. More common varieties of torso body armour provide protection against penetrating injury but probably do little to mitigate the effects of primary blast.

The pathophysiology of blast lung includes both immediate and delayed responses. There is an immediate bradycardia and apnoea of variable length, which is a likely to be a vagally mediated reflex.[16] The lung injury itself is typified by alveolar capillary rupture with subsequent intrapulmonary bleeding and oedema. The extent of this injury is proportional to the blast exposure and may range from microscopic petechial injury to areas of frank haemorrhage.

While rarely seen in isolation, primary blast may leave little external evidence of injury since the skin itself is rarely affected. Clinical features of blast lung include progressive hypoxia, which may not be apparent at time of injury and is related to the inflammatory response to intrapulmonary haemorrhage and worsening oedema.

Other structural lung injuries are associated with primary blast, although the prediction of these injuries by blast conditions is not consistent and likely complicated by tertiary impact. Pneumothoraces may occur due to pleural rupture in the absence of penetrating injury. Injury to the larger vessels may lead to haemothoraces and the formation of alveolar-venous or bronco-venous fistulae. Air embolism due to such fistulae may cause acute hypoxia with cardiovascular collapse and is a leading cause of death in those who do not survive until treatment.

Diagnosis of blast lung is clinical with findings of hypoxia following blast exposure. Typical 'bat-wing' pulmonary infiltrates are seen on chest radiograph and computed tomography may discriminate these injuries from the more peripheral contusions seen in blunt trauma. Imaging may be useful in detecting associated structural lung injuries.

Treatment of blast lung is largely supportive. Mechanical ventilation may be required but consideration should be given to the possibility of air embolism and pneumothorax that may be exacerbated. Some centres advocate the use of prophylactic bilateral pleural decompression, although there is little evidence to suggest an effect on outcomes. Patients with significant blast lung injury are highly likely to have sustained other blast related injuries and any management plan should consider their overall condition.

The abdomen may also be subject to primary blast. The incidence of abdominal injury due to air blast has not been extensively examined, although a recent review of multiple incidents, including a variety of blast conditions, showed that abdominal injury is not common – seen in around 3% of incidents.[17]

Damage is dependent on coupling of the blast overpressure and shockwave to a stress wave that travels through the abdomen. The effect of shockwave dispersal is most marked at tissue–air interfaces. As such, the hollow organs are those most commonly injured. The caecum segment is probably most sensitive to intestinal blast injury. Conversely, the small bowel and its extensive mesentery may be more susceptible to large shear waves causing mesenteric tearing.

Presentation of primary blast injury to the bowel may be delayed relative to the acute onset of blast lung. Abdominal symptoms may be absent initially with progression to pain and frank peritonitis should perforation and contamination occur. Given the lack of external injury, indications for operative intervention are largely clinical, as with conventional blunt abdominal trauma. The patient should be assessed anaesthetically with particular consideration to the effect of anaesthesia and ventilation on any concomitant blast lung injury.

The most common operative findings of intestinal blast are subserosal haemorrhage.[17] Tearing of the mucosal surface with bleeding into the lumen of the tract may occur following repeated exposure to relatively lower blast overpressures. As in blunt injury, there is a propensity for mural haematomata to progress to perforation due to tissue necrosis. Full-thickness injuries to the bowel with immediate perforation can occur with a greater exposure to blast overpressure.

The surgical management of blast bowel injury is that of any penetrating and blunt trauma, with primary repair or resection as indicated. Surgical judgment is essential regarding the findings of non-perforated but contused bowel. A damage control approach to such injuries may allow for repeat assessment later, but in a physiologically well patient, in whom a relook would not be justified, the surgeon must decide to resect a segment or risk future progression of these lesions to perforation.

The solid organs are more resistant to primary blast. Parenchymal disruption due to the shockwave has been described at very high levels of overpressure, although the experimental data for these injuries are sparse. Injury, with subsequent bleeding, may result from rapid distractions of organ attachments and mesenteries. These blast conditions are more likely encountered in enclosed conditions and differentiation of primary from tertiary injuries is difficult.

Secondary blast injury

Secondary blast injury refers to the effect of fragments that are accelerated away from the device following detonation. Sources of fragments include:

- the casing of the device;
- purposefully placed fragments within the device. These may include nails, bolts or ball bearings and are embedded within the device or adherent to the exterior;

Figure 30.5 Large anterior fragmentation injury.

- nearby objects including glass and stones;
- biological material including bone may be expelled, particularly following a suicide bomb or anti-personnel mine attack.

Shrapnel is often used to describe explosive fragments, although the term more strictly applied to a specific from of artillery shell.

The energy of a primary blast wave disperses quickly in proportion to the distance from the blast; it is subject to the inverse cube law. As such, only those within a reasonably small radius of the blast are affected. Conversely, the velocity and wounding potential of an energised fragment is subject to the inverse square law. Secondary blast injuries may occur at long range from the detonation. Fragments may be accelerated up to very high velocities. As with ballistics, injuries are dependent on the range and energy of the fragment.

In contrast to bullet wounds, the variability of fragments produces a wide range of wounds and no two wounds will be the same **(Figure 30.5)**. The irregular surfaces of fragments cause complex patterns of yaw and tumble. Both permanent and temporary wound cavities may be unpredictable and irregular.

The management of fragment wounds is similar to ballistic and conventional penetrating trauma. Wounds should be adequately debrided. Fragment wounds should be considered dirty and principles of septic surgery applied. Where possible, serial debridement and delayed primary closure should be attempted.

The fragments should be removed at time of surgery if easily accessible. Other indications for early removal include fragments within joint spaces or adjacent to structures with danger of erosion and further injuries. Late indications for fragment removal include ongoing sepsis, pain or lack of function.

Tertiary blast injury

Tertiary blast injury is the result of gross movement of personnel, objects or infrastructure by blast wind. Tertiary injury is analogous to conventional blunt trauma and may cause a

wide variety of injuries to all organ systems. Traumatic amputation is typically included within this category, although primary blast and the shattering or 'brissiance' effect on bone may play a part.

Quaternary and quinary injury

Quaternary blast injury refers to a miscellaneous group of injuries that do not fall within other categories. These include burns, inhalational injuries and late-onset respiratory problems. Quinary injury, a more novel concept, refers to injury caused by the intentional addition of either biologically or radioactively active material to an explosive device.

Environmental effects

As already alluded to, the shockwave of blast overpressure is modified by an enclosed or partially enclosed space. Environmental differences may make marked differences to injury rates and clinical presentations following blast. Higher rates of blast lung and TM rupture are seen following enclosed blast (in which both casualty and blast are enclosed). In contrast, secondary blast injuries may be lower in number as more people are protected from energised fragments. Tertiary injury is difficult to predict based on blast characteristics but a higher proportion of blunt injuries have been seen following enclosed blast.

A distinct pattern of injury has been described following underbody blast against military vehicles. Underbody blast casualties have a greater range of injuries and are overall more severely injured.[18] In addition to blunt injury sustained from displacement within the vehicle, the effect of blast is manifested both by propagation of the shockwave through a solid, with upwards deformation of the floor and a rapid upwards acceleration of the whole vehicle and subsequent deceleration following impact with the ground. The solid blast injury burden includes severe foot and ankle[19] and pelvic injury.[20] Mortality from underbody blast is most commonly caused by head injury and non-compressible torso haemorrhage including aortic disruption and liver laceration.

In contrast, the dismounted IED casualty may sustain a characteristic pattern of injuries including lower limb amputation, pelvic fracture and genital, perineal and rectal injuries (**Figure 30.6**).

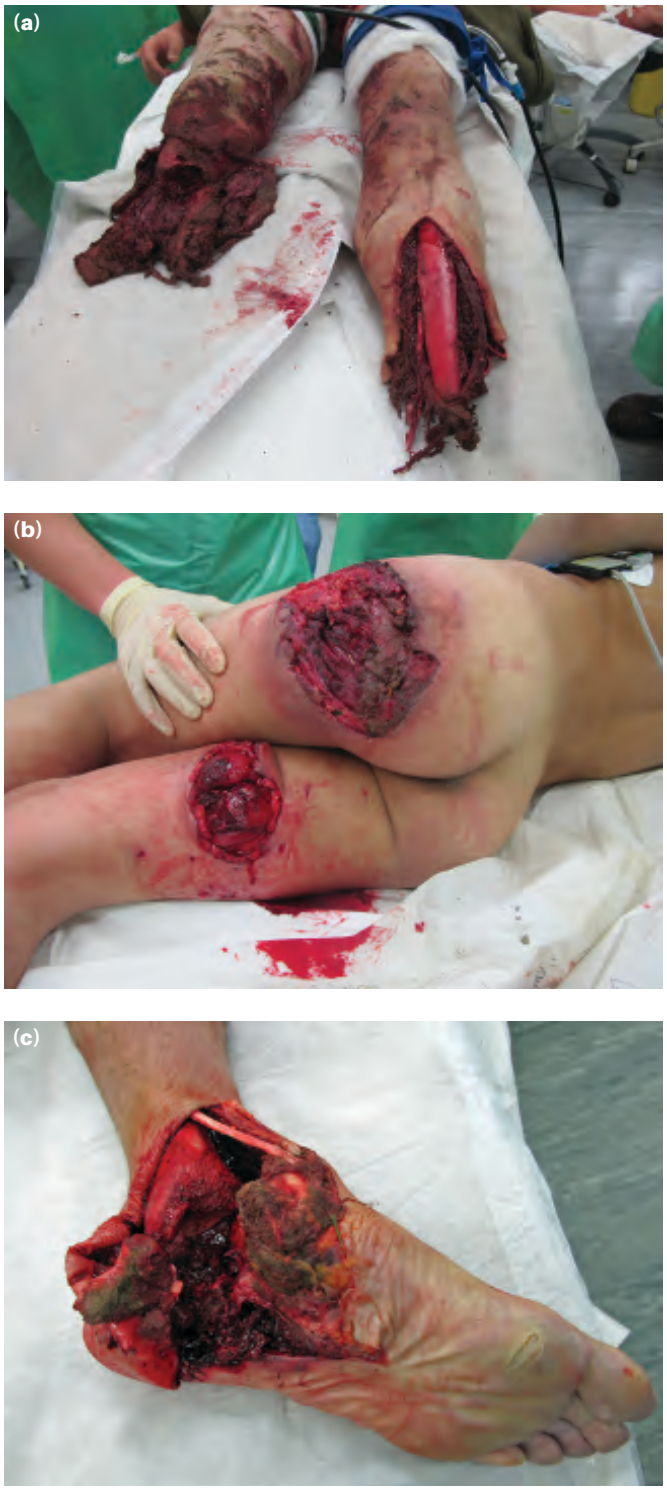

Figure 30.6 Blast injuries including bilateral lower limb amputation **(a)**, buttock and thigh soft tissue injury **(b)** and complex hind foot injury **(c)**. The need for extensive debridement is evident from the level of wound contamination and non-viable tissue.

INFECTION

Battlefield wounds are by their very nature grossly contaminated and the treatment and prevention of infection is one of the basic functions of war surgery. Wounds sustained during warfare are high-energy wounds with large areas of devitalised tissue. Wounding agents are all non-sterile and highly likely to be contaminated by bacteria. Both large calibre ballistic wounds and blast wounds may contain dirty clothing or contaminated fragments. Multiple steps in casualty evacuation and substantial delays before treatment may allow progression of contamination to clinically significant infection.

Specific organism patterns will depend on endemic flora, but commonly seen bacteria include:[21]

- Gram-positive cocci including staphylococci, streptococci and enterococci;
- Gram-negative rods including *Escherichia coli*, *Proteus* and *Klebsiella*;

- *Pseudomonas*, *Enterobacter*, *Acinetobacter* and *Serratia* are common nosocomial pathogens usually expected among casualties following long periods of hospitalisation;
- *Salmonella*, *Shigella* and *Vibrio* should be suspected in cases of bacterial dysentery.

Fungal infection including *Candida* should be considered in casualties hospitalised for prolonged periods, those malnourished or immunosuppressed, or those who have received broad-spectrum antibiotics, adrenocortical steroids or parenteral nutrition.

Techniques to reduce the infectious burden are part of every aspect of war surgery. At point of wounding, sterile dressings should be applied. Antibiotics, if available, should be administered if evacuation and further treatment is likely to be delayed.

Empirical antibiotic therapy should be commenced or continued following movement to a medical facility. The mainstay of treatment is prompt surgical control of the infectious cause with adequate debridement of non-viable tissue and drainage of infective material. Extensive irrigation should be employed to remove dead tissue and foreign bodies. High-pressure wound lavage has been shown to increase bacterial propagation into soft tissue and is not indicated.

With few exceptions (such as facial wounds), closure of contaminated war wounds should not be performed at time of first operation. The open wound should be left with clean, moist dressings. Negative pressure wound therapy should be considered for larger wounds.

Antibiotic therapy should be tailored to specific wounds with empirical antibiotic choice dependant on the injured body region or cavity. Microbial culture will aid the guidance of therapy for more established infection. Contaminated war wounds should be considered tetanus prone and appropriate tetanus prophylaxis administered.

Clinical experience and judgement are essential in the assessment of war wounds. Adequate exposure, often with extension of the wound, is mandated to ensure debridement of all devitalised tissue. Serial operations may be required. Early consideration should be given to soft tissue coverage. The skin is often remarkably resilient to injury and conservative debridement of it may facilitate more successful reconstruction.

PART 5

Elective orthopaedics

Chapter 31

History taking and clinical examination in musculoskeletal disease

Learning objectives

To understand how to:

- Take a comprehensive musculoskeletal history
- Perform a structured and systematic musculoskeletal examination
- Use and interpret special tests
- Use findings to understand the impact on a patient's pain and function

INTRODUCTION

The components of the musculoskeletal (MSK) system include the bones, joints, ligaments, muscles and tendons as well as the neurological and vascular structures. A simple system allows a concise yet comprehensive history to be taken and a reliable examination to be performed. This will permit diagnosis of the common, the rare and the clinically urgent musculoskeletal problems that are likely to be encountered in clinical practice.

HISTORY

Introduction

- Introduce yourself and check the patient's name and date of birth.
- Explain what you are going to do, obtain verbal consent and ensure that the patient is comfortable.

Take a history

- **Presenting complaint**. Start with an open-ended question. Ask the patient to 'explain what the problem is' in their own words, and ask the patient what their hopes and expectations are from the interview.
- **History of the presenting complaint** ('the three Ws'). When did you first notice the problem? What were you doing when it started? Was the onset sudden or did it develop gradually?
- **Associated symptoms**. Ask about the following: pain; swelling; instability – 'giving way'; mechanical symptoms (e.g. locking, clicking, clunking); loss of power; altered sensation.
- **Functional impairment**. Ask whether the patient is having difficulties performing activities of daily living: upper limb, e.g. personal hygiene, feeding; lower limb, e.g. putting on shoes and socks, standing, walking and climbing stairs.
- **Past medical history (PMH)**. Check for comorbid conditions which may contribute to the presenting problem or affect the patient's fitness for an anaesthetic, e.g. diabetes, asthma, previous heart attack or stroke. Check for any previous problems with anaesthetics.
- **Past surgical history**: relevant surgical procedures.
- **Drug history**. Ask about all medication and the following in particular: anticoagulants, steroids, aspirin, immunosuppressant therapy, oral contraceptive pill and hormone replacement therapy.
- **Social history**. Tailor questions to the patient's condition: patient's age; hand dominance; employment status; dependents; alcohol; smoking; hobbies; home help; accommodation – own house, residential or nursing home; use of walking aids; mental test score assessment.
- **Family history**. This may reveal a history of MSK disease.

Summary box 31.1

Taking a history

- Introduce yourself and put the patient at ease
- Explain what you are doing and ensure that the patient agrees
- Start with an open question to understand the presenting complaint
- Check for history of presenting complaint and associated symptoms
- Ask about functional impairment
- Check past medical history and relevant surgical and family history
- Check drug and social history

MUSCULOSKELETAL EXAMINATION

General principles

Apley described a useful and systematic approach to clinical examination. This approach is divided into three parts:

1 look;
2 feel;
3 move.

Look

The inspection begins as soon as you enter the examination room. Look for any walking aids. Remember to look at the whole patient and not just at the joint of interest. For example:

- look at the hands for rheumatoid arthritis;
- look at the eyes for Horner's syndrome;
- look for any obvious upper or lower limb or spinal deformity.

Gait

The gait cycle is all of the activity between the initial contact of the foot with the ground and the succeeding initial contact of the same limb. There are two main stages: the stance phase (60%) and the swing phase (40%). Ask the patient to stand, and inspect from the front, side and back. Then, ask the patient to walk using any walking aids. Some of the types of limp that might be present are described in *Table 31.1*.

Focused inspection

Adequately expose the joint above and below. Expose the opposite limb for comparison. Make sure that the patient is comfortable. It may be easier for you and the patient if they remain standing for the first part of the examination. When a couch is used, make sure that it is in the centre of the room (not against the wall) so that you can work on both sides of the patient. Remember that all joints are covered by an envelope of soft tissues and skin. Look at the skin for:

- surgical scars (arthroscopy scars may be difficult to see);
- bruising (may indicate recent injury or a bleeding disorder);
- erythema (e.g. cellulitis);
- ulcers (e.g. arterial, vascular or neuropathic);
- rashes;
- sinuses (e.g. secondary to osteomyelitis);
- hair loss and the presence or absence of sweating;
- pigmentations or raised lesion (e.g. café-au-lait spots or neurofibromas).

Look at the soft tissues for:

- swelling (e.g. may indicate a joint effusion);
- lumps (consider which tissue layer they are arising from);
- muscle wasting (e.g. may be secondary to disuse atrophy, neuropathy);
- muscle fasciculation (lower motor neurone pathology).

Look at the bones for:

- abnormal limb alignment – comparison with the other side may be helpful;
- deformity.

TABLE 31.1 Types of limp.

Cause	Pathogenesis	Presentation
Long	Osteoarthritis (in other leg)	Head dips. Cadence dash/dash
Incoordinated	Cerebral palsy	Head movement lacks coordination. No regular cadence
Muscle weakness	Osteoarthritis hip	Head moves from side to side (windscreen wiper)
Pain	Osteoarthritis hip	Head dips. Cadence dot/dash
Stiff	Arthrodesis hip	Head rocks too and fro
Limp	**Pathology**	
Antalgic	Hip joint arthritis	
Trendelenburg	Weakness of hip abductors	
High-stepping gait	Foot drop secondary to common peroneal nerve palsy	
Spastic	Cerebral palsy	
Ataxic	Cerebellar pathology	

Alan Graham Apley, 1914–1996, Director of Orthopaedic Surgery, St Thomas' Hospital, London, UK. As a consultant also at Rowley Bristow Orthopaedic Hospital, he conducted the most popular orthopaedic postgraduate course for the FRCS examination in Pyrford, Surrey, which became internationally known as the 'Pyrford Orthopaedic Course'.
Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.
Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Feel

Ask the patient if they have any areas of tenderness. Ensure that you do not cause the patient pain – watch their face as you feel. It may be easier (especially with children) to feel the normal side first.

Skin

The aim of sensory testing is to establish a pattern of sensory loss. Look for a dermatomal (may indicate spinal root or peripheral nerve pathology) or glove and stocking distribution (may indicate a neuropathy, e.g. diabetes). Perform a screening test by lightly stroking both limbs. Record whether the patient feels a difference. If none is noticed there is no need to spend more time on the neurological examination. If there is a difference, then a full neurological examination should now be performed.

Soft tissues

- **Tenderness**. Try to determine the actual anatomical structure from which the pain arises (e.g. subcutaneous fat, bursae, nerves, arteries).
- **Lumps and effusions**. Determine the characteristics of any lump or effusion using *Table 31.2* as a guide.
- **Pulses**. Palpate the distal pulses (or capillary return) of the limb. Recording distal neurovascular status both before and after surgery is important. Absence of distal pulses is an absolute contraindication to elective surgery in that limb. Acute loss of circulation to a limb is a surgical emergency.

Bone

Palpate the contours of the joint and assess for tenderness. For superficial joints, such as the knee, the joint line can be felt and checked for lumps and tenderness.

Move

There are three stages to assessing movement. The words used to describe a particular movement are shown in *Table 31.3*.

- **Active**. Ask the patient to move the joint within the limits of their pain.

TABLE 31.2 Swelling – an acronym for history and examination of a lump.

Start	Did it appear after trauma or gradually on its own?
Where	Anatomical site and layer (skin, fat, muscle); does it move in relation to these?
External features	Size, surface and definition of margins
Lymph nodes	Are the local ones enlarged?
Liquid	Is it fluctuant? Can it be transilluminated?
Internal features	Is it hard? Is it tender?
Noise	Is there a thrill? Is there a bruit?
General	Examination of the whole patient for general lumps

TABLE 31.3 Terminology used to describe the direction of movement.

Flexion	Forward or anterior movement of the trunk or limb
Lateral flexion	Bending of the forward-facing head and trunk to either side
Extension	Backward or posterior movement
Abduction	A movement away from the midline of the body
Adduction	A movement towards the midline of the body
Internal rotation	Rotation towards the midline of the body
External rotation	Rotation away from the midline
Supination	Movement of the forearm so that the palm faces anteriorly
Pronation	Movement of the forearm so that the palm faces posteriorly
Circumduction	A combination of flexion, abduction, extension and adduction without rotation
Inversion	Movement of the foot that directs the sole of the foot medially
Eversion	Movement of the foot that directs the sole of the foot laterally
Retraction	Backwards movement of the head, jaw or shoulders

- **Passive**. Move the limb or joint yourself. Record the range of movement in 'degrees' (a goniometer may be helpful). Comparison of active and passive range allows the three causes of loss of range of movement to be distinguished. In limitation caused by pain or stiffness the ranges are the same but one is painful. In weakness passive range is greater than active.
- **Stability**. Stability has a static and a dynamic component: static tests assess the integrity of the ligaments and joint (bone) surfaces; dynamic tests assess the integrity and functions of the muscles and tendons. Ask the patient to move the joint actively through its range of motion while you try to stop the movement. Record power using the Medical Research Council (MRC) grading system as illustrated in *Table 31.4*. Consider the muscles that drive each movement, the peripheral nerves that supply them and the nerve root values *(Table 31.5)*.

TABLE 31.4 The Medical Research Council grading system of muscle power.

Grade	Description
0	No movement
1	Flicker of movement
2	Active movement with gravity elimination
3	Active movement against gravity
4	Active movement against resistance but power less than full
5	Normal power

TABLE 31.5 Peripheral nerves.

Root level	Sensation	Motor	Reflex
C5	Lateral upper arm	Deltoid	Biceps
C6	Lateral forearm	Wrist extension	Brachioradialis
C7	Middle finger	Triceps	Triceps
C8	Little finger	Finger flexors	–
T1	Medial forearm	Interossei	–
L1	Anterior thigh	Psoas	–
L2	Anterior thigh/groin	Quadriceps	–
L3	Anterior and lateral thigh	Quadriceps	–
L4	Medial leg and foot	Tibialis anterior	Knee jerk
L5	Lateral leg and first dorsal web space	Extensor hallucis longus	–
S1	Lateral and plantar foot	Gastrocnemius/perineals	Achilles
S2–S4	Perianal	Bladder and foot intrinsics	–

In the following sections, in addition to the approach of 'Look, Feel, Move', we have included details of special tests for each joint as well as neurological examination of the limb. The peripheral nerve examination comprises sensory and motor testing, reflexes, tone and coordination and proprioception.

Summary box 31.2

Musculoskeletal examination

- Introduce yourself and put the patient at ease
- Assess the gait
- Look
- Feel
- Move
- Special tests
- Neurological examination
- Pulses

Figure 31.1 Plumb line.

CLINICAL EXAMINATION OF THE SPINE

The spinal column consists of 33 vertebrae with 23 intervertebral discs. This is supported by numerous ligaments and paraspinal muscles.

When observed from the front (coronal plane) with the patient standing and the hips and knees fully extended, the head should be centred over the sacrum. A 'plumb line' dropped from the spinous process of C7 should fall through the gluteal crease (**Figure 31.1**). If it falls to either side of the cleft, lateral tilt of the spine is present. The ear, shoulder and greater trochanter of the hip should lie in the same vertical plane. When the patient is observed from the side, assess the four physiological sagittal plane curves (cervical and lumbar lordosis, and thoracic and sacral kyphosis) (**Figure 31.2**).

Cervical spine

Look

Ensure that the shoulders, back muscles and scapulae can be seen. Look for muscle wasting and asymmetry of the neck creases and check that the shoulders are level and that there is a normal cervical lordosis (range 20–40°).

Feel

Stand behind the patient and support the patient's chin.

- **Soft tissues**. Feel for spasm of the paraspinal muscles.
- **Bone**. Palpate the spinous processes (tenderness and alignment); the spinous processes of C7 (vertebra prominens) and T1 are usually large and are easily palpable at the base of the neck.

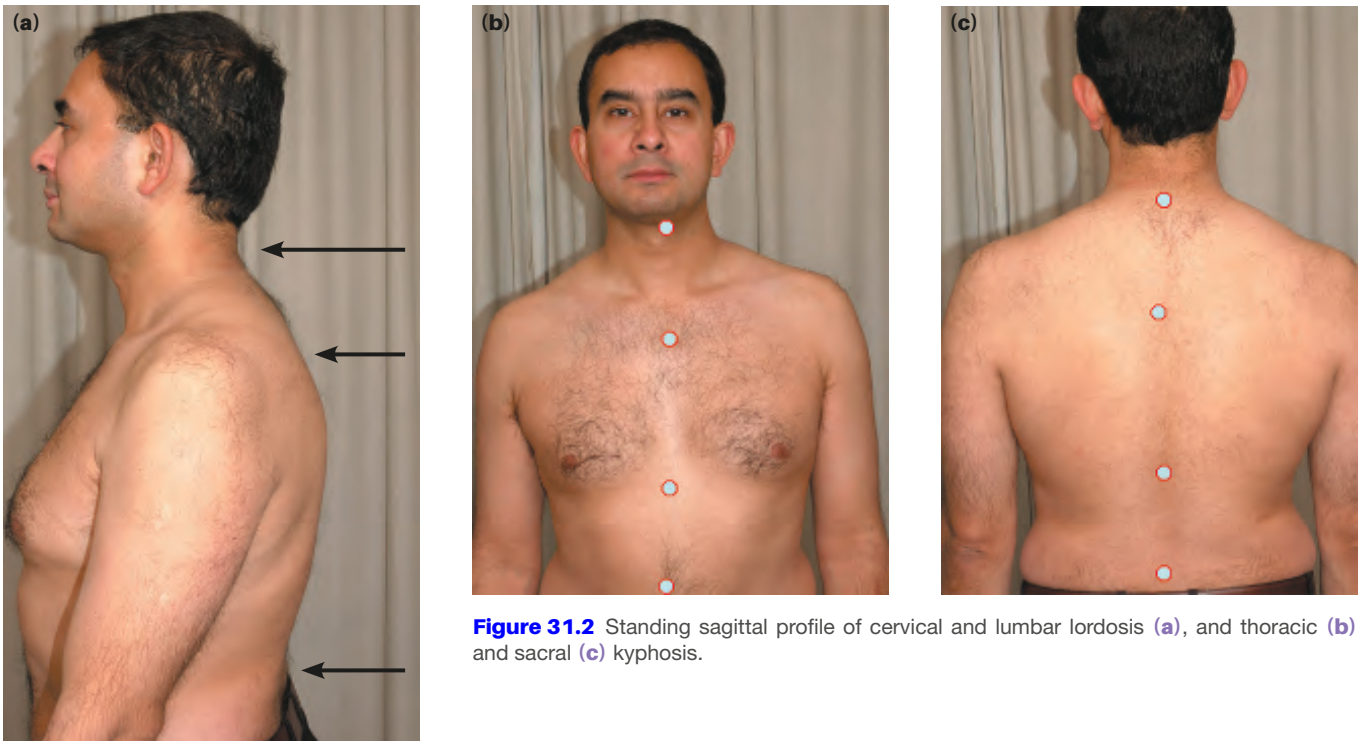

Figure 31.2 Standing sagittal profile of cervical and lumbar lordosis **(a)**, and thoracic **(b)** and sacral **(c)** kyphosis.

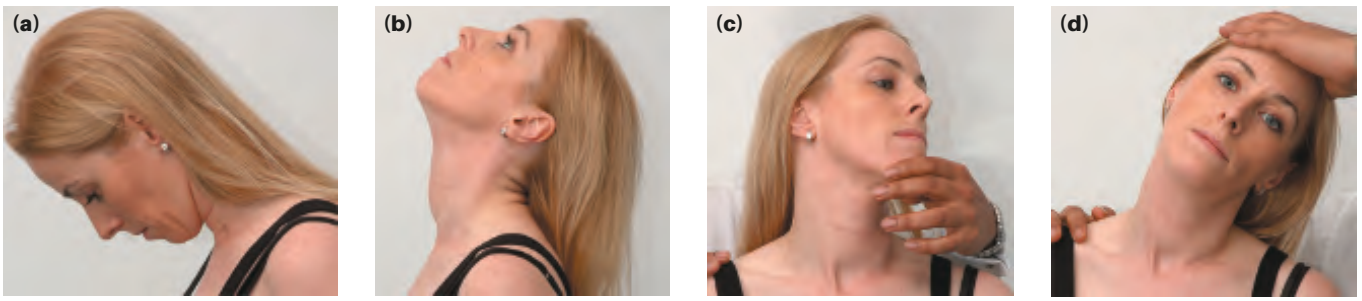

Figure 31.3 Cervical spine flexion/extension **(a, b)**, rotation **(c)** and bending **(d)**.

Move

Motion occurs in three planes: flexion/extension, bending and rotation (Figure 31.3).

- **Flexion (45°)/extension (55°)**. Ask the patient to bend their neck forwards – place the chin on the chest. Measure the distance from the chin to the sternum. Ask the patient to extend their neck by looking up at the ceiling.
- **Right/left rotation (70°)**. Ask the patient to look over each shoulder while not moving the chest wall.
- **Right/left bending (40°)**. Ask the patient to lay their ear on their ipsilateral shoulder.

Neurological

Focus your examination on the C5 to T1 nerve roots. These supply the upper extremities (Figure 31.4).

Figure 31.4 Spurling's test for cervical spine nerve root entrapment. Extend the cervical spine and rotate the head to each shoulder in turn. The presence of a shooting pain down the arm may indicate cervical nerve root compression.

Thoracic spine

Pathology commonly presents with pain and deformity. The thoracic spine is normally convex with a gentle kyphosis (normal range 20–45°).

Look

Ensure that the front and the back from the neck to the gluteal cleft can be visualised. Note skin markings (e.g. café-au-lait spots, hairy patches). These may suggest occult neurology or bony pathology.

- **Front**. Check for asymmetry of the shoulder and rib cage suggesting scoliosis.
- **Back**. Look for a difference in the height of the iliac crests (pelvic tilt). Assess for coronal plane deformity, such as scoliosis (lateral curvature of the thoracic spine with rotation). A rib hump suggesting a structural scoliosis may be visible.
- **Side**. Assess for sagittal plane deformity, such as an increased kyphosis.

Feel

Palpate, with one hand supporting the patient's pelvis.

Move

Range of motion is limited in the thoracic spine:

- **Forward bending test** (Figure 31.5). Ask the patient to bend forwards to touch their toes:
  - *structural scoliosis:* a rib hump will increase in size (bulge posteriorly on the thoracic convex side) as the patient bends forwards; this is diagnostic of idiopathic thoracic scoliosis (rotatory deformity);
  - *functional scoliosis*: the spine straightens as the patient bends forwards and no rib hump is visible; this flexible deformity is secondary to other abnormalities such as abnormal leg lengths and muscle spasm in the lumbar region.
- **Lateral bending**. This can be used to assess the flexibility of a scoliosis. Radiographs are taken in this position to supplement the assessment.

Lumbar spine

Examination should include the pelvis, hips, lower limbs, gait and peripheral vascular system as well as the lumbar region. Irritation of nerves in the lumbar spine can mimic problems in the lower limb. Always consider referred pain.

Look

- **Back**. Check the skin at the base of the spine for hairy tufts and dimples (underlying spina bifida). Prominence of the spinal muscles on one side may be the result of muscle spasm secondary to pain.
- **Side**. The lumbar spine has a smooth concavity known as the lumbar lordosis (normal range is 40–60°). Muscle spasm is a cause of loss of the normal lordosis.

Feel

Feel for any 'step-off' in the spinous processes. This may indicate forward slippage of one of the vertebrae on another.

Move

Movement occurs in flexion, extension, lateral bending and rotation (Figure 31.6). Record the motion in each plane in degrees. Remember that a significant portion of lumbar flexion is achieved through the hip joint.

- **Forward flexion**. This is a measure of lumbar flexibility. The skin of the lumbar spine stretches as the patient bends forwards. To measure flexion, place the tip of your thumb over the T12–L1 junction and the tip of your index finger of the same hand over the lumbosacral junction. Ask the patient to bend forwards and touch the toes (normal range 40–60°). Measure the distance by which your thumb and the tip of your index finger separate.
- **Lateral bending**. Ask the patient to slide their right hand down the outer side of their right leg and then their left hand down the outside of their left leg. Note the distance that each hand moves down that side of the thigh.
- **Rotation**. Stand behind the patient and hold their pelvis still with both hands. Ask the patient to twist around and Look over their shoulder. Note the angle that the shoulder girdle forms with the pelvis (range 3–18°).

Special tests

- **Lasègue's straight leg raise test** (Figure 31.7). This test increases tension along the sciatic nerve (L5 and S1 nerve roots). With the patient supine, elevate the leg with the knee bent to check pain-free movement of the hip. Then,

Figure 31.5 (a-c) Forward bending test.

Charles Ernest Lasègue, 1816–1863, Professor of Medicine, The University of Paris, and Physician, La Salpêtrière, Paris, France. This test was described by Lasègue's student, who named it after his teacher.

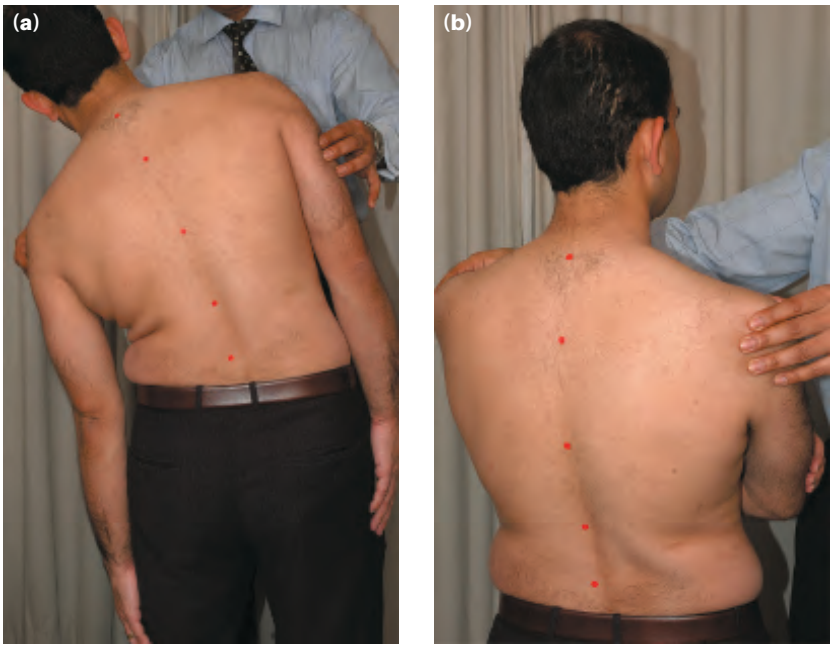

Figure 31.6 Lumbar flexion/extension, lateral bending **(a)** and rotation **(b)**.

straighten the knee and note the angle at which the hamstrings allow the hip to flex. Finally, allow the hip to extend until tension is removed from the hamstring muscles and then the ankle is dorsiflexed firmly (but without excessive force), which in turn pulls on the sciatic nerve. If the patient experiences pain running down the leg, then the test is positive.

- **Contralateral stretch test**. Elevate the asymptomatic leg; if pain is reproduced in the other leg the test is considered positive.

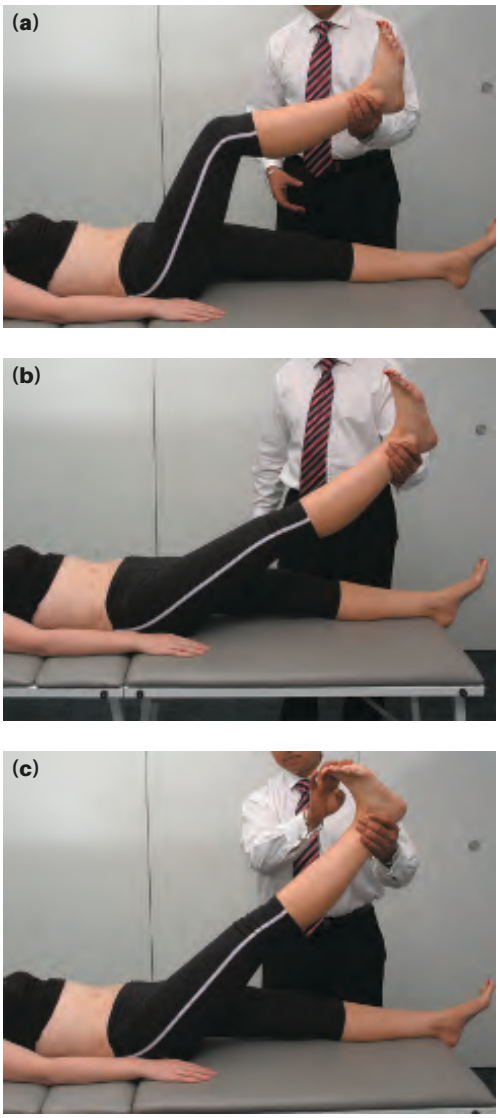

Figure 31.7(a-c) Lasègue's straight leg test.

Summary box 31.3

Spine examination

Inspection of the standing patient

- From the front and back (coronal plane)
- From the side (saggittal plane)
- Palpation
- Palpation of the posterior bony elements and the paraspinal muscles
- Move
- Assess flexion, extension, lateral rotation and bending

Neurological

- Assess sensation, tone, power, reflexes, proprioception and coordination

Special tests

- Spurling's test
- Forward bending test
- Lasègue's straight leg test
- Contralateral stretch test

CLINICAL EXAMINATION OF THE HAND AND WRIST

The hand and wrist should be thought of as one functional unit. The muscles may be divided into extrinsic (the muscle bellies in the forearm) and intrinsic (origins and insertions within the hand alone). The 'flexors' (volar side) flex the wrist and fingers and the 'extensors' (dorsal surface) extend the digits and fingers.

Look

Inspect the posture of both hands. A nerve lesion will produce a specific resting position (e.g. an ulnar nerve lesion will produce clawing of the little and ring fingers).

- **Skin**. Assess for scars, discolouration (café-au-lait spots, erythema) and loss of hair. The nails may reveal systemic disease (e.g. psoriatic pitting). Look for tight bands in the

palm (Dupuytren's contracture). Loss of sweating is seen in complex regional pain syndrome.

- **Soft tissue**. Centrally located swellings at the wrist may indicate a ganglion arising from the wrist joint itself; de Quervain's tenosynovitis may present with a swelling around the radial styloid.
- **Muscle wasting**. Check for thenar, hypothenar (**Figure 31.8**) and intrinsic muscle wasting. To assess thenar eminence wasting, place the hands side by side with the thumbs upwards and look down and compare the thenar regions. Patterns of muscle wasting are shown in *Table 31.6*.
- **Bones**. Look for bony deformity (dinner fork deformity, Colles' fracture). Typical bony deformities are described in *Table 31.7*.

TABLE 31.6 Patterns of muscle wasting in the hand.

Thenar wasting	Median nerve palsy (C8)
Hypothenar wasting	Ulnar nerve palsy (T1)
Intrinsic wasting	Ulnar nerve palsy (T1)

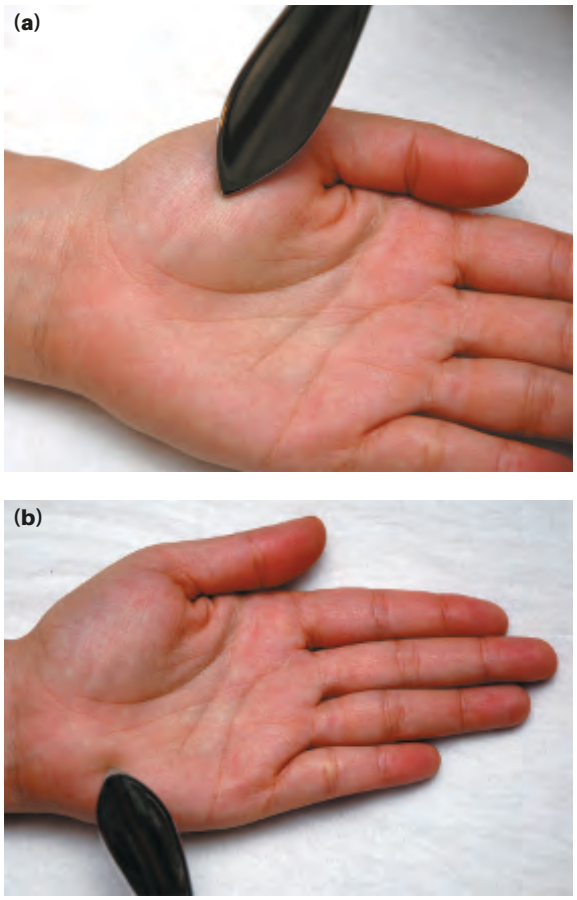

Figure 31.8 Thenar (**a**) and hypothenar (**b**) wasting.

TABLE 31.7 Bony deformities of the hand.

Anatomical site	Name	Association
Distal interphalangeal joint (DIPJ)	Heberden's nodes	Osteoarthritis
Proximal interphalangeal joint (PIPJ)	Bouchard's node	Osteoarthritis
Hyperextension of the metacarpophalangeal joint (MCPJ), flexion of the PIPJ and hyperextension of the DIPJ	Boutonnière deformity	Rheumatoid arthritis
Hyperextension of the MCPJ and PIPJ and flexion of the DIPJ	Swan neck deformity	Rheumatoid arthritis
Flexion of the MCPJ with hyperextension of the interphalangeal joint	Z deformity of the thumb	Rheumatoid arthritis
Subluxation of the MCPJ	Ulnar drift	Rheumatoid arthritis

Feel

- **Skin**. If there is any question of abnormal sensation on a simple stroke test comparing both sides, proceed to the two-point discrimination test using the sharp ends of a paper clip. Record the minimum distance between the tips of the paper clip at which the patient is able to recognise two points. *Table 31.8* describes the anatomical regions supplied by the median, ulnar and radial nerves.
  - *Pen sliding test*. To assess the absence or presence of sweating, slide a pen along the radial border of the index finger. If the pen slides smoothly, this may indicate loss of sweating.
- **Soft tissue**. Feel for muscle bulk and tendon thickening. Feel bony prominences, radial styloid, ulnar styloid, anatomical snuff box. Feel for sensation using two-point discrimination of medial nerve (radial aspect of index finger), radial nerve (in anatomical snuff box) and ulnar nerve (ulnar aspect of little finger).
  - *Blood vessels:* check the radial and ulnar artery pulses; assess the capillary refill time, which is normally less than 2 seconds; Allen's test should also be performed before surgery (*Table 31.9* and **Figure 31.9**).
  - *Nerves:* compressive neuropathies are most commonly seen affecting the median nerve (see Tinel's (**Figure 31.10a**) and Phalen's (**Figure 31.10b**) tests in *Table 31.9*).

TABLE 31.8 Sensory distribution of the nerve supply to the hand.

Nerve	Sensory distribution
Ulnar	Little finger and ulnar half of the ring finger
Median	Thumb, index, middle and radial half of the ring finger
Radial	Base of the thumb on the dorsum of the hand

Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described the condition in 1831.
Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.
William Heberden (Snr.), 1710–1801, physician, practised first in Cambridge and later in London, UK.
Charles Jacques Bouchard, 1837–1915, physician, Dean of the Faculty of Medicine, Paris, France.
Boutonnière is French for 'button-hole'.

TABLE 31.9 Special hand tests.

Test	Technique	Significance
Allen's test	Elevate the hand and apply digital pressure on the radial and ulnar arteries to occlude them. Ask the patient to make a fist several times. The tips of the finger should go pale. Release each artery in turn and observe the return of colour	Tests the adequacy of the blood supply to the hand from the radial and ulnar arteries and the arcade between them
Tinel's test	Tap over the nerve of interest. Tingling may indicate nerve compression	Identifies compression of a peripheral nerve
Phalen's test	Place the wrist in maximum flexion with the elbows extended	Compression of the medial nerve causes paraesthesia
Froment's sign	Ask the patient to grip a sheet of paper between the index finger and thumb of both hands. Grip the paper yourself similarly. Ask the patient to resist as you attempt to pull the paper away	A positive test indicated by flexion of the thumb interphalangeal joint suggests weakness of the adductor pollicis muscle supplied by the ulnar nerve. Recruitment of the median nerve-innervated flexor pollicis brevis explains the thumb posture

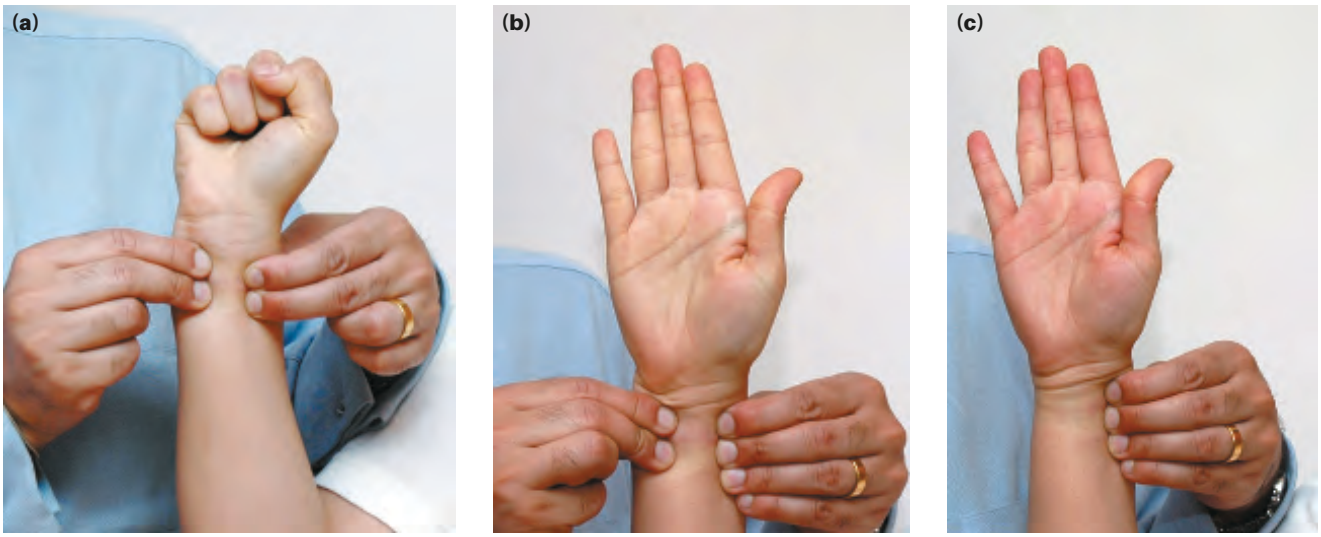

Figure 31.9 (a–c) Performing Allen's test.

- *Palmar fascia:* feel for palmar thickening and skin pits; long finger-like structures (cords), most commonly affecting the ring and little fingers, are suggestive of Dupuytren's disease.

- **Bones**. Palpate from the radial to the ulnar side of the wrist joint. In the trauma setting, palpate the anatomical snuff box (**Figure 31.11**). A fracture of the scaphoid may cause tenderness. The scaphoid tubercle, pisiform and the hook of hamate are all palpable on the volar aspect of the wrist.

Move

The wrist can be moved into flexion and extension, and ulnar and radial deviation.

- **Wrist**. Extension is tested by asking the patient to push the hands together into a 'prayer' position (**Figure 31.12a**). If there is loss of extension, the palms will not meet and/or one forearm will be dropped. Palmar flexion is tested in a similar fashion but with the hands pointing down and the back of the hands in contact (**Figure 31.12b**). Ulnar and radial deviation are tested by taking the patient's hand in your own and moving the hand into these directions.
- **Hand**. A general screening assessment is to ask the patient to roll up their fingers from full extension to full flexion. This will reveal a trigger finger.

Extensors and flexors

Asking the patient to grip two of your fingers in their fist tests the power of the extensors of the wrist (radial nerve) because they are needed to brace the wrist. It also tests the power of the flexors in the forearm (median nerve). Asking the patient then to extend and spread their fingers apart against resistance tests the intrinsic muscles of the hand (mainly the ulnar nerve).

Edgar van Nuys Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.
Jules Tinel, 1879–1952, Physician, Hôpital Beaujon, Paris, France.
George S Phalen, contemporary orthopaedic surgeon and Chief of Hand Surgery, The Cleveland Clinic, Cleveland, OH, USA. He helped to establish the American Society for Surgery of the Hand.
Jules Froment, 1878–1946, Professor of Clinical Medicine, Lyons, France.

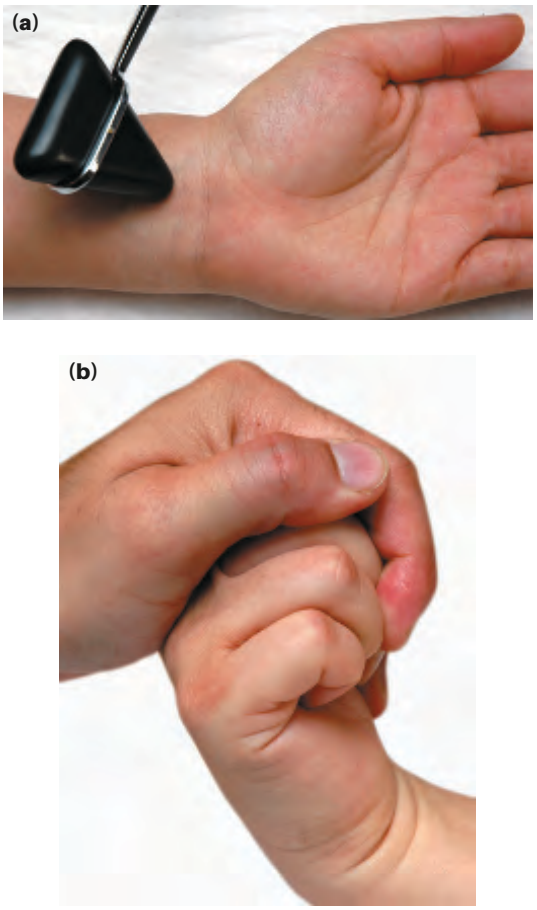

Figure 31.10 (a) Tinel's test; (b) Phalen's test.

Figure 31.11 Palpating the anatomical snuff box between the tendons of extensor pollicis longus and abductor pollicis brevis.

Finger flexors

- **Superficialis tendon test**. The flexor digitorum profundus (FDP) usually has one muscle belly from which tendons to all of the fingers arise. The FDP can be immobilised by holding all of the fingers (except the one being examined) in extension; this allows the superficialis tendon to be tested in isolation. If the test finger is able to flex, despite profundus being immobilised, then the superficialis tendon to that finger is working. Repeat the test for the other fingers individually (Figure 31.13).

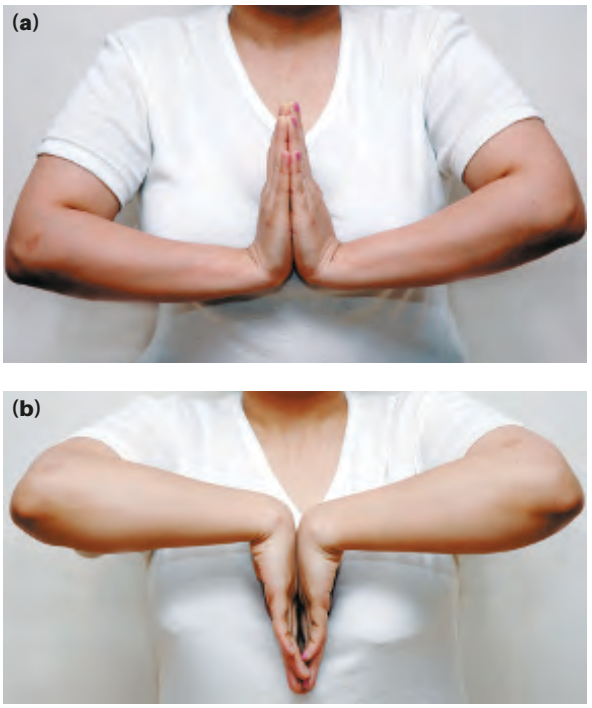

Figure 31.12 Testing the range of (a) wrist extension; (b) wrist flexion.

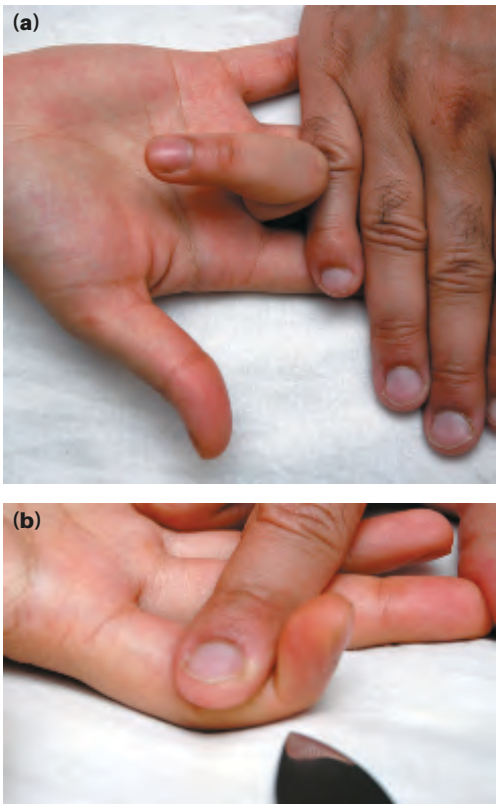

Figure 31.13 Testing the (a) flexor digitorum superficialis; (b) flexor digitorum profundus.

Thumb and thenar eminence

- **Abductor pollicis brevis, opponens pollicis and flexor pollicis brevis** can be tested together by opposing the thumb to the little finger.
- **Flexor pollicis longus**. The muscle is supplied by the anterior interosseus nerve (branch of the median nerve) and can be tested by asking the patient to bring the tips of the thumb and index finger together (the 'OK' sign – **Figure 31.14**).
- **Extensor pollicis longus**. The integrity of the tendon is tested by asking the patient to lift the thumb off a table with the palm flat on the table (**Figure 31.15**).
- **Adductor pollicis**. Test using Froment's sign (see *Table 31.9* and **Figure 31.16**).

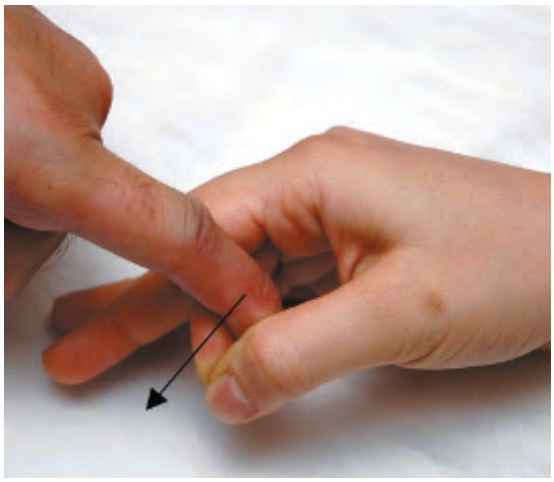

Figure 31.14 Test for flexor pollicis longus supplied by the anterior interosseus nerve.

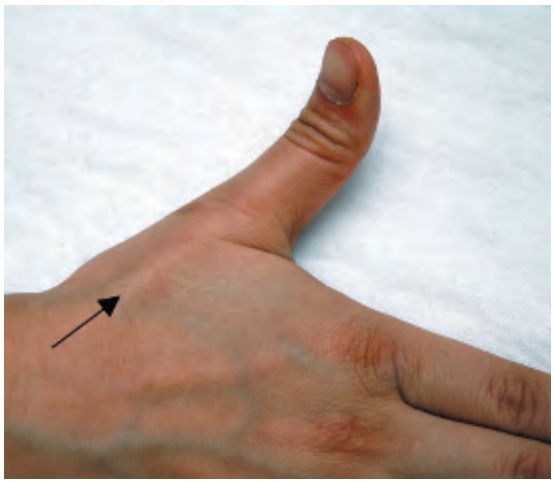

Figure 31.15 Testing the integrity of extensor pollicis longus.

- **Abductor pollicis brevis**. This muscle is supplied by the median nerve. With the hand lying flat on a table with the palm facing upwards, ask the patient to raise the thumb towards the ceiling. Ask the patient to resist as you push the thumb back towards the palm (**Figure 31.17**) .

Figure 31.16 Froment's sign; the arrow illustrates the flexed posture of the thumb interphalangeal joint, indicating weakness of the ulnar nerve-innervated adductor pollicis muscle.

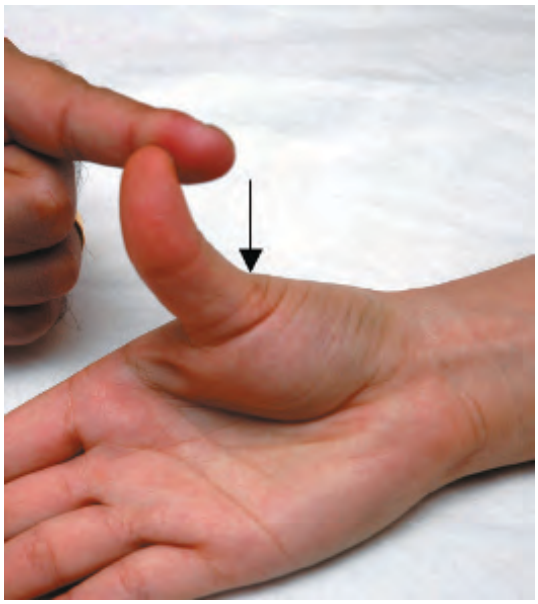

Figure 31.17 Testing the power of the abductor pollicis brevis supplied by the median nerve.

Summary box 31.4

Hand and wrist examination

Inspection of the standing patient

- Dorsum and palm – asymmetry, deformity, muscle wasting
- Inspection of the supine patient
- Skin, scars, soft tissues
- Palpation of bony structures and joints of the hand

Movements

- Wrist – flexion and extension, ulnar and radial deviation
- Hand – thumb movements, metatarsophalangeal joints and small joints of the hand

Special tests

- Allen's test
- Tinel's and Phalen's tests for the median nerve
- Froment's sign
- Finkelstein's test

CLINICAL EXAMINATION OF THE ELBOW

The elbow is a hinge joint formed by the articulation of the ulna and radius with the humerus.

Look

- **Skin**. Check the extensor surface for signs of psoriasis.
- **Soft tissues**. Look for any swellings, e.g. olecranon bursa, rheumatoid nodules, gouty tophi.
- **Muscle wasting**. Examine the biceps and triceps muscle bulk. Note that compression of the ulnar nerve at the elbow leads to wasting distally in the hypothenar eminence and intrinsic muscles of the hand – assess the hand for the presence of clawing and wasting.
- **Bone**. With the elbow in extension, look at the axis between the upper arm and forearm. There is a physiological valgus ('carrying angle') of 9–14° (2–3° greater in women) (**Figure 31.18**). This angle allows the elbow to be tucked into the waist depression above the iliac crest:
  - *cubitus varus* (gun-stock deformity): the carrying angle is reversed, secondary to a malunited supracondylar fracture;
  - *cubitus valgus:* the carrying angle is increased, caused by malunion of a distal humeral fracture;
  - *hyperextension:* there is normally a physiological hyperextension of the elbow (5°).

Figure 31.18 Carrying angle of the elbow illustrating the normal cubitus valgus.

Feel

- **Soft tissues**. An effusion may be detected by performing a cross fluctuation test. The ulnar nerve can be rolled under your fingers placed between the medial epicondyle and the olecranon. Test the distal sensation in the hand (especially in the distribution of the ulnar nerve) and assess the vascular status.
- **Bones**. The three palpation landmarks are the medial and lateral epicondyles and the apex of the olecranon. These form an equilateral triangle when the elbow is flexed to 90°. The radial head is palpated with the examiner's thumb while the other hand pronates and supinates the forearm. On the medial side, palpate the medial epicondyle. Posteriorly, palpate the olecranon fossa.

Move

- **Flexion–extension**. The normal range is from −5° (slight hyperextension) to 150°. Ask the patient to bend the elbow from the fully straight position (**Figure 31.19**).
- **Pronation and supination.** With the elbows at 90° and the palms facing upwards (full supination), ask the patient to turn the forearm so that the dorsum of the hand faces upwards (full pronation) (**Figure 31.20**). The normal values are 70° pronation and 90° supination.

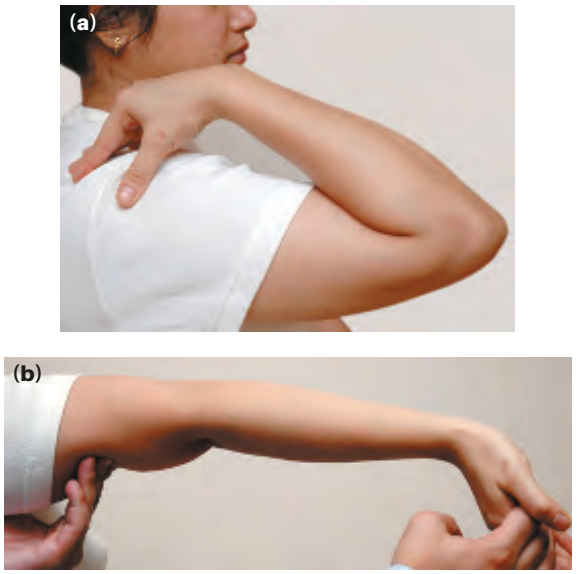

Figure 31.19 **(a)** Elbow flexion; **(b)** elbow extension.

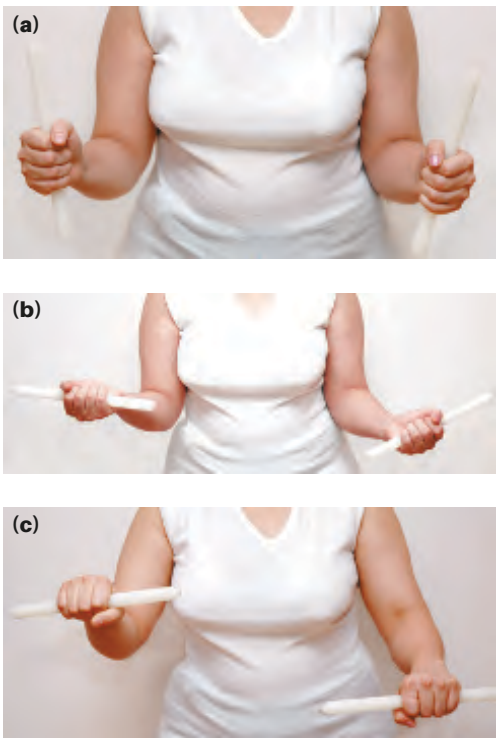

Figure 31.20 Testing forearm rotation: **(a)** mid-prone position; **(b)** full supination; **(c)** full pronation.

Special tests and diagnoses

Tennis elbow and golfer's elbow

Both conditions are inflammatory processes of the tendons that attach the large muscle mass of the forearm to the lateral or medial epicondyle.

- **Medial epicondylitis** (synonym = golfer's elbow). The medial epicondyle is the common origin of the forearm flexors and the pronator muscle. Palpate the medial epicondyle for tenderness. The diagnostic test is resisted wrist flexion, which reproduces the pain over the medial epicondyle.
- **Lateral epicondylitis** (synonym = tennis elbow). The lateral epicondyle is the common origin of the forearm extensors. Palpate for tenderness – usually just distal (5–10 mm) to the epicondyle near the origin of the extensor carpi radialis brevis muscle. Wrist extension against resistance with the elbow extended should provoke the patient's symptoms.

Summary box 31.5

Elbow examination

Inspection of the standing patient

- Front – asymmetry, carrying angle, deformity
- Back – olecranon fossa

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of bony structures

Movements

- Flexion and extension, pronation and supination

Special tests

- Tennis and golfer's elbow

CLINICAL EXAMINATION OF THE SHOULDER

Pain arising from the shoulder joint may be felt anterolaterally. Referred pain may present from the cervical spine, heart, mediastinum and the diaphragm.

Look

Assess the attitude of the limb.

- **Skin**. Check for surgical scars. An anterior scar is used for the deltopectoral approach. At the side, the deltoid splitting approach and lateral arthroscopic portals may be seen. Posteriorly, arthroscopic portal sites can be seen.
- **Soft tissues**. Wasting of the deltoid muscle is commonly seen after shoulder dislocation when there is a temporary loss of function of the axillary nerve that supplies it. The rotator cuff comprises four muscles: supraspinatus, infraspinatus, subscapularis and teres minor. Wasting of these muscles may occur following a rotator cuff problem.
- **Bone**. Look for any obvious deformity or prominence. A fracture of the middle third clavicle is the most common cause. A dislocation may be suspected by a loss of normal shoulder contour. The more common anterior dislocation often presents with an anterior bulge and a squared-off shoulder.

Feel

Generalised pain in the shoulder may arise from the neck or the shoulder joint itself. More localised pain is often indicative of acromioclavicular joint pathology.

- **Skin**. Test sensation in the upper part of the lateral aspect of the arm ('regimental badge area') (**Figure 31.21**). Loss may indicate damage to the axillary nerve (following shoulder dislocation).
- **Bones**. Palpate the acromioclavicular and sternoclavicular joints and the clavicle.

Figure 31.21 The area of skin supplied by the axillary nerve – the 'regimental badge area'.

Move

Differentiate between movements of the shoulder joint and scapulothoracic movement of the scapula on the chest wall. Patients with a painful shoulder will commonly move from the scapulothoracic joint. Stabilise the scapula by placing the thumb over the coracoid process and the fingers of the same hand over the spine of the scapula. Start in the 'neutral position' with the arms by the sides, elbows extended and the palms facing forwards. Note any pain throughout the range of movement (**Figure 31.22**).

Figure 31.22 Movements of the shoulder: **(a)** forward flexion; **(b)** extension; **(c)** adduction; **(d)** internal rotation; **(e)** external rotation.

- **Forward flexion**. Ask the patient to raise their hands in front to touch the ceiling while keeping the elbows extended (0–180°).
- **Extension**. Ask the patient to extend both arms behind (0–30°).
- **Abduction**. Shoulder abduction involves the glenohumeral joint and scapulothoracic movement. The first 60° of movement is mainly at the glenohumeral joint. Beyond this the scapula begins to rotate on the thorax and final movements are almost entirely scapulothoracic. Raise the arms sideways until the fingers point to the ceiling (180°).
- **Adduction**. Ask the patient to touch their other shoulder tip.
- **Internal rotation**. Ask the patient to touch their back with the dorsum of the hand and to raise their hand up the back as high as possible (normal range is thoracic spine level T7–9).
- **External rotation**. With the arms by the sides, bend the elbows to 90° and rotate the forearms to the mid-prone position. Ask the patient to separate their hands as much as possible (0–40°).

Special tests and diagnoses

Impingement syndrome

This is impairment of rotator cuff function within the subacromial bursa. It may lead to inflammation (tendinitis) or a partial or full-thickness tear. Impingement is characterised by pain and weakness on abduction and internal rotation.

- **Painful arc test** (Figure 31.23). Ask the patient to abduct their arms from their sides. The presence of pain from 60° to 120° is positive.
- **Jobe's test** (empty can) (Figure 31.24). Ask the patient to abduct the arm to 90° elevation in the scapular plane with full internal rotation (empty can position). Ask the patient to resist downward pressure. The presence of pain is a positive test.

Shoulder instability

Instability may be defined as a shoulder that slips in and out of joint (dislocation) more than once or twice, or frequently slips partially out of joint and then returns on its own. Instability can be anterior, posterior, inferior or multidirectional.

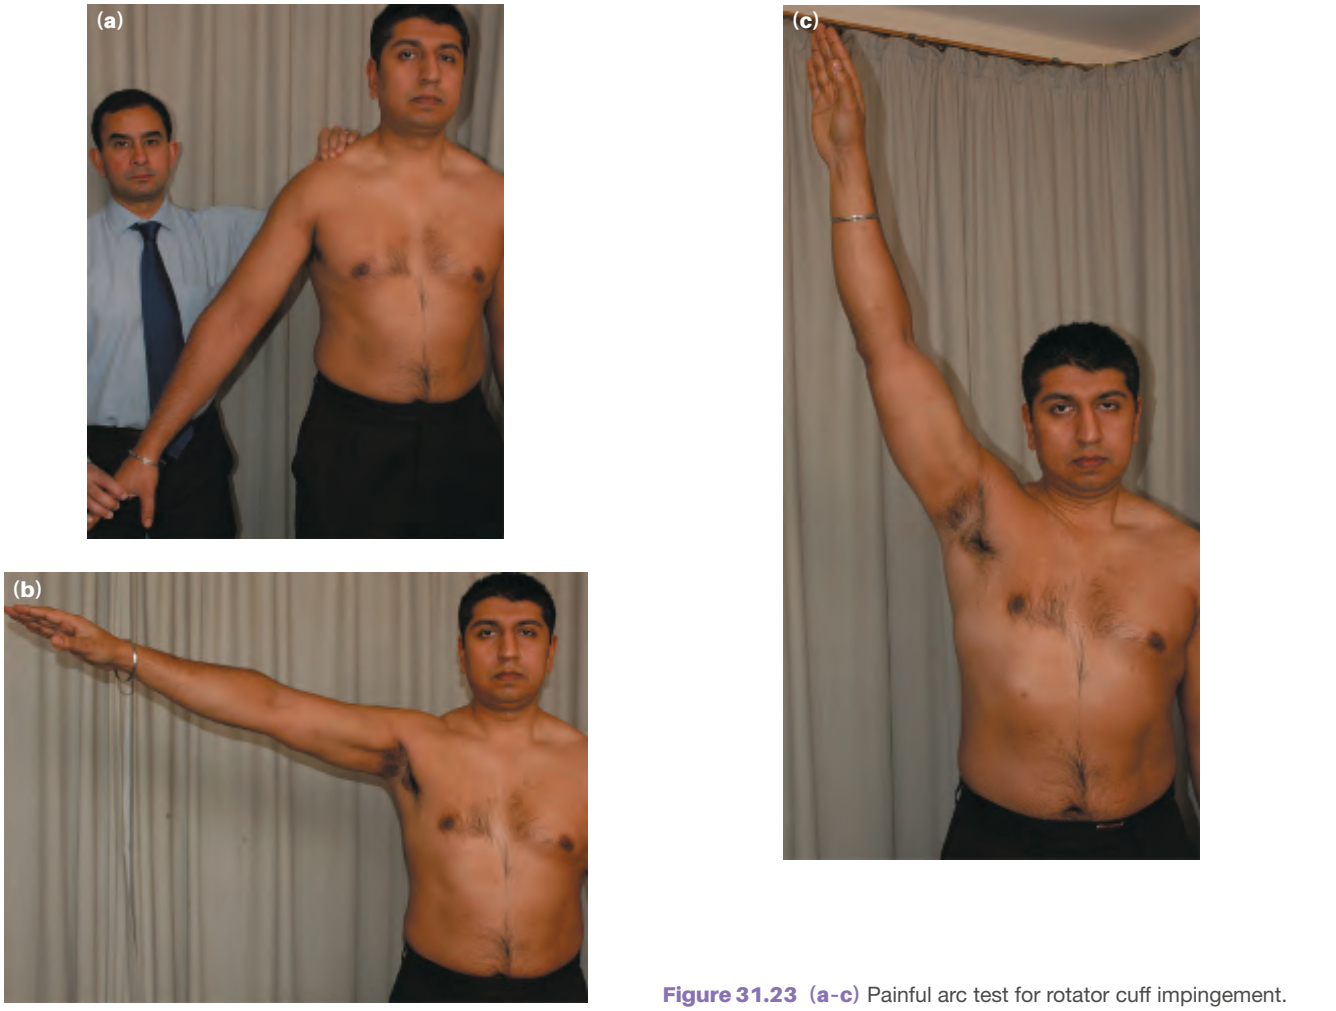

Figure 31.23 (a-c) Painful arc test for rotator cuff impingement.

Figure 31.24 Jobe's test for rotator cuff impingement.

Figure 31.25 Anterior apprehension test for anterior shoulder instability.

- **Apprehension test** (Figure 31.25). With the patient supine or standing, flex the elbow to 90° and abduct the shoulder to 90°. Now externally rotate the shoulder. Apprehension indicates anterior instability.

Summary box 31.6

Shoulder examination

Inspection of the standing patient

- Front – asymmetry, deformity
- Side – muscle wasting
- Back – muscle wasting, scapula

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of shoulder girdle (sternum to scapula)

Movements

- Flexion and extension, abduction and adduction, internal and external rotation

Special tests

- Impingement syndrome – painful arc, Jobe's test, Hawkins' test (see also Chapter 34)
- Shoulder instability – apprehension, relocation test, sulcus sign
- Rotator cuff assessment
- Acromioclavicular joint pathology
- Frozen shoulder versus glenohumeral osteoarthritis

CLINICAL EXAMINATION OF THE HIP JOINT

The hip is a synovium-lined ball and socket joint. Typical clinical diseases of the hip that may be encountered in children and adults are shown in *Table 31.10*. A patient complaining of hip pain should undergo a careful examination of the spine, abdomen, pelvis, groin and thigh. In addition, consider a gynaecological examination in women.

TABLE 31.10 Common clinical diseases of the hip in children and adults.

Children	Adults
Developmental dysplasia of the hip	Primary osteoarthritis
Transient synovitis of the hip	Secondary osteoarthritis
Perthe's disease	Inflammatory arthritis
Septic arthritis and osteomyelitis	Avascular necrosis
Slipped capital femoral epiphysis	Labral tears
Juvenile idiopathic arthritis	Referred pain

Look

With the patient standing, look at the front, side and back of the hip. Look around the room for walking aids and heel raises in the shoes.

- **Skin**. Look for scars and sinuses.
- **Soft tissues**. Muscle wasting may be present as a consequence of hip arthritis or primary muscle or neurological disease.
- **Bone**. Look at the posture of the limb and assess for adduction deformity; fixed adduction may be present in severe osteoarthritis and cerebral palsy, and makes the leg appear short because the pelvis is tilted (apparent shortening).

Feel

- **Soft tissues**. Tenderness overlying the greater trochanter may suggest trochanteric bursitis or an abductor enthesopathy.
- **Bone**. Bony landmarks can be palpated; these include the anterior superior iliac spine (ASIS), iliac crest and the greater trochanter of the femur.

Other areas for palpation include the inguinal ligament, which may have a local hernia or lymphadenopathy. The femoral artery can be palpated as it passes under the inguinal ligament at its midpoint halfway between the ASIS and the pubic tubercle.

Move

The hip joint can be moved into flexion, extension, abduction and adduction, and internal and external rotation (**Figure 31.26**). True hip movement ends when the pelvis begins to move. To detect true hip movement, simultaneously place a finger/hand on the anterior superior iliac spine (ASIS) contralateral to the hip being examined. Remember to compare both sides.

Passive movement

HIP FLEXION (120–0°) WHEN LYING SUPINE

The patient is asked to lie on their back and then roll themselves into a ball, flexing the hips and the spine fully. A comparison of the flexion of the two hips can be made in this position. The patient is then asked to hold onto the knee of the 'bad' leg with both hands (thereby fixing the pelvis in flexion) and the other leg is allowed to extend down onto the couch. A note is made of any fixed flexion deformity (inability of the thigh to come down onto the couch). This 'good' hip is then returned to full flexion and the patient grasps that knee while dropping the other, 'bad', hip into extension. This modified Thomas's test is the most comfortable and accurate way of measuring flexion and extension of the hip, minimising movement of the painful hip (**Figure 31.27**).

HIP EXTENSION (0–10°) WHEN LYING IN A PRONE POSITION

Hip extension can be measured by asking the patient to roll onto their front and extend the hip.

ROTATION

- **Internal rotation (45°)**. With the hip flexed to 45° and the knee in 90° of flexion, hold the front of the knee with one hand and the foot with the other. Internally rotate the hip (the foot goes outwards), then externally rotate

Hugh Owen Thomas, 1834–1891, general practitioner, Liverpool, UK. He is regarded as the founder of orthopaedic surgery although never holding a hospital appointment, preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

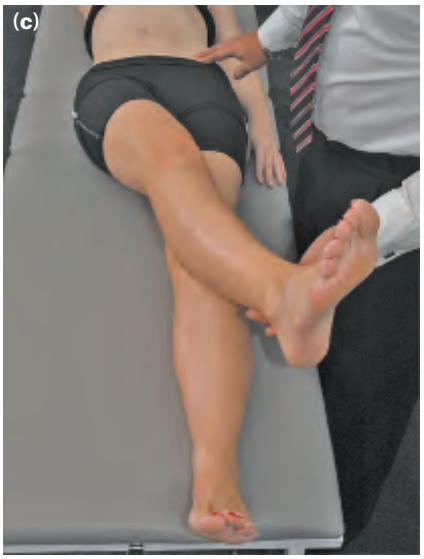

Figure 31.26 Hip movements: **(a)** internal rotation; **(b)** external rotation; **(c)** adduction; **(d)** abduction.

Figure 31.27 Modified Thomas's test for assessing a fixed flexion deformity. A fixed flexion deformity of the right hip is indicated by an inability to fully straighten the right leg (arrow).

the hip (the foot goes in). The angle that the tibia makes with the vertical indicates the range of movement. Pain at the extremes of movement suggests inflammation in the hip.

- **Abduction (40°)**. The hip should be abducted by moving the leg away from the midline with the other hand on the patient's pelvis to detect any tilt in the pelvis.

Special tests

- **Trendelenburg test** (Figure 31.28). Face the patient and ask them to place their hands on the palm of your hands for support. Then ask them to stand first on one leg, then the other. Increased pressure from the opposite hand as they take weight through the weak hip indicates a positive Trendelenburg test.
- **Leg length discrepancy (LLD)**. The inequality may be in the hip joint, femur, tibia, ankle or foot or a combination of these. The pathology may be from the bone being too short or too long. When assessing LLD, square the pelvis. If that is not possible then place both legs in the same position. For example, if there is an adduction deformity present in the affected leg, place the good leg in the same degree of adduction. LLD can be caused by a real difference in the leg lengths (the bones are different lengths) or by a deformity that makes the leg appear short because the pelvis must be tilted to get the leg onto the ground. The first is called 'real' LLD, measured ASIS to medial malleolus. The second is called 'apparent' LLD, measured midline, e.g. xiphisternum to medial malleolus. Each differs in

Summary box 31.7

Common causes of limb length inequality in the hip

- Osteoarthritis
- Hip fracture
- Hip dislocation
- Hip dysplasia
- Avascular necrosis
- Fixed flexion deformity

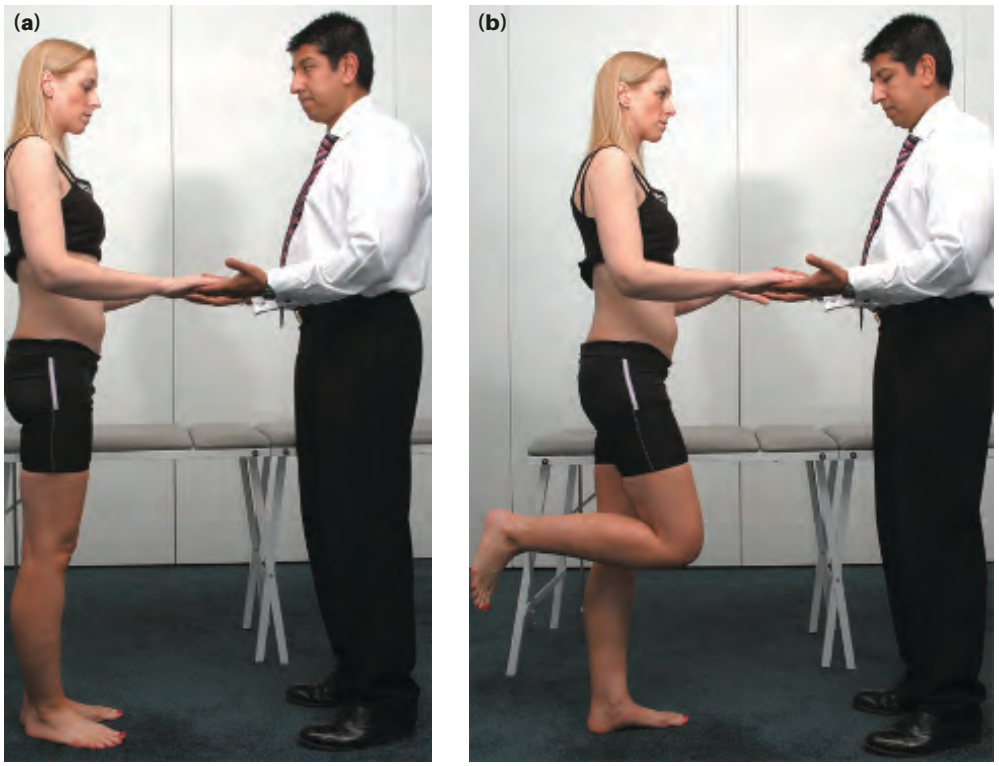

Figure 31.28 (a, b) Trendelenburg test.

cause and therefore treatment. The LLD apparent to the patient can also be measured using wooden blocks placed under the patient's 'short' leg until the patient feels level.

- **Gait**. Hip disease can present with an altered gait pattern. The common types of abnormal gait are described in *Table 31.11* (also see *Summary box 31.8*).
- **Impingement test**. To assess for femoroacetabular impingement, perform two tests: first, hip flexion at greater than 90° combined with some adduction and internal rotation (FADIR test). The second test is placing the hip into flexion, full adduction and internal rotation. A positive test is indicated by pain.

TABLE 31.11 Common limps observed in hip disease.

Gait pattern	Description
Weak: Trendelenburg	May lead to pelvic sway or tilt. The patient swings the body over the weak hip to stay in balance when it is weight bearing
Painful: antalgic	The rhythm is dot–dash, with a short period spent on the painful limb
Unbalanced: broad-based	May be caused by ataxia, e.g. cerebellar pathology. The rhythm also tends to be disordered
Loss of muscle control: high-stepping	May be due to loss of proprioception or a drop foot. This leads to difficulty in clearing the toes during the swing phase: the patient compensates by externally rotating the leg and flexing the hip and knee
Deformity: in-toeing	Can be caused by persistent femoral anteversion. The foot may catch on the back of the calf of the weight-bearing leg, tripping the patient

Summary box 31.8

Hip examination

Inspection of the standing patient

- Front – pelvic tilt, rotational deformity
- Side – lumbar lordosis
- Back – pelvic tilt, scoliosis, gluteal wasting
- Gait – Trendelenburg, antalgic

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of the anterior joint line, adductor origin, greater trochanter, ischial tuberosity

Movements

- Flexion and extension
- Abduction and adduction
- Internal and external rotation

Special tests

- Thomas's test
- Leg length assessment – real/apparent
- Trendelenburg test
- Snapping hip
- Impingement tests

CLINICAL EXAMINATION OF THE KNEE

The knee is a synovial hinged joint. There are three compartments: medial, lateral and patellofemoral. The quadriceps,

quadriceps tendon, patella, patellar tendon and tibial tuberosity comprise the extensor mechanism of the knee.

The anterior cruciate ligament (ACL) provides primary restraint to anterior displacement of the tibia. The posterior cruciate ligament (PCL) provides posterior restraint of the tibia. The medial collateral ligament (MCL) resists valgus and external rotation forces whereas the lateral collateral ligament (LCL) resists varus forces.

Look

Look at the front, sides and back of both knees and for any walking or mobility aids or external appliances.

- **Skin**. Check for scars.
- **Soft tissues**. Look for wasting of the quadriceps and swelling in front of and behind the knee.
- **Bone**. Look for overall alignment (varus or valgus deformity). Measure the intermalleolar distance if a valgus deformity is present. With varus deformity, measure the distance between the medial aspects of the knees. From the side of the knee, look for fixed flexion or recurvatum hyperextension).

Gait

Look for antalgic gait (osteoarthritis) and varus thrust (collapse of the knee into more varus as weight is taken on that leg).

Feel

- **Soft tissue**. Feel the tendons for quadriceps and patellar tendon rupture.
- **Fluid displacement or stroke test**. First empty the medial side of the knee by stroking any fluid up from the medial side into the suprapatellar pouch. Then place your hand on the superior aspect of the suprapatellar pouch and move it inferiorly, attempting to displace any fluid into the knee joint. Maintain your hand at the level of the superior pole of the patella. Now look to see whether the normal gutters on either side of the knee are less noticeable because of fluid distension. Stroke the back of your hand over each gutter in turn. Look at the opposite gutter to see if there is cross-filling.
- **Patellar tap test**. This test is used when a large effusion is present. Place one hand on either side of the patella and, with the other hand, push down on the patella. With an effusion, fluctuance is present as the patella moves towards the joint.
- **Bone**. Feel the tibial tuberosity, inferior pole of the patella, patellar facets, origin and insertion of the knee ligaments and joint line (medial and lateral). Remember to palpate for any popliteal swellings. Note the height of the patella.

Move

The knee moves principally in flexion (0–135°) and extension (from 0 to −10°) (**Figure 31.29**). Assess hyperextension by placing one of your hands on the anterior aspect of the distal femur. Now lift the distal tibia with the other hand. Measure the angle or the height that the heel can be lifted off the couch before the knee starts to move.

Figure 31.29 **(a)** Knee flexion and **(b)** extension.

Perform a lag test to assess the integrity of the extensor mechanism. The patient is asked to lift the whole leg up off the bed (10°) with the knee straight. They are then asked to bend the knee and then try to straighten it again with the leg still held in the air. If they are unable to re-straighten the knee they have a positive lag. This indicates significant weakness of the quadriceps mechanism.

In the presence of an apparent fixed flexion deformity of the knee (seen in osteoarthritis), decide whether this is arising from the knee or the hip joint. To differentiate, sit the patient up with the knees hanging over the edge of the couch; this obliterates the effect of any hip flexion deformity. Passively try to extend the knee fully. With a flexion deformity of the knee, this is not possible.

Special tests

Collateral ligaments

To assess the ligaments, place the leg under your arm. Flex the knee to 10° (not more) to relax the posterior capsule (the MCL and LCL are taut in full extension and lax in flexion). Stress each ligament in turn by applying a valgus or varus force. With your index fingers simultaneously palpate over the collateral ligaments. Assess for signs of instability (excessive opening of the joint). The quality of the end point should be noted (is it firm or spongy?). Compare both sides (**Figure 31.30**).

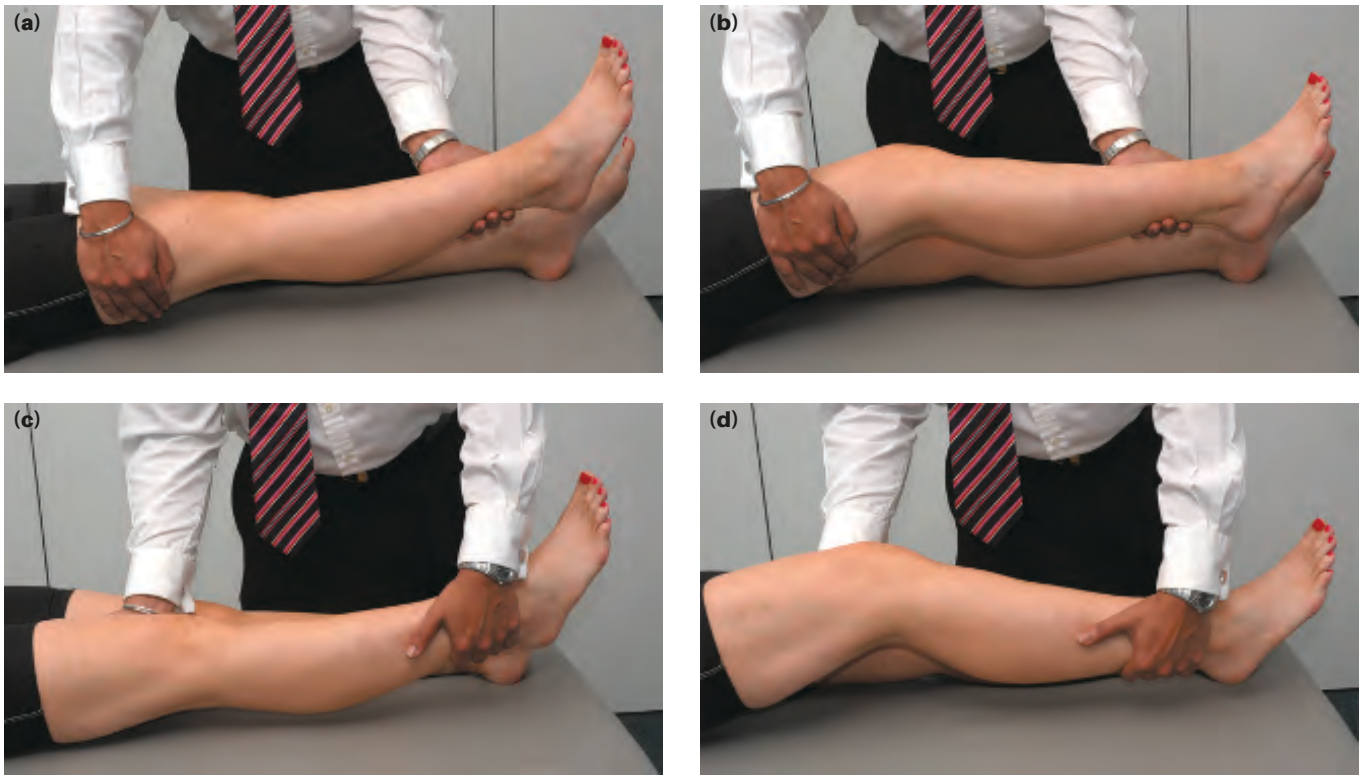

Figure 31.30 Assessing the medial **(a, b)** and lateral **(c, d)** collateral ligaments.

- **Medial collateral ligament**. A lax MCL or deficient lateral compartment may cause knee instability when applying a valgus stress. It is important to note that the valgus stress test should be applied with the knee in 30° of flexion. Valgus instability in full extension (0°) should alert you to a possible posterior structure injury (e.g. posterior capsule, posterior cruciate ligament).
- **Lateral collateral ligament**. A lax LCL or deficient medial compartment may cause knee instability when applying a varus stress in 10° of flexion. Instability in full extension (0°) suggests injury to the posterior structures. In a suspected lateral injury, evaluation of the peroneal nerve must be performed.

Figure 31.31 Lachmann's test: flex the knee to 15–30° and pull the proximal tibia forwards.

Anterior cruciate ligament

The most sensitive test for evaluation of the ACL is the Lachmann test.

- **The Lachmann test** (Figure 31.31). Flex the knee to 15–30° and pull the proximal tibia gently forwards. Excessive laxity may indicate rupture of the ACL. Anterior translation of the tibia associated with a soft or no end point is a positive test. The test may be negative in chronic ruptures because the ACL stump can scar to the PCL.
- **Anterior draw test** (Figure 31.32a). Flex both knees to 90° and look for a posterior sag (compare the height of the tibial tuberosities looking from the side). This may indicate an injury to the PCL. Stabilise the feet by sitting on them. Now place your hands around the proximal and posterior aspect of the tibia. With your index fingers, push up the hamstrings to encourage them to relax. Now draw the tibia gently forwards and measure any laxity, comparing it with the other knee. The degree of laxity can be graded: grade I (0–5 mm), grade II (5–10 mm) and grade III (>10 mm).

Posterior cruciate ligament

The PCL is the primary restraint to posterior tibial translation between 30 and 90° of knee flexion. At 90°, the PCL accepts 95% by the degree of posterior translation of the tibia with the knee in 90° of flexion. Look for a posterior sag with the knees flexed to 90°. The posterior draw test is the most reliable clinical test for a PCL injury.

- **Posterior draw test** (Figure 31.32b). Perform the test with the knee flexed to 90°. Push the anterior aspect of

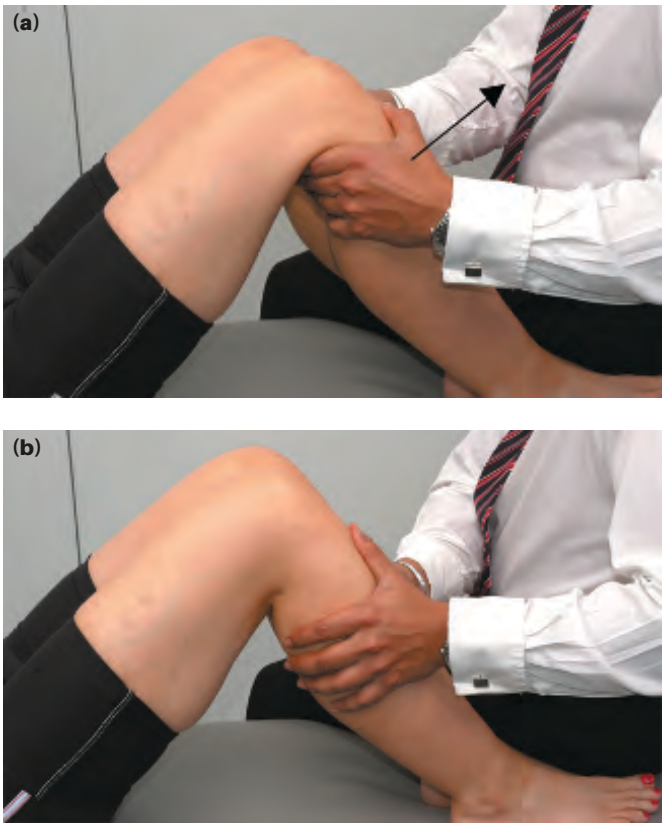

Figure 31.32 **(a)** Anterior draw test for anterior cruciate ligament stability; **(b)** posterior draw test for posterior cruciate ligament stability.

the proximal tibia posteriorly and compare any laxity with the other side. If more than 10 mm of posterior tibial translation is noted at 30 and/or 90° of knee flexion, a combined PCL and posterolateral corner injury may be present. An evaluation of the competency of the posterolateral corner is necessary.

Menisci

The presence of palpable joint line tenderness is the most sensitive clinical examination test for a meniscal tear. Flex the knee to 90° and palpate the joint line using your thumb and index finger. Note any areas of tenderness. Tests for meniscal damage are not very reliable but, combined with a history of mechanical symptoms, locking, catching and pain, may be helpful. With posterior medial meniscal tears patients suffer pain on high flexion or squatting. The well-known test for meniscal tears is McMurray's test. The patient lies supine with their knee flexed to 45° and hip flexed to 45°. The examiner braces the lower leg: one hand holds the ankle; the other hand holds the knee. For assessment of the medial meniscus, palpate the medial joint line with knee flexed. A 'click' may be felt suggesting meniscus relocation. A valgus stress is applied to the flexed knee. Externally rotate the leg (toes point outward), and slowly extend the knee while it is still in valgus.

Patellofemoral joint

The patella normally enters the trochlea from a lateral position and becomes centralised with increasing knee flexion, travelling in a 'J' pattern.

- **Patellar tracking** (Figure 31.33). Sit the patient and ask them to let their legs hang off the end of the couch with the knees flexed to 90°. Ask the patient to extend the knee slowly to full extension. Towards the end of extension, look for lateral subluxation of the patella ('J' sign). This indicates maltracking.
- **Patellar apprehension** (Fairbank's) test (for instability). Attempt to displace the patella laterally with the knee in

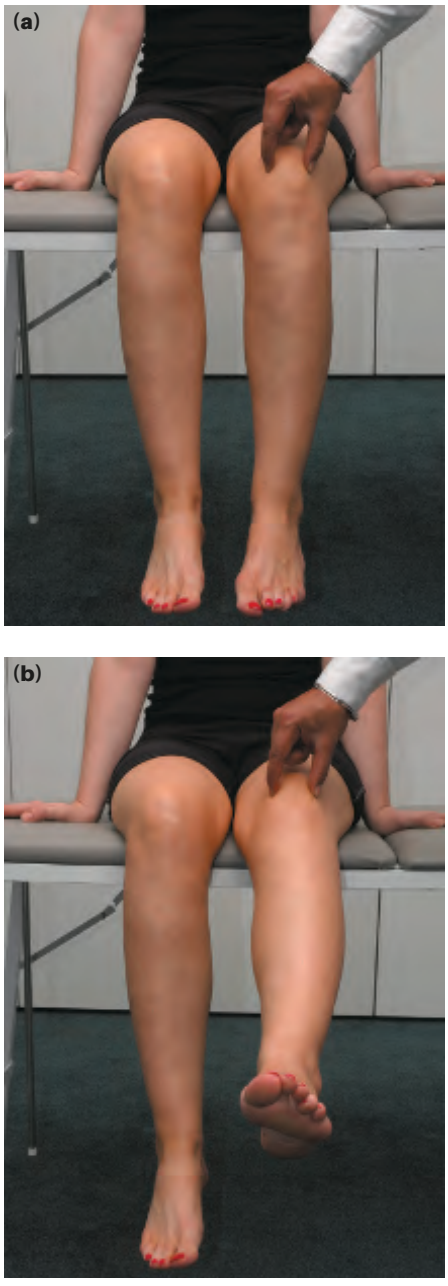

Figure 31.33 **(a, b)** Patellar tracking.

Thomas Porter McMurray, 1887–1949, Professor of Orthopaedic Surgery, Liverpool University, Liverpool, UK.
Sir Harold Arthur Thomas Fairbank, 1876–1961, orthopaedic surgeon, King's College Hospital, London, UK.

extension. Patients with instability contract their quadriceps muscle or complain of pain. With the patient supine and the quadriceps relaxed, flex the knee to 30° while trying to push the patella laterally. With instability the patient may react with apprehension. In addition, the quadriceps muscle may contract in an attempt to realign the patella.

Patellar tendon

The patellar tendon serves as the distal limit of the extensor mechanism. Rupture usually occurs at the osseotendinous junction. This results in an inability actively to perform and maintain full knee extension. A rupture presents with diffuse swelling in the anterior knee. A high-riding patella (patella alta) is present secondary to the unopposed pull of the quadriceps muscle. A defect in the tendon is usually palpable. When the rupture extends through the medial and lateral retinaculae, active extension is lost.

Summary box 31.9

Knee examination

Inspection of the standing patient

- Front – alignment (varus/valgus/rotational deformity), muscle bulk
- Side – fixed flexion deformity
- Back – popliteal swellings, hamstrings
- Gait – antalgic, high stepping gait (foot drop), varus thrust

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of the extensor mechanism, medial and lateral joint lines and collateral ligaments, hamstrings, tibial tuberosity, fibular head

Movements

- Flexion and extension

Special tests

- Patellar apprehension test and extensor mechanism
- Cruciate ligaments
- Collateral ligaments
- Menisci

CLINICAL EXAMINATION OF THE FOOT AND ANKLE

The foot can be divided into three parts: the hindfoot (calcaneus, talus), the midfoot (navicular, cuboids, cuneiforms) and the forefoot (metatarsals and phalanges).

Look

Ask the patient to stand, and assess the overall limb alignment. Assess pelvic obliquity, limb length discrepancy (and its level), valgus/varus deformities of the knee and rotational alignment. Check for contractures of the hips and knees. Now focus your attention on the foot itself:

- **Foot shape**. Assess the overall shape of the forefoot from the front. From the side, look for the normal medial arch (**Figure 31.34a**). The hindfoot is best appreciated from behind. Now look at the vertical relationship between the Achilles tendon and the calcaneus (normal heel valgus of 5–7°). Look from behind and count the number of toes that can be seen. The 'too many toes' sign demonstrates increased forefoot abduction (pes planus (flat foot)) and a splayed forefoot. Foot shapes that may be encountered include neutral foot (no overall deformity), skew foot (hindfoot valgus and forefoot adduction), metatarsus adductus (neutral hindfoot and adduction of the metatarsus), pes planus (collapse of the medial arch) and pes cavus or high arch (increased medial arch). The possible causes of pes planus and pes cavus are shown in *Summary boxes 31.10* and *31.11*, respectively.

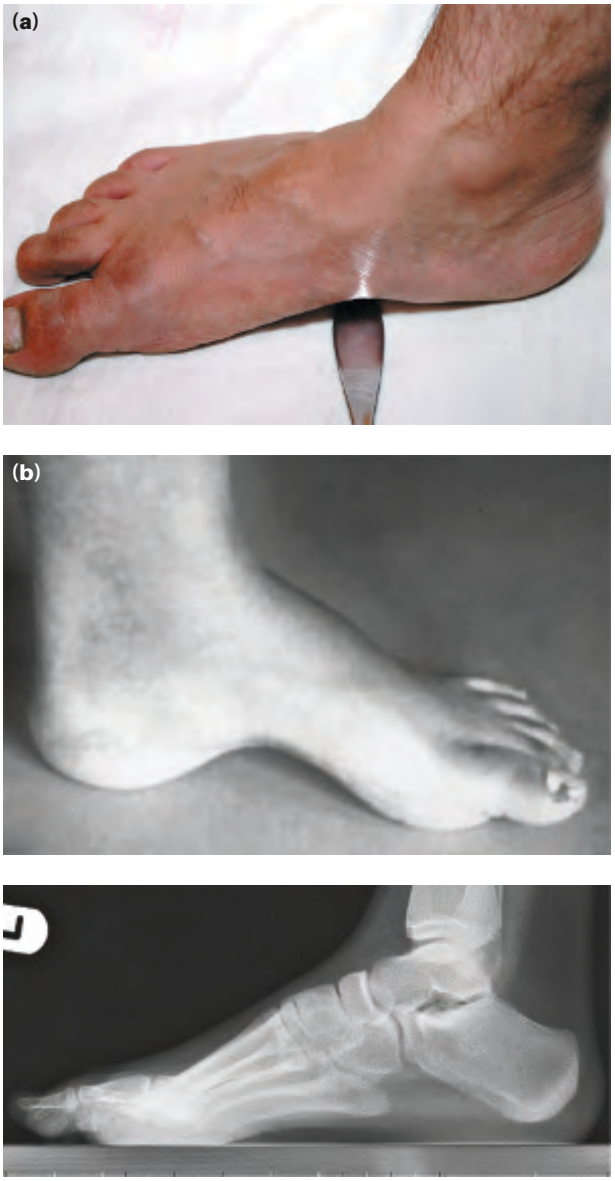

Figure 31.34 **(a)** Normal medial longitudinal arch of the foot. **(b)** Clinical and radiological appearance of pes cavus.

Summary box 31.10

Causes of pes planus

- Normal variant
- Hyperlaxity syndrome, e.g. Marfan's syndrome
- Tarsal coalition – rigid and painful flat foot (see **Figure 31.39a**)
- Tibial posterior dysfunction

Summary box 31.11

Causes of pes cavus (Figure 31.34b)

- Spinal anomalies, e.g. spina bifida
- Hereditary sensorimotor neuropathies, such as Charcot–Marie–Tooth disease
- Charcot foot (e.g. neuropathic foot)
- Post-compartment syndrome (e.g. Volkmann's ischaemic contracture)

- **Skin**. A bunion or red swelling on the medial aspect of the metatarsophalangeal joint (MTPJ) is common. This is an area of inflamed skin with an underlying subcutaneous bursa and a joint osteophyte. Systemic manifestations include gouty tophi and thin fat pads under the metatarsal heads as seen in rheumatoid arthritis. Corns are callosities which form where toes rub against the inside of shoes. Remember to assess the appearance of the nails.
- **Soft tissues**. Swelling may indicate soft tissue or joint pathology. Muscle wasting is most commonly seen on the dorsum of the foot and in the clefts between the metatarsals. If this is present, a full neurological examination of the upper and lower limbs should be performed, including the spine.
- **Bones**. Look for any bony prominences or exostoses. Common forefoot deformities are shown in *Table 31.12*.

Gait

Look for a high stepping gait (foot drop), painful (antalgic) gait (ankle and foot joint pain) and a short propulsive phase (forefoot pain).

Footwear

Inspect the footwear. This may reveal areas of abnormal weight bearing. With normal wear of the sole, a corner is typically worn off the posterolateral aspect of the heel (heel strike). In addition, there may be a circular wear pattern under the ball of the big toe (toe-off phase).

- **External appearance**. Look at the materials used, the metal supports and heel raise, depth and width.
- **Internal appearance**. Look at the insoles, arch supports and heel cups.

Feel

- **Skin**. Reduced sensation in a glove and stocking distribution is seen with diabetes.
- **Soft tissues**. The posterior tibial and the dorsal pedis pulses should be identified (**Figure 31.35**). Palpate the tibialis anterior tendon and the long extensor tendons on the dorsum of the foot. From the back, palpate the Achilles tendon. Palpate the peroneal tendons from the lateral side and the tibialis posterior tendon from the medial side. The sinus tarsi can be assessed. This is an anatomical space bounded by the talus and calcaneus and is recognisable as a soft-tissue depression anterior to the lateral malleolus. It is filled with fat and the extensor digitorum brevis muscle. Sinus tarsi syndrome may occur. This may be caused by injury to the interosseous talocalcaneal ligament or the subtalar joint. There is pain and tenderness over the sinus tarsi with subjective hindfoot instability. The pain is characteristically relieved by local anaesthetic injection.
- **Bones**. Feel for deformity, bony prominences and loose bodies:
  - ankle joint: the medial and lateral malleoli, anterior and posterior joint line, lateral gutter and ligament complex, the syndesmosis (front of the ankle), medial gutter and medial ligament complex;
  - subtalar joint: palpate each facet;
  - midtarsal joints: the talonavicular and calcaneocuboid joints;
  - tarsometatarsal joints (TMTJ): note that the second TMTJ is several millimetres proximal to the others; movement is minimal in the second ray, limited in the

TABLE 31.12 Common forefoot deformities.

Deformity	Metatarsophalangeal joint	Proximal interphalangeal joint	Distal interphalangeal joint
Claw toe	Hyperextension	Flexion	Flexion
Hammer toe	Normal	Flexion	Flexion
Mallet toe	Normal	Normal	Flexion
Hallux valgus or varus	Valgus or varus position	Normal	–

Antoine Bernard-Jean Marfan, 1858–1942, physician, Hôpital des Infants-Malades, Paris, France, described this syndrome in 1896.
Jean Martin Charcot, 1825–1893, physician, La Salpêtrière, Paris, France.
Pierre Marie, 1853–1940, neurologist, Hospice de Bicêtre, Paris, France, later became Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.
Howard Henry Tooth, 1856–1925, physician, St Bartholomew's Hospital and the National Hospital for Nervous Diseases, Queen's Square, London, UK, described peroneal muscular atrophy in 1886, independently of Charcot and Marie.

Figure 31.35 **(a)** Palpation of the posterior tibial pulse. **(b)** Palpation of the dorsalis pedis pulse.

third ray, moderate in the fourth and fifth rays and very variable in the first ray.

- **Specific structures** to palpate:
  - calcaneus (heel bone): the most common cause of pain is plantar fasciitis; this may present with numbness, burning and electric shock sensations, which are worse in the morning and improve as the day goes on; identify the exact point of tenderness;
  - tendons: examine for contracture of the Achilles tendon insertion and the peroneal or tibialis posterior tendons;
  - head of talus: invert and evert the patient's foot;
  - sustentaculum tali: palpate one fingerbreadth below the medial malleolus; this important structure serves as an attachment for the spring ligament;
  - cuneiforms (medial, middle and lateral), MTPJs, web spaces and all the forefoot bones.

Move

The movements of the foot and ankle are linked via the ankle, subtalar and midfoot joints. Remember the acronyms PAED – pronation, abduction, eversion and dorsiflexion – and SAPI – supination, adduction, plantarflexion and inversion. These are the two common general foot deformities.

Ankle (Figure 31.36)

- **Dorsiflexion**. Test dorsiflexion with the knee both flexed and extended. If restriction is greater with the knee extended than flexed, the contracture is principally in the gastrocnemius. Restriction that is equal in all knee positions is caused by a contracture principally of the soleus.
- **Plantarflexion**. Ask the patient to touch the floor with their foot (15°). Weakness suggests injury to the Achilles tendon or pathology affecting the S1 nerve root.

Subtalar joint (Figures 31.37 and 31.38)

Hold the talar neck and ask the patient to move their heel from side to side. Repeat using a hand on the heel to move the joint and apply a varus and valgus stress while feeling for movements of the talus. Holding the talus as opposed to the tibia isolates subtalar from ankle motion. (Normal range is 5° in each direction.)

Figure 31.36 **(a)** Ankle dorsiflexion and **(b)** ankle plantarflexion.

Figure 31.37 Testing subtalar joint motion.

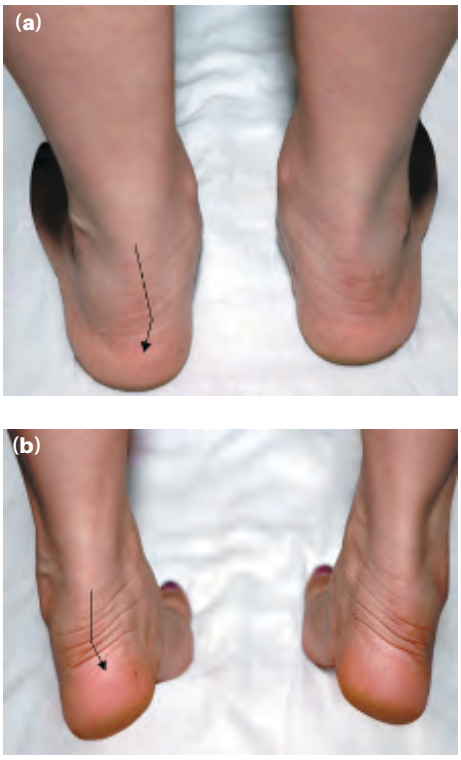

Figure 31.38 (a, b) Testing subtalar joint flexibility.

- Inversion. Ask the patient to move their foot in towards them.
- Eversion. Ask the patient to move their foot out to the side.

Midtarsal joint

Hold the heel with one hand and move the forefoot medially (adduction = 20°) and laterally (abduction = 10°) with the other hand.

Tarsometatarsal joint

Hold the midfoot and manipulate each metatarsal up and down to estimate the passive range of movement.

Metatarsophalangeal joint

Test extension (70–90°) by asking the patient to lift the toes to the ceiling and test flexion (45°) by pointing the toes to the floor. Normal toe-off requires 35–40° of dorsiflexion.

Special tests

Achilles tendon

Feel the gastrocnemius and soleus bellies and the whole length of the tendon for gaps (rupture), tenderness or swelling. Also identify the posterolateral (Haglund's) prominence of the calcaneus and palpate the retro-Achilles bursa.

The test for integrity of the tendon is the Thompson's or Simmonds' test. Do not be misled by the patient's ability to stand on tiptoes – some people can do this using their long toe flexors alone. Lie the patient prone and allow their calves to rest on your forearms. Squeeze each calf in turn and watch for movement at the ankle joint. Lack of movement may indicate a rupture.

Subtalar joint flexibility

Ask the patient to stand on their toes and observe the heel from behind; the heel moves normally from valgus to varus, indicating flexibility. The Coleman's block test is used to assess the flexibility of the subtalar joint. Ask the patient to stand on a 2-cm block with the great toe over the medial edge, resting on the floor. Now look from behind. If the hindfoot varus remains, the subtalar joint is fixed. If it corrects to valgus, the joint is mobile (**Figure 31.38**).

Flat foot flexibility

Use the Windlass and Jack's tests to distinguish a flexible from a fixed flat foot (**Figure 31.39**).

- **Windlass test**. Ask the patient to stand on their toes, and observe the arch of the foot on the medial aspect. As soon as the patient stands on their toes, the arch forms. Failure of this indicates a fixed flat foot.
- **Jack's test**. With the patient standing, lift up the great toe. The arch should form in the flexible flat foot.

Ankle stability

Trauma to the ankle is a common cause of instability. Accurate assessment may be difficult in the acute setting because of pain.

Patrik Haglund, 1870–1937, Swedish orthopaedic surgeon.
Frankin Adin Simmonds, 1911–1983, orthopaedic surgeon, The Rowley Bristow Hospital, Pyrford, Surrey, UK.

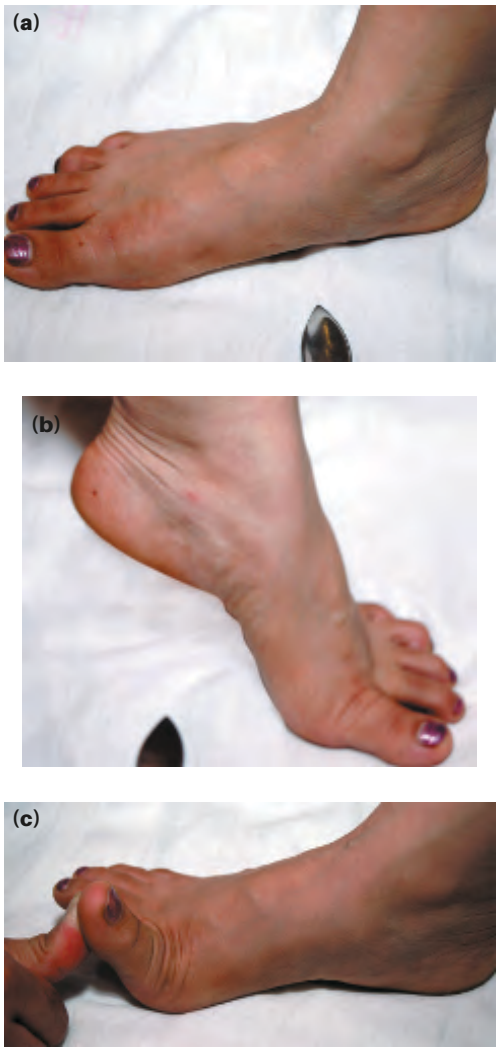

Figure 31.39 **(a)** Flat foot appearance with a reduced medial longitudinal arch; **(b)** Windlass test; **(c)** Jack's test.

- **Anterior draw test**. With the foot resting over the bed, hold the heel with one hand and the front of the tibia with the other. Move the heel forwards on the fixed tibia. Compare with the other side. Instability of the syndesmosis may be palpable **(Figure 31.40)**.

Figure 31.40 Anterior draw test.

- **Squeeze test for distal tibiofibular stability**. Compress the proximal calf. Pain at the ankle may indicate separation of the distal fibula from the tibia.
- **Tilt test**. Hold the talus at the neck rather than the heel so that you can be sure that any tilt is in the ankle and not the subtalar joint.

Tarsometatarsal joint stability

Stability can be assessed by pushing each joint up and down. Standing lateral radiographs may be used in addition.

Tibialis anterior

Ask the patient to walk on their heels with their feet inverted; the tibialis anterior tendon can be seen. With the patient's feet resting over the edge of the couch, ask the patient actively to dorsiflex and invert their foot to reach your hand. Palpate the tibialis anterior muscle.

Tibialis posterior

Pathology of the tibialis posterior typically presents with posteromedial ankle pain, swelling and gradual onset of a flat foot. When assessing the tendon, look for swelling along its course, a flat foot with heel valgus, the 'too many toes' sign and prominence of the talar head. Palpate for tenderness, swelling or gaps in the tendon.

- **To test integrity**, ask the patient to perform a single foot tiptoe test on both sides. The inability to lift the affected heel off the ground is suggestive of a tibialis posterior tendon injury or insufficiency.
- **To test strength**, position the foot in the plantarflexed and inverted position. Ask the patient to hold this position while you push against their foot.

Dorsiflexors

Tendinitis of the long toe dorsiflexors usually presents in athletes. Pain affects gait in the early contact phase. Palpate for swelling, gaps or any tenderness. Ask the patient to move the foot into dorsiflexion and to hold this position while you push the foot down.

Inability to dorsiflex the foot is referred to as foot drop. Causes include stroke, spinal injury, spinal stenosis or disc prolapse, peripheral nerve injury (e.g. sciatic, common and deep peroneal) or a peripheral neuropathy.

Peroneal tendons

Peroneal tendon pathology presents with swelling and/or pain of the lateral hindfoot or midfoot. There may be a history of the ankle 'giving way'. Presentations of peroneal tendon pathology include:

- **'peroneal spasm'**: may be seen in tarsal coalition; here, the muscles are usually contracted secondary to the hindfoot valgus;
- **peroneal tendon dislocation**: attempt to dislocate the tendons by dorsiflexing and everting the foot.

The peroneus longus may be palpated just before it crosses under the foot to insert onto the base of the first metatarsal. Ask the patient to plantarflex the first metatarsal. Test

strength and integrity by active and resisted eversion while you palpate the tendons for swelling, tenderness or gaps.

Morton's neuroma

This condition represents thickening of the tissue that surrounds the digital nerve leading to the toes as the nerve passes under the ligament connecting the metatarsals in the forefoot. It is most frequent between the third and fourth toes. A neuroma presents with burning pain in the ball of the foot that radiates to the involved toes. The condition is difficult to diagnose and requires a high index of suspicion. Palpate in the web space between the symptomatic toes for a mass. Compression of the metatarsals may elicit a 'click' between the bones (Molders' click).

Summary box 31.12

Ankle and foot examination

Inspection of the standing patient

- Front – alignment, foot shape and deformity
- Side – medial arch
- Back – heel position
- Gait – antalgic, high stepping gait (foot drop)

Inspection of the supine patient

- Skin, scars, soft tissues, bony deformity
- Palpation of the ankle, subtalar, midfoot and forefoot joints

Movements

- Dorsiflexion, plantarflexion, inversion, eversion

Special tests

- Flexibility of the subtalar joint and a flat foot
- Joint stability, Morton's neuroma
- Tendons – tibialis posterior and anterior, Achilles tendon, peroneals and dorsiflexors

Thomas George Morton, 1835–1903, surgeon, The Pennsylvania Hospital, Philadelphia, PA, USA.

Chapter 32

Sports medicine and sports injuries

Learning objectives:

- To understand the important issues behind a patient's sporting injury in the context of taking a history
- To know the common sports injuries
- To know the appropriate ways of imaging to confirm or refute a diagnosis
- To assess the patient and offer treatment and rehabilitation plans

INTRODUCTION

Regular physical exercise is integral to the body staying healthy. However, stressing the human body to its limits may lead to injury. Sports medicine is the science of understanding how these injuries can be avoided, recognised when they do occur, and then treated appropriately. Sports injuries are, in principle, the same as other injuries. The major difference can be in the expectations of the patients. The injuries can be classified into three broad groups. Acute extrinsic injuries are those which arise from a direct external blow. These are commonly wounds, bruises and fractures. Acute intrinsic injuries result from failure of the patient's anatomical structures as a result of excessive loading. Examples are tendon ruptures, avulsion fractures and ligament injuries. Chronic injuries are those with an insidious or unknown onset and commonly involve degeneration or failure secondary to repetitive loading. Examples are tendinosis of the Achilles tendon and stress fractures.

Summary box 32.1

Types of sports injury

- Acute extrinsic – caused by direct external blow (bruises)
- Acute intrinsic – internal failure secondary to excessive external force (ligament tear)
- Chronic – repetitive and stress injuries

DIAGNOSIS OF SPORTS INJURIES

There are some additional questions that need to be asked in the history when treating a patient with a sports injury:

1. How was the injury sustained?
2. What type of training are they undertaking: mixed training or only one type of sport?
3. How many hours of training are they doing and has this changed recently?
4. Have they had previous injury? When did they sustain the injury and what rehabilitation have they had?
5. What are they aiming for in the way of competitions or level of sport that they perform?
6. Do they want to compete again or are they worried about competing?

The examination should follow the system described in Chapter 31.

TENDON DISEASE

Tendons can become weak and/or painful because of physical damage or as a result of inflammation of the tendon sheath around them (peritendonitis). Tendon injury is either due to overload (the strength of the tendon being exceeded by the force applied) or to overuse, where there is repetitive load leading to fatigue and failure. In this case the patient may present with tendinosis rather than rupture.

Current opinion now accepts that both tendinopathy and tenosynovitis are predominantly degenerative but do contain an inflammatory response on histology so the word 'tendinitis' can still be used.

Overuse injuries

Internal factors

Overuse injury can be precipitated in a tendon by decreased oxygen supply, decreased nutrition, hormonal changes, chronic inflammation and ageing.

External factors

A change in the environment (new running surface) or worn out equipment (old running shoes) may both bring about an overuse injury, as can excessive training when the patient is not fit enough to tolerate it.

In younger patients, the weakest area of a tendon is the apophyseal attachment. In adults, the musculotendinous junction is more liable to injury. In adolescents, the common sites of injury are tendon insertions. Examples are the anterior superior iliac spine (origin of sartorius), the anterior inferior iliac spine (rectus femoris), the lesser trochanter of the femur (iliopsoas), and the ischial tuberosity (hamstrings).

Summary box 32.2

Problems with tendons

- Rupture due to excessive loads and internal delamination
- Pain and degeneration due to repetitive or abnormal loading

MUSCLE INJURY

Muscle injuries or strains can be classified into a sprain, partial tear, complete tear or re-tear (if there has been previous injury). Most will heal spontaneously but may leave a painless defect in the muscle belly (*Table 32.1*). Muscle injuries leave an area of weakness that can re-tear in 30% of athletes. Despite extensive research we cannot predict the return to sport after such an injury but if the injury is large and involves the myotendinous junction it is more significant and likely to take longer.

TABLE 32.1 Muscle injuries graded according to severity.

Grade	Description
0	Normal muscle
1	Subtle muscle abnormality/sprain
2	Definite muscle disruption without muscle retraction
3	Complete muscle tear with retraction

LIGAMENTS

Ligament injuries are acute intrinsic injuries and can be graded according to their severity (*Table 32.2*).

In the acute phase it may be difficult to assess the ligament injury thoroughly. Once the acute injury has settled, any difference in laxity when comparing the two sides is diagnostic. However, the laxity of ligaments varies dramatically between patients and with age so absolute measurements are not reliable. When the diagnosis remains in doubt, imaging can be useful, for example ultrasound or magnetic resonance imaging (MRI). Grade 1 and 2 ligament injuries can be treated with pain relief, splinting and gentle mobilisation to avoid stiffness. Grade 3 injuries may require surgical repair to bring together the torn ends of the ligament, or another reconstructive procedure. The treatment depends on the site of the ligament and joint stability. For example, in ankle inversion injuries, the patient will recover without anterior talofibular ligament reconstruction.

TABLE 32.2 Ligament injuries graded according to severity.

Grade	Description
0	Normal ligament
1	No increase in joint laxity but there is tenderness around the injured ligament
2	Partial disruption of the ligament fibres with increased joint laxity, and a soft end point
3	Complete disruption of the ligament; there is a marked increase in joint laxity with no end point clinically

Summary box 32.3

Ligament injuries

- Difficult to assess clinically in the acute phase
- Use the opposite side for comparison
- If doubt, use imaging (ultrasound or MRI) to assess further
- Surgical repair may be needed for complete disruption, in a small percentage
- The stability of the joint is the most important factor in making this decision

BURSAE

Bursae are found between the joints and overlying tissues or muscles and tendons and are small fluid-filled endothelium-lined sacks. They decrease frictional forces between structures, but can become inflamed. The most commonly affected sites are over the first metatarsophalangeal joint (bunion), in front of the patella (housemaid's knee), behind the elbow (olecranon bursa) and the shoulder (subdeltoid subacromial bursitis). They can become inflamed or even infected. On the rare occasion that they fail to settle with appropriate treatment, they can be surgically excised.

BONE FRACTURES AND STRESS FRACTURES

True fractures can be encountered in any sport, but the fracture type found more commonly in sportsmen and -women is a stress fracture. This is caused by multiple repetitions of moderate loads that would not be expected to cause fracture in a single application. Clinically these lesions give poorly localised pain, which is worse on exercise. They are more common in runners, especially women who may have reduced bone density. The most common sites for stress fractures are the metatarsals and the tibia.

INJURIES ASSOCIATED WITH INDIVIDUAL SPORTS

Golf

The shoulder and the back are the commonest site of overuse injuries. Golfer's elbow or medial epicondylitis is due to

a common flexor origin tendinosis. It does not just occur in golfers. Tennis elbow is, however, more common in golfers than golfer's elbow.

Tennis

Tennis elbow is tendinosis of the common extensor origin. It occurs in novice tennis players but not the elite.

Partial ruptures of the calf muscles, especially the medial head of the gastrocnemius, are also found in tennis players (called tennis leg), and in other sports requiring sudden extreme acceleration.

Rowing

The common problems with rowing **(Figure 32.1)** are rib fractures and intercostal muscle tears **(Figure 32.2)**, and tendon problems such as tenosynovitis at the wrist, which is more common than intersection syndrome (a tendinosis where the first and second extensor tendon compartments of the forearm cross)

Figure 32.1 Rowers in action at an English regatta (© Vladislav Gagic–Fotolia).

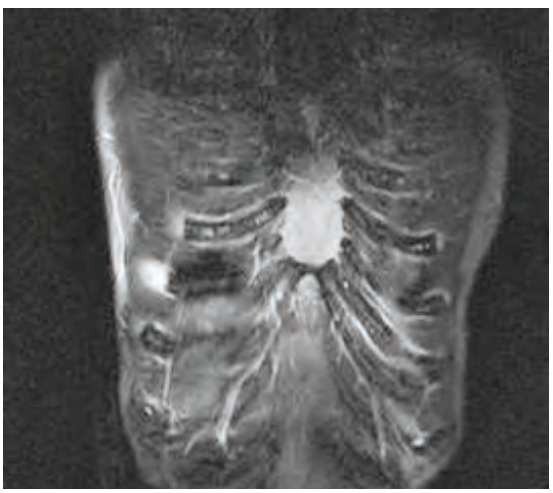

Figure 32.2 Coronal magnetic resonance imaging scan of the chest showing an intercostal muscle injury in a rower.

Football

The main injuries are fractures, groin injuries, muscle tears and twisting injuries to the knees and ankles leading to ligament tears **(Figures 32.3 and 32.4)**. Injuries specific to football include turf toe and neuromas to the deep peroneal nerve on the dorsum of the foot due to repetitive trauma from kicking the football. Goalkeepers get wrist and hand injuries, including occult scaphoid fractures.

Figure 32.3 A footballer in action (© lilufoto–Fotolia).

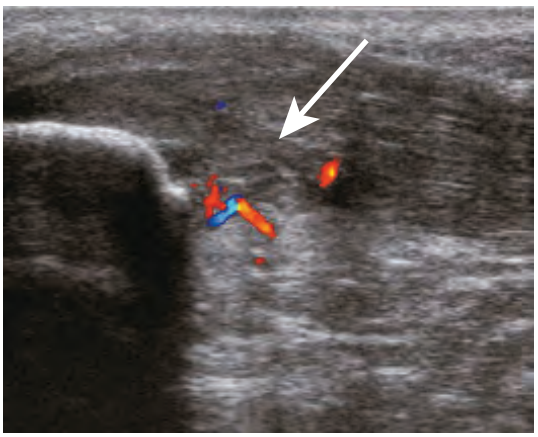

Figure 32.4 Ultrasound showing a patellar tendinosis with neovascularisation in a footballer (arrow).

Rugby

This is a high intensity contact sport so injuries include concussion due to head trauma, neck injuries including fractures to the cervical spine, muscle tears, shoulder, acromioclavicular joint and finger injuries, including dislocation of the phalanges, and tendon injuries e.g. rugger jersey finger where there is injury to the flexor profundus tendon.

Javelin

Javelin throwers get injuries due to abnormal stresses on the elbow similar to those seen in baseball. This causes abnormalities of the ulnar collateral ligament and capitellum.

Swimming

Shoulder injuries are more common in swimmers, especially in those performing the crawl or the butterfly stroke because these can lead to impingement syndromes (rotator cuff tendinosis and tears).

Volleyball, netball and basketball

Hand injuries are common, as is patellar tendinopathy and internal derangements of the ankle and knee.

Ballet dancing

Ballet dancers (Figure 32.5) have problems with posterior impingement of the ankle and tendinopathy of the flexor hallucis longus tendon when working on pointe (tip-toe). Stress fractures are also found in female dancers due to the abnormal stresses (Figure 32.6). Male ballet dancers are prone to back and shoulder injuries due to carrying ballerinas. Young dancers often complain of clicking and pain around the hip which may be due to iliopsoas tendinopathy.

Figure 32.5 Ballet dancer on pointe (© Zoja–Fotolia).

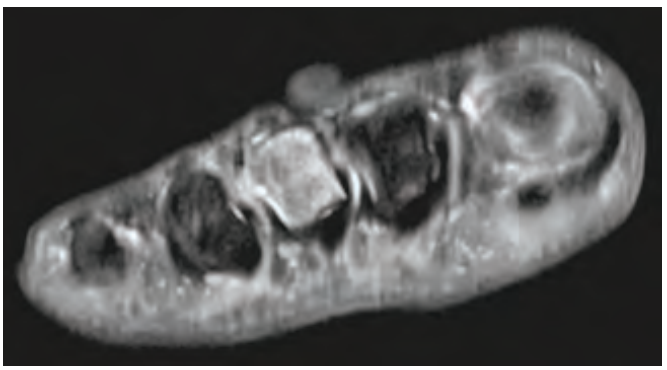

Figure 32.6 Magnetic resonance imaging short T1 inversion recovery (MRI STIR) sequence showing a stress injury to a metatarsal.

Snowboarding and skiing

Participants in both sports (Figure 32.7) have the full range of injuries associated with a high-speed sport. The rigid high boots used by skiers protect the ankle, but increase the loads transmitted up the limb, risking fracture of the tibia and ligament disruption of the knee (especially the anterior cruciate) (Figure 32.8). Novice snowboarders tend to get wrist fractures, whilst all levels of snowboarder can injure the acromioclavicular joint.

Figure 32.7 Skiers in action (©Alexander Rochau–Fotolia).

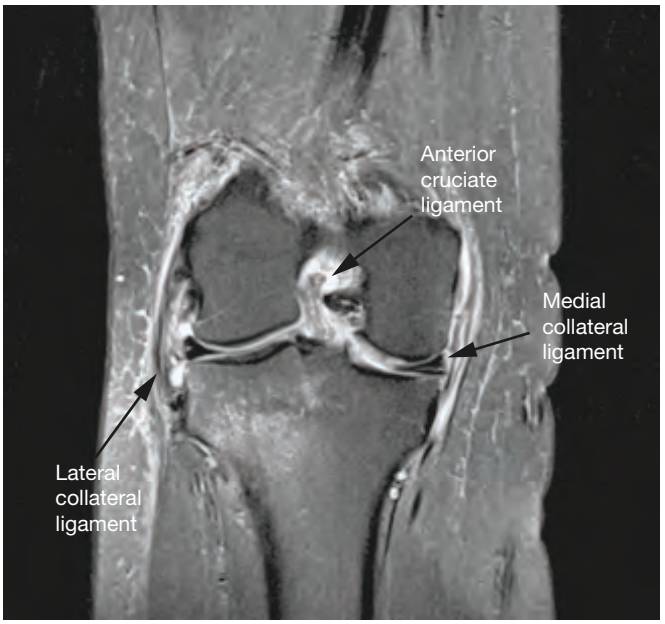

Figure 32.8 A knee magnetic resonance imaging scan showing a significant skiing injury with tears of the anterior cruciate ligament, medial collateral ligament and lateral collateral ligament.

Martial arts: judo, karate and taekwondo

All are associated with acute extrinsic injuries (direct blows) and acute intrinsic injuries (failure of ligaments and other structures due to sudden excessive loads).

Weight training

Weight training tends to produce the third type of sports injury (chronic), for example problems with the shoulders, including pectoralis major tears, carpal tunnel syndrome and the spine.

Kayaking

This causes problems with the forearm, including posterior interosseous nerve compression at the level of the elbow.

Marathon running

Problems include iliotibial band syndrome and stress fractures in the feet and shins.

INJURIES ACCORDING TO REGION OF SYMPTOMS

Pelvis, hip and thigh injuries

- **Thigh bruise** (Charley Horse, corked thigh or helmet thigh): These occur in all contact sports and can be both large and painful. They require prolonged rest as they are slow to settle and can rebleed. A pseudo-tumour may develop. Surgical drainage should be avoided if possible as it can lead to infection of the haematoma. Percutaneous aspiration of the liquefied haematoma under antibiotic cover is being performed by some groups to speed recovery with good results.
- **Quadriceps tears**: these most commonly occur in the rectus femoris muscle. They may be due to a direct blow, but more commonly they are due to twisting injury and occur along the aponeurosis of the rectus femoris, which is a weak point where the two muscle bellies join.
- **Complete quadriceps rupture**: this is less common, but may occur when kicking balls or in older patients. The patient can often perform a straight leg raise due to trick manoeuvres. However, they cannot restraighten the raised leg (quadriceps lag). Surgical repair is not usually needed in the elderly but is necessary in athletes.
- **Hamstring injury**: this commonly occurs due to twisting injuries following sudden and maximal muscle contraction. The injuries most commonly occur in the biceps femoris tendon, but can occur in the semimembranosus and to a lesser degree semitendinosus.

Groin pain

This is a very difficult area to assess as referred pain to the groin can come from many sources.

These include:

- the hip (labral tears and osteoarthritis);
- adductor tendon injuries;
- stress fractures of the femur, especially femoral neck and pubis;
- hernias (these may be small and include femoral and obturator hernias);
- tumours;
- sexually transmitted diseases;
- gynaecological and urinary problems;
- referred pain from the lumbar spine.

Adductor tendon injuries produce localised tenderness over the adductor origin.

A labral tear of the hip may cause clicking and pain; characteristically, on examination this occurs in internal rotation and adduction – the impingement sign (see Chapter 31).

Knee injury

Acute

Knee injuries are common in contact sports because of studded boots applying excessive loads to the knee in rapid turning. It is also a common site of injury in skiers. If the patient cannot play on and the knee swells immediately then there is likely to be blood in the knee (haemarthrosis). The most likely causes are a tear of the anterior cruciate ligament, dislocation of the patella (which usually relocates again immediately), and an intra-articular fracture (when there will be marrow fat globules visible in the aspirate).

If the patient plays on and the knee swells later then the diagnosis is more likely to be a tear of a meniscus and the fluid aspirated will be clear. The early diagnosis of a knee injury is very difficult as the knee is too painful to examine. Aspiration of any effusion, using full sterile precautions, followed by early physiotherapy to maintain quadriceps strength, will allow most acute injuries to settle.

Patellar dislocation is more common in the hypermobile patient and in contact sports. If it has not already relocated, straightening the knee allows it to relocate.

Subsequent diagnosis

Patients who have had a patellar dislocation will have a patellar apprehension sign (see Chapter 31). True locking is caused by a loose body in the knee (osteochondritis dissecans), or a torn meniscus. The patient will be moving normally at the time (unlike pseudo-locking) and will suddenly find that they are unable to straighten or even bend the knee. After a period of 'jiggling' the knee they may be able to release the block and move normally again. Thessaly's test is said to have high sensitivity and specificity for this condition. Imaging should be performed on locked knees because clinical assessment is difficult and an arthroscopy may not be needed.

If a meniscal tear is diagnosed but is peripheral (where there is a blood supply providing an environment for healing) then meniscal repair should be undertaken.

Giving way can be caused by weakness, pain or instability. Weakness will usually be the result of quadriceps wasting secondary to the injury and is best treated with physiotherapy.

Patellofemoral pain can arise spontaneously in adolescents, but can also arise after a knee injury when the vastus medialis wastes rapidly, and the patella starts to mal-track. Clinically the patient will give a history of finding it difficult to descend stairs and experience severe pain and giving way when trying to move the knee after a period when it has been

held still (pseudo-locking). Once again physiotherapy is the treatment of choice.

Instability may be the result of disruption of the anterior cruciate ligament with or without medial collateral ligament damage. The knee will give way on twisting or turning, and on examination the Lachmann test (see also anterior draw test) may be positive (see Chapter 31).

If physiotherapy fails to build the patient's muscles enough to stabilise the knee (it often does) then reconstruction of the cruciate ligament must be considered, using a synthetic graft or a length of tendon transferred from elsewhere.

If there is a posterolateral corner ligamentous injury in addition to the anterior cruciate ligament rupture, then surgery is mandatory to regain stability.

Iliotibial band syndrome is due to a friction injury of the iliotibial band both proximally over the greater trochanter and distally over the tibia. It occurs most commonly in long distance runners, such as marathon runners, and occurs proximally in females and distally as it extends over the lateral femoral epicondyle in males. If it does not respond to stretching and rest then sometimes a steroid injection in the adjacent bursae can help.

Summary box 32.4

Knee injuries

- Very difficult to examine in the acute stage clinically
- Effusions should be aspirated and early physiotherapy started
- Patellar dislocations will have a positive apprehension sign
- Anterior cruciate reconstruction should only be undertaken once the patient has been given a trial of physiotherapy in non-complex injuries (i.e. when there is an isolated anterior cruciate ligament rupture)

Ankle injury

Ankle sprains are a common cause of morbidity. Most occur due to a predominant inversion when the lateral ligament complex and the fibula and lateral talus can be injured. There is usually an eversion component to this injury. Isolated eversion or abduction injuries are much less common and will cause trauma to the medial ligament complex.

The ankle should only have radiographs taken if the Ottawa ankle rules are fulfilled (*Table 32.3*) as otherwise the likelihood of a fracture is very low.

Ankle dislocations should be reduced immediately as otherwise necrosis of the tented skin will occur, and ischaemia of the foot.

TABLE 32.3 Ottawa ankle rules.

- Bone tenderness along the distal 6 cm of the posterior margin or at the tip of the lateral malleolus
- Bone tenderness along the distal 6 cm of the posterior margin or at the tip of the medial malleolus
- Inability to bear weight at the time of the accident or at the time of examination

Sprains of the ankle should be treated with analgesia (but not non-steroidal anti-inflammatories because they decrease soft tissue healing) and PRICE (protection, rest, ice, compression and elevation) until the swelling has subsided, and then a physiotherapy programme should be started to reintroduce proprioception to the ankle. If this is not done, repeat injuries are more likely.

If there is diastasis of the distal tibiofibular joint then surgery may be required to regain stability of the ankle.

In adolescents, the peroneal tendon retinaculum can be torn. This leads to a subluxating peroneal tendon, with a painful flicking sensation over the lateral malleolus. In younger patients, this is best treated by immobilisation for a month, but if this does not resolve the problem then surgical intervention may be needed.

The Achilles tendon is a common site for tendinosis due to repetitive trauma. There is a fusiform swelling of the central tendon.

Tendon rupture classically occurs in middle-aged squash and badminton players. Simmonds or Thompson test is usually diagnostic (see Chapter 31). If there is the classic history of a feeling of a 'kick to the calf' and Simmonds test is negative, then ultrasound or MRI examination is mandatory as the Achilles rupture may be masked by the presence of a plantaris tendon. The Achilles tendon (see Chapter 36) can be allowed to heal in plaster with the foot plantar flexed to bring the tendon ends into contact. This takes several months. Alternatively, a surgical repair can be attempted. This opposes the ends and so should speed return to function, but risks compromising the blood supply to the tendon ends and so delays healing if the incision for access is large. In small-incision surgery, the risks are markedly reduced.

Summary box 32.5

Ankle injuries

- Dislocated ankles should be reduced immediately
- Radiographs should only be performed if the Ottawa ankle rules are fulfilled
- Physiotherapy to rebuild proprioception reduces the risk of recurrence of ankle sprains
- In Achilles tendon rupture, Simmonds–Thompson test is often positive (when there is no movement of the foot on squeezing the calf)

Foot injuries

Turf toe is pain, swelling and stiffness in the first metatarsophalangeal joint due to rupture of the plantar plate and injury to the joint capsule following hyperextension of the toe. Treatment is symptomatic.

Stress fractures are a common source of pain in marathon runners. These cause localised pain over a metatarsal on pressure and running. They can be identified by MRI or ultrasound. Navicular stress fractures are difficult to detect clinically and MRI should be performed if there is unexplained pain. Prolonged rest is the best treatment.

Shoulder and upper limb injuries

Shoulder dislocations occur in contact sports such as rugby. Almost all are anterior. Those who dislocate for the first time should be treated with intensive physiotherapy and rehabilitation. However, over half will have significant anatomical damage (tear of the labrum) (**Figure 32.9**) and 60% will go on to become recurrent dislocators. In these cases, surgical stabilisation (either open or arthroscopic) is the only treatment.

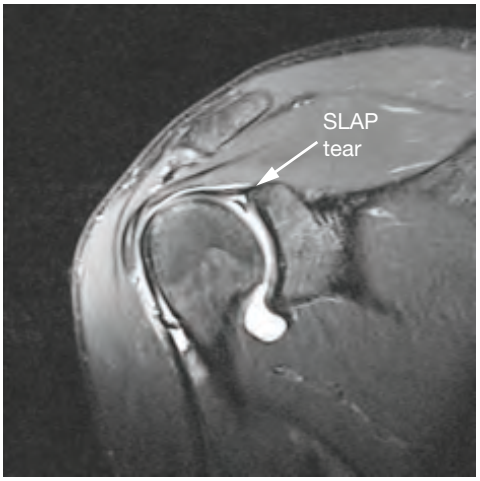

Figure 32.9 A magnetic resonance arthrogram of the shoulder showing a labral (superior labrum anterior posterior; SLAP) tear in a rugby player.

Shoulder instability can also result from overuse. This happens with throwing sports and also during sports such as gymnastics, and while serving in tennis and squash.

Tendinosis of the rotator cuff can also occur with overuse in patients who perform overhead sports repetitively, such as tennis players and cricket bowlers. Overload leads to impingement and then inflammation and tendinosis. Subacromial subdeltoid bursitis will cause pain radiating down the arm and to the wrist. This can be worse at night. Impingement can be significant in the overhead position and the patient may have difficulty combing their hair. The supraspinatus tendon can also tear, either secondary to impingement or after an acute injury. In the younger athlete this should be repaired surgically.

The acromioclavicular joint can be injured by direct impact in wrestlers, rugby players and cyclists. Treatment is usually symptomatic as surgical repair is not easy. If osteoarthritis develops in the joint, the distal end of the clavicle can be excised.

Summary box 32.6

Shoulder injuries

- Anterior dislocations are initially treated with physiotherapy
- Recurrent dislocations will require surgical stabilisation
- Overuse injuries are common in throwing sports
- Rotator cuff impingement is common
- Torn rotator cuffs should be repaired in young patients

Biceps injuries can occur in the long head of biceps proximally and the distal biceps tendon in weightlifters, wrestlers and gym users on anabolic steroids, but can also occur as part of a significant rotator cuff injury proximally where the rotator cuff can be torn from the supraspinatus across the anterior interval and into the subscapularis tendon. There is no treatment needed in proximal injuries.

Arm and hand injuries

Medial and lateral epicondylitis are discussed above (**Figure 32.10**). Treatment should commence with physiotherapy and an epicondyle support. Percutaneous interventions should then be tried before surgical treatment.

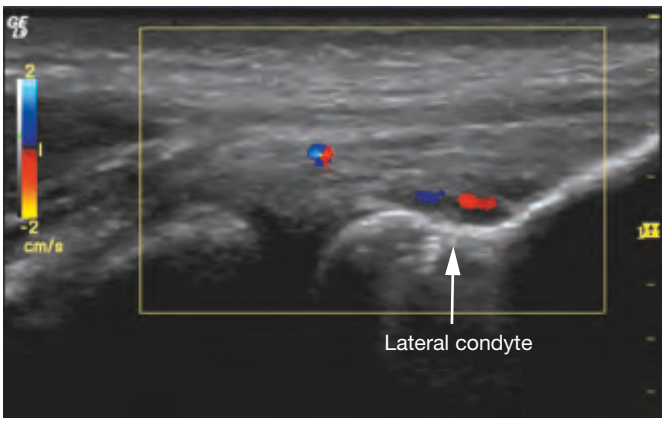

Figure 32.10 An ultrasound scan of the common extensor origin at the elbow showing a tendinosis with neovascularisation.

De Quervain's tenosynovitis occurs in repetitive injuries involving the fingers. This can be treated effectively with physiotherapy and steroid injections into the tendon sheath.

Skiers (or gamekeeper's) thumb occurs where the proximal phalanx of the thumb is forced radially in a fall. The ulnar collateral ligament of the thumb at the level of the metacarpophalangeal joint is damaged. If it is avulsed, the aponeurosis of the abductor pollicis brevis can become interposed (a Stener lesion) and so surgical intervention in this scenario is the only option if this lesion is to repair.

Mallet fingers or baseball fingers occur when there is a rupture of the distal insertion of the extensor tendon into the distal phalanx. This can be treated conservatively with a mallet splint.

The radial slips of the extensor tendon can be torn at the level of the metacarpophalangeal joints in boxing injuries and here the retinaculum needs reattaching surgically.

Disruption of the flexor tendon pulleys in the hand occurs in climbers, and leads to bow stringing of the flexor tendons. If this occurs, surgical intervention is needed.

All of these hand injuries can be assessed by the use of ultrasound examination using dynamic stress, which is better in resolution and specificity than MRI.

Summary box 32.7

Arm and hand injuries

- Medial and lateral epicondylitis should be treated symptomatically
- Ulnar collateral ligament injuries of the thumb may require surgical repair if a Stener lesion is present
- Flexor tendon pulley injuries require surgical repair

TREATMENT OF INJURIES

Initial care

In the acute phases of a sports injury PRICE describes the treatment plan (*Table 32.4*).

TABLE 32.4 PRICE for the nonoperative management of the acute sports injury.

- Protection
- Rest
- Ice
- Compression
- Elevation

Analgesia

In the initial phase of an injury, non-steroidal anti-inflammatory drugs are thought to slow healing, but may reduce pain and oedema. This is especially true for fracture healing. Paracetamol and codeine have less of an effect on injury healing and can also help with pain relief.

When prescribing any drugs it is important to be aware of the World Anti-Doping Agency (WADA) guidelines on doping for athletes as some substances are banned in competition and training. Spot checks are performed on athletes so they need to adhere to this throughout the year. A prohibited list is available on their website (http://www.wada-ama.org).

If steroids are needed to help with continued rehabilitation, then a TUE or temporary use exemption certificate needs to be given to the athlete so that if they are spot checked for drugs they will not be disqualified.

Rehabilitation

After an initial period of rest, passive movements should be started, followed by more active movements as healing occurs. Physiotherapy is an essential part of rehabilitation and close liaison between the sports doctor and the coach are needed in getting an athlete back to their sport. Steroid treatment should not be used around the Achilles tendon (according to advice from the National Institute for Health and Clinical Excellence and the British National Formulary).

Some patients develop myositis ossificans after a muscle haematoma. This presents itself as increasing swelling and pain. It can be treated with indomethacin, which helps prevent further formation, but it will resolve naturally.

Chapter 33

The spine

Learning objectives

To learn:

- The salient features relating to the history and examination of the spine
- The investigations commonly used in the field of spinal disorders
- The treatment principles for common conditions affecting the spine
- The global issues in spinal surgery

EPIDEMIOLOGY

The lifetime prevalence of low back pain has been reported at between 60 and 80%. By contrast, the lifetime prevalence of true sciatica is between 2 and 4%. It is generally accepted that 90% of acute low back pain episodes settle, allowing return to work within 6 weeks. However, some 5–7% of the population aged between 45 and 64 years will report back problems as a 'chronic sickness'. Up to 70% of acute episodes of sciatica resolve within 3 months.

Summary box 33.1

Epidemiology

- Low back pain is extremely common
- 90% of acute low back pain episodes settle within 6 weeks
- Sciatica is much less frequent
- 70% of acute sciatic episodes settle within 3 months

CLINICAL ANATOMY

The normal cervical lordosis measures between 35° and 45°. The normal lumbar lordosis is between 40° and 80° (mean 60°) and decreases with age. Most lumbar lordosis occurs between L4 and S1. The normal thoracic kyphosis is between 20° and 50° (mean 35°) and increases with age. When standing, the normal sagittal vertical axis (sagittal plumb-line) falls from the odontoid process through the C7–T1 disc space and crosses the spinal column at the T12–L1 disc space, before reaching the posterosuperior corner of the S1 vertebral body. For an energy efficient posture, cervical and lumbar lordosis will balance thoracic kyphosis.

The spinal canal is formed behind the articulated vertebral body by the posterior elements of the vertebral column and can be divided into a **central** portion and two **lateral** portions. The central portion is occupied by the thecal sac containing the spinal cord which terminates behind the body of L1. The lateral portions contain the nerve roots.

The spinal nerve roots comprise 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. Dorsal and ventral roots join to form spinal nerves. The ventral root and the dorsal root ganglion lie within the intervertebral foramen. This foramen is bounded superiorly and inferiorly by pedicles, anteriorly by the disc and posteriorly by the facet joint. Degenerative changes in these structures may lead to neural compromise. Laminar overlap within the lumbar spine decreases from L1 to S1 so that, at the L5–S1 level, access to the intervertebral disc requires less bone removal than at a more proximal level.

The blood supply of the spinal cord is derived from the vertebral, deep cervical, intercostal and lumbar arteries. The arteries of the spinal cord include the anterior spinal artery and two posterior spinal arteries, with the anterior spinal artery supplying the majority of the vascular supply to the spinal cord. The radicular artery of Adamkiewicz makes a major contribution to the anterior spinal artery, supplying the lower spinal cord. It originates on the left in 80% of people, usually accompanying the ventral root of T9, T10 or T11, but can originate anywhere from T5 to L5. Ligation of this important artery may lead to critical ischaemia of the spinal cord. Ligating segmental vessels over the midpoint of the vertebral body will minimise the risk of injury to this important artery during anterior approaches to the spine.

Albert Adamkiewicz, 1850–1921, Professor of Pathology, the University of Krakow (Cracow), Poland, described the arterial supply to the spinal cord in 1882.

PATIENT HISTORY

The commonest reasons for referral to a spinal clinic include **pain** and **spinal deformity**. A detailed history of the pain including site, type, severity, duration, frequency and aggravating factors should be sought. Has there been any history of trauma? Is the pain present at night? Is there associated pain in the upper limbs (brachalgia) or lower limbs (sciatica)? Is there associated numbness, tingling, weakness or difficulty with gait? Is there a family history of ankylosing spondylitis or rheumatoid arthritis? Are there concurrent medical conditions such as diabetes, peripheral vascular diseases, osteoarthritis of the hip or previous malignancies? Are there systemic symptoms such as unexplained weight loss, chills or fever? *Table 33.1* lists the commonly accepted 'red flags' that allow diagnostic triage into those with serious pathology of the spine (such as fractures, tumours, infection or cauda equina syndrome) and those without serious pathology.

TABLE 33.1 'Red flags': when present in patients with back pain, red flags suggest the likelihood of serious underlying pathology.

- Age <20 years or >50 years
- Recent significant trauma
- History of malignant disease
- Unexplained weight loss
- Constitutional symptoms (fever, chills)
- Immunosuppression (intravenous drug abuse, prolonged corticosteroid use)
- Severe or progressive sensory alteration or motor weakness
- Acute difficulty with micturition (painless retention)
- Numbness in perineum or buttocks and/or faecal incontinence

Pain may arise from the spine, but non-spinal causes of pain must also be considered *(Table 33.2)*. Patients should always be asked about the presence of perineal numbness (saddle area) and/or difficulties passing urine or faeces, as these symptoms may indicate a cauda equina syndrome *(Table 33.3)*.

TABLE 33.2 Non-spinal causes of low back pain: referred pain.

- Respiratory, e.g. mesothelioma
- Vascular, e.g. abdominal aortic aneurysm
- Renal, e.g. pyelonephritis
- Gastrointestinal, e.g. peptic ulcer, pancreatitis
- Urogenital, e.g. testicular, ovarian or prostatic cancinoma

Patients should be asked whether the pain is interfering with their ability to work. What treatment has the patient already tried and how effective were these treatments (e.g. analgesics, exercise, physiotherapy or spinal injections)? Pending litigation or worker's compensation claims may have a negative prognostic effect on future treatments and therefore should be enquired about.

Spinal deformities, e.g. scoliosis and excessive kyphosis (>50°), are generally painless in children, but may be symptomatic in adult life. How quickly has the spinal deformity progressed? It is important to assess skeletal maturity and whether the child has gone through a recent growth spurt. Has menstruation commenced in the female or has the voice dropped in the male, indicating the onset of puberty?

TABLE 33.3 Cauda equina syndrome presentation.

- Low back pain
- Uni- or bilateral sciatica
- Saddle anaesthesia
- Motor weakness in the lower extremities
- Variable rectal and urinary symptoms

PHYSICAL EXAMINATION

The patient should be undressed and posture should be evaluated in both the frontal and sagittal planes. Shoulder or waist asymmetry suggests the presence of scoliosis. The Adam's forward bend test will accentuate trunk asymmetry and allow appreciation of rib or loin prominence on the convex side of each curve. The skin should be examined for cutaneous neurofibromata, café-au-lait patches or axillary freckling commonly present in neurofibromatosis. Neurological examination should include abdominal reflexes. Leg lengths should be measured. In the case of kyphosis, the sagittal alignment and forward gaze should be assessed.

William Adams described the forward bending test for scoliosis in 1865. His understanding of the nature of the rotational element of scoliosis was given by a postmortem examination he performed on an eminent surgeon and geologist, Gideon Mantell. The clinical history of Dr Mantell is well documented.

Palpation is useful to locate specific areas of tenderness. Ranges of motion should be assessed. The normal range of motion in the cervical spine is 45° of flexion, 55° of extension, 70° of rotation and 40° of lateral bend. The normal range of motion in the lumbar spine is 40–60° of flexion, 20–35° of extension, 15–20° of lateral bending and 3–18° of rotation. Schober's test is a simple clinical test to evaluate spinal mobility. A tape measure is used to mark the skin midway between the posterior superior iliac spines and at points 10 cm proximal and 5 cm distal to this mark while the patient is standing. The patient is then asked to bend forward as far as possible and the distance between the two points is measured with the patient in the flexed position. Normally one would expect to see an increase of at least 5 cm between the two points in the erect and flexed positions. A distance of less than 5 cm between these points may indicate ankylosing spondylitis.

Neurological examination of the upper and lower limbs will focus on tone, power, coordination, reflexes, sensation and gait (*Tables 33.4* and *33.5*). A rectal examination should be performed if there is any concern about cauda equina integrity. The superficial abdominal reflex is an upper motor neurone reflex. It is performed by stroking one of four abdominal quandrants in succession. The umbilicus should move toward the quandrant that was stroked. The reflex should be symmetrical from side to side. Absent or asymmetrical abdominal

TABLE 33.4 Neurological evaluation of the upper limb.

Neurological level	Motor	Sensation	Reflexes
C5	Deltoid	Lateral arm	Biceps (C5–C6)
C6	Wrist extensors	Lateral forearm	Brachioradialis (C5–C6)
C7	Triceps	Middle finger	Triceps (C7–C8)
C8	Long finger flexors	Medial forearm	No reflex
T1	Interosseus muscles	Medial arm	No reflex

TABLE 33.5 Neurological evaluation of the lower limb.

Neurological level	Motor	Sensation	Reflex
L2	Hip flexion	Anterior thigh, groin	No reflex
L3	Knee extension	Anterior and lateral thigh	Patellar (L3–L4)
L4	Ankle dorsiflexion	Medial leg and foot	Patellar (L3–L4)
L5	Extensor hallucis longus	Lateral leg and foot	No reflex
S1	Ankle plantarflexion	Lateral foot and little toe	Achilles (S1–S2)

reflexes may indicate intraspinal pathology such as syringomyelia or spinal cord injury.

Myelopathy or upper motor neurone (UMN) lesions are suggested by spasticity, motor weakness, hyper-reflexia, positive Hoffmann's sign (forceful flexion of the distal phalanx of the middle finger results in flexion of the thumb and index finger), upgoing Babinski response, and patellar and ankle clonus.

Summary box 33.2

Upper motor neurone lesions are characterised by:

- Increased tone – spastic
- Hyper-reflexia
- Muscle spasms
- Motor weakness
- Disuse atrophy
- Positive Hoffman's sign
- Ankle and patellar clonus
- Upgoing plantar response

Typical signs of radiculopathy (lower motor neurone (LMN) lesion) include sensory loss, motor weakness, flaccid paralysis, muscle atrophy, loss of reflexes and muscle fasciculation.

The straight leg raise (SLR) test is performed with the patient in the supine position. The leg is elevated with the knee straight to increase tension along the L5 and S1 nerve roots. The test is positive if the leg elevation provokes radicular pain. The crossed SLR test is carried out by elevating the asymptomatic leg, and produces sciatic symptoms in the opposite leg. A positive test is associated with a herniated disc in 97% of patients. Lasègue's sign denotes radicular pain aggravated by ankle dorsiflexion.

The femoral nerve stretch test is performed with the patient in the prone position by extending the hip and flexing the knee. This creates tension on the L2, L3 and L4 nerve roots. The femoral nerve stretch test is considered positive if radicular pain occurs in the anterior thigh region during the test.

The examination should include, where appropriate, examination of the shoulder, hip, knee, sacroiliac joint and vascular system, as dual pathology is common in the ageing community.

In 1979, Waddell and colleagues developed and validated a series of signs and tests that have proved helpful in identifying individuals who are magnifying or exaggerating symptoms, possibly for secondary gain (*Table 33.6*).

TABLE 33.6 Non-organic physical signs in low back pain.

- *Tenderness*: superficial or non-anatomical
- *Simulation tests*: axial loading or rotation
- *Distraction tests*: variable straight leg raises
- *Regional disturbances*: non-anatomical sensory or motor loss
- *Over-reaction*: grimacing, muscle tremor, etc.

Summary box 33.3

Lower motor neurone lesions are characterised by:

- Decreased tone – flaccid
- Hyporeflexia
- Denervation fasciculations
- Motor weakness
- Sensory loss
- Severe atrophy
- Downgoing plantar response

Charles Ernest Lasègue, 1816–1863, Professor of Medicine, University of Paris, and physician, La Salpêtrière, Paris, France.

INVESTIGATIONS

The most common diagnostic imaging tests used to evaluate spinal disorders include plain radiographs, computed tomography (CT), magnetic resonance imaging (MRI), CT myelography and isotope bone scanning. These investigations are extremely sensitive, but relatively non-specific. For example, at least one-third of asymptomatic patients have been noted to have 'abnormalities' on MRI scans. All investigations must therefore be carefully correlated with the clinical findings.

Plain radiographs

It is not appropriate to order spine radiographs for every patient presenting with neck or low back pain. Patients with red flag signs or symptoms and those who have not responded to conservative treatment require imaging, with most units in resource-rich countries utilising MRI (no radiation penalty) in this situation. Standing radiographs of the whole spine are important for the assessment of scoliosis. Radiographs cannot diagnose early-stage tumour or infection, because significant bone destruction (between 40% and 60% of bone mass) must occur before a radiographic abnormality is detected

Computed tomography

This investigation is the best test for assessing bone anatomy. Three-dimensional reconstructions are often useful for the assessment of congenital spinal deformity. However, one should remember that a typical CT of the lumbar spine will expose the patient to an effective dose of 5–10 milliseiverts (mSv), which would be equivalent to 2.5–5 years of background radiation.

Magnetic resonance imaging

This allows detailed visualisation of the spinal cord, thecal sac, epidural space, intervertebral discs, nerve roots, paraspinal soft tissues and bone marrow. It is contraindicated for patients with certain pacemakers and coronary stents, intracranial metal clips, metallic bodies in the eye, spinal cord stimulators and certain drug pumps.

Bone scintigraphy

Isotope bone scans are highly sensitive, but non-specific, tests useful for screening the skeletal system for metastatic disease, discitis or vertebral body osteomyelitis, or to assess the relative activity of bone lesions such as osteoid osteoma, osteoblastoma, defects in the pars interarticulares or a pseudarthrosis (incomplete fusion). In the case of multiple myeloma or purely lytic metastases, the bone scan may not show increased activity as these tumours may not stimulate a significant **osteoblastic** response.

Bone densitometry

Bone density and osteoporosis can be measured using dual-energy x-ray absorptiometry (DEXA) of the hip, wrist and spine.

Provocative discography

This investigation involves the placement of a 24-gauge needle into the centre of the intervertebral disc in a conscious patient. One to 3.5 mL of radio-opaque contrast agent is then injected into the disc. The contrast pattern will allow the discrimination of different degrees of disc degeneration; cottonball or lobular would be considered normal whereas irregular, fissured or ruptured would be considered degenerate (**Figure 33.1**). The patient is asked if they are experiencing their 'usual type of back pain'. To diagnose discogenic low back pain one must document evidence of disc degeneration and concordant pain during the injection. Treatment options may include spinal fusion or disc replacement

Facet joint injections

For patients with facet joint arthropathy, x-ray-guided local anaesthetic and steroid injections may be both diagnostic and therapeutic for 4–6 weeks. Longer-term relief may be obtained by facet joint rhizolysis. This percutaneous procedure denervates the facet joint using heat.

Foraminal epidural steroid injections

For patients with radiculopathy due to a prolapsed intervertebral disc or lateral recess stenosis, a targeted foraminal epidural steroid injection of local anaesthetic and steroid may provide important diagnostic information and have a lasting therapeutic effect.

Spinal biopsy

Either CT-guided or open biopsy is often performed to obtain tissue for diagnostic study in cases of suspected tumour and/or infection.

DEGENERATIVE CONDITIONS OF THE SPINE

Cervical radiculopathy

Patients present with neck and arm pain (brachalgia), paraesthesia and motor weakness in the distribution of the compromised nerve root (radiculopathy). This may be caused by disc herniation or degenerative stenosis. Symptoms often respond to conservative treatment including physiotherapy and medication for neuropathic pain (amitriptyline, gabapentin or pregabalin) or CT-guided foraminal epidural steroid injections of local anaesthetic and steroid. Intractable pain and/or functional neurological deficit are indications for surgical intervention. Surgical options include anterior cervical discectomy and fusion (using a cage packed with bone graft and plate), cervical total disc replacement (**Figure 33.2**) or posterior laminoforaminotomy. Randomised controlled trials have compared anterior cervical discectomy and fusion to cervical disc replacement. Similar clinical outcomes have been observed in both groups. However, cervical disc replacements preserve motion in the operated level, and may protect against adjacent segment disease in the longer term.

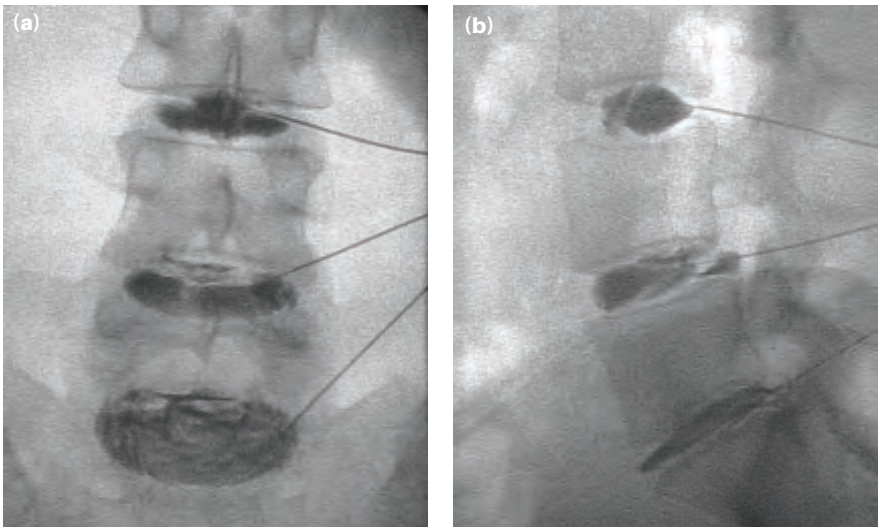

Figure 33.1 Lumbar discography. Antero-posterior **(a)** and lateral **(b)** radiographs following injection of contrast media into the lower three lumbar discs. Morphology: L3/4 cottonball, L4/5 fissured, L5/S1 ruptured. Concordant low back pain was reproduced when injecting the L4/5 and L5/S1 discs. No pain was experienced when the L3/4 disc was injected. The patient underwent a posterolateral fusion L4 to S1.

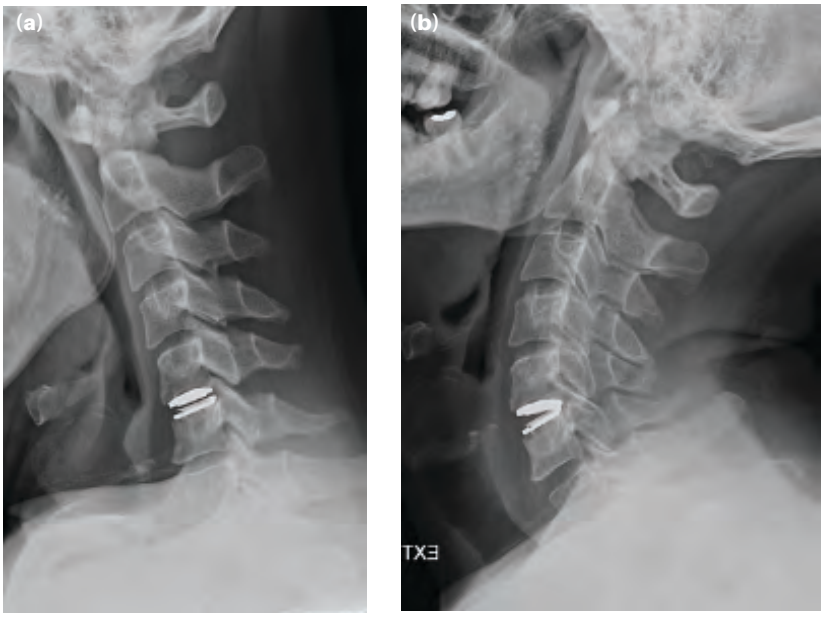

Figure 33.2 Cervical total disc replacement. The patient presented with severe left-sided C6 radiculopathy. MRI scan confirmed a left C5/6 disc herniation. The patient underwent a C5/6 discectomy and decompression of the left C6 nerve root, followed by insertion of a cervical disc replacement. Lateral radiographs in flexion **(a)** and extension **(b)** show restored motion to the C5/6 level.

Cervical myelopathy

Degenerative change in the cervical spine leading to spinal cord compression is the commonest cause of cervical myelopathy in patients over 55 years of age. Lower motor neurone changes occur **at the level** of the lesion, with atrophy of the upper extremity muscles, particularly the intrinsic muscles of the hands. Upper motor neurone findings are noted **below** the level of the lesion and may involve both upper and lower extremities. If surgery is considered appropriate then an anterior or posterior decompression may be required.

Thoracic disc herniation

Thoracic disc herniations that require surgical intervention are rare, accounting for less than 2% of all discectomy procedures. Typically, the patient presents with axial pain, radiculopathy or myelopathy. Conservative treatment including non-steroidal anti-inflammatory drugs, physiotherapy and general fitness improvement should be considered initially. If required, thoracic discectomy may be performed via a thoracotomy or, for a soft disc prolapse, via a thoracoscopic approach.

Cauda equina syndrome

Cauda equina syndrome (CES) is rare, accounting for only 2–6% of all lumbar disc herniations. It presents most commonly in the 20–45-year age group, with some or all of the following symptoms: low back pain, unilateral or bilateral sciatica, lower limb motor weakness, sensory abnormalities including saddle anaesthesia, bladder dysfunction (painless retention in early stages, overflow incontinence in later stages), sexual and bowel dysfunction. CES may result from acute or chronic compression of the cauda equina nerve roots. The most frequent cause is a massive central lumbar disc protrusion at L4/5; other causes include lumbar fractures, postoperative epidural haematoma, spinal stenosis, spinal tumours

and occlusion of the lumbar arteries by dissection or aneurysm of the abdominal aorta.

Cauda equina nerve roots lack epineurium and perineurium, and only have a thin endoneurium root sheath, making them more susceptible to compression forces when compared with peripheral nerves. The syndrome can result in permanent motor deficit, and bladder, bowel and sexual dysfunction. It represents a true spinal emergency and requires urgent surgical decompression. The outcome for patients who undergo surgical decompression within 24 hours of the onset of loss of bladder or bowel control is significantly better than that of those who undergo surgery beyond this 24-hour period.

Summary box 33.4

Cauda equina syndrome

- Commonest presenting symptoms: perineal numbness, painless urinary retention and faecal incontinence
- Urgent investigation with MRI is required for all suspected cases
- Confirmed CES requires surgical decompression within 24 hours to achieve optimum outcomes

Lumbar disc herniation

Symptomatic lumbar disc herniation occurs during the lifetime of approximately 2–4% of the population. Risk factors include family history, male gender, age (30–50 years), heavy lifting or twisting, stressful occupation, lower income and cigarette smoking.

Over 90% of lumbar disc herniations occur at the L4/5 or L5/S1 levels. A posterolateral disc protrusion will affect the **traversing** root, e.g. an L4/5 disc protrusion will affect the L5 nerve root. A far-lateral disc protrusion (extraforaminal) will affect the **exiting** nerve root, e.g. a far-lateral L5/S1 disc protrusion will affect the L5 nerve root. Symptoms typically commence with a period of back pain followed by sciatica. There may be paraesthesia, motor weakness, loss of reflexes and a reduction in straight leg raise.

For simple sciatica, a period of 6–12 weeks of conservative treatment is advised. Up to 70% of patients will settle within this period. A trial of pregabalin (GABA analogue) and/or a transforaminal epidural steroid injection maybe helpful. Microdiscectomy is the standard surgical intervention for those in whom conservative treatment has failed. The procedure is carried out in the prone position with radiographic confirmation of the correct level. Loupes with a headlight or use of the operating microscope greatly facilitate the procedure. A 3–5 cm incision is made with a unilateral take down of the multifidus. The spinal canal is entered via removal of the ligamentum flavum under the lamina. The thecal sac and traversing nerve root are identified. The dura and nerve root are retracted medially and the offending disc prolapse incised via a transverse annulotomy. The disc fragment is removed and the disc space cleared of any remaining nuclear material with rongeurs and multiple washouts of the disc space. The wound is closed. Patients are generally discharged the next morning.

Spinal stenosis

Spinal stenosis may be defined as any type of narrowing of the spinal canal, nerve root canal or intervertebral foramen. The resultant nerve root compression leads to nerve root ischaemia, presenting with back, buttock or leg pain provoked by exercise. Spinal stenosis may be congenital, as is the case in achondroplasia, or acquired, as is the case for degenerative types (commonly presenting between 50 and 70 years of age). The narrowing is caused by facet joint hypertrophy, disc bulging and ligamentum flavum thickening.

Symptoms of spinal claudication can be distinguished from vascular claudication because they are frequently associated with neurological symptoms, are often worse in extension, and pedal pulses are present on clinical examination. Symptoms progress in approximately 20–33% of patients who receive no treatment. The condition may be treated successfully by surgical decompression alone with preservation of the facet joints.

Summary box 33.5

Spinal stenosis

- Extremely common condition in the 50–70-year age group
- Classic symptoms: back, buttock, thigh and calf pain
- Provoked by walking and extended posture
- Relieved by flexed posture
- Symptoms progress in up to one-third of untreated patients

Discogenic low back pain

Discogenic low back pain has been defined as a continuum of diagnostic categories (internal disc disruption, degenerative disc disease, segmental instability) reflecting various stages of degenerative pathology affecting the intervertebral disc. Not all degenerate discs are painful. Patients typically present with chronic relapsing episodes of low back pain between the ages of 40 and 60 years.

A recent study has compared rehabilitation with spinal fusion for discogenic pain. Both groups reported reductions in disability, with the authors strongly recommending a course of rehabilitation **before** surgical intervention. For those who fail to improve with conservative measures, provocative lumbar discography (see **Figure 33.1**) may help to identify the source of pain, and surgery in the form of a lumbar spinal fusion (**Figure 33.3**) or lumbar disc replacement (**Figure 33.4**) may be considered.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis

This is a unilateral or bilateral defect in the pars interarticularis without vertebral slippage. The incidence is reported at approximately 6% by the age of 14 years, but is much higher in the young athletic population. Many cases remain

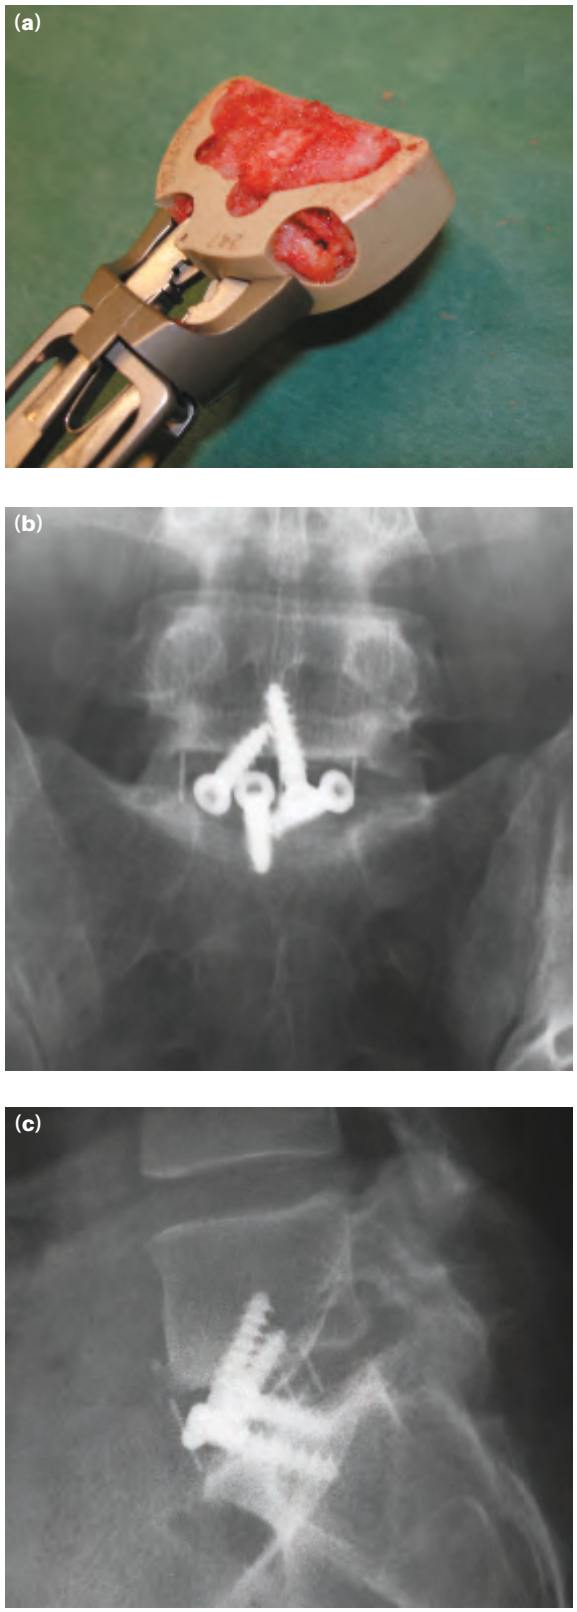

Figure 33.3 Anterior lumbar interbody fusion. **(a)** The PEEK (poly-ethyl-ethyl-ketone) cage has been packed with bone graft prior to insertion; **(b)** and **(c)** show the anteroposterior and lateral postoperative radiographs, respectively.

asymptomatic. The diagnosis is difficult to confirm with plain radiographs. Reverse gantry CT, MRI and single photon emission computed tomography (SPECT) are very useful investigations for this condition. Treatment involves rest, non-steroidal anti-inflammatory medication, activity modification and a lumbosacral orthosis. For patients who remain symptomatic despite an adequate trial of non-operative care, surgery in the form of a direct repair of the pseudarthrosis by a Buck's fusion may be indicated.

Summary box 33.6

Spondylolysis

- Incidence in general population 6% by 14 years
- Incidence in athletic population 15–47%
- May be completely asymptomatic/incidental finding on radiograph
- Difficult to image, but MRI proving more useful
- Conservative treatment: activity modification, antilordotic brace
- Surgical treatment: direct repair preserving motion or spinal fusion if associated disc degeneration

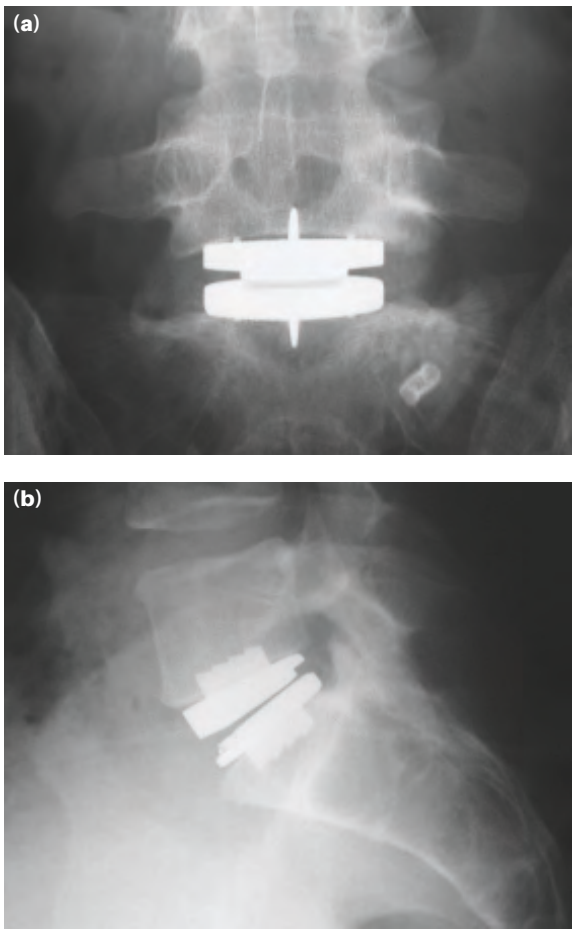

Figure 33.4 Lumbar total disc replacement. **(a)** Anteroposterior radiograph with 30° of cranial inclination. **(b)** Lateral radiograph with the implant appropriately positioned.

Spondylolisthesis

Spondylolisthesis is a forward slippage of the vertebral body engendered by a break in the continuity or elongation of the pars interarticularis and presents in 4% of the adult population. Spondylolisthesis can be classified into six types by causation (*Table 33.7*), or by the degree of slip (*Table 33.8*).

For skeletally immature patients (<18 years old) who have progressive slips in the spine, and in individuals with intractable low back or radicular pain, or neurological symptoms, surgery may be indicated. For low-grade slips (Meyerding Grade I and II) fusion-*in-situ* is the procedure of choice. If there is **objective** evidence of neural compression (e.g. weakness of extensor hallucis longus), a spinal decompression should be performed at the same time. For high-grade slips (Meyerding Grade III or IV) (**Figure 33.5**), opinion is divided on whether to reduce the slip first and then fuse, or simply to fuse *in situ*.

TUMOURS OF THE SPINE

Metastatic tumours

These are the most common tumours affecting the spine, accounting for 98% of all spine lesions. The commonest malignancies that metastasise to the spine are shown in *Table 33.9*. Red flags picked up on history or examination will alert the clinician to this possible diagnosis.

Over 80% of patients with spinal metastases present with progressive pain, and only 20% present with spinal cord compression. Relevant investigations include full blood count (FBC), urea and electrolytes, liver function tests, calcium, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), prostate-specific antigen (PSA), serum protein electrophoresis, thyroid function tests (where a thyroid mass has been palpated) and nutritional indices. Plain radiographs may show an absent pedicle ('winking owl' sign), vertebral cortical erosion and/or vertebral collapse. MRI of the whole spine will detect most metastases. Most metastases are **osteoblastic** and will show up on bone scintigraphy; however, osteolytic lesions such as multiple myeloma and renal cell carcinoma may not show up on an isotope bone scan. Metastases from the prostate may be sclerotic. Biopsies may be obtained via a percutaneous CT-guided method or open biopsy.

Treatment options include orthotics, steroids (dexamethasone), radiotherapy, chemotherapy, hormonal therapy, surgery or a combination of any of the above. Radiotherapy promotes reossification of the vertebral body and reduces tumour load. It can be very effective for reducing 'bone pain'. Lymphoma, breast, lung and prostate metastases are highly radiosensitive. Gastrointestinal adenocarcinoma, metastatic melanoma, thyroid and renal carcinoma are radioresistant. Small cell carcinoma of the lung, Ewing's sarcoma, thyroid carcinoma, breast carcinoma and neuroblastoma are usually sensitive to chemotherapy and should have chemotherapeutic agents as the first-line management. Adenocarcinoma of the lung is resistant to chemotherapy. Prostate metastases may respond well to antiandrogenic hormone medication.

Extensive reconstructive tumour surgery should be reserved for those patients whose life expectancy exceeds 3–6 months. For patients with malignant spinal cord compression, the combination of decompressive surgery with stabilisation and postoperative radiotherapy has been shown to be superior in outcome when compared with radiotherapy alone. In one randomised trial, surgery and radiotherapy permitted most patients to remain ambulatory for the remainder of their lives, whereas patients treated with radiotherapy alone spent a large portion of their remaining time as paraplegics.

TABLE 33.7 Wiltse classification of spondylolisthesis.

Type 1	Dysplastic	Associated with congenital deficiency of the L5–S1 articulation
Type 2	Isthmic	Associated with a lesion of the pars interarticulares Three subtypes:
		2A: lytic defect of the pars
		2B: elongated or attenuated pars
		2C: acute pars fracture
Type 3	Degenerative spondylolisthesis	Segmental instability due to disc degeneration/facet arthrosis
Type 4	Traumatic	Acute fracture in the region of the posterior elements, other than the pars interarticulares
Type 5	Pathological	Generalised bone disease resulting in attenuation of the pars (e.g. metabolic, neoplastic)
Type 6	Postsurgical	After decompression of the lumbar spine

TABLE 33.8 The Meyerding classification for the degree of slip of spondylolisthesis.

Grade I	1–25%
Grade II	26–50%
Grade III	51–75%
Grade IV	76–100%

TABLE 33.9 Commonest malignancies that metastasise to the spine and their frequency.

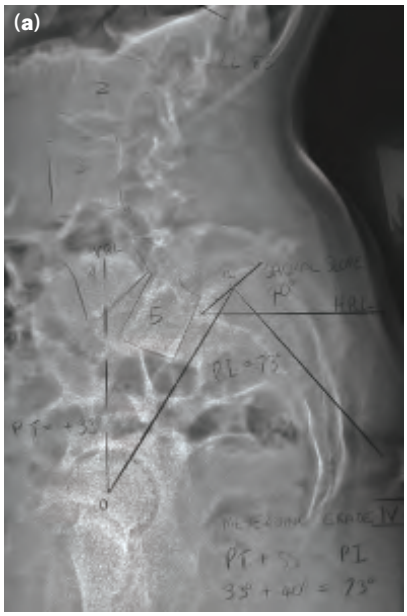
• Breast	21%
• Lung	14%
• Prostate	7.5%
• Renal	5%
• Gastrointestinal	5%
• Thyroid	2.5%

Summary box 33.7

Metastatic tumours of the spine

- Commonest presentation is progressive spinal pain
- Whole spine MRI will detect most metastases
- Surgery is indicated for instability, pain, progressive deformity or neurological deficit

James Ewing, 1866–1943, Professor of Pathology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.



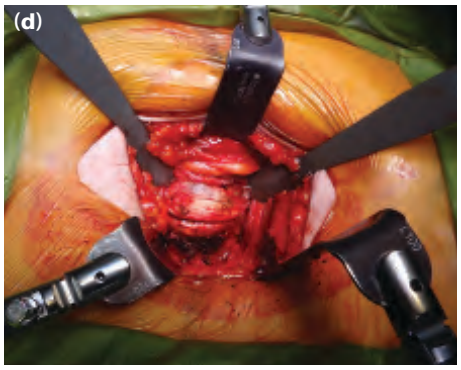


Figure 33.5 High-grade spondylolisthesis. Lateral standing radiograph **(a)** demonstrates Meyerding Grade IV slip associated with high pelvic incidence. Anteroposterior (AP) radiograph **(b)** demonstrates the inverted Napoleon hat sign. T2-weighted mid-sagittal magnetic resonance imaging scan **(c)** shows the 'domed sacrum'. The patient underwent a modified Gaines procedure under one anaesthetic **(d)**, with anterior vertebral resection of L5 along with the L4/5 and L5/S1 intervertebral discs, followed by resection of the posterior elements, articular process and L5 pedicles. AP **(e)** and lateral radiographs **(f)** demonstrate final reduction of L4 onto the sacrum with pedicle fixation from L4 to S2. **(g)** Full-length lateral standing radiograph at 12 months postoperatively.

Primary tumours of the spine

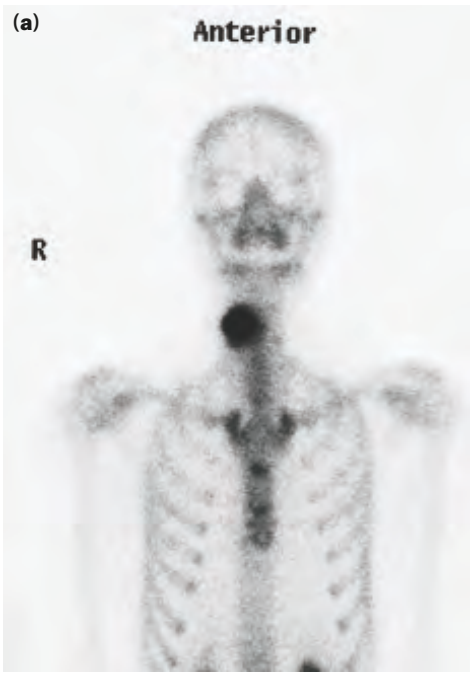
Primary bone tumours of the spine account for only 2% of all spinal tumours. They arise *de novo* in the bone, cartilage, neural or ligamentous structures of the spine. They may be benign, intermediate or malignant. Benign primary spine tumours include osteoid osteoma, osteoblastoma (**Figure 33.6**), chondroma, chondroblastoma, chondromyxoid fibroma, giant cell tumours, haemangioma, lymphangioma and lipoma. Intermediate primary spine tumours include aggressive osteoblastoma, haemangiopericytoma, haemangioendothelioma and chordoma. Malignant primary spinal tumours include osteosarcoma, chondrosarcoma, Ewing's sarcoma, neuroectodermal tumours, malignant lymphoma, myeloma, angiosarcoma, fibrosarcoma and liposarcoma. The reader is referred to Chapter 37 for more specific aspects of orthopaedic oncology.

In patients less than 18 years of age, 68% of all tumours are benign. For those patients who present over 18 years of age, more than 80% of tumours are malignant. Benign tumours tend to occur in the posterior elements; malignant tumours tend to involve the vertebral body.

Intradural tumours

These are rare. They may be intramedullary (within the substance of the cord) or extramedullary (outside the cord). Most are extramedullary and benign; the commonest are meningiomas and neurofibromas.

Meningiomas are usually benign and arise from the meninges. They are generally slow growing and often warrant radiological surveillance. If the lesion is large and impinges on the spinal cord or nerve roots, steroids and early surgery may be indicated.



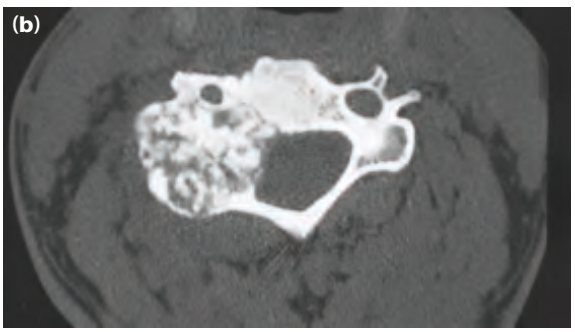


Figure 33.6 Osteoblastoma arising from the posterior elements of C5. This 21-year-old man presented with severe unremitting neck pain. Isotope bone scan **(a)** demonstrated increased uptake in C5. An axial CT scan **(b)** further delineated the expansive lesion. The tumour was successfully removed with the aid of an intraoperative gamma probe to confirm complete excision; **(c)** and **(d)** show the postoperative anteroposterior and lateral radiographs, respectively, following reconstruction with a tricortical bone graft, lateral mass screws and rods.

Neurofibromas are benign tumours that arise from the nerve sheath. There are three major types of neurofibroma: cutaneous, spinal and plexiform. In 90% of cases they present as solitary lesions, with the remainder presenting in patients with neurofibromatosis type 1 (NF1), an autosomal dominant genetically inherited disease. NF1 occurs in 1 in 3000 births and has been referred to as peripheral neurofibromatosis or von Recklinghausen disease. Diagnosis of NF1 is confirmed when an individual has two or more of the following: at least six café-au-lait macules >5 mm diameter before puberty, or six café-au-lait macules >15 mm after puberty, two or more neurofibromas of any type or one plexiform neurofibroma, multiple freckles in the axillary or inguinal regions, a distinctive bone abnormality involving the eye socket or arm/leg bones, optic glioma in the brain, two or more Lisch nodules in the eye, and a parent, sibling or child with NF1. Neurofibromatosis type 2 (NF2) is a genetically determined disorder which affects 1 in 40 000 individuals worldwide. A diagnosis of NF2 is made when an individual has the following findings: schwannomas on both 8th cranial (vestibular) nerves or a parent, sibling or child with NF2 plus one vestibular schwannoma in a person less than 30 years of age, or any two of the following: meningioma, glioma, schwannoma, juvenile cataracts.

INFECTIONS OF THE SPINE

Pyogenic infections

Pyogenic vertebral osteomyelitis is primarily a lesion of the disc and its osseous margins. The most common method by which an organism spreads to the spine is via the haematogenous route. The disc is nearly always involved in pyogenic vertebral infection. In contrast, granulomatous infection, such as tuberculosis, typically does not involve the disc space.

Risk factors for pyogenic vertebral osteomyelitis include advancing age, intravenous drug abuse, diabetes, renal failure, recent infections and trauma. *Staphylococcus aureus* accounts for 30–55% of the infections. Gram-negative organisms such as *Escherichia coli*, *Pseudomonas* species and *Proteus* species are associated with recent genitourinary infections and intravenous drug abuse. Anaerobic infections are uncommon, but may be seen in diabetic patients and after penetrating trauma.

Operative intervention should be considered for:

- open biopsy (when a closed biopsy has failed);
- failure of medical management (persistent pain, elevated ESR, CRP);
- drainage of abscesses;
- decompression of spinal cord compression;
- correction of progressive spinal deformity;
- stabilisation of progressive spinal instability.

Epidural abscess

This condition is often a surgical emergency. The majority of cases occur within the thoracic spine. Without treatment, neurological deficit including paralysis may develop.

Tuberculosis

This is discussed in Chapters 6 and 38.

INFLAMMATORY SPONDYLOARTHROPATHY

Rheumatoid arthritis

Between 33% and 50% of patients develop atlantoaxial subluxation (AAS) within 5 years of the diagnosis of rheumatoid arthritis. Some 2–10% of patients with AAS develop myelopathy over the next 10 years. Once diagnosed with myelopathy, 50% of patients die within 1 year. Approximately 20% of patients develop symptomatic subaxial disease. Neurological symptoms may occur as a result of direct compression by bone or soft tissue or from neural ischaemia. Care needs to be taken with these patients whenever they require surgery. The degree of subluxation may need to be checked by performing flexion and extension radiographs, and the theatre staff (especially the anaesthetist) need to be warned to take special care especially with intubation. The indications for surgery to stabilise the cervical spine are given in *Table 33.10*.

TABLE 33.10 Recommendations for spinal surgery in rheumatoid arthritis.

- AAS with a PADI of 14 mm or less
- AAS with at least 5 mm of basilar invagination
- Subaxial subluxation with a sagittal canal diameter of 14 mm or less

AAS, atlantoaxial subluxation; PADI, posterior atlantodental interval.

Ankylosing spondylitis

Should a patient with ankylosing spondylitis (AS) present following trauma, a high index of suspicion for occult fractures should be present. It is common for patients with AS to develop epidural haematomas with subtle neurological deficit.

Patients with a significant fixed flexion deformity at the cervicothoracic junction ('chin-on-chest' deformity), limited forward gaze, eating and swallowing difficulties may be treated with a closing wedge osteotomy at the cervicothoracic junction (**Figure 33.7**). Extension osteotomies can also be performed in the thoracic and lumbar spine.

Freidrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.
Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.
Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the *Bacterium Coli Commune* in 1886.

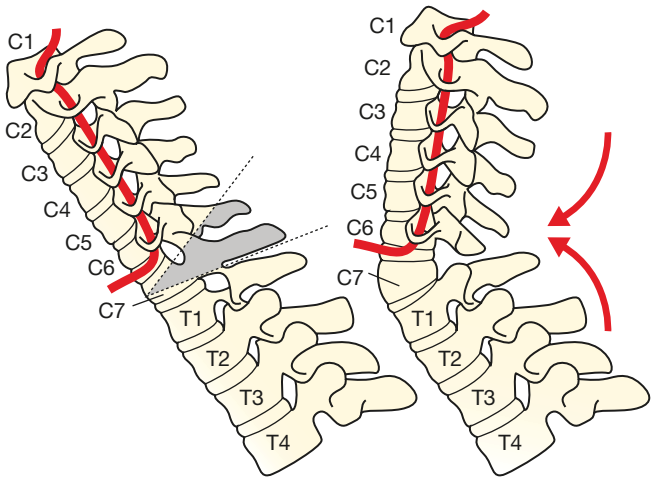

Figure 33.7 C7 closing wedge osteotomy for correction of cervicothoracic kyphosis in patients with ankylosing spondylitis. Planned resection lateral view (left) and lateral view after closure of the osteotomy (right).

SPINAL DEFORMITY

Spinal deformity may be categorised into a coronal plane deformity (scoliosis) or a sagittal plane deformity (kyphosis and lordosis). Further classification may be made on the basis of aetiology into congenital, neuromuscular, idiopathic or syndromic. Appropriate radiographs for the assessment of scoliosis include a full posteroanterior and lateral standing spine. When surgery is contemplated, supine lateral bending radiographs are obtained to assess the flexibility of the curve(s). Curve magnitude is measured in degrees and is known as the Cobb angle. The criterion for diagnosis of scoliosis is a Cobb angle of 10° or more. The causes of scoliosis are given in *Table 33.11*.

TABLE 33.11 Aetiology of scoliosis.

- Idiopathic
- Neuromuscular
- Congenital
- Syndrome-related

Idiopathic scoliosis

Idiopathic scoliosis accounts for 70% of presentations. It can be classified into **early onset** (before 8 years of age) (**Figure 33.8**) and **late onset** (after 8 years of age; typical adolescent idiopathic scoliosis). The distinction is important, as the number of alveoli in the lung does not increase after the age of 8 years. Patients with severe curves in the early-onset group may develop cor pulmonale and right ventricular failure resulting in premature death. Adolescent idiopathic scoliosis is associated with a normal or near-normal life expectancy.

The prevalence of curves with a Cobb angle >10° is between 0.5% and 3%. The prevalence of curves >30° is between 1.5 and 3 per 1000. Risk factors for progression include female gender, remaining skeletal growth, curve location and curve magnitude. Not all curves stabilise when skeletal maturity is reached. In long-term studies, 68% experienced curve progression; the most marked progression of 1° per year was observed in patients with thoracic curves between 50 and 75°.

Idiopathic curves of less than 25° are monitored with clinical and radiographic examination. In growing children (premenarchal) with curves between 20° and 29°, a brace may be indicated. Bracing is used to **prevent** curve progression and generally does not lead to permanent curve correction. Curves beyond 45° are not amenable to brace treatment.

Surgery in the form of corrective instrumentation and spinal fusion is indicated for curve progression beyond 40°, truncal imbalance and unacceptable cosmesis. During surgery, continuous spinal cord monitoring is used in the form of somatosensory evoked potentials (SSEP), motor-evoked potentials (MEP) and free-run and stimulated electromyographic (EMG) activity to minimise the risk of neurological damage. The risk of neurological injury is 0.4% (1 in 250).

Neuromuscular scoliosis

This may be due to neuropathic disorders, such as cerebral palsy, spinocerebellar degeneration, syringomyelia, tetraplegia (**Figure 33.9**), spinal muscular atrophy and poliomyelitis, or **myopathic** disorders, such as Duchenne muscular dystrophy and myotonic dystrophy. There is good evidence that stabilisation of the spine in children with Duchenne muscular dystrophy who are able to walk (before respiratory compromise is too severe to preclude a general anaesthetic) may increase their lifespan by several years.

Congenital scoliosis

This is caused by vertebral anomalies that produce a frontal plane growth asymmetry. The anomalies are present at birth, but the curvature may take years to be clinically evident. Close observation of spinal growth is required until skeletal maturity is reached. Brace treatment is ineffective for the primary structural curves, which are often short and rigid, but it may have a role in the control of compensatory curves. For progressive curves, surgical options include growing rod constructs such as magnetically controlled growing rod (MCGR) procedures, hemivertebra excision, correction and fusion or posterior instrumented correction and fusion.

Summary box 33.8

Spinal deformity

- Early onset idiopathic scoliosis (<8 years old) has potential to impair lung function
- Neuromuscular scoliosis: timely surgery may prolong life
- Congenital scoliosis: rigid curves do not respond to brace treatment

John R. Cobb, American surgeon, wrote a paper in 1948 on how to measure the angle on an x-ray in scoliosis.
Guillaume Benjamin Amand Duchenne, 1806–1875, neurologist, worked successively in Boulogne and Paris, France, but who never held a hospital appointment.

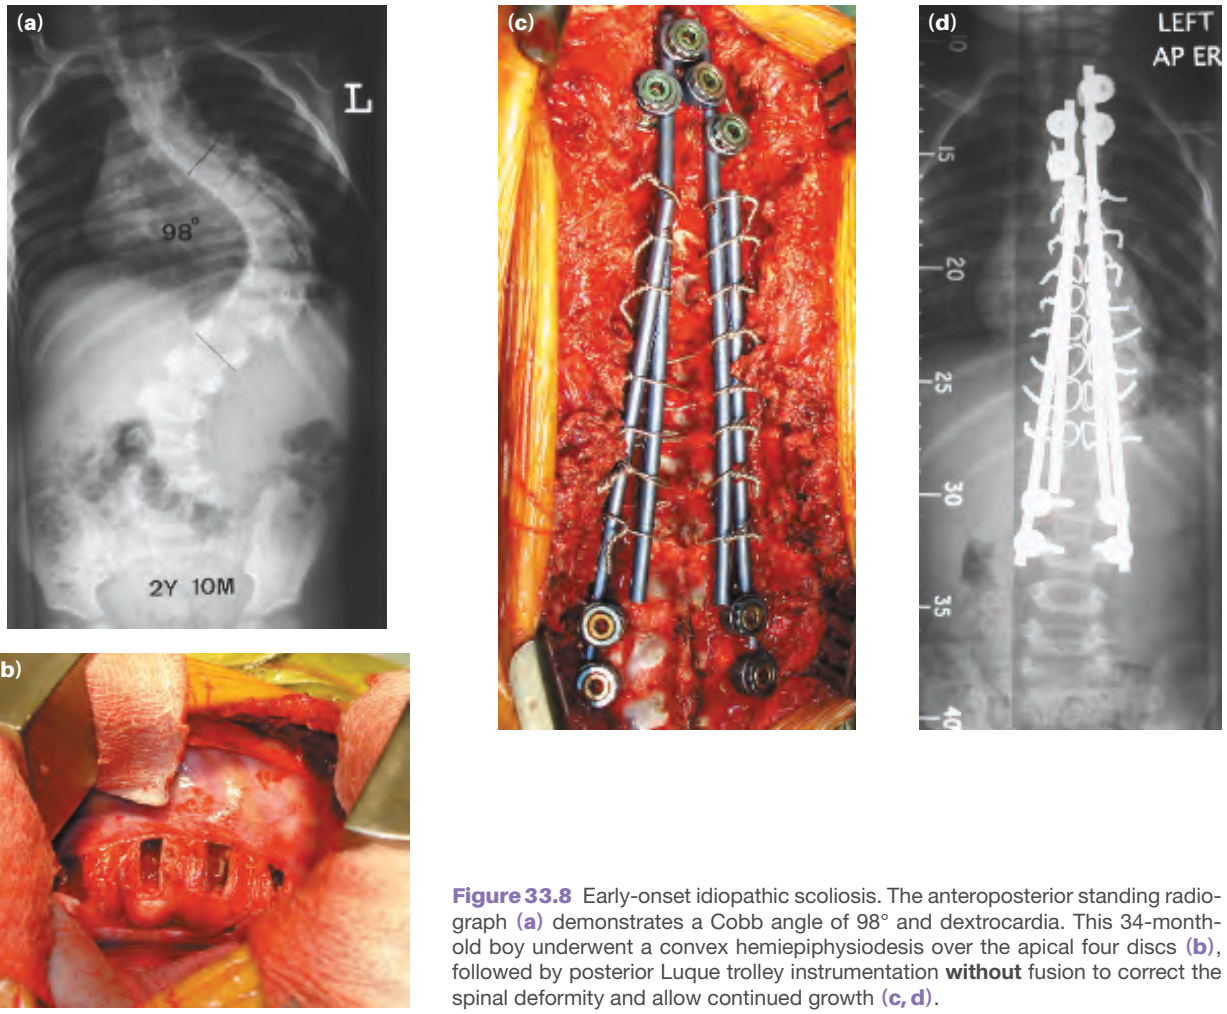

Figure 33.8 Early-onset idiopathic scoliosis. The anteroposterior standing radiograph **(a)** demonstrates a Cobb angle of 98° and dextrocardia. This 34-month-old boy underwent a convex hemiepiphysiodesis over the apical four discs **(b)**, followed by posterior Luque trolley instrumentation **without** fusion to correct the spinal deformity and allow continued growth **(c, d)**.

Scheuermann's kyphosis

Typically, in this condition, there is wedging of the 7th to 10th thoracic vertebrae. The patient presents with both apical pain and low back pain (due to attempts by lumbar musculature to compensate for the thoracic hyperkyphosis). The incidence has been estimated at 1–8% of the population, and it is more common in males. Physiotherapy may be useful. Bracing for skeletally immature patients with kyphosis up to 65° may be effective in arresting progression. Indications for surgery include pain (apical or low back pain produced by compensatory hyperlordosis), progressive deformity greater than 70°, unacceptable cosmesis and neurological and/or cardiopulmonary compromise. If surgery is contemplated, it may require anterior release followed by posterior correction and fusion. Increasingly, posterior chevron osteotomies carried out at the time of posterior instrumentation may prevent the need for the initial anterior release.

DEVELOPMENTAL ABNORMALITIES

Developmental abnormalities of the spine and spinal cord can be divided into primary bony disorders (e.g. congenital scoliosis, as discussed above) and primary neurological disorders (e.g. spina bifida, Arnold–Chiari malformation and spinal dysraphism).

Spina bifida

Spina bifida is caused by a failure of fusion of the vertebral arches and possibly the underlying neural tube. Spina bifida cystica has an incidence of 1 in 300 live births and is associated with hydrocephalus. It is now decreasing as a consequence of folic acid supplementation, antenatal ultrasound and the measurement of α-fetoprotein (AFP) levels. There are two basic types:

Holger Weriel Scheuermann, 1877–1960, radiologist, the Municipal Hospital, Sundby, Copenhagen, Denmark, described juvenile kyphosis in 1920.
Julius Arnold, 1835–1915, Professor of Pathological Anatomy, the University of Heidelberg, Heidelberg, Germany, described this condition in 1894.
Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Stragbourg was returned to France in 1918 after the end of the First World War), gave his account of this condition in 1891.

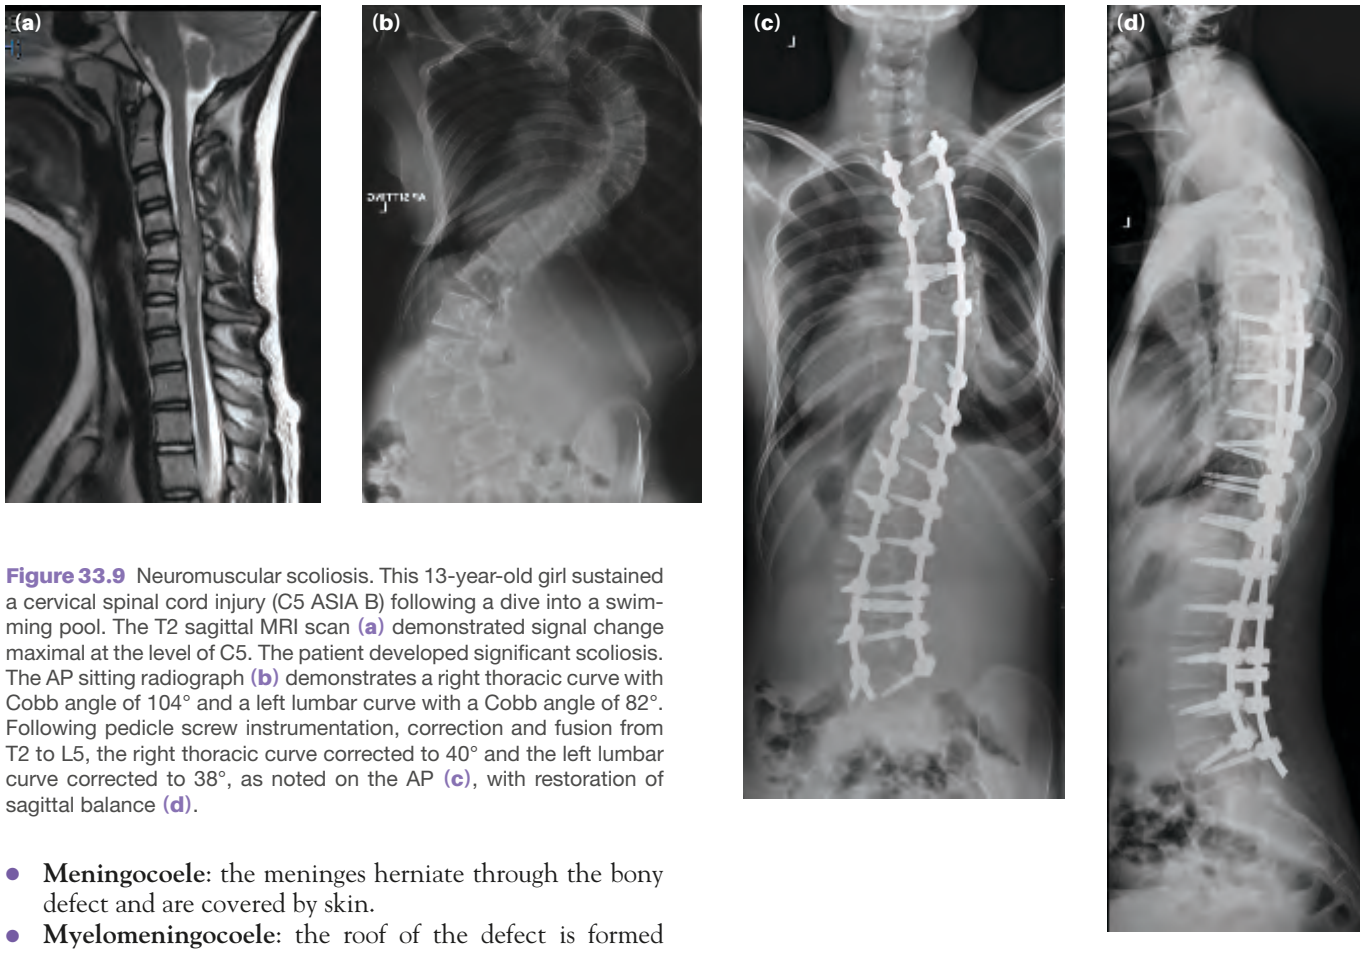

Figure 33.9 Neuromuscular scoliosis. This 13-year-old girl sustained a cervical spinal cord injury (C5 ASIA B) following a dive into a swimming pool. The T2 sagittal MRI scan **(a)** demonstrated signal change maximal at the level of C5. The patient developed significant scoliosis. The AP sitting radiograph **(b)** demonstrates a right thoracic curve with Cobb angle of 104° and a left lumbar curve with a Cobb angle of 82°. Following pedicle screw instrumentation, correction and fusion from T2 to L5, the right thoracic curve corrected to 40° and the left lumbar curve corrected to 38°, as noted on the AP **(c)**, with restoration of sagittal balance **(d)**.

- **Meningocoele**: the meninges herniate through the bony defect and are covered by skin.
- **Myelomeningocoele**: the roof of the defect is formed by exposed neural tissue, with 75% of cases developing hydrocephalus.

A meningocoele with good-quality skin over the defect may be treated conservatively. A meningocoele with a more prominent sac can be excised at 3–6 months. The management of myelomeningocoele is more controversial. Enthusiasm for closing all defects has been replaced by a more selective approach with the recognition that it was inappropriate to operate on children with severe hydrocephalus, a large open defect and no distal neurological function. The majority of these children die in their first year if closure is not attempted. With antibiotics, early surgical closure and shunts to prevent hydrocephalus, half the children who survive the first 24 hours will reach school age, but long-term problems remain, including skin problems, neuromuscular scoliosis, bone and joint deformity and the complications associated with a neuropathic bladder.

Arnold–Chiari malformation

Arnold–Chiari malformation occurs when the medulla oblongata and the cerebellar tonsils extend through the foramen magnum into the cervical spinal canal, causing pressure on the lower medulla. Hydrocephalus and impaired neurological function are common, and there is a strong association with spina bifida and syringomyelia. Symptoms may include headache, vomiting, visual disturbances, mental impairment, cerebellar ataxia, sensory disturbances or paralysis. Management consists of decompressing the foramen magnum and, usually, the posterior arch of the atlas to restore normal cerebrospinal fluid flow.

Spinal dysraphism

This is a group of disorders arising from abnormal embryological formation of tissues; all are associated with a progressive neurological deficit as the result of spinal cord tethering and traction or cord compression. There is a strong association with spina bifida.

In diastematomyelia, there is an abnormal bony or cartilaginous spur projecting across the middle of the vertebral canal, dividing the dural tube and spinal cord in two. Between 50% and 70% of patients are seen to have a skin naevus, dimple or hairy patch when the spine is examined. Surgical release of the tethering has variable results.

Syringomyelia

Patients may present with sensory disturbance, weakness of the hands, loss of pain and temperature sensation, asymmetrical abdominal reflexes or progressive kyphoscoliosis. It is associated with Arnold–Chiari malformation and spinal cord tumours. Where syringomyelia is associated with an Arnold–Chiari malformation and scoliosis, a posterior cranial fossa

decompression should be carried out first to resolve the syringomyelia. The scoliosis may then be corrected at a later date.

METABOLIC BONE DISEASES AFFECTING THE SPINE

Osteoporosis

Patients with osteoporosis may present with pain following minimal trauma, loss of height and exaggerated thoracic kyphosis. Medications used to prevent and treat osteoporosis include calcium, vitamin D, bisphosphonates (alendronate, risedronate, once-yearly intravenous zoledronic acid), denosumab, strontium ranelate, selective oestrogen receptor modulators (SERMS) such as raloxifene, hormone replacement therapy and teriparatide.

Patients with painful thoracic fractures may be treated with short-term bed rest, analgesics and a spinal orthosis. If the back is still painful 6 weeks after the injury, patients may be considered for vertebroplasty or kyphoplasty. Vertebroplasty involves the injection of polymethylmethacrylate bone cement (PMMA) under pressure into the vertebral body with fluoroscopic guidance. The goals of the procedure are to **stabilise the spine** and **decrease the pain** associated with compression fractures. Kyphoplasty, on the other hand, involves inserting bilateral bone tamps with balloons into the vertebral body. These are inflated under fluoroscopic control with the bone tamp re-expanding the body, and elevating the end plates to reduce the fracture deformity. The balloons are then deflated and removed, and PMMA is placed in the cavity created by the balloons. The goals of kyphoplasty are **spinal stabilisation, pain relief and restoration of vertebral body height**. Significant complications have been reported, including nerve root injury and spinal cord injury resulting from cement extravasation, along with cement embolism, infection and hypotension.

GLOBAL ISSUES IN SPINE SURGERY

It is important that the information presented in this chapter, which is widely used throughout the world for teaching and training, outlines the very best evidence-based treatment that is available for surgical conditions. The text has covered the essentials of spine surgery and has very rightly demonstrated current techniques which involve up-to-date equipment. It is, however, an inescapable fact that the majority of the world's population does not have access to state-of-the-art spinal surgery. There are two main reasons for this: first, the cost of spinal surgery and, second, the lack of trained surgeons.

Cost implications of modern spinal surgery

There have been dramatic advances in spinal surgery due to modern imaging, modern instruments and implants, and advanced spinal cord monitoring equipment. The widespread availability of MRI in high-income countries such as the USA, UK and most of Europe has meant that diagnostic accuracy is available to the whole population in these countries. This is not, however, the case for most of the world, where there is no free or state-sponsored MRI service, and a private scan costing US$500 is unaffordable to most. If a family cannot afford a scan, then they also cannot afford the cost of an operation, the spinal implants, spinal cord monitoring and the use of expensive disposable instruments such as high-speed burrs.

The lack of trained spinal surgeons

In the last 20 years high income countries have seen the rapid development of spinal surgery, and the rapid development of spinal surgery as a complete career. It is now normal in such countries for spine surgeons to practise only in the field of spinal surgery and no longer to undertake general orthopaedic or neurosurgical operations. This has inevitably led to refinement of skills and increasing subspecialisation. In low-income countries, where there may be a single orthopaedic surgeon for 1 million people, doing 'just spinal surgery' is not an option, and a much more general approach is needed. In the map shown in **Figure 33.10**, each country in the world is represented with an area proportional to the number of people in the population per active surgeon. This represents surgeons of all types, but it shows that, in many parts of Africa, there are more than half a million people per surgeon. The map showing the population covered by each **spine** surgeon would be even more striking.

Can good spine care be given without modern imaging and equipment?

The key to good surgery in all disciplines is a surgeon who is dedicated to the care of his or her patient, who takes a good history and examination, then offers the best treatment that is available under the circumstances. In a high-income country this will often involve MRI scanning, dissection under microscope control and expensive titanium implants. In a resource-poor, low-income country it may involve just as much time and skill, but often a much more conservative approach. When surgery is needed the surgeon may have to do the best that he or she can with the equipment available. The case in **Figure 33.11** illustrates this point well. Note the lateral cervical spine radiograph with a fracture/dislocation at C2/C3 sustained by a patient living in a low-income country. The pedicles of C2 are fractured, allowing C2 to subluxate forwards on C3 and compress the spinal cord. The patient was admitted several days after a car crash, holding his head with his hands for stability. In a high-income country where there was imaging and fluoroscopic-guided pedicle screw fixation available, the fracture could easily have been fixed. In the low-income country, there was no cervical spine instrumentation available and the surgeon used a low-risk, low-technology technique of wiring the arch of C1 to the spine of C2 with a

piece of stainless steel wire, then laying on corticocancellous bone graft. The reduction was stable, the graft incorporated and the patient was thankful. It is not appropriate to say that this was inadequate treatment compared to the best that the world has to offer, because the best that the world has to offer was not available.

Chapter 34

Upper limb

Learning objectives

To understand:

- Anatomy and physiology relevant to upper limb pathology

To be able to explain:

- The diagnosis and treatment of common upper limb conditions

SHOULDER GIRDLE

Anatomy and function

The shoulder girdle (scapula and clavicle) is controlled and supported by muscles crossing between the spine, thorax, scapula and humerus. The sternoclavicular joint is the only synovial joint between the upper limb and the axial skeleton. The glenohumeral joint is most closely controlled by the deltoid and rotator cuff muscles (subscapularis, supraspinatus, infraspinatus and teres minor). The scapula is integral to shoulder motion, both gliding and rotating on the posterior surface of the thorax (**Figure 34.1**).

Congenital abnormalities

Sprengel's shoulder

The commonest congenital abnormality is due to abnormal scapular descent from its embryonic midcervical position. The typical presentation is a high, small, rotated scapula which remains connected to the cervical spine by a bony bar, fibrous band or an omovertebral body (**Figure 34.2**). Other

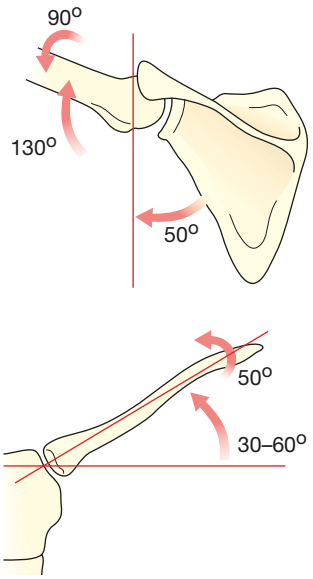

Figure 34.1 Relative motion of the elements of the shoulder girdle.

Otto Gerhard Karl Sprengel, 1852–1915, surgeon, Grossherzogliches Krankenhaus (the Grand Ducal Hospital), Brunswick, Germany, described congenital high scapula in 1891.

congenital deformities are rib abnormalities, and cervical or thoracic abnormalities including scoliosis and Klippel–Feil syndrome (congenital fusion of cervical vertebrae).

Acquired abnormalities

History

Patients usually associate the onset of their symptoms with an unusual event (trauma or excessive activity) even though the causation may not be as clear as the patient thinks. Even so, the onset (sudden or gradual) and duration are important, as is the age of the patient, and their occupation. Pain presenting in the shoulder (or anywhere in the upper limb) can arise from the nerves of the neck, so the history should include questions about neck problems.

Examination

If the patient can localise the source of the pain to an exact point around the shoulder, then the problem is unlikely to be referred from the neck. Tests for inflammation and impingement involve trying to reproduce the pain by loading the limb in the position that creates the problem (Hawkin's test for impingement, **Figure 34.3**). Tests for tears in structures such as the rotator cuff look specifically for weakness, while apprehension tests check for instability (such as may predispose to recurrent shoulder dislocation).

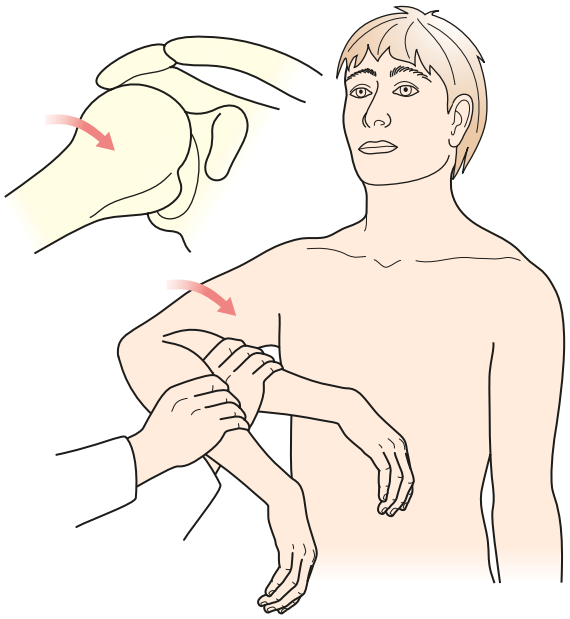

Figure 34.3 Hawkin's impingement test. Impingement pain is reproduced when the shoulder is internally rotated with 90° of forward flexion, thereby locating the greater tuberosity underneath the acromion.

Investigations

Radiographs are of limited value because most lesions in the shoulder involve damage to the soft tissues. However, a reduced subacromial space may be clearly visible in full thickness rotator cuff tears **(Figure 34.4a)**. The appearance of a typical subacromial spur can be seen on the radiograph in **Figure 34.4b** and morphological variants are shown in **Figure 34.5**. The appearance of a spur is usually due to calcification within the coracoacromial ligament and it may be a secondary consequence of degenerative cuff disease rather than a primary event.

Both ultrasound and magnetic resonance imaging (MRI) allow the integrity and health of the rotator cuff to be checked, and MR arthrography also gives information on the integrity of the labrum of the glenohumeral joint **(Figure 34.6)**.

Local anaesthetic injections may help to localise the source of inflammation and pain.
